• Shorter hospital stay (5 to 7 days rather than 7 to 10 days)

Nursing Safety Priority QSEN

Action Alert

Respiratory care is the highest postoperative priority for patients having an esophagectomy. For those who had traditional surgery, intubation with mechanical ventilation is needed for at least the first 16 to 24 hours. Pulmonary complications include atelectasis and pneumonia. The risk for postoperative pulmonary complications is increased in the patient who has received preoperative radiation. Once the patient is extubated, begin deep breathing, turning, and coughing every 1 to 2 hours. Assess the patient for decreased breath sounds and shortness of breath every 1 to 2 hours. Provide incisional support and adequate analgesia for effective coughing.

Remind nursing and other staff to keep the patient in a semi-Fowler's or high-Fowler's position to support ventilation and prevent reflux. The health care provider prescribes prophylactic antibiotics and supplemental oxygen. *Ensure the patency of the chest tube drainage system, and monitor for changes in the volume or color of the drainage.*

Cardiovascular complications, particularly hypotension during surgery, can occur as a result of pressure placed on the posterior heart and usually respond well to IV fluid administration.

Nursing Safety Priority QSEN

Action Alert

Monitor for manifestations of fluid volume overload, particularly in older patients and in those who have undergone lymph node dissection. Assess for edema, crackles in the lungs, and increased jugular venous pressure. In the immediate postoperative phase, the patient is often admitted to the intensive care unit. Critical care nurses assess hemodynamic parameters such as cardiac output, cardiac index, and systemic vascular resistance every 2 hours to monitor for myocardial ischemia. Observe for atrial fibrillation that results from irritation of the vagus nerve during surgery, and manage according to agency protocol.

The patient with poor nutrition or prior radiation or chemotherapy is at risk for infection. For those who undergo more radical surgical procedures,

there is a serious risk for leakage at the anastomosis (surgical connection) sites. This situation is especially true with colon interpositions because several sites are stressed by the effects of tension, poor blood supply, and delayed healing. *Mediastinitis* (inflammation of the mediastinum) resulting from an anastomotic leak can lead to fatal sepsis.

Wound management is another major postoperative concern for conventional surgery because the patient typically has multiple incisions and drains. *Provide direct support to the incision during turning and coughing to prevent dehiscence.* Wound infection can occur 4 to 5 days after surgery. Leakage from the site of anastomosis is a dreaded complication that can appear 2 to 10 days after surgery. If an anastomotic leak occurs, all oral intake is discontinued and is not resumed until the site of the leak has healed.

Nursing Safety Priority QSEN

Critical Rescue

After esophageal surgery, carefully assess for fever, fluid accumulation, signs of inflammation, and symptoms of early shock (e.g., tachycardia, tachypnea). Report any of these findings to the surgeon **or** Rapid Response Team immediately!

A nasogastric (NG) tube is placed intraoperatively to decompress the stomach to prevent tension on the suture line. Monitor the NG tube for patency, and carefully secure the tube to prevent dislodgment, which can disrupt the sutures at the anastomosis. *Do not irrigate or reposition the NG tube in patients who have undergone esophageal surgery unless requested by the surgeon!* The initial nasogastric drainage is bloody but should change to a greenish yellow color by the end of the first postoperative day. The continued presence of blood may indicate internal bleeding at the suture line. Commonly, an antacid will be prescribed to support the patient's healing. Provide oral hygiene for the patient every 2 to 4 hours while the tube is in place, or delegate and supervise this activity (Chart 54-8).

Chart 54-8 Best Practice for Patient Safety & Quality Care QSEN

Managing the Patient with a Nasogastric Tube after Esophageal Surgery

- Check for tube placement every 4 to 8 hours.
- Ensure that the tube is patent (open) and draining; drainage should turn from bloody to yellowish green by the end of the first postoperative day.
- Secure the tube well to prevent dislodgment.
- Do not irrigate or reposition the tube without a physician's request.
- Provide meticulous oral and nasal hygiene every 2 to 4 hours.
- Keep the head of the bed elevated to at least 30 degrees.
- When the patient is permitted to have a small amount of water, place him or her in an upright position and observe for dysphagia (difficulty swallowing).
- Observe for leakage from the anastomosis site, as indicated by fever, fluid accumulation, and manifestations of early shock (tachycardia, tachypnea, altered mental status).

Nutrition management of the patient who has undergone esophageal surgery is an early postoperative concern. After conventional surgery, on the second postoperative day, initial feedings usually begin through the jejunostomy tube (J tube). Do not aspirate for residual, because this increases the risk for mucosal tearing. Feedings are slowly increased over the next several days. Feeding by this method can be discontinued once the patient is taking adequate oral nutrition.

Before beginning oral feedings, a cine-esophagram study is performed to detect any anastomotic leaks, strictures, or signs of aspiration. If no leaks are seen, a liquid diet is started. If liquids are well tolerated, the patient's diet is advanced to include semi-solid foods and then solid foods.

Place the patient in an upright position, and supervise all initial swallowing efforts. The food storage area of the stomach has been radically decreased, and gravity is the only defense against reflux. *Teach the patient and/or family the importance of the patient eating six to eight small meals per day. Fluids should be taken between, rather than with, meals to prevent diarrhea.* Diarrhea can occur 20 minutes to 2 hours after eating and can be managed with loperamide (Imodium) before meals. The diarrhea is thought to be the result of *vagotomy syndrome,* which develops as a result of interrupted vagal fibers to the abdominal organs during surgery.

Community-Based Care

Patients with esophageal cancer have many challenges to face once they

are discharged home. The combination treatment regimens cause long-lasting side effects, such as fatigue and weakness. These complex treatments also require the patient and family to be knowledgeable about symptom management and to know when to report concerns to the health care provider.

Home Care Management.

Once the patient is discharged to home, ongoing respiratory care remains a priority. Give the patient and family instructions for ambulation and incentive spirometer use. Encourage the patient to be as active as possible and to avoid excessive bedrest because this can lead to complications of immobility. In accordance with The Joint Commission National Patient Safety Goals for 2014, teach the family to protect the patient from infection and to contact the health care provider immediately if signs of respiratory infection develop. Patients should stay away from people with infections and avoid large crowds.

Self-Management Education.

Remind the patient and family to wash their hands frequently, and teach them to inspect the incisions daily for redness, tenderness, swelling, odor, and discharge because proper wound healing is still a concern at the time of discharge. Instruct them to report a temperature greater than 101° F (38.3° C), or 100° F (37.8° C) for older adults, which may be a sign of infection. Prepare written instructions about the signs of anastomosis leakage. *Teach the patient or family to immediately report to the health care provider the presence of fever and a swollen, painful neck incision.*

Nutrition support is important. Encourage the patient to continue increasing oral feedings as tolerated. Remind him or her to eat small, frequent meals containing high-calorie, high-protein foods that are soft and easily swallowed. Teach the value of using supplemental milkshakes between meals, and instruct the patient to eat slowly. Patients who have undergone esophageal resection can lose up to 10% of their body weight. Teach the patient to monitor his or her weight at home and to report a weight loss of 5 pounds or more in 1 month. If sufficient oral intake is not possible, the patient and family may need instruction about tube feedings or parenteral nutrition at home.

Emphasize the importance of remaining upright after meals. Dysphagia or odynophagia may recur because of stricture, reflux, or cancer recurrence. These symptoms should be promptly reported to the health care provider. Despite radical surgery, the patient with cancer of the esophagus often still has a terminal illness and a relatively short life

expectancy. Emphasis is placed on maximizing quality of life. Realistic planning is important as the patient's condition eventually worsens, and the patient and family are assisted to plan for the future together. Assist family members in exploring formal and informal sources of support. Help the family or significant others arrange for hospice care when it is needed. Chapter 7 describes end-of-life care, including hospice.

Health Care Resources.

Referrals to community or home care organizations assist the family in providing care in the home. The patient may need transportation to the radiation treatment center 5 times per week for up to 6 weeks. Oncology nursing care may be needed to monitor and evaluate the patient who is receiving chemotherapy at home through venous access devices or portable infusion pumps. Inform the patient and family about the services available through the American Cancer Society (www.cancer.org), including support groups and transportation. Familiarize the family with area hospice services for future planning. Coordinate resource referrals with the case manager or home care agency.

Evaluation: Expected Outcomes

Evaluate the care of the patient with esophageal cancer based on the identified priority patient problems. The major expected outcome is that the patient will be able to consume adequate nutrition and maintain a stable weight.

Clinical Judgment Challenge

Teamwork and Collaboration; Safety; Evidence-Based Practice QSEN

A 55-year-old patient has undergone a partial esophagectomy. He has a history of alcoholism and states that he quit drinking when he found out about his diagnosis. Just prior to discharge, you are preparing to teach him and his family about self-management.

1. For what postoperative complications will you monitor, and why could they occur after this surgery?
2. Of all potential postoperative complications, which signs and symptoms should the patient and family be instructed to *immediately* report?
3. Why is the patient's history of alcoholism significant? What referrals

would you provide to support his choice to discontinue using alcohol?
4. The patient's life partner tells you that the patient is the family's primary provider of income. His life partner is concerned that the patient may not recover well enough to return to work. How might you respond to his concern?
5. To what community agencies would you refer the patient and his family?

Esophageal Diverticula

Diverticula are sacs resulting from the herniation of esophageal mucosa and submucosa into surrounding tissue. They may develop anywhere along the length of the esophagus. No environmental risk factors are known to be involved in their development. The incomplete or late opening of swallowing muscles can cause high pressure in the hypopharynx and lead to *Zenker's diverticula,* the most common form. This type occurs most often in older adults. Patients report dysphagia (difficulty swallowing), regurgitation (reflux), nocturnal cough, and halitosis (bad breath). They can also be at risk for perforation because the mucosa is without the protection of the normal esophageal muscle layer.

Esophageal diverticula are diagnosed most often by *esophagogastroduodenoscopy (EGD).* This procedure must be performed with strict care because of the risk for perforation. Nutrition therapy and positioning are the major interventions for controlling symptoms related to diverticula. Collaborate with the dietitian to assist the patient in exploring variations in the size and frequency of meals and in food texture and consistency. Semisoft foods and smaller meals are often best tolerated and may reduce or relieve the symptoms of pressure and reflux. Nocturnal reflux associated with diverticula is managed by teaching the patient to sleep with the head of the bed elevated and to avoid the supine position for at least 2 hours after eating. Advise the patient to avoid vigorous exercise after meals. Teach him or her to avoid restrictive clothing and frequent stooping or bending.

Surgical management is aimed at removing the diverticula. Postoperatively, the patient is NPO status for several days to promote healing. During that period, the patient receives IV fluids for hydration and tube feedings; after that, he or she is given oral fluid and food. Provide pain relief measures, and monitor for complications such as bleeding or perforation. *A nasogastric (NG) tube is placed during surgery for decompression and is not irrigated or repositioned unless specifically requested by the surgeon.*

Community-based care includes teaching the patient and family about:

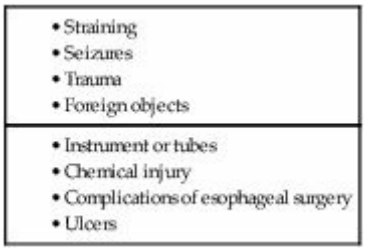
- Nutrition therapy
- Positioning guidelines to prevent reflux
- Warning signs of complications, such as bleeding or infection

Esophageal Trauma

Trauma to the esophagus can result from blunt injuries, chemical burns, surgery or endoscopy (rare), or the stress of continuous severe vomiting (Table 54-2). Trauma may affect the esophagus directly, impairing swallowing and nutrition, or it may create problems in related structures such as the lungs or mediastinum. The incidence of most forms of esophageal trauma is low in adults. When excessive force is exerted on the esophageal mucosa, it may perforate or rupture, allowing the caustic acid secretions to enter the mediastinal cavity. These tears are associated with a high mortality rate related to shock, respiratory impairment, or sepsis.

TABLE 54-2

Common Causes of Esophageal Perforation



Chemical injury is usually a result of the accidental or intentional ingestion of caustic substances. The damage to the mouth and esophagus is rapid and severe. Acid burns tend to affect the superficial mucosal lining, whereas alkaline substances cause deeper penetrating injuries. Strong alkalis can cause full perforation of the esophagus within 1 minute. Additional problems may include aspiration pneumonia and hemorrhage. Esophageal strictures may develop as scar tissue forms.

Patients with esophageal trauma are initially evaluated and treated in the emergency department. Assessment focuses on the nature of the injury and the circumstances surrounding it. *Assess for airway patency, breathing, chest pain, dysphagia, vomiting, and bleeding as the priorities for patient care.* If the risk for extending the damage is not excessive, an endoscopic study may be requested to evaluate tears or perforation. A CT scan of the chest can be done to assess for the presence of mediastinal air.

After the injury, keep the patient NPO to prevent further leakage of esophageal secretions. Esophageal and gastric suction can be used for drainage and to rest the esophagus. Esophageal rest is maintained for more than a week after injury to allow for initial healing of the mucosa.

Total parenteral nutrition (TPN) is prescribed to provide calories and protein for wound healing while the patient is not eating.

To prevent sepsis, the health care provider prescribes broad-spectrum antibiotics. High-dose corticosteroids may be administered to suppress inflammation and prevent strictures (esophageal narrowing). In addition, opioid and non-opioid analgesics are prescribed for pain management. When caustic burns involve the mouth, topical agents such as lidocaine (Xylocaine Viscous) may be used for analgesia and local anti-inflammatory action.

If nonsurgical management is not effective in healing traumatized esophageal tissue, the patient may need surgery to remove the damaged tissue. Those with severe injuries may require resection of part of the esophagus with a gastric pull-through and repositioning or replacement by a bowel segment; also, gastrostomy tube (G-tube) placement may be needed to meet nutrition needs while healing.

Nursing Concepts and Clinical Judgment Review

What might you NOTICE if the patient has inadequate digestion and nutrition as a result of chronic esophageal problems?

- Dysphagia (difficulty swallowing)
- Odynophagia (painful swallowing)
- Dyspepsia (indigestion)
- Regurgitation (reflux)
- Eructation (belching)
- Chronic cough
- Choking
- Halitosis (foul breath)
- Weight loss
- Vomiting
- Chest pain

What should you INTERPRET and how should you RESPOND to a patient experiencing inadequate digestion and nutrition as a result of chronic esophageal problems?

Perform and interpret focused physical findings, including:

- Assessing ability to chew and swallow food
- Assessing chest pain (dyspepsia) for quality, location, and intensity
- Assessing body weight change
- Auscultating lungs

- Assessing readiness to learn

Respond by:

- Providing semi-solid or thickened liquids if solid foods cannot be swallowed comfortably
- Collaborating with the dietitian and occupational therapist (OT) for swallowing evaluation and training
- Monitoring for aspiration of secretions or food
- Teaching lifestyle changes, such as foods to avoid, smoking and alcohol cessation, weight reduction (if obese), and importance of drug therapy to control symptoms
- Monitoring weight
- Monitoring for increased dysphagia

On what should you REFLECT?

- Evaluate for rapid weight changes (decrease if obese, and increase if severe weight loss has occurred).
- Monitor for manifestations of aspiration.
- Observe patient for improvement in GI symptoms.
- Evaluate effectiveness of health teaching.
- Consider ways to promote digestion and nutrition.

Get Ready for the NCLEX® Examination!

Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Consult with the dietitian, patient, and family regarding nutrition restrictions for patients with GERD. **Teamwork and Collaboration** QSEN
- Collaborate with the health care team for the patient with impaired swallowing and/or limited nutrition. **Teamwork and Collaboration** QSEN
- Teach the patient and family to recognize the symptoms of dysphagia. **Safety** QSEN
- Remain with the dysphagic patient during meals to prevent or assist with choking episodes. **Safety** QSEN

Health Promotion and Maintenance

- Teach the patient oral exercises aimed at improving swallowing.
- Stress the importance of recognizing and controlling reflux through nutrition therapy and medications to avoid further esophageal damage that could lead to Barrett's esophagus.
- Teach the patient to elevate the head of the bed by 6 inches for sleep to prevent nighttime reflux.
- Instruct the patient to sleep in the right side-lying position to minimize the effects of nighttime episodes of reflux.
- Teach the patient with esophageal cancer to monitor his or her body weight and to notify the health care provider of weight loss.
- Teach the patient to avoid alcoholic beverages, smoking, and other substances as listed in Chart 54-2 because they lead to increased gastroesophageal reflux.
- Teach the patient to prevent gas bloat syndrome by avoiding drinking carbonated beverages, eating gas-producing foods, chewing gum, and drinking with a straw.
- Review postprocedure instructions for patients having the Stretta procedure for GERD as outlined in Chart 54-3.

Psychosocial Integrity

- Allow the patient the opportunity to express fear or anxiety regarding the diagnosis of esophageal cancer and related treatment regimen of

surgery, chemotherapy, and radiation. **Patient-Centered Care** QSEN
- Explain all procedures, restrictions, drug therapy, and follow-up care to the patient and family.
- Refer the patient or family members to psychological counseling, hospice, pastoral care, and the case manager as needed. **Teamwork and Collaboration** QSEN

Physiological Integrity

- For patients with GERD, teach the importance of strict adherence to anti-reflux agents in preventing esophageal damage (see Chapter 55, Chart 55-3).
- Be aware that laparoscopic Nissen fundoplication (LNF) and laparoscopic paraesophageal repairs are common surgical procedures for patients with GERD and hiatal hernia.
- Assess for complications and provide postoperative care for patients having the LNF procedure, as described in Chart 54-6. **Safety** QSEN
- Be sure to frequently monitor the nutrition status of the patient with esophageal cancer.
- Teach the patient having open conventional esophageal surgery about incisions, drains, and jejunostomy tube placement before he or she undergoes surgery for esophageal cancer.
- For the patient with a nasogastric (NG) tube, check the NG tube every 4 to 8 hours for proper placement and anchorage; follow guidelines as outlined in Chart 54-8.
- Assess the patient after esophageal surgery for pulmonary and cardiac complications of surgery, and report changes to the health care provider. **Safety** QSEN
- Assess patients for key features of esophageal tumors as listed in Chart 54-7.

CHAPTER 55

Care of Patients with Stomach Disorders

Lara Carver

PRIORITY CONCEPTS

- Nutrition
- Pain
- Inflammation
- Infection

Learning Outcomes

Safe and Effective Care Environment

1. Describe the importance of collaborating with members of the health care team when caring for patients with gastric (stomach) disorders.

Health Promotion and Maintenance

2. Identify community resources for patients with gastric disorders.
3. Develop a teaching plan for patients about complementary and alternative therapies that have been used to help manage gastritis and peptic ulcer disease (PUD).
4. Plan interventions to promote GI health and prevent gastritis.

Psychosocial Integrity

5. Identify the need for end-of-life care for patients with advanced gastric cancer.

Physiological Integrity

6. Compare assessment findings of acute and chronic gastritis.

7. Compare and contrast assessment findings associated with gastric and duodenal ulcers.
8. Identify the most common medical complications that can result from PUD.
9. Describe the purpose and adverse effects of drug therapy for gastritis and PUD.
10. To promote patient safety and quality care, monitor patients with PUD and gastric cancer for signs of upper GI bleeding.
11. Prioritize evidence-based interventions for patients with upper GI bleeding.
12. To prevent complications, develop a collaborative preoperative and postoperative plan of care for the patient undergoing gastric surgery.

 http://evolve.elsevier.com/Iggy/

Although only a few diseases affect the stomach, they can be very serious and in some cases life threatening. The most common disorders include gastritis, peptic ulcer disease, and gastric cancer. Each of these health problems can result in impaired or altered *digestion* and nutrition. In addition, inflammation and infection associated with these problems can cause pain. The stomach is part of the upper GI system that is responsible for a large part of the digestive process. Patient-centered collaborative care for stomach disorders often includes therapies to meet the patient's need for adequate nutrition.

Gastritis

Gastritis is the inflammation of gastric mucosa (stomach lining). It can be scattered or localized and can be classified according to cause, cellular changes, or distribution of the lesions. Gastritis can be erosive (causing ulcers) or nonerosive. Although the mucosal changes that result from *acute* gastritis typically heal after several months, this is not true for *chronic* gastritis.

❖ Pathophysiology

Prostaglandins provide a protective mucosal barrier that prevents the stomach from digesting itself by a process called acid **autodigestion**. If there is a break in the protective barrier, mucosal injury occurs. The resulting injury is worsened by histamine release and vagus nerve stimulation. Hydrochloric acid can then diffuse back into the mucosa and injure small vessels. This back-diffusion causes edema, hemorrhage, and erosion of the stomach's lining. The pathologic changes of gastritis include vascular congestion, edema, acute inflammatory cell infiltration, and degenerative changes in the superficial epithelium of the stomach lining.

Types of Gastritis

Inflammation of the gastric mucosa or submucosa after exposure to local irritants or other causes can result in **acute gastritis**. The early pathologic manifestation of gastritis is a thickened, reddened mucous membrane with prominent **rugae**, or folds. Various degrees of mucosal necrosis and inflammatory reaction occur in acute disease. The diagnosis cannot be based solely on clinical symptoms. Complete regeneration and healing usually occur within a few days. If the stomach muscle is not involved, complete recovery usually occurs with no residual evidence of gastric inflammatory reaction. If the muscle is affected, hemorrhage may occur during an episode of acute gastritis.

Chronic gastritis appears as a patchy, diffuse (spread out) inflammation of the mucosal lining of the stomach. As the disease progresses, the walls and lining of the stomach thin and atrophy. With progressive gastric atrophy from chronic mucosal injury, the function of the parietal (acid-secreting) cells decreases and the source of intrinsic factor is lost. Intrinsic factor is critical for absorption of vitamin B_{12}. When body stores of vitamin B_{12} are eventually depleted, **pernicious anemia** results. The amount and concentration of acid in stomach secretions gradually

decrease until the secretions consist of only mucus and water.

Chronic gastritis is associated with an increased risk for gastric cancer. The persistent inflammation extends deep into the mucosa, causing destruction of the gastric glands and cellular changes. Chronic gastritis may be categorized as type A, type B, or atrophic (McCance et al., 2014).

Type A (nonerosive) chronic gastritis refers to an inflammation of the glands as well as the fundus and body of the stomach. Type B chronic gastritis usually affects the glands of the antrum but may involve the entire stomach. In atrophic chronic gastritis, diffuse inflammation and destruction of deeply located glands accompany the condition. Chronic atrophic gastritis affects all layers of the stomach, thus decreasing the number of cells. The muscle thickens, and inflammation is present. Chronic atrophic gastritis is characterized by total loss of fundal glands, minimal inflammation, thinning of the gastric mucosa, and intestinal metaplasia (abnormal tissue development). These cellular changes can lead to peptic ulcer disease (PUD) and gastric cancer (McCance et al., 2014).

Etiology and Genetic Risk

The onset of infection with *Helicobacter pylori* can result in acute gastritis. *H. pylori* is a gram-negative bacterium that penetrates the mucosal gel layer of the gastric epithelium. Although less common, other forms of bacterial gastritis from organisms such as staphylococci, streptococci, *Escherichia coli*, or salmonella can cause life-threatening problems such as sepsis and extensive tissue necrosis (death).

Long-term NSAID use creates a high risk for acute gastritis. NSAIDs inhibit prostaglandin production in the mucosal barrier. Other risk factors include alcohol, coffee, caffeine, and corticosteroids. Acute gastritis is also caused by local irritation from radiation therapy and accidental or intentional ingestion of corrosive substances, including acids or alkalis (e.g., lye and drain cleaners).

Type A chronic gastritis has been associated with the presence of antibodies to parietal cells and intrinsic factor. Therefore an autoimmune cause for this type of gastritis is likely. Parietal cell antibodies have been found in most patients with pernicious anemia and in more than one half of those with type A gastritis. A genetic link to this disease, with an autosomal dominant pattern of inheritance, has been found in the relatives of patients with pernicious anemia (McCance et al., 2014).

The most common form of chronic gastritis is **type B gastritis**, caused by *H. pylori* infection. A direct correlation exists between the number of

organisms and the degree of cellular abnormality present. The host response to the *H. pylori* infection is activation of lymphocytes and neutrophils. Release of inflammatory cytokines, such as interleukin (IL)-1, IL-8, and tumor necrosis factor (TNF)–alpha, damages the gastric mucosa (McCance et al., 2014).

Chronic local irritation and toxic effects caused by alcohol ingestion, radiation therapy, and smoking have been linked to chronic gastritis. Surgical procedures that involve the pyloric sphincter, such as a pyloroplasty, can lead to gastritis by causing reflux of alkaline secretions into the stomach. Other systemic disorders such as Crohn's disease, graft-versus-host disease, and uremia can also precipitate the development of chronic gastritis.

Atrophic gastritis is a type of chronic gastritis that is seen most often in older adults. It can occur after exposure to toxic substances in the workplace (e.g., benzene, lead, nickel) or *H. pylori* infection, or it can be related to autoimmune factors. Atrophic gastritis can lead to two types of cancer: gastric cancer and gastric mucosa-associated lymphoid tissue (MALT) lymphoma. See p. 1138 for a more detailed explanation of gastric cancer.

Health Promotion and Maintenance

Gastritis is a very common health problem in the United States. A balanced diet, regular exercise, and stress-reduction techniques can help prevent it (Chart 55-1). A balanced diet includes following the recommendations of the U.S. Department of Agriculture (USDA) and limiting intake of foods and spices that can cause gastric distress, such as caffeine, chocolate, mustard, pepper, and other strong or hot spices. Alcohol and tobacco should also be avoided. Regular exercise maintains peristalsis, which helps prevent gastric contents from irritating the gastric mucosa. Stress-reduction techniques can include aerobic exercise, meditation, reading, and/or yoga, depending on individual preferences.

Chart 55-1 Patient and Family Education: Preparing for Self-Management

Gastritis Prevention

- Eat a well-balanced diet.
- Avoid drinking excessive amounts of alcoholic beverages.
- Use caution in taking large doses of aspirin, other NSAIDs (e.g., ibuprofen), and corticosteroids.

- Avoid excessive intake of coffee (even decaffeinated).
- Be sure that foods and water are safe, to avoid contamination.
- Manage stress levels using complementary and alternative therapies such as relaxation and meditation techniques.
- Stop smoking.
- Protect yourself against exposure to toxic substances in the workplace such as lead and nickel.
- Seek medical treatment if you are experiencing symptoms of esophageal reflux (see Chapter 54).

Excessive use of aspirin and other NSAIDs should also be avoided. If a family member has *H. pylori* infection or has had it in the past, patient testing should be considered. This test can identify the bacteria before they cause gastritis.

Patient-Centered Collaborative Care

Assessment

Symptoms of *acute* gastritis range from mild to severe. The patient may report epigastric discomfort or pain, anorexia, cramping, nausea, and vomiting (Chart 55-2). Assess for abdominal tenderness and bloating, **hematemesis** (vomiting blood), or **melena** (dark, sticky feces, as evidence of blood in the stool). Symptoms last only a few hours or days and vary with the cause. Aspirin/NSAID–related gastritis may result in **dyspepsia** (heartburn). Gastritis or food poisoning caused by endotoxins, such as staphylococcal endotoxin, has an abrupt onset. Severe nausea and vomiting often occur within 5 hours of ingestion of the contaminated food. *In some cases gastric hemorrhage is the presenting symptom, which is a life-threatening emergency.*

Chart 55-2 Key Features

Gastritis

Acute Gastritis

- Rapid onset of epigastric pain or discomfort
- Nausea and vomiting
- Hematemesis (vomiting blood)
- Gastric hemorrhage
- Dyspepsia (heartburn)
- Anorexia

Chronic Gastritis

- Vague report of epigastric pain that is relieved by food
- Anorexia
- Nausea or vomiting
- Intolerance of fatty and spicy foods
- Pernicious anemia

Chronic gastritis causes few symptoms unless ulceration occurs. Patients may report nausea, vomiting, or upper abdominal discomfort. Periodic epigastric pain may occur after a meal. Some patients have anorexia (see Chart 55-2).

Esophagogastroduodenoscopy (EGD) via an endoscope with biopsy is the gold standard for diagnosing gastritis. (See Chapter 52 for discussion of nursing care associated with this diagnostic procedure.) The physician performs a biopsy to establish a definitive diagnosis of the type of gastritis. If lesions are patchy and diffuse, biopsy of several suspicious areas may be necessary to avoid misdiagnosis. A *cytologic examination* of the biopsy specimen is performed to confirm or rule out gastric cancer. Tissue samples can also be taken to detect *H. pylori* infection using *rapid urease testing*. The results of these tests are more reliable if the patient has discontinued taking antacids for at least a week (Pagana & Pagana, 2014).

Interventions

Patients with gastritis are not often seen in the acute care setting unless they have an exacerbation ("flare-up") of acute or chronic gastritis that results in fluid and electrolyte imbalance, bleeding, or increased pain. Collaborative care is directed toward supportive care for relieving the symptoms and removing or reducing the cause of discomfort.

Acute gastritis is treated symptomatically and supportively because the healing process is spontaneous, usually occurring within a few days. When the cause is removed, pain and discomfort usually subside. If bleeding is severe, a blood transfusion may be necessary. Fluid replacement is prescribed for patients with severe fluid loss. Surgery, such as partial gastrectomy, pyloroplasty, and/or vagotomy, may be needed for patients with major bleeding or ulceration. Treatment of *chronic* gastritis varies with the cause. The approach to management includes the elimination of causative agents, treatment of any underlying disease (e.g., uremia, Crohn's disease), avoidance of toxic substances (e.g., alcohol, tobacco), and health teaching.

Eliminating the causative factors, such as *H. pylori* infection if present, is the primary treatment approach. Drugs and nutritional therapy are also used. In the *acute* phase the health care provider prescribes drugs that block and buffer gastric acid secretions to relieve pain.

H_2-receptor antagonists, such as famotidine (Pepcid) and nizatidine (Axid), are typically used to block gastric secretions. Sucralfate (Carafate, Sulcrate), a *mucosal barrier fortifier,* may also be prescribed. *Antacids* used as buffering agents include aluminum hydroxide combined with magnesium hydroxide (Maalox) and aluminum hydroxide combined with simethicone and magnesium hydroxide (Mylanta). Antisecretory agents **(proton pump inhibitors [PPIs])** such as omeprazole (Prilosec) or pantoprazole (Protonix) may be prescribed to suppress gastric acid secretion (see Chart 55-3).

Nursing Safety Priority QSEN

Drug Alert

Teach the patient to monitor for symptom relief and side effects of drugs to treat gastritis and to notify the health care provider of any adverse effects or worsening of gastric distress. The dose, frequency, or type of drug may need to be changed if symptoms of gastric irritation appear or persist. *Remind patients not to take additional over-the-counter (OTC) drugs such as Pepcid AC or Axid AR if they are taking similar prescribed drugs.*

Patients with *chronic* gastritis may require vitamin B_{12} for prevention or treatment of pernicious anemia. If *H. pylori* is found, the health care provider treats the infection. Current practice for infection treatment is described on p. 1134 in the discussion of Drug Therapy in the Peptic Ulcer Disease section.

The nurse, primary care provider, or pharmacist teaches patients to avoid drugs and other irritants that are associated with gastritis episodes, if possible. These drugs include corticosteroids, erythromycin (E-Mycin, Erythromid), ASA (aspirin), and NSAIDs such as naproxen (Naprosyn) and ibuprofen (Motrin, Advil, Amersol, Novo-Profen). NSAIDs are also available as OTC drugs and should not be used. Teach patients to read all OTC drug labels because many preparations contain aspirin or other NSAID.

Instruct the patient to limit intake of any foods and spices that cause distress, such as those that contain caffeine or high acid content (e.g.,

tomato products, citrus juices) or those that are heavily seasoned with strong or hot spices. Bell peppers and onions are also commonly irritating foods. Most patients seem to progress better with a bland, non-spicy diet and smaller, more frequent meals. Alcohol and tobacco should also be avoided.

Teach the patient about various techniques that reduce stress and discomfort, such as progressive relaxation, cutaneous stimulation, guided imagery, and distraction. Table 55-1 lists commonly used complementary and alternative therapies for gastritis and peptic ulcer disease.

TABLE 55-1

Commonly Used Complementary and Alternative Therapies for Gastritis and Peptic Ulcer Disease (PUD)

Herbs and Vitamins

Homeopathy
• Carbo vegetabilis • Ipecacuanha • Nux vomica • Pulsatilla

Peptic Ulcer Disease

A **peptic ulcer** is a mucosal lesion of the stomach or duodenum. **Peptic ulcer disease (PUD)** results when mucosal defenses become impaired and no longer protect the epithelium from the effects of acid and pepsin.

❖ Pathophysiology

Types of Ulcers

Three types of ulcers may occur: gastric ulcers, duodenal ulcers, and stress ulcers (less common). Most gastric and duodenal ulcers are caused by *H. pylori* infection. Although it is not certain about how *H. pylori* is transmitted, it is believed to be spread through contaminated food or water. Studies have also suggested that contact with stool, vomit, and sometimes saliva of an infected person can spread the infection (National Digestive Diseases Information Clearinghouse, 2012).

As a response to the bacteria, cytokines, neutrophils, and other substances are activated and cause epithelial cell necrosis. These bacteria produce substances that damage the mucosa. Urease produced by *H. pylori* breaks down urea into ammonia, which neutralizes the acidity of the stomach. Urease can be detected through laboratory testing to confirm the *H. pylori* infection. Also, the helical shape of *H. pylori* allows the bacterium to burrow into the mucus layer of the stomach and become undetectable by the body's immune cells. Although this bacterium does not cause illness in most people, it is a major risk factor for peptic and duodenal ulcers and gastric cancer (McCance et al., 2014).

Gastric ulcers usually develop in the antrum of the stomach near acid-secreting mucosa. When a break in the mucosal barrier occurs (such as that caused by *H. pylori* infection), hydrochloric acid injures the epithelium. Gastric ulcers may then result from back-diffusion of acid or dysfunction of the pyloric sphincter (Fig. 55-1). Without normal functioning of the pyloric sphincter, bile refluxes (backs up) into the stomach. This reflux of bile acids may break the integrity of the mucosal barrier, which leads to mucosal inflammation. Toxic agents and bile then destroy the membrane of the gastric mucosa.

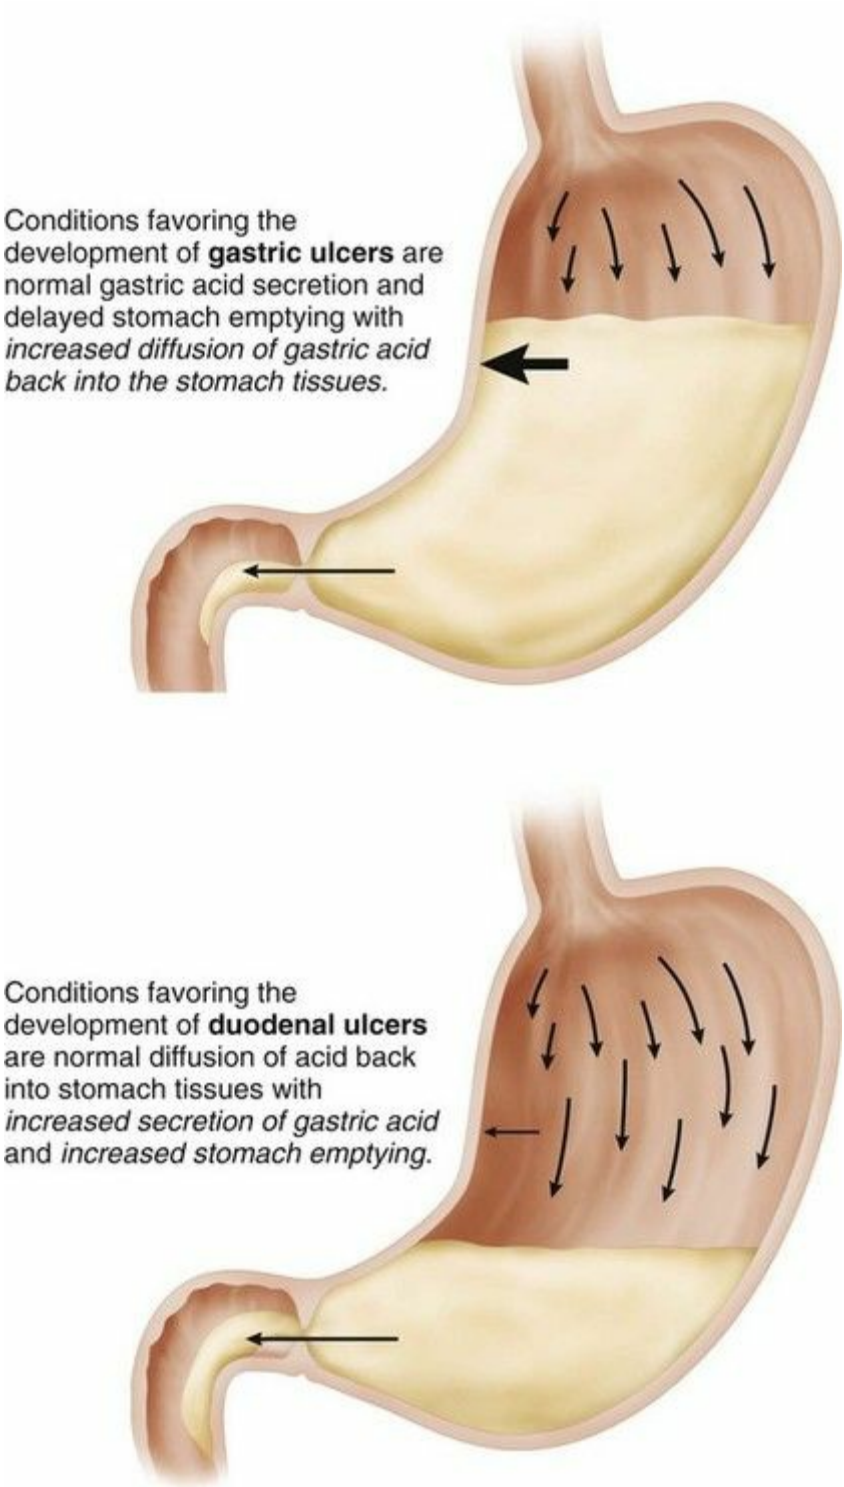

FIG. 55-1 The pathophysiology of peptic ulcer.

Gastric emptying is often delayed in patients with gastric ulceration. This causes regurgitation of duodenal contents, which worsens the gastric mucosal injury. Decreased blood flow to the gastric mucosa may also alter the defense barrier and thereby allow ulceration to occur. Gastric ulcers are deep and penetrating, and they usually occur on the lesser curvature of the stomach, near the pylorus (Fig. 55-2).

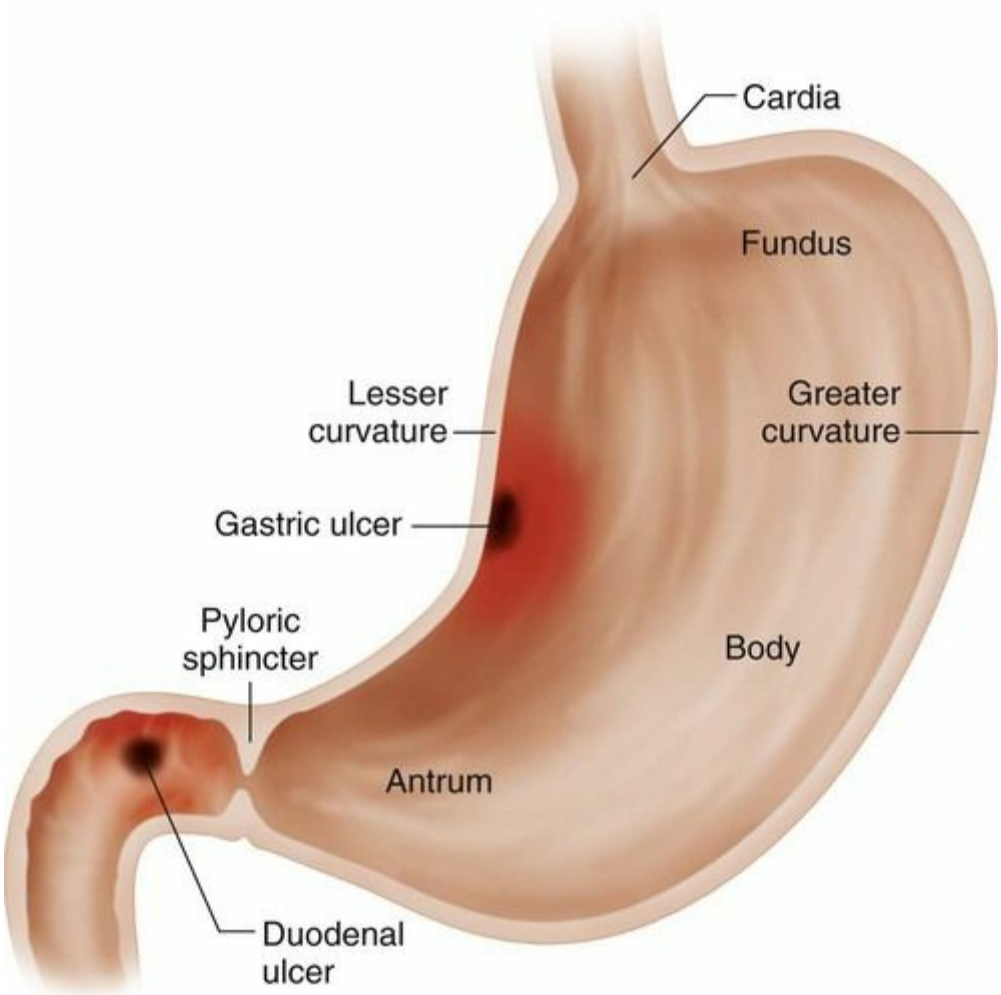

FIG. 55-2 The most common sites for peptic ulcers.

Most *duodenal ulcers* occur in the upper portion of the duodenum. They are deep, sharply demarcated lesions that penetrate through the mucosa and submucosa into the muscularis propria (muscle layer). The floor of the ulcer consists of a necrotic area residing on granulation tissue and surrounded by areas of fibrosis (McCance et al., 2014).

The main feature of a duodenal ulcer is high gastric acid secretion, although a wide range of secretory levels are found. In patients with duodenal ulcers, pH levels are low (excess acid) in the duodenum for long periods. Protein-rich meals, calcium, and vagus nerve excitation stimulate acid secretion. Combined with hypersecretion, a rapid emptying of food from the stomach reduces the buffering effect of food and delivers a large acid bolus to the duodenum. Inhibitory secretory mechanisms and pancreatic secretion may be insufficient to control the acid load.

Stress ulcers are acute gastric mucosal lesions occurring after an acute medical crisis or trauma, such as sepsis or a head injury. In the patient who is NPO for major surgery, gastritis may lead to **stress ulcers**, which

are multiple shallow erosions of the stomach and occasionally the proximal duodenum. Patients who are critically ill, especially those with extensive burns **(Curling's ulcer)**, sepsis (ischemic ulcer), or increased intracranial pressure **(Cushing's ulcer)**, are also susceptible to these ulcers.

Bleeding caused by gastric erosion is the main manifestation of acute stress ulcers. Multifocal lesions associated with stress ulcers occur in the stomach and proximal duodenum. These lesions begin as areas of ischemia and evolve into erosions and ulcerations that may progress to massive hemorrhage. Little is known of the exact etiology of stress ulcers. Stress ulcers are associated with lengthened hospital stay and increased mortality rates. Therefore most patients who have major trauma or surgery receive IV drug therapy (e.g., PPI) to prevent stress ulcer development.

Complications of Ulcers

The most common complications of PUD are hemorrhage, perforation, pyloric obstruction, and intractable disease. *Hemorrhage is the most serious complication*. It tends to occur more often in patients with *gastric* ulcers and in older adults. Many patients have a second episode of bleeding if underlying infection with *H. pylori* remains untreated or if therapy does not include an H_2 antagonist. With massive bleeding the patient vomits bright red or coffee-ground blood **(hematemesis)**. Hematemesis usually indicates bleeding at or above the duodenojejunal junction (upper GI bleeding) (Chart 55-3).

Chart 55-3 Key Features

Upper GI Bleeding

- Bright red or coffee-ground vomitus (hematemesis)
- Melena (tarry or dark, sticky) stools
- Decreased blood pressure
- Increased heart rate
- Weak peripheral pulses
- Acute confusion (in older adults)
- Vertigo
- Dizziness or light-headedness
- Syncope (loss of consciousness)
- Decreased hemoglobin and hematocrit

Minimal bleeding from ulcers is manifested by occult blood in a dark, "tarry" stool **(melena)**. The digestion of blood within the duodenum and small intestine may result in this black stool. Melena may occur in patients with gastric ulcers but is more common in those with duodenal ulcers. Gastric acid digestion of blood typically results in a granular dark vomitus *(coffee-ground appearance).*

Gastric and duodenal ulcers can perforate and bleed (Fig. 55-3). *Perforation* occurs when the ulcer becomes so deep that the entire thickness of the stomach or duodenum is worn away. The stomach or duodenal contents can then leak into the peritoneal cavity. Sudden, sharp pain begins in the midepigastric region and spreads over the entire abdomen. The amount of pain correlates with the amount and type of GI contents spilled. The classic pain causes the patient to be apprehensive. The abdomen is tender, rigid, and boardlike **(peritonitis)**. The patient often assumes a "fetal" position to decrease the tension on the abdominal muscles. He or she can become severely ill within hours. Bacterial septicemia and hypovolemic shock follow. Peristalsis diminishes, and paralytic ileus develops. *Peptic ulcer perforation is a surgical emergency and can be life threatening!*

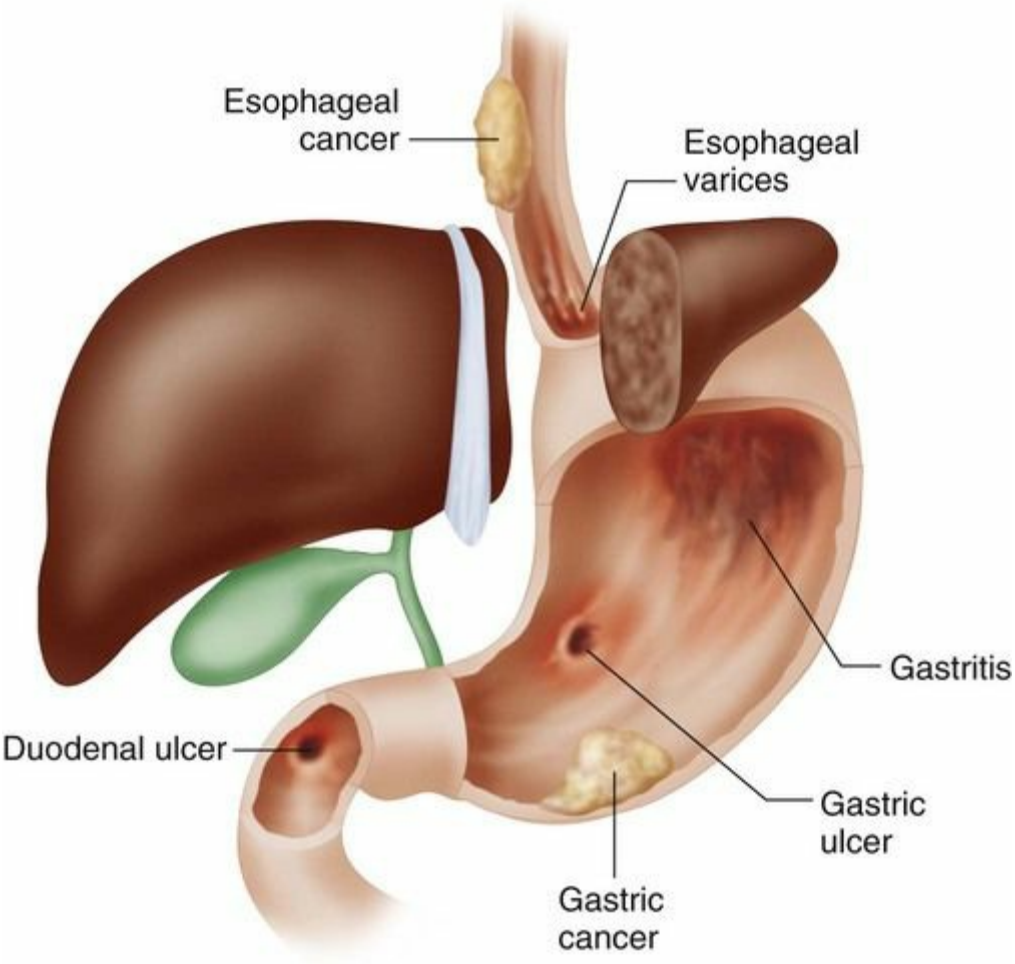

FIG. 55-3 Common causes of upper GI bleeding.

NCLEX Examination Challenge

Safe and Effective Care Environment

The nurse has been assigned to provide care for four clients at the beginning of the day shift. In what order does the nurse assess these clients?

A A client planned for an esophagogastroduodenoscopy (EGD) at 1 pm (1300)
B A client requesting pain medication 2 days after a partial gastrectomy
C A client with peptic ulcer disease experiencing a sudden onset of acute stomach pain
D A client who is NPO for tests to rule out gastric cancer

Pyloric (gastric outlet) obstruction (blockage) occurs in a small percentage of patients and is manifested by vomiting caused by stasis and gastric dilation. Obstruction occurs at the pylorus (the gastric outlet) and is caused by scarring, edema, inflammation, or a combination of these

factors.

Symptoms of obstruction include abdominal bloating, nausea, and vomiting. When vomiting persists, the patient may have hypochloremic (metabolic) alkalosis from loss of large quantities of acid gastric juice (hydrogen and chloride ions) in the vomitus. Hypokalemia may also result from the vomiting or metabolic alkalosis.

Many patients with ulcers have a single episode with no recurrence. However, *intractability* may develop from complications of ulcers, excessive stressors in the patient's life, or an inability to adhere to long-term therapy. He or she no longer responds to conservative management, or recurrences of symptoms interfere with ADLs. In general, the patient continues to have recurrent pain and discomfort despite treatment. Those who fail to respond to traditional treatments or who have a relapse after discontinuation of therapy are referred to a gastroenterologist.

Etiology and Genetic Risk

Peptic ulcer disease is caused most often by bacterial infection with *H. pylori* and NSAIDs. NSAIDs (e.g., ibuprofen) break down the mucosal barrier and disrupt the mucosal protection mediated systemically by cyclooxygenase (COX) inhibition. COX-2 inhibitors (celecoxib [Celebrex]) are less likely to cause mucosal damage but place patients at high risk for cardiovascular events, such as myocardial infarction. In addition, NSAIDs cause decreased endogenous prostaglandins, resulting in local gastric mucosal injury (Lilley et al., 2014). GI complications from NSAID use can occur at any time, even after long-term uncomplicated use. NSAID-related ulcers are difficult to treat, even with long-term therapy, because these ulcers have a high rate of recurrence.

Certain substances may contribute to gastroduodenal ulceration by altering gastric secretion, which produces localized damage to mucosa and interferes with the healing process. For example, corticosteroids (e.g., prednisone), theophylline (Theo-Dur), and caffeine stimulate hydrochloric acid production. Patients receiving radiation therapy may also develop GI ulcers. Other risk factors for PUD are the same as for gastritis (see Chart 55-1).

Incidence and Prevalence

PUD affects millions of people across the world. However, health care provider visits, hospitalizations, and the mortality rate for PUD have decreased in the past few decades. The use of proton pump inhibitors and *H. pylori* treatment may explain these declines.

❖ Patient-Centered Collaborative Care

◆ Assessment

History.

Collect data related to the causes and risk factors for peptic ulcer disease (PUD). Question the patient about factors that can influence the development of PUD, including alcohol intake and tobacco use. Note if certain foods such as tomatoes or caffeinated beverages precipitate or worsen symptoms. Information regarding actual or perceived daily stressors should also be obtained.

A history of current or past medical conditions focuses on GI problems, particularly any history of diagnosis or treatment for *H. pylori* infection. Review all prescription and OTC drugs the patient is taking. Specifically inquire whether the patient is taking corticosteroids, chemotherapy, or NSAIDs. Also ask whether he or she has ever undergone radiation treatments. Assess whether the patient has had any GI surgeries, especially a partial gastrectomy, which can cause chronic gastritis.

A history of GI upset, pain and its relationship to eating and sleep patterns, and actions taken to relieve pain are also important. Inquire about any changes in the character of the pain, because this may signal the development of complications. For example, if pain that was once intermittent and relieved by food and antacids becomes constant and radiates to the back or upper quadrant, the patient may have ulcer perforation. However, many people with active duodenal or gastric ulcers report having no ulcer symptoms.

Physical Assessment/Clinical Manifestations.

Physical assessment findings may reveal epigastric tenderness, usually located at the midline between the umbilicus and the xiphoid process. *If perforation into the peritoneal cavity is present, the patient typically has a rigid, boardlike abdomen accompanied by rebound tenderness and pain.* Initially, auscultation of the abdomen may reveal hyperactive bowel sounds, but these may diminish with progression of the disorder.

Dyspepsia *(indigestion) is the most commonly reported symptom associated with PUD.* It is typically described as sharp, burning, or gnawing pain. Some patients may perceive discomfort as a sensation of abdominal pressure or of fullness or hunger. Older adults often have more nausea and vomiting rather than abdominal discomfort (DeRanieri, 2013). Specific differences between gastric and duodenal ulcers are listed in

Table 55-2.

TABLE 55-2

Differential Features of Gastric and Duodenal Ulcers

FEATURE	GASTRIC ULCER	DUODENAL ULCER
Age	Usually 50 yr or older	Usually 50 yr or older
Gender	Male/female ratio of 1.1 : 1	Male/female ratio of 1 : 1
Blood group	No differentiation	Most often type O
General nourishment	May be malnourished	Usually well nourished
Stomach acid production	Normal secretion or hyposecretion	Hypersecretion
Occurrence	Mucosa exposed to acid-pepsin secretion	Mucosa exposed to acid-pepsin secretion
Clinical course	Healing and recurrence	Healing and recurrence
Pain	Occurs 30-60 min after a meal; at night: rarely Worsened by ingestion of food	Occurs 1½ -3 hr after a meal; at night: often awakens patient between 1 and 2 am Relieved by ingestion of food
Response to treatment	Healing with appropriate therapy	Healing with appropriate therapy
Hemorrhage	Hematemesis more common than melena	Melena more common than hematemesis
Malignant change	Perhaps in less than 10%	Rare
Recurrence	Tends to heal, and recurs often in the same location	60% recur within 1 yr; 90% recur within 2 yr
Surrounding mucosa	Atrophic gastritis	No gastritis

Gastric ulcer pain often occurs in the upper epigastrium with localization to the left of the midline and is aggravated by food. *Duodenal* ulcer pain is usually located to the right of or below the epigastrium. The pain associated with a duodenal ulcer occurs 90 minutes to 3 hours *after* eating and often awakens the patient at night (McCance et al., 2014). Pain may also be exacerbated (made worse) by certain foods (e.g., tomatoes, hot spices, fried foods, onions, alcohol, caffeine drinks) and certain drugs (e.g., NSAIDs, corticosteroids). Perform a comprehensive pain assessment.

Nausea and vomiting may be symptoms accompanying ulcer disease, most commonly with pyloric sphincter dysfunction. It may result from gastric stasis associated with pyloric obstruction. Appetite is generally maintained in patients with a peptic ulcer unless pyloric obstruction is present.

To assess for fluid volume deficit that occurs from bleeding, take orthostatic blood pressures and monitor for signs and symptoms of dehydration. Also assess for dizziness, especially when the patient is upright, because this is a symptom of fluid volume deficit. Older adults often experience dizziness when they get out of bed and are at risk for falls.

NCLEX Examination Challenge

Physiological Integrity

When taking a history of a client diagnosed with a gastric ulcer, which assessment findings does the nurse expect? **Select all that apply**.
A Vomiting
B Weight loss
C Epigastric pain at night
D Relief of epigastric pain after eating
E Melena

Psychosocial Assessment.

Assess the impact of ulcer disease on the patient's lifestyle, occupation, family, and social and leisure activities. Evaluate the impact that lifestyle changes will have on the patient and family. This assessment may reveal information about the patient's ability to adhere to the prescribed treatment regimen and to obtain the needed social support to alter his or her lifestyle.

Laboratory Assessment.

There are three simple, noninvasive tests to detect *H. pylori* in the patient's blood, breath, or stool. Although the breath and stool tests are considered more accurate, *serologic testing* for *H. pylori* antibodies is the most common method to confirm *H. pylori* infection. The *urea breath test* involves swallowing a capsule, liquid, or pudding that contains urea with a special carbon atom. After a few minutes the patient exhales, and if the special carbon atom is found, the bacterium is present. The *stool antigen test* is performed on a stool sample provided by the patient and is tested for *H. pylori* antigens. Patients who have venous bleeding from a peptic ulcer may have *decreased hemoglobin and hematocrit* values. The *stool* may also be positive for occult (not seen) blood if bleeding is present (Pagana & Pagana, 2014).

Imaging Assessment.

If perforation is suspected, the health care provider may request a *chest and abdomen x-ray series*, but other diagnostic tests are more helpful in diagnosis.

Other Diagnostic Assessment.

The major diagnostic test for PUD is esophagogastroduodenoscopy (EGD), which is the most accurate means of establishing a diagnosis. Direct visualization of the ulcer crater by EGD allows the health care provider to

take specimens for *H. pylori* testing and for biopsy and cytologic studies for ruling out gastric cancer. The rapid urease test can confirm a quick diagnosis because urease is produced by the bacteria in the gastric mucosa. EGD may be repeated at 4- to 6-week intervals while the health care provider evaluates the progress of healing in response to therapy. Chapter 52 describes this test in more detail.

GI bleeding may be tested using a *nuclear medicine scan*. No special preparation is required for this scan. The patient is injected with a contrast medium (usually Tc99m), and the GI system is scanned for the presence of bleeding after a waiting period. A second scan may be done 1 to 2 days after the bleeding is treated to determine if the interventions were effective.

Analysis

The priority NANDA-I nursing diagnoses and collaborative problems for patients with peptic ulcer disease (PUD) include:
1. Acute Pain or Chronic Pain related to gastric and/or duodenal ulceration (NANDA-I)
2. Upper GI bleeding related to perforation

Planning and Implementation

Managing Acute Pain or Chronic Pain

Planning: Expected Outcomes.

The patient with PUD is expected to report pain control as evidenced by no more than a 3 on a 0-to-10 pain intensity scale.

Interventions.

PUD causes significant discomfort that impacts many aspects of daily living. Interventions to manage pain focus on drug therapy and dietary changes.

Drug Therapy.

The primary purposes of drug therapy in the treatment of PUD are to (1) provide pain relief, (2) eliminate *H. pylori* infection, (3) heal ulcerations, and (4) prevent recurrence. Several different regimens can be used. In selecting a therapeutic drug regimen, the health care provider considers the efficacy of the treatment, the anticipated side effects, the ability of the patient to adhere to the regimen, and the cost of the treatment.

Although numerous drugs have been evaluated for the treatment of *H. pylori* infection, no single agent has been used successfully against the organism. A common drug regimen for *H. pylori* infection is PPI–triple therapy, which includes a proton pump inhibitor (PPI) such as lansoprazole (Prevacid) plus two antibiotics such as metronidazole (Flagyl, Novonidazol) and tetracycline (Ala-Tet, Panmycin, Nu-Tetra) or clarithromycin (Biaxin, Biaxin XL) and amoxicillin (Amoxil, Amoxi) for 10 to 14 days. Some health care providers may prefer to use quadruple therapy, which contains combination of a proton pump inhibitor (PPI), any two commonly used antibiotics as described above, with the addition of bismuth (Pepto-Bismol). Bismuth therapy is often used in patients who are allergic to penicillin-based medications.

Considerations for Older Adults

Patient-Centered Care QSEN

Many older adults have *H. pylori* infection that is undiagnosed because of vague symptoms associated with physiologic changes of aging and comorbidities that mask dyspepsia. Because the average age of gastric cancer diagnosis is 70 years, it is important to teach older adults about the symptoms of PUD and to consider *H. pylori* screening. Early detection and aggressive treatment can prevent PUD and gastric cancer.

Hyposecretory drugs reduce gastric acid secretions and are therefore used for both peptic ulcer disease (PUD) and gastritis management. The primary prescribed drugs include proton pump inhibitors and H_2-receptor antagonists (Chart 55-4).

Chart 55-4 Common Examples of Drug Therapy

Peptic Ulcer Disease

DRUG AND USUAL DOSAGE	PURPOSE OF DRUG	NURSING INTERVENTIONS	RATIONALES
Antacids			
Magnesium hydroxide with aluminum hydroxide (Maalox, Mylanta) 50-80 mEq orally 1 hr and 3 hr after meals and at bedtime	Increases pH of gastric contents by deactivating pepsin	Give 2 hr after meals and at bedtime.	Hydrogen ion load is high after ingestion of foods.
		Use liquid rather than tablets.	Suspensions are more effective than chewable tablets.
		Do not give other drugs within 1-2 hr of antacids.	Antacids interfere with absorption of other drugs.
		Assess patients for a history of renal disease.	Hypermagnesemia may result. These antacids have a high sodium content. These antacids contain magnesium, which cannot be excreted by poorly functioning kidneys, thus causing toxicity.
		Assess the patient for a history of heart failure.	Inadequate renal perfusion from heart failure decreases the ability of the kidneys to excrete magnesium, thus causing toxicity.
		Observe the patient for the side effect of diarrhea.	Magnesium often causes diarrhea.
Aluminum hydroxide (Amphojel) 50-80 mEq orally 1 hr and 3 hr after meals and at bedtime		Give 1 hr after meals and at bedtime.	Hydrogen ion load is high after ingestion of food.
		Use liquid rather than tablets if palatable.	Suspensions are more effective than chewable tablets.
		Do not give other drugs within 1-2 hr of antacids.	Antacids interfere with absorption of other drugs.
		Observe patients for the side effect of constipation. If constipation occurs, consider alternating with magnesium antacid.	Aluminum causes constipation, and magnesium has a laxative effect.
		Use for patients with renal failure.	Aluminum binds with phosphates in the GI tract. This antacid does not contain magnesium.
H_2 Antagonists (Blockers)			
Ranitidine (Zantac) 150 mg orally twice daily or 300 mg orally at bedtime; 50 mg IV every 6 hr or 8 mg/hr IV (continuous) Famotidine (Pepcid) 40 mg orally once daily or in two divided doses; 20 mg IV every 12 hr Nizatidine (Axid) 150 mg orally twice daily or 300 mg at bedtime	Decreases gastric acid secretions by blocking histamine receptors in parietal cells	Give single dose at bedtime for treatment of GI ulcers, heartburn, and PUD. **Note:** IV famotidine or IV ranitidine may also be given to prevent surgical stress ulcers.	Bedtime administration suppresses nocturnal acid production.
Mucosal Barrier Fortifiers			
Sucralfate (Carafate, Sulcrate) 1 g orally four times daily or 2 g twice daily	Binds with bile acids and pepsin to protect stomach mucosa	Give 1 hr before and 2 hr after meals and at bedtime.	Food may interfere with drug's adherence to mucosa.
		Do not give within 30 min of giving antacids or other drugs.	Antacids may interfere with effect.
Bismuth Subsalicylate (Pepto-Bismol) 525 mg (30 mL) orally four times daily	Stimulates mucosal protection and prostaglandin production Inhibits *H. pylori* from binding to mucosal lining	Patients cannot take aspirin while on this drug. **Note:** May cause the stools to be discolored black.	Aspirin is a salicylic acid and will lead to overdose of aspirin.
	Proton Pump Inhibitors		
Omeprazole (Prilosec, Losec) 20-40 mg orally daily	Suppresses H^+K^+–ATPase enzyme system of gastric acid secretion Indications for short-term and long-term use for PUD, symptomatic heartburn, and *H. pylori* treatment	Have patients take capsule whole; do not crush.	Delayed-release capsules allow absorption after granules leave the stomach.
		Give 30 minutes before the main meal of the day.	The proton pump is activated by the presence of food. Therefore the drug needs a chance to work before the patient eats.
Lansoprazole (Prevacid) 15-30 mg orally daily		Give 30 min before the main meal of the day.	The proton pump is activated by the presence of food. Therefore the drug needs a chance to work before the patient eats.
Rabeprazole (Aciphex) 20 mg orally once daily		Take after the morning meal.	Drug promotes healing and symptom relief of duodenal ulcers.
		Do not crush capsule.	Drug is a sustained-release capsule.
Pantoprazole (Protonix) 40 mg orally or IV daily for 7-10 days		Do not crush.	Drug is enteric-coated.
		IV form must be given on a pump with a filter and in a separate line.	Given IV, drug precipitates easily.

DRUG AND USUAL DOSAGE	PURPOSE OF DRUG	NURSING INTERVENTIONS	RATIONALES
		Do not give Protonix IV with other IV drugs. **Note:** This medication may have several adverse drug interactions. Be aware of the patient's other medications.	The IV form is not compatible with most other drugs. This medication will alter how other drugs are metabolized, either increasing or decreasing their effectiveness.
Esomeprazole (Nexium) 20 or 40 mg orally daily (or IV daily for 7-10 days)		Assess for hepatic impairment.	Patients with severe hepatic problems need a low dose.
		Do not give Nexium IV with other IV drugs. **Note:** This medication may have several adverse drug interactions. Be aware of the patient's other medications.	The IV form is not compatible with most other drugs. This medication will alter how other drugs are metabolized, either increasing or decreasing the effectiveness.
Prostaglandin Analogs			
Misoprostol (Cytotec) 200 mcg orally four times daily	Synthetic prostaglandin that stimulates mucosal protection and decreases gastric acid secretions Helps resist mucosal injury in patients taking NSAIDs and/or high-dose corticosteroids	Avoid magnesium-containing antacids. **Note:** Do not use in pregnant women.	Both misoprostol and magnesium-containing antacids can cause diarrhea. Can cause abortion, premature birth, or birth defects.
Antimicrobials			
Clarithromycin (Biaxin) 500 mg orally three times daily	Treats *H. pylori* infection	Be aware that the drug should be given with caution to patients with renal impairment; monitor renal function lab values.	The drug can increase the patient's BUN level and should be monitored.
Amoxicillin (Amoxil) 1 g orally twice daily	Treats *H. pylori* infection	Teach patients to take the drug with food or immediately after a meal.	The drug can cause GI disturbances, including nausea, vomiting, and diarrhea.
Tetracycline 500 mg orally four times daily	Treats *H. pylori* infection	Teach patients to take the drug at least 1 hour before meals or 2 hours after meals.	Dairy products and other foods may interfere with drug absorption.
		Teach patients to avoid direct sunlight and wear sunscreen when outdoors.	The drug can cause the skin to burn due to photosensitivity.
Metronidazole (Flagyl) 250 mg orally three times daily and at bedtime	Treats *H. pylori* infection	Teach patients to take the drug with food.	The drug can cause GI disturbances, especially nausea.
		Teach patients to avoid alcohol during drug therapy and for at least 3 days after therapy is completed.	The patient can experience a drug-alcohol reaction, including severe nausea, vomiting, and headache.

Proton pump inhibitors (PPIs) is the drug class of choice for treating patients with acid-related disorders. Examples include omeprazole (Prilosec), lansoprazole (Prevacid), rabeprazole (Aciphex), pantoprazole (Protonix), and esomeprazole (Nexium). These drugs suppress the H,K–ATPase enzyme system of gastric acid production, and several of them are available as over-the-counter (OTC) drugs (Lilley et al., 2014).

Omeprazole, lansoprazole, and esomeprazole are each available as delayed-release capsules designed to release their contents after they pass through the stomach. Omeprazole and lansoprazole may be dissolved in a sodium bicarbonate solution and given through any feeding tube. Bicarbonate protects the dissolved omeprazole and lansoprazole granules in gastric acid. Therefore the drugs are still absorbed correctly. These capsules can also be opened. The enteric-coated capsules can be put in apple juice or orange juice and given through a large-bore feeding tube. Rabeprazole (Aciphex) and pantoprazole (Protonix) are enteric-coated tablets that quickly dissolve after the tablet has moved through the stomach and should not be crushed before giving them. Several of the PPIs are also available in an

IV form, which may be helpful for patients who are NPO.

Some patients use these PPIs for years and perhaps a lifetime. However, these drugs should not be used for a prolonged period because, over time, they may contribute to osteoporotic-related fractures, especially spinal fractures in older women (Kwok et al., 2010). Omeprazole (Prilosec and Prilosec OTC) reduces the effect of clopidogrel (Plavix), an antiplatelet drug. Teach patients to tell their health care provider if they are taking clopidogrel. PPIs should not be discontinued abruptly to prevent rebound activation of the proton pump. Therefore, a step-down approach over several days is recommended (Zarowitz, 2011).

H_2-receptor antagonists are drugs that block histamine-stimulated gastric secretions. These drugs may also be used for indigestion and gastritis. Lower-dose forms are available in over-the-counter (OTC) products. H_2-receptor antagonists block the action of the H_2 receptors of the parietal cells, thus inhibiting gastric acid secretion. Two of the most common drugs are famotidine (Pepcid) and nizatidine (Axid) and are available as Pepcid OTC and Axid AR in OTC form. These drugs are typically administered in a single dose at bedtime and are used for 4 to 6 weeks in combination with other therapy.

Antacids buffer gastric acid and prevent the formation of pepsin. They may help small duodenal ulcers heal but are usually not used alone as drug therapy. Liquid suspensions are the most therapeutic form, but tablets may be more convenient and enhance adherence. The most widely used preparations are mixtures of aluminum hydroxide and magnesium hydroxide. This combination overcomes the unpleasant GI side effects of either of these preparations when used alone. Mylanta and Maalox are examples of this type of combination antacid formulation. The aluminum and magnesium hydroxide combination products neutralize well at small doses. These products must be administered cautiously to patients with renal impairment because elimination is reduced and excessive amounts are retained in the body.

Nursing Safety Priority QSEN

Drug Alert

Teach the patient that to achieve a therapeutic effect, sufficient antacid must be ingested to neutralize the hourly production of acid. For optimal effect, take antacids about 2 hours after meals to reduce the hydrogen ion load in the duodenum. Antacids may be effective from 30 minutes to 3 hours after ingestion. If taken on an empty stomach, they

are quickly evacuated. Thus the neutralizing effect is reduced (Lilley et al., 2014).

Calcium carbonate (Tums) is a potent antacid, but it triggers gastrin release, causing a rebound acid secretion. Therefore its use in acid inhibition is not recommended.

Antacids can interact with certain drugs such as phenytoin (Dilantin), tetracycline (Ala-Tet, Nu-Tetra), and ketoconazole (Nizoral) and interfere with their effectiveness. Ask what other drugs the patient is using before a specific antacid is prescribed. Other drugs are given 1 to 2 hours before or after the antacid. Inform the patient that flavored antacids, especially wintergreen, should be avoided. The flavoring increases the emptying time of the stomach. Thus the desired effect of the antacid is negated.

Teach the patient with past or present heart failure to avoid antacids with high sodium content, such as aluminum hydroxide, magnesium hydroxide, sodium bicarbonate, and simethicone combination products (Gelusil and Mylanta). Magaldrate (Riopan) has the lowest sodium concentration.

Sucralfate (Carafate) is a *mucosal barrier fortifier* (protector) that forms complexes with proteins at the base of a peptic ulcer. This protective coat prevents further digestive action of both acid and pepsin. Sucralfate does not inhibit acid secretion. Rather, it binds bile acids and pepsins, reducing injury from these substances. The drug may be used in conjunction with H_2-receptor antagonists and antacids but should not be administered within 1 hour of the antacid. Sucralfate is given on an empty stomach 1 hour before each meal and at bedtime. The main side effect of this drug is constipation.

Bismuth subsalicylate (Pepto-Bismol) inhibits *H. pylori* from binding to the mucosal lining and stimulates mucosal protection and prostaglandin production. Teach patients they cannot take aspirin while on this drug because aspirin is a salicylic acid and could cause an overdose of salicylates. Patients should also be taught that this medication may cause the stools to be discolored black. This discoloration is temporary and harmless.

Nutrition Therapy.

The role of diet in the management of ulcer disease is controversial. There is no evidence that dietary restriction reduces gastric acid secretion or promotes tissue healing, although a bland diet may assist in relieving symptoms. Food itself acts as an antacid by neutralizing gastric acid for

30 to 60 minutes. An increased rate of gastric acid secretion, called *rebound*, may follow.

Nursing Safety Priority QSEN

Action Alert

Teach the patient with peptic ulcer disease to avoid substances that increase gastric acid secretion. This includes caffeine-containing beverages (coffee, tea, cola). Both caffeinated and decaffeinated coffees should be avoided, because coffee contains peptides that stimulate gastrin release (McCance et al., 2014).

Teach the patient to exclude any foods that cause discomfort. A bland, nonirritating diet is recommended during the acute symptomatic phase. Bedtime snacks are avoided because they may stimulate gastric acid secretion. Eating six smaller meals daily may help, but this regimen is no longer a regular part of therapy. No evidence supports the theory that eating six meals daily promotes healing of the ulcer. This practice may actually stimulate gastric acid secretion. Patients should avoid alcohol and tobacco because of their stimulatory effects on gastric acid secretion.

Complementary and Alternative Therapies.

Teach patients about complementary and alternative therapies that can reduce stress, including hypnosis and imagery. For example, the use of yoga and meditation techniques has demonstrated a beneficial effect on anxiety disorders. Many have suggested that GI disorders result from the dysfunction of both the GI tract itself and the brain. This means that emotional stress is thought to worsen GI disorders such as peptic ulcer disease. Yoga may alter the activities of the central and autonomic nervous systems.

Many herbs, such as powders of slippery elm and marshmallow root, quercetin, and licorice, are used commonly by patients with gastritis and PUD. These herbs may help heal inflamed tissue and increase blood flow to the gastric mucosa. Other substances include zinc, vitamin C, essential fatty acids, acidophilus, vitamin A, and glutamine. Table 55-1 provides a list of therapies that have been used by many patients with gastric disorders. Many of them have been scientifically supported in animal studies but have not been thoroughly studied in humans.

Nursing Safety Priority QSEN

Action Alert

Teach the patient who has peptic ulcer disease to seek immediate medical attention if experiencing any of these symptoms:

- Sharp, sudden, persistent, and severe epigastric or abdominal pain
- Bloody or black stools
- Bloody vomit or vomit that looks like coffee grounds

Managing Upper GI Bleeding

Planning: Expected Outcomes.

The patient with upper GI bleeding (often called *upper GI hemorrhage* or *UGH*) is expected to have bleeding promptly and effectively controlled and vital signs within normal limits.

Interventions.

Blood loss from PUD results in high morbidity and mortality. Fluid volume loss secondary to vomiting can lead to dehydration and electrolyte imbalances. Interventions aimed at managing complications associated with PUD include prevention and/or management of bleeding, perforation, and gastric outlet obstruction. In some cases surgical treatment of complications becomes necessary.

Nonsurgical Management.

Because prevention or early detection of complications is needed to obtain a positive clinical outcome, monitor the patient carefully and immediately report changes to the health care provider. The type of intervention selected will depend on the type and severity of the complication.

Emergency: Upper GI Bleeding.

The patient who is actively bleeding has a life-threatening emergency. He or she needs supportive therapy to prevent hypovolemic shock and possible death.

Nursing Safety Priority QSEN

Critical Rescue

The first priority for care of the patient with upper GI bleeding is to

*maintain **a**irway, **b**reathing, and **c**irculation (ABCs).* Provide oxygen and other ventilatory support as needed. Start two large-bore IV lines for replacing fluids and blood. Monitor vital signs, hematocrit, and oxygen saturation.

The purpose of managing hypovolemia is to expand intravascular fluid in a patient who is volume depleted. Carefully monitor the patient's fluid status, including intake and output. *Fluid replacement in older adults should be closely monitored to prevent fluid overload.* Serum electrolytes are also assessed because depletions from vomiting or nasogastric suctioning must be replaced. Volume replacement with isotonic solutions (e.g., 0.9% normal saline solution, lactated Ringer's solution) should be started immediately. The health care provider may prescribe blood products such as packed red blood cells to expand volume and correct a low hemoglobin and hematocrit. For patients with active bleeding, fresh frozen plasma may be given if the prothrombin time is 1.5 times higher than the midrange control value.

Continue to monitor the patient's hematocrit, hemoglobin, and coagulation studies for changes from the baseline measurements. With mild bleeding (less than 500 mL), slight feelings of weakness and mild perspiration may be present. When blood loss exceeds 1 L/24 hr, manifestations of shock may occur, such as hypotension, chills, palpitations, diaphoresis, and a weak, thready pulse.

A combination of several different treatments, including nasogastric tube (NGT) placement and lavage, endoscopic therapy, interventional radiologic procedures, and acid suppression, can be used to control acute bleeding and prevent rebleeding. If the patient is actively bleeding at home, he or she is usually admitted to the emergency department for GI lavage. If the patient is already a patient in the hospital, lavage can be done at the bedside. After the bleeding has stopped, H_2-receptor antagonists, proton pump inhibitors, and antacids are the primary drugs used.

Nasogastric Tube Placement and Lavage.

Upper GI bleeding often requires the primary care provider or nurse to insert a large-bore nasogastric tube (NGT) to:

- Determine the presence or absence of blood in the stomach
- Assess the rate of bleeding
- Prevent gastric dilation
- Administer lavage

Although not performed as commonly today, **gastric lavage** requires

the insertion of a large-bore NGT with instillation of a room-temperature solution in volumes of 200 to 300 mL. There is no evidence that sterile saline or sterile water is better than tap water for this procedure. Follow agency protocol for the solution that is required. The solution and blood are repeatedly withdrawn manually until returns are clear or light pink and without clots. Instruct the patient to lie on the left side during this procedure. The NGT may remain in place for a few days or be removed after lavage.

Endoscopic Therapy.

Endoscopic therapy via an esophagogastroduodenoscopy (EGD) can assist in achieving homeostasis during an acute hemorrhage by isolating the bleeding artery to embolize (clot) it. A physician can insert instruments through the endoscope during the procedure to stop bleeding in three different ways: (1) inject chemicals into the bleeding site; (2) treat the bleeding area with heat, electric current, or laser; or (3) close the affected blood vessels with a band or clip. During the EGD, a specialized endoscopy nurse and technician assist the physician with the procedure.

Pre-EGD nursing care involves inserting one or two large-bore IV catheters if they are not in place. A large catheter allows the patient to receive IV moderate sedation (e.g., midazolam [Versed] and an opioid) and possibly a blood transfusion. Keep the patient NPO for 4 to 6 hours before the procedure. This prevents the risk for aspiration and allows the endoscopist to view and treat the ulcer. A patient must sign a consent form before the EGD *after* the physician informs him or her about the procedure.

Nursing Safety Priority QSEN

Action Alert

After esophagogastroduodenoscopy (EGD), monitor vital signs, heart rhythm, and oxygen saturation frequently until they return to baseline. In addition, frequently assess the patient's ability to swallow saliva. The patient's gag reflex may initially be absent after an EGD because of anesthetizing (numbing) the throat with a spray before the procedure. *After the procedure, do not allow the patient to have food or liquids until the gag reflex is intact!*

Endoscopic therapy is beneficial for most patients with active bleeding.

However, ulcers that continue to bleed or continue to rebleed despite endoscopic therapy may require an interventional radiologic procedure or surgical repair.

Interventional Radiologic Procedures.

For patients with persistent, massive upper GI bleeding or those who are not surgical candidates, catheter-directed embolization may be performed. This endovascular procedure is usually done if endoscopic procedures are not successful or available. A femoral approach is most often used, but brachial access may be used. An arteriogram is performed to identify the arterial anatomy and find the exact location of the bleeding. The physician injects medication or other material into the blood vessels to stop the bleeding. Post-arteriogram nursing care should be provided after the procedure as described in Chapter 36.

Acid Suppression.

Aggressive acid suppression is used to prevent rebleeding. When acute bleeding is stopped and clot formation has taken place within the ulcer crater, the clot remains in contact with gastric contents. Acid-suppressive agents are used to stabilize the clot by raising the pH level of gastric contents. Several types of drugs are used. H_2-receptor antagonists prevent acid from being produced by parietal cells. Proton pump inhibitors prevent the transport of acid across the parietal cell membrane, whereas antacids buffer acid produced in the stomach.

Perforation is managed by immediately replacing fluid, blood, and electrolytes, administering antibiotics, and keeping the patient NPO. Maintain nasogastric suction to drain gastric secretions and thus prevent further peritoneal spillage. Carefully monitor intake and output and check vital signs at least hourly. Monitor the patient for clinical manifestations of septic shock, such as fever, pain, tachycardia, lethargy, or anxiety.

Pyloric obstruction is caused by edema, spasm, or scar tissue. Symptoms of obstruction related to difficulty in emptying the stomach include feelings of fullness, distention, or nausea after eating, as well as vomiting copious amounts of undigested food.

Treatment of obstruction is directed toward restoring fluid and electrolyte balance and decompressing the dilated stomach. Obstruction related to edema and spasm generally responds to medical therapy. First, the stomach must be decompressed with nasogastric suction. Next, interventions are directed at correcting metabolic alkalosis and

dehydration. The NGT is clamped after about 72 hours. Check the patient for retention of gastric contents. If the amount retained is not more than 50 mL in 30 minutes, the health care provider may allow oral fluids. In some cases, surgical intervention may be required to treat PUD.

Surgical Management.

Evidence-based guidelines for the treatment of PUD that include *H. pylori* treatment and the development of nonsurgical means of controlling bleeding have led to a decline in the need for surgical intervention. In PUD, surgical intervention may be used to:

- Treat patients who do not respond to medical therapy or other nonsurgical procedures
- Treat a surgical emergency that develops as a complication of PUD, such as perforation

Two general surgical approaches are available for PUD—minimally invasive surgery and conventional open surgery.

Minimally invasive surgery (MIS) via laparoscopy (a type of endoscope) may be used to remove a chronic gastric ulcer or treat hemorrhage from perforation. Several small incisions allow access to the stomach and duodenum. The patient may have partial stomach removal (subtotal gastrectomy), pyloroplasty (to open the pylorus), and/or a vagotomy (vagus nerve cutting) to control acid secretion. Acid-reduction surgery may not be necessary due to the increased use of PPIs and endoscopic procedures in the treatment of PUD. The advantages of MIS over traditional open surgical procedures include a shorter hospital stay, fewer complications, less pain, and better, quicker recovery.

Clinical Judgment Challenge

Prioritization, Delegation, and Supervision

A 67-year-old man drove himself to the emergency department (ED) after vomiting bright red blood twice within 6 hours. He is alert and oriented and admits to having a few drinks last weekend. He takes some medicine for his stomach, but he cannot recall the name of the drug. He reports intermittent dizziness and fatigue over the past 2 days. His skin is dry and pale, and his abdomen is slightly distended. He reports pain (4/10) in the mid-epigastric area. His BP is 140/90, heart rate is 110/min, respirations are 24/min, and temperature is 98.9° F.

1. What actions are appropriate in the care of this patient in the ED? As the nurse in the ER, what additional questions will you ask his wife?

2. What data will you document?
3. Which task is most appropriate to assign to the nursing assistant working with you?
4. You are performing additional assessment and history on the patient. Which finding should you immediately report to the health care provider?
5. What medication is the physician most likely to prescribe for emergency treatment of acute and severe bleeding of the patient's ulcer?

Community-Based Care

Patients may be discharged from the hospital as long as there is no evidence of ongoing bleeding, orthostatic changes, or cardiopulmonary distress or compromise. Those discharged after treatment for peptic ulcer disease (PUD) and/or complications secondary to the disease must face several challenges to manage the disease successfully. Long-term adherence to drug therapy may require the patient to take several drugs each day. Permanent lifestyle alterations in nutrition habits must also be made.

Home Care Management.

Most patients are discharged to the home to continue their recovery. Those who have had major surgery or have had complications, such as hemorrhage, may require one or two visits from a home care nurse to assess clinical progress, especially if the patient is an older adult (Chart 55-5).

Chart 55-5 Home Care Assessment

The Patient with Ulcer Disease

Assess gastrointestinal and cardiovascular status, including:

- Vital signs, including orthostatic vital signs
- Skin color
- Presence of abdominal pain (location, severity, character, duration, precipitating factors, and relief measures)
- Character, color, and consistency of stools
- Changes in bowel elimination pattern
- Hemoglobin and hematocrit
- Bowel sounds; palpate for areas of tenderness

Assess nutritional status, including:

- Dietary patterns and habits
- Intake of coffee and alcohol
- Relationship of food to symptoms

Assess medication history:

- Use of steroids
- Use of NSAIDs
- Use of over-the-counter medications

Assess patient's coping style:

- Recent stressors
- Past coping style

Assess patient's understanding of illness and ability to adhere to the therapeutic regimen:

- Symptoms to report to health care provider
- Expected and side effects of medications
- Food and drug interactions
- Need for smoking cessation

Self-Management Education.

The primary focus of home care preparation is patient and family teaching regarding risk factors for the recurrence of PUD. Teach them how to recognize new complications and what to do if they occur, especially abdominal pain; nausea and vomiting; black, tarry stools; and weakness or dizziness.

Teach the patient and family about risk factors for recurring peptic ulcers. Help them plan ways to make needed lifestyle changes. For postsurgical patients, especially those who have undergone partial stomach removal, smaller meals may be required. Other postoperative nutrition changes are described on p. 1142 in the discussion of Self-Management Education in the Gastric Cancer section.

Nursing Safety Priority QSEN

Action Alert

Teach the patient who has had surgery for PUD to avoid any OTC product containing aspirin or other NSAID. Emphasize the importance of following the treatment regimen for *H. pylori* infection and healing the ulcer. Emphasize the importance of keeping all follow-up appointments. Help the patient identify situations that cause stress, describe feelings during stressful situations, and develop a plan for coping with stressors.

Health Care Resources.

If needed, refer the patient and family to the National Digestive Diseases Information Clearinghouse (www.digestive.niddk.nih.gov/). This group provides information and support to patients who have digestive disorders.

Evaluation: Outcomes

Evaluate the care of the patient with peptic ulcer disease (PUD) based on the identified priority patient problems. The expected outcomes are that the patient:

- Does not have active PUD or associated complications
- Verbalizes pain relief or control
- Adheres to the drug regimen and lifestyle changes to prevent recurrence and heal the ulcer
- Does not experience an upper GI bleed; if bleeding occurs, it will be promptly and effectively managed

Gastric Cancer

Most cancers of the stomach are adenocarcinomas. This type of cancer develops in the mucosal cells that form the innermost lining of any portion or all of the stomach. *Often there are no symptoms in the early stages and the disease is advanced when detected.*

❖ Pathophysiology

Gastric cancer usually begins in the glands of the stomach mucosa. Atrophic gastritis and intestinal metaplasia (abnormal tissue development) are precancerous conditions. Inadequate acid secretion in patients with atrophic gastritis creates an alkaline environment that allows bacteria (especially *H. pylori*) to multiply. This infection causes mucosa-associated lymphoid tissue (MALT) lymphoma, which starts in the stomach (McCance et al., 2014).

Gastric cancers spread by direct extension through the gastric wall and into regional lymphatics, which carry tumor deposits to lymph nodes. Direct invasion of and adherence to adjacent organs (e.g., the liver, pancreas, and transverse colon) may also result. Hematogenous spread via the portal vein to the liver and via the systemic circulation to the lungs and bones is the most common mode of metastasis. Peritoneal seeding of cancer cells from the tumor areas to the omentum, peritoneum, ovary, and pelvic cul-de-sac can also occur.

In people with *advanced* gastric cancer, there is invasion of the muscularis (stomach muscle) or beyond. These lesions are not cured by surgical resection. The overall 5-year survival rate of people with stomach cancer in the United States is poor because most patients have no symptoms until the disease advances.

Etiology and Genetic Risk

Infection with *H. pylori* is the largest risk factor for gastric cancer because it carries the cytotoxin-associated gene A *(CagA)* gene. Patients with pernicious anemia, gastric polyps, chronic atrophic gastritis, and **achlorhydria** (absence of secretion of hydrochloric acid) are 2 to 3 times more likely to develop gastric cancer.

The disease also seems to be positively correlated with eating pickled foods, nitrates from processed foods, and salt added to food. The ingestion of these foods over a long period can lead to atrophic gastritis, a precancerous condition. A low intake of fruits and vegetables is also a risk factor for cancer (McCance et al., 2014).

Gastric surgery seems to increase the risk for gastric cancer because of the eventual development of atrophic gastritis, which results in changes to the mucosa. Patients with Barrett's esophagus from prolonged or severe gastroesophageal reflux disease (GERD) have an increased risk for cancer in the cardia (at the point where the stomach connects to the esophagus).

Incidence and Prevalence

Generally, stomach cancer rates are about twice as high in males as in females. Over 70% of new cases and gastric cancer deaths occur in developing countries (Jemal et al., 2011). The highest incidence rates are in Eastern Asia, Eastern Europe, and South America, and the lowest rates are in North America and parts of Africa (Jemal et al., 2011). The average age for developing gastric cancer is 70 years (American Cancer Society, 2014).

Nurses are uniquely positioned to improve gastric cancer survival rates by ensuring that patients with high risk and suspicious symptoms are assessed and diagnosed early (Bailey, 2011). Maintaining functional status and quality of life during gastric cancer care is a priority for nursing care.

Health Promotion and Maintenance

Teach patients with gastritis and/or *H. pylori* infection to follow the treatment regimen to ensure that gastritis heals and *H. pylori* infection is eliminated. *Stress the need for eating a well-balanced diet and limiting pickled foods, salted foods, and processed foods to help prevent gastric cancer.*

❖ Patient-Centered Collaborative Care

◆ Assessment

Question the patient about known risk factors for the development of gastric cancer. Ask about preferred foods, especially pickled, salted, or smoked foods. Inquire whether the patient has ever been diagnosed with or treated for *H. pylori* infection, gastritis, or pernicious anemia. Note whether he or she has a history of gastric surgery or polyps. Also ask whether any of the patient's immediate relatives have gastric cancer.

Although patients with *early* gastric cancer may be asymptomatic, indigestion (heartburn) and abdominal discomfort are the *most* common symptoms (Chart 55-6). These symptoms are often ignored, however, or a change in diet or use of antacids relieves them. As the tumor grows, these symptoms become more severe and do not respond to nutrition

changes or antacids. Epigastric or back pain is also an early symptom that may go unrecognized.

Chart 55-6 Key Features

Early Versus Advanced Gastric Cancer

Early Gastric Cancer*

- Indigestion
- Abdominal discomfort initially relieved with antacids
- Feeling of fullness
- Epigastric, back, or retrosternal pain

Advanced Gastric Cancer

- Nausea and vomiting
- Obstructive symptoms
- Iron deficiency anemia
- Palpable epigastric mass
- Enlarged lymph nodes
- Weakness and fatigue
- Progressive weight loss

*__NOTE:__ Many patients with early gastric cancer have no clinical manifestations.

In *advanced* gastric cancer, progressive weight loss, nausea, and vomiting can occur. Vomiting represents pronounced dilation, thickening of the stomach wall, or pyloric obstruction. Obstructive symptoms appear earlier with tumors located near the pylorus than with those in the fundus. Patients with advanced disease may have weakness, fatigue, and anemia. Physical assessment findings in advanced disease may be absent, or a palpable epigastric mass may suggest hepatomegaly (liver enlargement) from metastatic disease. Hard, enlarged lymph nodes in the left supraclavicular chain, left axilla, or umbilicus result from metastasis from gastric cancer. Masses on the right suggest metastasis in the perigastric lymph nodes or liver.

In patients with advanced disease, anemia is evidenced by *low hematocrit* and hemoglobin values. Patients may have macrocytic or microcytic anemia associated with decreased iron or vitamin B_{12} absorption. *The stool may be positive for occult blood. Hypoalbuminemia* and *abnormal results of liver tests* (e.g., bilirubin and alkaline phosphatase)

occur with advanced disease and with hepatic metastasis. The level of carcinoembryonic antigen (CEA) is elevated in advanced cancer of the stomach (Pagana & Pagana, 2014).

The health care provider uses esophagogastroduodenoscopy (EGD) with biopsy for definitive diagnosis of gastric cancer. (See Chapter 52 for a discussion of nursing care associated with this diagnostic test.) The lesion can be viewed directly, and biopsies of all visible lesions can be obtained to determine the presence of cancer cells. During the endoscopy, an endoscopic (endoluminal) ultrasound (EUS) of the gastric mucosa can also be performed. This technology allows the health care provider to evaluate the depth of the tumor and the presence of lymph node involvement, which permits more accurate staging of the disease. CT, positron emission tomography (PET), and MRI scans of the chest, abdomen, and pelvis are used in determining the extent of the disease and planning therapy.

Interventions

Management of gastric cancer includes drug therapy, radiation, and/or surgery. Drug therapy and radiation may be used instead of surgery or as an adjunct before and/or after surgery.

Nonsurgical Management.

The treatment of gastric cancer depends highly on the stage of the disease. Radiation and chemotherapy commonly prolong survival of patients with advanced gastric disease.

Combination *chemotherapy* with multiple cycles of drugs such as cisplatin (Platinol) and epirubicin (Elience) before and after surgery may be given. Bone marrow suppression, nausea, and vomiting are common adverse drug effects. Chapter 22 discusses the general nursing care of patients receiving chemotherapy.

Although gastric cancers are somewhat sensitive to the effects of radiation, the use of this treatment is limited because the disease is often widely spread to other abdominal organs on diagnosis. Organs such as the liver, kidneys, and spinal cord can endure only a limited amount of radiation. Intraoperative radiotherapy (IORT) is available in large tertiary care health care systems. Radiation may be used for palliative management when surgery is not an option.

The most common side effects of radiation include impaired skin integrity, fatigue, and anorexia. Nausea, vomiting, and diarrhea may occur about 1 week after treatment is initiated and diminish a month or

more after treatment ends. (See Chapter 22 for more information on radiation therapy.)

Surgical Management.

Surgical resection by removing the tumor is the preferred method for treating gastric cancer. The primary surgical procedures for the treatment of gastric cancer are total gastrectomy and subtotal (partial) gastrectomy. In early stages, laparoscopic surgery (minimally invasive surgery [MIS]) plus adjuvant chemotherapy or radiation may be curative. Patients having MIS have less pain, shorter hospital stays, rare postoperative complications, and quicker recovery. However, MIS is seldom performed because very few patients are diagnosed in the early stage of the disease.

Most patients with advanced disease are candidates for palliative surgical treatment. Metastasis in the supraclavicular lymph nodes, inguinal lymph nodes, liver, umbilicus, or perirectal wall indicates that the opportunity for cure by resection has been lost. Palliative resection may significantly improve the quality of life for a patient suffering from obstruction, hemorrhage, or pain.

Preoperative Care.

Before conventional open-approach surgery, a nasogastric tube (NGT) is often inserted and connected to suction to remove secretions and empty the stomach. This allows surgery to take place without contamination of the peritoneal cavity by gastric secretions. The NGT remains in place for a few days *postoperatively* to prevent the accumulation of secretions, which may lead to vomiting or GI distention and pressure on the incision. Patients having laparoscopic surgery (minimally invasive surgery [MIS]) do not require an NGT.

Because weight loss is problematic for patients with gastric cancer, nutrition therapy is a vital aspect of preoperative and postoperative management. Preoperatively, compression by the tumor can prevent adequate nutritional intake. To correct malnutrition before surgery, the health care provider may prescribe enteral supplements to the diet and/or total parenteral nutrition (TPN). Vitamin, mineral, iron, and protein supplements are essential to correct nutritional deficits.

Other preoperative nursing measures for the patient undergoing open gastric surgery are the same as those for any patient undergoing abdominal surgery and general anesthesia (see Chapter 14).

Operative Procedures.

The surgeon usually removes part or all of the stomach to take out the

tumor. When the tumor is located in the mid-portion or distal (lower) portion of the stomach, a subtotal (partial) gastrectomy is typically performed. The omentum, spleen, and relevant nodes are also removed. The surgery may be performed as an MIS procedure or as an open conventional surgical technique, with or without robotic assistance.

For the patient with a removable growth in the proximal (upper) third of the stomach, a total gastrectomy is performed (Fig. 55-4). In this procedure the surgeon removes the entire stomach along with the lymph nodes and omentum. The surgeon sutures the esophagus to the duodenum or jejunum to reestablish continuity of the GI tract. More radical surgery involving removal of the spleen and distal pancreas is controversial, although the Whipple procedure may be used to prolong life. However, the complications of this drastic surgery are very serious and common. For patients with advanced disease, total gastrectomy is performed only when gastric bleeding or obstruction is present.

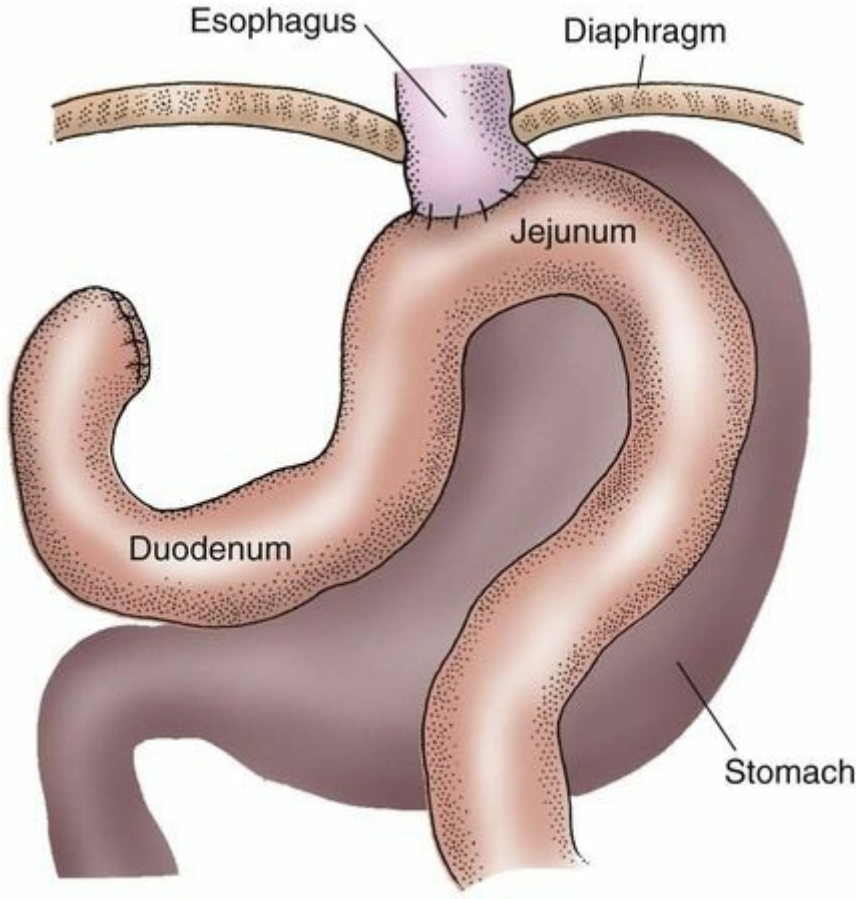

FIG. 55-4 Total gastrectomy with anastomosis of the esophagus to the jejunum (esophagojejunostomy) is the principal surgical intervention for extensive gastric cancer.

Patients with tumors at the gastric outlet who are not candidates for

subtotal or total gastrectomy may undergo gastroenterostomy for palliation. The surgeon creates a passage between the body of the stomach and the small bowel, often the duodenum.

Postoperative Care.

Provide the usual postoperative care for patients who have had general anesthesia to prevent atelectasis, paralytic ileus, wound infection, and peritonitis (see Chapter 16). Document and report any signs and symptoms of these complications immediately to the surgeon. Patients who have the laparoscopic surgery usually have less postoperative pain, fewer complications, and a shorter stay in the hospital.

Auscultate the lungs for adventitious sounds (crackles or reduced breath sounds), and monitor for the return of bowel sounds. Take vital signs as appropriate to detect signs of infection or bleeding. Aggressive pulmonary exercises and early ambulation can help prevent respiratory complications and deep vein thrombosis. Also inspect the operative site every 8 to 12 hours for the presence of redness, swelling, or drainage, which indicates wound infection. Keep the head of the bed elevated to prevent aspiration from reflux.

Decreased patency caused by a clogged NGT can result in *acute gastric dilation* after surgery. This problem is manifested by epigastric pain and a feeling of fullness, hiccups, tachycardia, and hypotension. Irrigation or replacement of the NGT by request of the surgeon can relieve these symptoms.

Dumping syndrome is a term that refers to a group of vasomotor symptoms that occur after eating. This syndrome is believed to occur as a result of the rapid emptying of food contents into the small intestine, which shifts fluid into the gut, causing abdominal distention. Observe for *early* manifestations of this syndrome, which typically occur within 30 minutes of eating. Symptoms include vertigo, tachycardia, syncope, sweating, pallor, palpitations, and the desire to lie down. Report these manifestations to the surgeon, and encourage the patient to lie down. Monitor the patient for late symptoms.

Late dumping syndrome, which occurs 90 minutes to 3 hours after eating, is caused by a release of an excessive amount of insulin. The insulin release follows a rapid rise in the blood glucose level that results from the rapid entry of high-carbohydrate food into the jejunum. Observe for manifestations, including dizziness, light-headedness, palpitations, diaphoresis, and confusion.

Dumping syndrome is managed by nutrition changes that include decreasing the amount of food taken at one time and eliminating liquids

ingested with meals. In collaboration with the dietitian, teach the patient to eat a high-protein, high-fat, low- to moderate-carbohydrate diet (Table 55-3). Acarbose may be used to decrease carbohydrate absorption. A somatostatin analog, octreotide (Sandostatin), 50 mcg subcutaneously 2 or 3 times daily 30 minutes before meals may be prescribed in severe cases. This drug decreases gastric and intestinal hormone secretion and slows stomach and intestinal transit time.

TABLE 55-3

Diet for Dumping Syndrome

FOOD GROUP	FOODS ALLOWED OR ENCOURAGED	FOODS TO USE WITH CAUTION	FOODS THAT MUST BE EXCLUDED
Soups		Fluids 1 hr before and after meals	Spicy soups
Meat and meat substitutes	8 oz or more per day: fish, poultry, beef, pork, veal, lamb, eggs, cheese, and peanut butter		Spicy meats or meat substitutes
Potatoes	Potato, rice, pasta, starchy vegetables (small amount)		Highly spiced potatoes or potato substitutes
Bread and cereal	White bread, rolls, muffins, crackers, and cereals (small amount)	Whole-grain bread, rolls, crackers, and cereals	Breads with frosting or jelly, sweet rolls, and coffee cake
Vegetables	Two or more cooked vegetables	Gas-producing vegetables, such as cabbage, onions, broccoli, or raw vegetables	
Fruits	Limit three per day: unsweetened cooked or canned fruits	Unsweetened juice or fruit drinks 30-45 min after meals; fresh fruit	Sweetened fruit or juice
Beverages	Dietetic drinks	Limit to 1 hr after meals; caffeine-containing beverages, such as coffee, tea, and cola; if tolerated, diet carbonated beverages	Milk shakes, malts, and other sweet drinks; regular carbonated beverages and alcohol
Fats	Margarine, oils, shortening, butter, bacon, and salad dressings	Mayonnaise	Any fats with milk products
Desserts	Fruit (see Fruits)	Sugar-free gelatin, pudding, and custard	All sweets, cakes, pies, cookies, candy, ice cream, and sherbet
Seasonings and miscellaneous	Diet jelly, diet syrups, sugar substitutes	Excessive amounts of salt	Excessive amounts of spices, sugar, jelly, honey, syrup, or molasses
General Principles			
• Several small meals daily • Relatively high fat and protein content • Low roughage • Relatively low carbohydrate content • No milk, sweets, or sugars • Liquid between meals *only*			

Alkaline reflux gastropathy, also known as *bile reflux gastropathy,* is a complication of gastric surgery in which the pylorus is bypassed or removed. Endoscopic examination reveals regurgitated bile in the stomach and mucosal hyperemia. Symptoms include early satiety (satisfied quickly with little food), abdominal discomfort, and vomiting.

Delayed gastric emptying is often present after gastric surgery and usually resolves within 1 week. Edema at the anastomosis (surgical connection areas) or adhesions (scar tissue) obstructing the distal loop may cause mechanical blockage. Metabolic causes (e.g., hypokalemia, hypoproteinemia, or hyponatremia) should be considered. The edema is resolved with nasogastric suction, maintenance of fluid and electrolyte balance, and proper nutrition.

Several problems related to nutrition develop as a result of partial removal of the stomach, including deficiencies of vitamin B_{12}, folic acid, and iron; impaired calcium metabolism; and reduced absorption of calcium and vitamin D. These problems are caused by a reduction of intrinsic factor. The decrease results from the resection and from inadequate absorption because of rapid entry of food into the bowel. In the absence of intrinsic factor, clinical manifestations of pernicious anemia may occur. Assess for the development of atrophic glossitis secondary to vitamin B_{12} deficiency. In atrophic glossitis, the tongue takes on a shiny, smooth, and "beefy" appearance. The patient may also have signs of anemia secondary to folic acid and iron deficiency. Monitor the complete blood count (CBC) for signs of megaloblastic anemia (low red blood cell [RBC] level) and leukopenia (low white blood cell [WBC] level). These manifestations are corrected by the administration of vitamin B_{12}. The health care provider may also prescribe folic acid or iron preparations.

NCLEX Examination Challenge

Physiological Integrity

A client has undergone a subtotal (partial) gastrectomy for gastric cancer and is scheduled to begin radiation therapy. What is the most important information for the nurse to include in the teaching plan for this client?

A Management of alopecia
B Medication management
C Nutritional intake
D Skin care

Community-Based Care

Patients who have undergone total gastrectomy and those who are debilitated with advanced gastric cancer are discharged to home with maximal assistance and support or to a transitional care unit or skilled nursing facility. Patients who have undergone subtotal gastrectomy and are not debilitated may be discharged to home with partial assistance for ADLs. Recurrence of cancer is common, and patients need regular follow-up examinations and imaging assessments. Collaborate with the case manager (CM) to ensure continuity of care and thorough follow-up with diagnostic testing.

Home Care Management.

Gastric cancer is a life-threatening illness. Therefore the patient and family members require physical and emotional care. Assess their ability to cope with the disease and the possible need for end-of-life care. The adverse effects of gastric cancer treatment can be debilitating, and patients need to learn symptom management strategies. Hospice programs can help both the patient and the family cope with these physical and emotional needs.

Patients may fear returning home because of their inability for self-management. Enlisting family and health care resources for the patient may ease some of this anxiety. Provide the family with adequate information about community support systems to make the transition to home care easier. If the prognosis is poor, they need continued professional support from case managers, social workers, and/or nurses to cope with death and dying. (See Chapter 7 for a discussion of end-of-life care.)

Self-Management Education.

Educate the patient and family about any continuing needs, drug therapy, and nutrition therapy. If patients are discharged to home with surgical dressings, teach the patient and family how to change them. Review the manifestations of incisional infection (e.g., fever, redness, and drainage) that they should report to their surgeon.

Patients who will be receiving radiation therapy or chemotherapy require instructions related to the side effects of these treatments. Nausea and vomiting are common side effects of chemotherapy, and instruction in the use of prescribed antiemetics may be needed. (See Chapter 22 for health teaching for patients receiving chemotherapy or radiation therapy.)

In collaboration with the dietitian, teach the patient and family about the type and quantity of foods that will provide optimal nutritional value. Interventions to minimize dumping syndrome and decrease gastric stimulants are also emphasized (see Table 55-3). Remind the patient to:

- Eat small, frequent meals
- Avoid drinking liquids with meals
- Avoid foods that cause discomfort
- Eliminate caffeine and alcohol consumption
- Begin a smoking-cessation program, if needed
- Receive B_{12} injections, as prescribed
- Lie flat after eating for a short time

Health Care Resources.

A home care referral provides continued assessment, assistance, and encouragement to the patient and family. A home care nurse can help with care procedures and provide valuable psychological support. Additional referrals to a dietitian, professional counselor, or clergy/spiritual leader may be necessary. Referral to a hospice agency can be of great assistance for the patient with advanced disease. Hospice care may be delivered in the home or in an institutional setting. Appropriate support groups (e.g., I Can Cope, provided by the American Cancer Society [www.cancer.org/treatment/supportprogramsservices/i-can-cope]) can be a major resource.

Nursing Concepts and Clinical Judgment Review

What might you NOTICE if the patient is experiencing impaired digestion and nutrition as a result of a stomach disorder?

- Report of epigastric pain or indigestion before or after a meal
- Report of inability to tolerate certain foods
- Nausea and/or vomiting (with or without blood)
- Melena or frank blood in stools

What should you INTERPRET and how should you RESPOND to a patient experiencing impaired digestion and nutrition as a result of a stomach disorder?

Perform and interpret physical assessment, including:

- Taking vital signs
- Observing and documenting assessment findings
- Interpreting laboratory values and other diagnostic findings:
  - Presence of *H. pylori*
  - Decreased hemoglobin and hematocrit

Respond by:

- Maintaining **a**irway, **b**reathing, and **c**irculation (ABCs)
- Placing the patient in a sitting position or on the left side to prevent aspiration if vomiting
- Preparing to assist with gastric lavage if hematemesis is present

On what should you REFLECT?

- Think about what else you could do to care for this patient.
- Consider with whom you should collaborate to improve or maintain digestion and nutrition for this patient.

- After patient interventions, monitor for changes in vital signs, hematocrit, and hemoglobin.

Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- When caring for patients with gastric health problems, collaborate with the pharmacist, dietitian, health care provider, and/or case manager. **Teamwork and Collaboration** QSEN

Health Promotion and Maintenance

- Refer the patient to the American Cancer Society if gastric cancer is the diagnosis.
- Identify patients at risk for gastritis and PUD, especially older adults who take large amounts of NSAIDs and those with *H. pylori.* **Safety** QSEN
- Teach patients behaviors to prevent PUD, such as avoiding large consumption of caffeine, alcohol, coffee, aspirin, and other NSAIDs. Also teach them to avoid contaminated foods and water and to avoid smoking (Chart 55-1). **Evidence-Based Practice** QSEN
- Teach patients the importance of adhering to *H. pylori* treatment to prevent the risk for gastric cancer.

Psychosocial Integrity

- Allow patients with gastric cancer to express feelings of grief, fear, and anxiety. **Patient-Centered Care** QSEN
- For patients with advanced gastric cancer, identify the need for end-of-life care, including referral to hospice care.

Physiological Integrity

- Recall that *acute* gastritis causes a rapid onset of epigastric pain and dyspepsia; *chronic* gastritis causes vague epigastric pain (usually relieved with food) and an intolerance to fatty and spicy foods (Chart 55-2).
- Be aware that assessment findings vary depending on whether the patient has a gastric or duodenal ulcer: patients with gastric ulcers may be malnourished and have pain that is worsened by ingestion of food; patients with duodenal ulcers are usually well nourished, have pain that is relieved by ingestion of food, and usually awaken with pain during the night (Table 55-2).

- For patients who have undergone a gastrectomy, collaborate with the dietitian and instruct the patient regarding diet changes to avoid abdominal distention and dumping syndrome. **Teamwork and Collaboration** QSEN
- Teach patients with abnormal symptoms (e.g., abdominal tenderness, abdominal pain that is relieved by food, or pain that becomes worse 3 hours after eating, dyspepsia, melena, and/or distention) to consult with their physician immediately for a prompt diagnosis and treatment.
- Teach patients that hematemesis is a medical emergency and that they should go to the emergency department for prompt treatment. **Safety** QSEN
- Teach the proper administration of antacids (one or two after meals). Tell patients that antacids can interfere with the effectiveness of certain drugs, such as phenytoin (Dilantin).
- Teach the proper administration of H_2 antagonists. Explain that they should be given at bedtime (Chart 55-3).
- Teach the proper administration of antisecretory agents, noting that most cannot be crushed because they are sustained-release or enteric-coated tablets.
- Monitor patients with ulcers for any of the signs and symptoms of upper GI bleeding that are listed in Chart 55-4. Report any of these symptoms if noted to a physician immediately.
- After an EGD, monitor the patient's vital signs, heart rhythm, and oxygen saturation frequently until they return to baseline. To prevent aspiration, assess the gag reflex and ensure that it is intact before giving the patient food or fluids. **Safety** QSEN
- Observe the patient for signs and symptoms of dumping syndrome after gastric surgery; teach the manifestations and management of this syndrome. Advise the patient to eat six small meals per day and to consume a diet high in protein and fat but low in carbohydrate-rich foods. Liquids should not be taken with meals. **Evidence-Based Practice** QSEN

CHAPTER 56

Care of Patients with Noninflammatory Intestinal Disorders

Donna D. Ignatavicius

PRIORITY CONCEPTS

- Elimination
- Nutrition
- Pain
- Fluid and Electrolyte Balance

Learning Outcomes

Safe and Effective Care Environment

1. Prioritize nursing care for the patient with abdominal trauma.
2. Describe the importance of collaborating with health care team members to provide care for patients with colorectal cancer (CRC).

Health Promotion and Maintenance

3. Identify community-based resources for patients with CRC.
4. Teach people health promotion practices to prevent noninflammatory intestinal disorders.
5. Plan health teaching for patients to promote self-management when caring for a colostomy based on patient preferences and values.

Psychosocial Integrity

6. Assess patient and family response to a diagnosis of CRC.

Physiological Integrity

7. Develop a plan of care for a patient undergoing a minimally invasive inguinal hernia repair.
8. Interpret assessment findings for patients with CRC.
9. Explain the role of the nurse in managing the patient with CRC.
10. Develop an evidence-based perioperative plan of care for a patient undergoing a colon resection and colostomy.
11. Explain the differences between assessment findings associated with small-bowel and large-bowel obstructions.
12. Describe the postoperative care for a patient having a hemorrhoid surgical procedure.
13. Identify collaborative interventions for patients with malabsorption disorders.

 http://evolve.elsevier.com/Iggy/

Intestinal health problems may be inflammatory or noninflammatory. This chapter describes those disorders that are noninflammatory in origin. Noninflammatory intestinal problems often cause rectal bleeding, changing bowel patterns, and abdominal pain. If not diagnosed and managed early, some intestinal problems can lead to inadequate absorption of vital nutrients and therefore affect the need for nutrition and elimination. If these disorders become severe or progress, pain and problems with fluid and electrolyte balance may occur.

Irritable Bowel Syndrome

❖ Pathophysiology

Irritable bowel syndrome (IBS) is a functional GI disorder that causes chronic or recurrent diarrhea, constipation, and/or abdominal pain and bloating. It is sometimes referred to as *spastic colon, mucous colon,* or *nervous colon* (Fig. 56-1). *IBS is the most common digestive disorder seen in clinical practice* and may affect as many as one in five people in the United States (McCance et al., 2014).

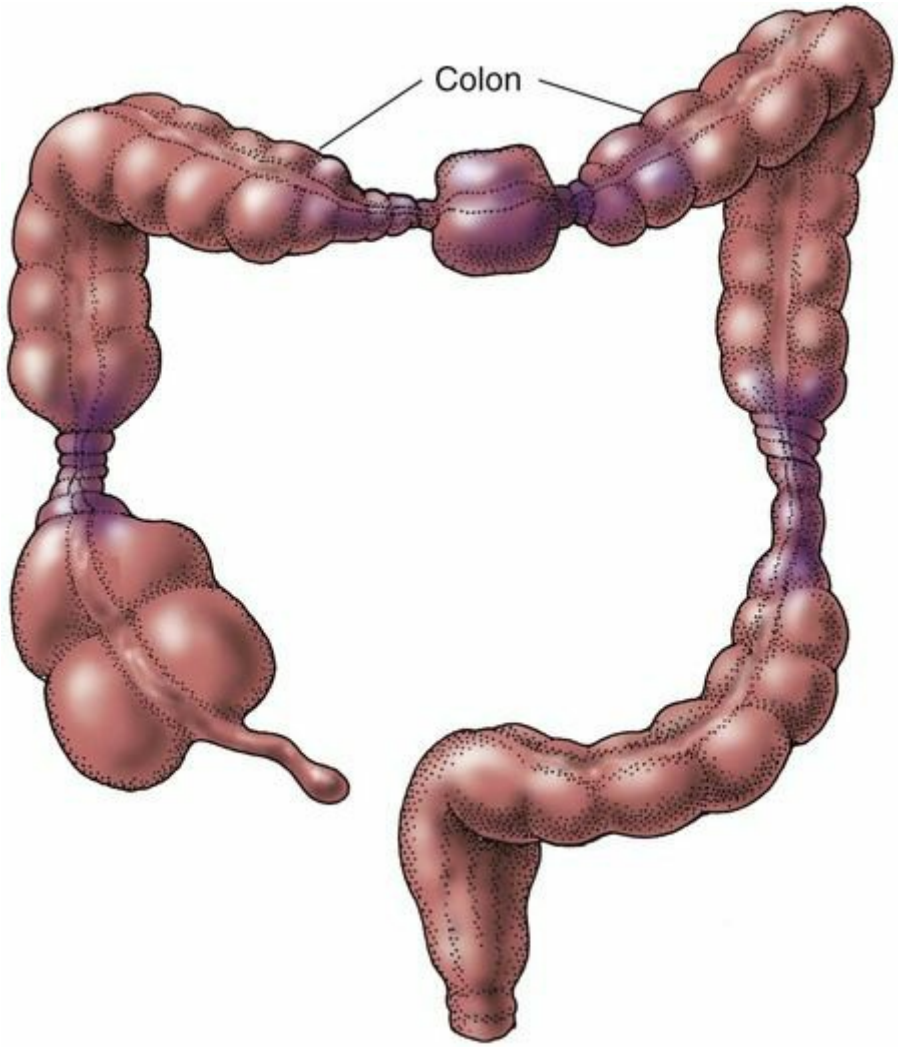

FIG. 56-1 Spastic contractions of the colon as they occur with irritable bowel syndrome.

In patients with IBS, bowel motility changes and increased or decreased bowel transit times result in changes in the normal *bowel elimination* pattern to one of these classifications: diarrhea (IBS-D), constipation (IBS-C), alternating diarrhea and constipation (IBS-A), or a mix of diarrhea and constipation (IBS-M). Symptoms of the disease

typically begin to appear in young adulthood and continue throughout the patient's life.

The etiology of IBS remains unclear. Research suggests that a combination of environmental, immunologic, genetic, hormonal, and stress factors play a role in the development and course of the disorder. Examples of environmental factors include foods and fluids like caffeinated or carbonated beverages and dairy products. Infectious agents have also been identified. Several studies have found that patients with IBS often have small-bowel bacterial overgrowth, which causes bloating and abdominal distention. Multiple normal flora and pathogenic agents have been identified, including *Pseudomonas aeruginosa* (Kerckhoffs et al., 2011). Other researchers believe that these agents are less causative and serve as measurable biomarkers for the disease (Malinen et al., 2010).

Immunologic and genetic factors have also been associated with IBS, especially cytokine genes, including pro-inflammatory interleukins (IL), such as IL-6, and tumor necrosis factor (TNF)–alpha (Barkhordari et al., 2010). These findings may provide the basis of targeted drug therapy for the disease.

In the United States, women are 2 times more likely to have IBS than are men. This difference may be the result of hormonal differences. However, in other areas of the world, this distribution pattern may not occur. For example, researchers found that there is not a female predominance for the disease in Asian countries (Gwee et al., 2010).

Considerable evidence relates the role of stress and mental or behavioral illness, especially anxiety and depression, to IBS. Many patients diagnosed with IBS meet the criteria for at least one primary mental health disorder. Some researchers suggest that psychosocial problems may be a cause for IBS (Nicholl et al., 2008). However, the pain and other chronic symptoms of the disease may lead to secondary mental health disorders. For example, when diarrhea is predominant, patients fear that there will be no bathroom facilities available and can become very anxious. As a result, they may not want to leave their homes or travel on trips where bathrooms are not available at all times. The long-term nature of dealing with a chronic disease for which there is no cure can lead to secondary depression in some patients.

❖ Patient-Centered Collaborative Care

◆ Assessment

Ask the patient about a history of weight change, fatigue, malaise,

abdominal pain, changes in the bowel pattern (constipation, diarrhea, or an alternating pattern of both) or consistency of stools, and the passage of mucus. Patients with IBS do not usually lose weight. Ask whether the patient has had any GI infections. Collect information on all drugs the patient is taking, because some of them can cause symptoms similar to those of IBS. Ask about the nutrition history, including the use of caffeinated drinks or beverages sweetened with sorbitol or fructose, which can cause bloating or diarrhea.

The course of the illness is specific to each patient. Most patients can identify factors that cause exacerbations, such as diet, stress, or anxiety. Food intolerance may be associated with IBS. Dairy products (e.g., for those with lactose intolerance), raw fruits, and grains can contribute to bloating, **flatulence** (gas), and abdominal distention. Patients may keep a food diary to record possible triggers for IBS symptoms.

A flare-up of worsening cramps, abdominal pain, and diarrhea and/or constipation may bring the patient to the health care provider. One of the *most common concerns of patients with IBS is pain in the left lower quadrant of the abdomen.* Assess the location, intensity, and quality of the pain. Some patients have internal visceral (organ) hypersensitivity that can cause or contribute to the pain. Nausea may be associated with mealtime and defecation. The constipated stools are small and hard and are generally followed by several softer stools. The diarrheal stools are soft and watery, and mucus is often present in the stools. Patients with IBS often report belching, gas, anorexia, and bloating.

The patient generally appears well, with a stable weight, and nutritional and fluid status are within normal ranges. Inspect and auscultate the abdomen. Bowel sounds vary but are generally within normal range. With constipation, bowel sounds may be hypoactive; with severe diarrhea, they may be hyperactive.

Routine laboratory values (including a complete blood count [CBC], serum albumin, erythrocyte sedimentation rate [ESR], and stools for occult blood) are normal in IBS. Some health care providers request a *hydrogen breath test* (Lindberg, 2009). When small-intestinal bacterial overgrowth or malabsorption of nutrients is present, excess hydrogen is produced. Some of this hydrogen is absorbed into the bloodstream and travels to the lungs where it is exhaled. Patients with IBS often exhale an increased amount of hydrogen.

Teach the patient that he or she will need to be NPO (may have water) for at least 12 hours before the hydrogen breath test. At the beginning of the test, the patient blows into a hydrogen analyzer. Then, small amounts of test sugar are ingested, depending on the purpose of the test, and

additional breath samples are taken every 15 minutes for 1 hour or longer (Pagana & Pagana, 2014).

Interventions

The patient with IBS is usually managed on an ambulatory care basis and learns self-management strategies. Interventions include health teaching, drug therapy, and stress reduction. Some patients also use complementary and alternative therapies. A holistic approach to patient care is essential for positive outcomes (Bengtsson et al., 2010).

Dietary fiber and bulk help produce bulky, soft stools and establish regular bowel elimination habits. The patient should ingest about 30 to 40 g of fiber each day. Eating regular meals, drinking 8 to 10 cups of liquid each day, and chewing food slowly help promote normal bowel function.

Drug therapy depends on the main symptom of IBS. The health care provider may prescribe bulk-forming or antidiarrheal agents and/or newer drugs to control symptoms.

For the treatment of *constipation-predominant IBS (IBS-C),* bulk-forming laxatives, such as *psyllium* hydrophilic mucilloid (Metamucil), are generally taken at mealtimes with a glass of water. The hydrophilic properties of these drugs help prevent dry, hard, or liquid stools. *Lubiprostone* (Amitiza) is an oral laxative approved for women with IBS-C, which increases fluid in the intestines to promote bowel elimination. Teach the patient to take the drug with food and water. Linaclotide (Linzess) is the newest drug for IBS-C, which works by simulating receptors in the intestines to increase fluid and promote bowel transit time. The drug also helps relieve pain and cramping that are associated with IBS. Teach patients to take this drug once a day about 30 minutes before breakfast.

Diarrhea-predominant IBS (IBS-D) may be treated with antidiarrheal agents, such as loperamide (Imodium), and psyllium (a bulk-forming agent). *Alosetron* (Lotronex), a selective serotonin (5-HT3) receptor antagonist, may be used with caution in women with IBS-D as a last resort when they have not responded to conventional therapy. Patients taking this drug must agree to report symptoms of colitis or constipation early because it is associated with potentially life-threatening bowel complications, including ischemic colitis (lack of blood flow to the colon).

Nursing Safety Priority QSEN

Drug Alert

Before the patient begins alosetron, take a thorough drug (including

herbs) history, both prescribed and over the counter, because it interacts with many drugs in a variety of classes. Remind patients that they should not take psychoactive drugs and antihistamines while taking alosetron. Teach patients to report severe constipation, fever, increasing abdominal pain, increasing fatigue, darkened urine, bloody diarrhea, or rectal bleeding as soon as it occurs and stop the drug immediately (Lilley et al., 2014).

Many patients with IBS who have bloating and abdominal distention without constipation have success with *rifaximin* (Xifaxan), an antibiotic that works locally with little systemic absorption (Pimental et al., 2011). Although the drug has been approved for "traveler's diarrhea" and other illnesses, the U.S. Food and Drug Administration (FDA) has not yet approved its use for patients with IBS.

A newer group of drugs called *muscarinic-receptor antagonists* also inhibit intestinal motility. Some of these agents have been approved for people with overactive bladders but have not yet received FDA approval for IBS. Examples in this group currently undergoing clinical trials for IBS are darifenacin (Enablex) and fesoterodine (Toviaz).

For IBS in which pain is the predominant symptom, tricyclic antidepressants such as amitriptyline (Elavil) have also been successfully used. It is unclear whether their effectiveness is due to the antidepressant or anticholinergic effects of the drugs. If patients have postprandial (after eating) discomfort, they should take these drugs 30 to 45 minutes before mealtime.

Complementary and Alternative Therapies.

For patients with increased intestinal bacterial overgrowth, recommend daily probiotic supplements. *Probiotics* have been shown to be effective for reducing bacteria and successfully alleviating GI symptoms of IBS (Lyra et al., 2010). There is also evidence that peppermint oil capsules may be effective in reducing symptoms for patients with IBS (Pirotta, 2009).

Stress management is also an important part of holistic care. Suggest relaxation techniques, meditation, and/or yoga to help the patient decrease GI symptoms. If the patient is in a stressful work or family situation, personal counseling may be helpful. Based on patient preference, make appropriate referrals or assist in making appointments if needed. The opportunity to discuss problems and attempt creative problem solving is often helpful. Teach the patient that regular exercise is important for managing stress and promoting regular bowel elimination.

Herniation

❖ Pathophysiology

A **hernia** is a weakness in the abdominal muscle wall through which a segment of the bowel or other abdominal structure protrudes. Hernias can also penetrate through any other defect in the abdominal wall, through the diaphragm, or through other structures in the abdominal cavity.

The most important elements in the development of a hernia are congenital or acquired muscle weakness and increased intra-abdominal pressure. The most significant factors contributing to increased intra-abdominal pressure are obesity, pregnancy, and lifting heavy objects.

The most common types of abdominal hernias (Fig. 56-2) are indirect, direct, femoral, umbilical, and incisional (McCance et al., 2014).

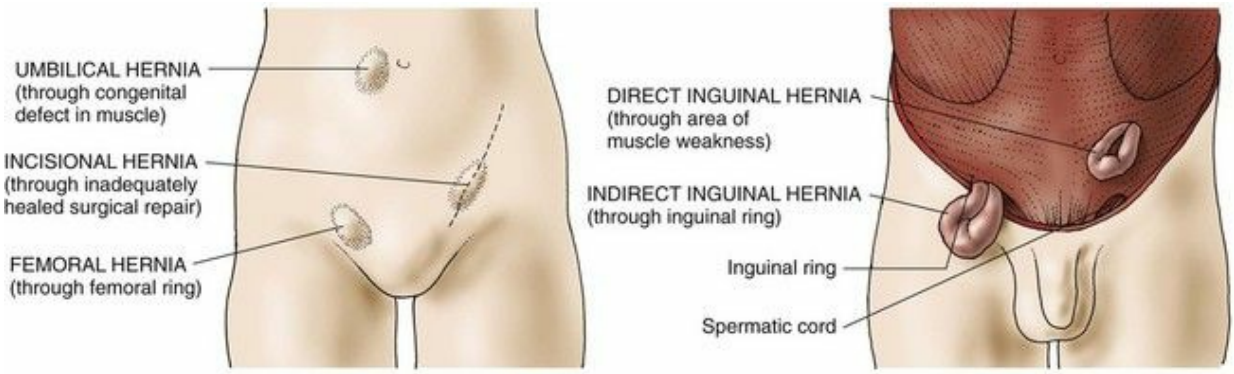

FIG. 56-2 Types of abdominal hernias.

- An **indirect inguinal hernia** is a sac formed from the peritoneum that contains a portion of the intestine or omentum. The hernia pushes downward at an angle into the inguinal canal. In males, indirect inguinal hernias can become large and often descend into the scrotum.
- **Direct inguinal hernias,** in contrast, pass through a weak point in the abdominal wall.
- **Femoral hernias** protrude through the femoral ring. A plug of fat in the femoral canal enlarges and eventually pulls the peritoneum and often the urinary bladder into the sac.
- **Umbilical hernias** are congenital or acquired. Congenital umbilical hernias appear in infancy. Acquired umbilical hernias directly result from increased intra-abdominal pressure. They are most commonly seen in people who are obese.
- **Incisional,** or **ventral, hernias** occur at the site of a previous surgical incision. These hernias result from inadequate healing of the incision,

which is usually caused by postoperative wound infections, inadequate nutrition, and obesity.

Hernias may also be classified as reducible, irreducible (incarcerated), or strangulated. A hernia is **reducible** when the contents of the hernial sac can be placed back into the abdominal cavity by gentle pressure. An **irreducible** (incarcerated) hernia cannot be reduced or placed back into the abdominal cavity. *Any hernia that is not reducible requires immediate surgical evaluation.*

A hernia is **strangulated** when the blood supply to the herniated segment of the bowel is cut off by pressure from the hernial ring (the band of muscle around the hernia). If a hernia is strangulated, there is ischemia and obstruction of the bowel loop. *This can lead to necrosis of the bowel and possibly bowel perforation. Signs of strangulation are abdominal distention, nausea, vomiting, pain, fever, and tachycardia.*

Indirect inguinal hernias, the most common type, occur mostly in men because they follow the tract that develops when the testes descend into the scrotum before birth. Direct hernias occur more often in older adults. Femoral and adult umbilical hernias are most common in obese or pregnant women. Incisional hernias can occur in people who have undergone abdominal surgery.

❖ Patient-Centered Collaborative Care

◆ Assessment

The patient with a hernia typically comes to the health care provider's office, clinic, or the emergency department with a report of a “lump” or protrusion felt at the involved site. The development of the hernia may be associated with straining or lifting.

Perform an abdominal assessment inspecting the abdomen when the patient is lying and again when he or she is standing. If the hernia is reducible, it may disappear when the patient is lying flat. The advanced practice nurse or other health care provider asks the patient to strain or perform the Valsalva maneuver and observes for bulging. Auscultate for active bowel sounds. *Absent bowel sounds may indicate obstruction and strangulation, which is a medical emergency!*

To palpate an inguinal hernia, the health care provider gently examines the ring and its contents by inserting a finger in the ring and noting any changes when the patient coughs. *The hernia is never forcibly reduced; that maneuver could cause strangulated intestine to rupture.*

If a male patient suspects a hernia in his groin, the health care provider has him stand for the examination. Using the right hand for the

patient's right side and the left hand for the patient's left side, the examiner pushes in the loose scrotal skin with the index finger, following the spermatic cord upward to the external inguinal cord. At this point, the patient is asked to cough and any palpable herniation is noted.

Interventions

The type of treatment selected depends on patient factors such as age, as well as the type and severity of the hernia.

Nonsurgical Management.

If the patient is not a surgical candidate (often an older man with multiple health problems), the health care provider may prescribe a truss for an inguinal hernia, usually for men. A **truss** is a pad made with firm material. It is held in place over the hernia with a belt to help keep the abdominal contents from protruding into the hernial sac. If a truss is used, it is applied only after the physician has reduced the hernia if it is not incarcerated. The patient usually applies the truss upon awakening. Teach him to assess the skin under the truss daily and to protect it with a light layer of powder.

Surgical Management.

Most hernias are inguinal, and surgical repair is the treatment of choice. Surgery is usually performed on an ambulatory care basis for patients who have no pre-existing health conditions that would complicate the operative course. In same-day surgery centers, anesthesia may be regional or general and the procedure is typically laparoscopic. More extensive surgery, such as a bowel resection or temporary colostomy, may be necessary if strangulation results in a gangrenous section of bowel. Patients undergoing this extensive surgery are hospitalized for a longer period.

A **minimally invasive inguinal hernia repair (MIIHR)** through a laparoscope, also called **herniorrhaphy,** is the surgery of choice. A conventional open herniorrhaphy may be performed when laparoscopy is not appropriate. Patients having minimally invasive surgery (MIS) recover more quickly, have less pain, and develop fewer postoperative complications compared with those having the conventional surgery.

In addition to patient education about the procedure, the most important preoperative preparation is to teach the patient to remain NPO for the number of hours before surgery that the surgeon specifies. If same-day surgery is planned, remind the patient to arrange for

someone to take him or her home and be available for the rest of the day at home. For patients having an open surgical approach, provide general preoperative care as described in Chapter 14.

During an MIHR, the surgeon makes several small incisions, identifies the defect, and places the intestinal contents back into the abdomen. During a traditional herniorrhaphy, the surgeon makes an abdominal incision to perform this procedure. When a **hernioplasty** is also performed, the surgeon reinforces the weakened outside abdominal muscle wall with a mesh patch.

The patient who has had MIHR is discharged from the surgical center in 3 to 5 hours, depending on recovery from anesthesia. Teach him or her to avoid strenuous activity for several days before returning to work and a normal routine. A stool softener may be needed to prevent constipation. Caution patients who are taking oral opioids for pain management to not drive or operate heavy machinery. Teach them to observe incisions for redness, swelling, heat, drainage, and increased pain and promptly report their occurrence to the surgeon. Remind patients that soreness and discomfort rather than severe, acute pain are common after MIS. Be sure to make a follow-up telephone call on the day after surgery to check on the patient's status.

General postoperative care of patients having a hernia repair is the same as that described in Chapter 16 *except that they should avoid coughing.* To promote lung expansion, encourage deep breathing and ambulation. With repair of an indirect inguinal hernia, the physician may suggest a scrotal support and ice bags applied to the scrotum to prevent swelling, which often contributes to pain. Elevation of the scrotum with a soft pillow helps prevent and control swelling.

In the immediate postoperative period, male patients who have had an inguinal hernia repair may experience difficulty voiding. Encourage them to stand to allow a more natural position for gravity to facilitate voiding and bladder emptying. Urine output of less than 30 mL per hour should be reported to the surgeon. Techniques to stimulate voiding such as allowing water to run may also be used. A fluid intake of at least 1500 to 2500 mL daily prevents dehydration, maintains urinary function, and minimizes constipation. A "straight" or intermittent ("in and out") catheterization is required if the patient cannot void. Chart 56-1 summarizes best nursing practices for postoperative care after an MIHR.

Chart 56-1 Best Practice for Patient Safety & Quality

Care QSEN

Nursing Care of the Postoperative Patient Having a Minimally Invasive Inguinal Hernia Repair (MIIHR)

- Monitor vital signs, especially blood pressure, for indications of internal bleeding.
- Assess and manage incisional pain with oral analgesics; report and document severe pain that does not respond to drug therapy immediately.
- Encourage deep breathing after surgery; avoid excessive coughing.
- Encourage ambulation with assistance as soon as possible after surgery (within the first few hours).
- Apply ice packs as prescribed to the surgical area.
- Assist the patient to void by standing the first time after surgery.
- Teach patients at discharge to:
  - Rest for several days after surgery.
  - Observe the incision sites for redness or drainage, and report these findings to the surgeon.
  - Shower after 24 to 36 hours after removing any bandage (do not remove Steri-Strips); be aware that the Steri-Strips will fall off in about a week.
  - Monitor temperature for the first few days, and report the occurrence of a fever.
  - Do not lift more than 10 pounds until allowed by the surgeon.
  - Avoid constipation by eating high-fiber foods and drinking extra fluids.
  - Return to work when allowed by the surgeon, usually in 1 to 2 weeks, depending on the patient's work responsibilities.

Most patients have uneventful recoveries after a hernia repair. Surgeons generally allow them to return to their usual activities after surgery, with avoidance of straining and lifting for several weeks while subcutaneous tissues heal and strengthen.

Provide oral instructions and a written list of symptoms to be reported, including fever, chills, wound drainage, redness or separation of the incision, and increasing incisional pain. Teach the patient to keep the wound dry and clean with antibacterial soap and water. Showering is usually permitted in a few days (see Chart 56-1).

NCLEX Examination Challenge

Physiological Integrity

A nurse is caring for a client following a laparoscopic hernia repair surgery. Which assessment finding will the nurse report to the surgeon immediately?

A Severe abdominal pain
B Blood pressure of 140/86 mm Hg
C Respiratory rate of 26 breaths per minute
D Mild abdominal distention

Colorectal Cancer

Pathophysiology

Colorectal refers to the colon and rectum, which together make up the large intestine, also known as the *large bowel*. Colorectal cancer (CRC) is cancer of the colon or rectum and is a major health problem worldwide. In the United States it is one of the most common malignancies. Patients often consider a diagnosis of cancer as a "death sentence," but colon cancer for many patients is highly curable.

Tumors occur in different areas of the colon, with about two thirds occurring within the rectosigmoid region as shown in Fig. 56-3. Most CRCs are **adenocarcinomas,** which are tumors that arise from the glandular epithelial tissue of the colon. They develop as a multi-step process affecting immunity, resulting in a number of molecular changes. These changes include loss of key tumor suppressor genes and activation of certain oncogenes that alter colonic mucosa cell division. The increased proliferation of the colonic mucosa forms polyps that can transform into malignant tumors. Most CRCs are believed to arise from adenomatous polyps that present as visible protrusions from the mucosal surface of the bowel (McCance et al., 2014).

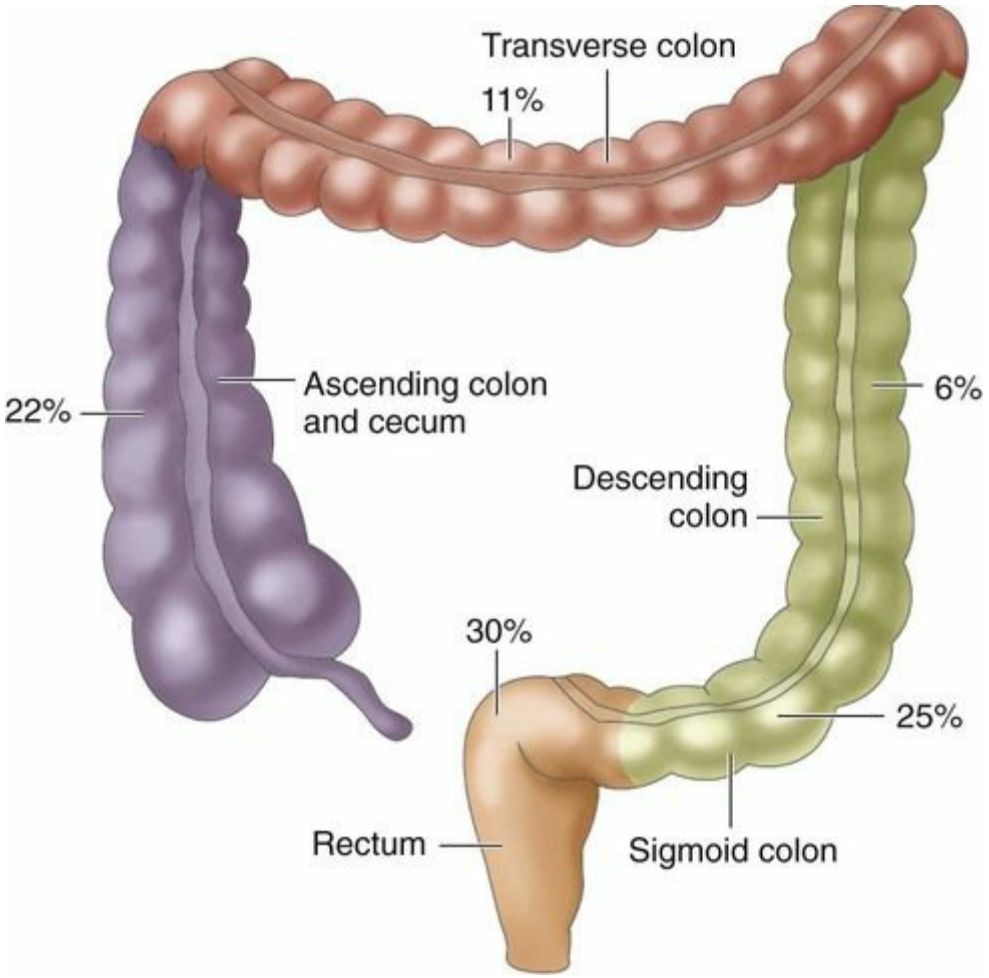

FIG. 56-3 The incidence of cancer in relation to colorectal anatomy.

CRC can metastasize by direct extension or by spreading through the blood or lymph. The tumor may spread locally into the four layers of the bowel wall and into neighboring organs. It may enlarge into the lumen of the bowel or spread through the lymphatics or the circulatory system. The circulatory system is entered directly from the primary tumor through blood vessels in the bowel or via the lymphatic system. The liver is the most common site of metastasis from circulatory spread. Metastasis to the lungs, brain, bones, and adrenal glands may also occur. Colon tumors can also spread by peritoneal seeding during surgical resection of the tumor. Seeding may occur when a tumor is excised and cancer cells break off from the tumor into the peritoneal cavity. For this reason, special techniques are used during surgery to decrease this possibility.

Complications related to the increasing growth of the tumor locally or through metastatic spread include bowel obstruction or perforation with resultant peritonitis, abscess formation, and fistula formation to the urinary bladder or the vagina. The tumor may invade neighboring blood vessels and cause frank bleeding. Tumors growing into the bowel lumen

can gradually obstruct the intestine and eventually block it completely. Those extending beyond the bowel wall may place pressure on neighboring organs (uterus, urinary bladder, and ureters) and cause symptoms that mask those of the cancer. Chapter 21 discusses cancer pathophysiology in more detail.

Etiology and Genetic Risk

The major risk factors for the development of colorectal cancer (CRC) include being older than 50 years, genetic predisposition, personal or family history of cancer, and/or diseases that predispose the patient to cancer such as familial adenomatous polyposis (FAP), Crohn's disease, and ulcerative colitis (McCance et al., 2014). Only a small percentage of colorectal cancers are familial and transmitted genetically.

Genetic/Genomic Considerations

Patient-Centered Care QSEN

People with a first-degree relative (parent, sibling, or child) diagnosed with colorectal cancer (CRC) have 3 to 4 times the risk for developing the disease. An autosomal dominant inherited genetic disorder known as *familial adenomatous polyposis (FAP)* accounts for 1% of CRCs. FAP is the result of one or more mutations in the adenomatous polyposis coli (APC) gene (McCance et al., 2014). In these very young patients, thousands of adenomatous polyps develop over the course of 10 to 15 years and have nearly a 100% chance of becoming malignant. By 20 years of age, most patients require surgical intervention, usually a colectomy with ileostomy or ileoanal pull-through, to prevent cancer. Chemotherapy may also be used for cancer prevention.

Hereditary nonpolyposis colorectal cancer (HNPCC) is another autosomal dominant disorder and accounts for a small percentage of all colorectal cancers. HNPCC is also caused by gene mutations, including *MLH1* and *MLH2*. People with these mutations have an 80% chance of developing CRC at an average of 45 years of age. They also tend to have a higher incidence of endometrial, ovarian, stomach, and ureteral cancers (Nussbaum et al., 2007). Genetic testing is available for both of these familial CRC syndromes. Refer patients for genetic counseling and possible testing if the patient prefers.

The role of infectious agents in the development of colorectal and anal cancer continues to be investigated. Some lower GI cancers are related to

Helicobacter pylori, *Streptococcus bovis*, John Cunningham (JC) virus, and human papilloma virus (HPV) infections.

There is also strong evidence that long-term smoking, obesity, physical inactivity, and heavy alcohol consumption are risk factors for colorectal cancer (American Cancer Society [ACS], 2014). A high-fat diet, particularly animal fat from red meats, increases bile acid secretion and anaerobic bacteria, which are thought to be carcinogenic within the bowel. Diets with large amounts of refined carbohydrates that lack fiber decrease bowel transit time.

Incidence and Prevalence

Colorectal cancer (CRC) is the third most common cause of cancer death in the United States (ACS, 2014). It is not common before 40 years of age, but the incidence in younger adults is slowly increasing, most likely due to increases in HPV infections (Stubenrauch, 2010). The overall incidence of CRC has decreased over the past 20 years, probably as a result of increased cancer screenings (Wilkes, 2013). The disease is most common in African Americans, and their survival rate is lower than that of Euro-Americans (Caucasians). The possible reasons for this difference include less use of diagnostic testing (especially colonoscopy), decreased access to health care, lack of health insurance, cultural beliefs, and lack of education about the need for early cancer detection (Good et al., 2010; Oliver et al., 2012).

Health Promotion and Maintenance

People at risk can take action to decrease their chance of getting CRC and/or increase their chance of surviving it. For example, those whose family members have had hereditary CRC should be genetically tested for FAP and HNPCC. If gene mutations are present, the person at risk can collaborate with the health care team to decide what prevention or treatment plan to implement.

Teach people about the need for diagnostic screening. An integrative review by Rawl et al. (2012) found that most efforts to increase CRC screening interventions have focused on Euro-Americans. However, other groups are more at risk than Euro-Americans (see the Evidence-Based Practice box).

Evidence-Based Practice QSEN

How Effective are Interventions to Promote Colorectal Cancer

Screening?

Rawl, S.M., Menon, U., Burness, A., & Breslau, E.S. (2012). Interventions to promote colorectal cancer screening: An integrative review. *Nursing Outlook, 60*(4), 172-181.

The researchers reviewed and evaluated 33 randomized trials of colorectal cancer screening (CRC) interventions that were published between 1997 and 2007 using a modified version of TREND criteria to draw conclusions. Significant effects of interventions were reported in 6 of the 10 trials that studied fecal occult blood testing, 4 of the 7 trials that focused on colonoscopy or sigmoidoscopy interventions, and 9 of the 16 trials that included any type of recommended CRC screening method. Most of these trials studied effectiveness of interventions in Euro-Americans (Caucasians). The authors concluded that further research is needed to examine factors that contribute to successful CRC screening. Other groups in addition to Euro-Americans should also be studied, especially given their risk for the disease.

Level of Evidence: 1

This study was an integrative review and evaluation of multiple randomized trials.

Commentary: Implications for Practice and Research

Nurses should continue to teach people about the need for and effectiveness of screening to detect CRC early for the best possible outcome. Further research is needed to explore the factors that enable many patients to have regular screening for CRC. This research should include diverse subjects for comparison and analysis.

When an adult turns 40 years of age, he or she should discuss with the health care provider the need for colon cancer screening. The interval depends on level of risk. People of average risk who are 50 years of age and older and without a family history should undergo regular CRC screening. The screening includes fecal occult blood testing (FOBT) and colonoscopy every 10 years or double-contrast barium enema every 5 years. People who have a personal or family history of the disease should begin screening earlier and more frequently. Teach all patients to follow the American Cancer Society recommendations for CRC screening listed in Chart 56-2.

Chart 56-2 Best Practice for Patient Safety & Quality

Care QSEN

Screening Recommendations for Men and Women Ages 50 Years and Older at Average Risk for Colorectal Cancer

PROCEDURE: CHOICE OF ONE OF THE FOLLOWING	INTERVAL AFTER SCREENING INITIATED AT AGE 50 YEARS	COMMENTS
FOBT and sigmoidoscopy	Every 5 years	FOBT procedure: two or three samples from three consecutive bowel movements obtained at home; tested by physician or nurse
OR		
Double-contrast barium enema	Every 5 years	
OR		
Colonoscopy	Every 10 years	

FOBT, Fecal occult blood testing.

Teach people, regardless of risk, to modify their diets as needed to decrease fat, refined carbohydrates, and low-fiber foods. Encourage baked or broiled foods, especially those high in fiber and low in animal fat. Remind people to eat increased amounts of brassica vegetables, including broccoli, cabbage, cauliflower, and sprouts. These foods help protect the intestinal mucosa from colon cancer (ACS, 2014).

Teach people the hazards of smoking, excessive alcohol, and physical inactivity. Refer patients as needed for smoking- or alcohol-cessation programs, and recommend ways to increase regular physical exercise. These programs are discussed elsewhere in this text.

Patient-Centered Collaborative Care

Assessment

History.

When taking a history, ask the patient about major risk factors, such as a personal history of breast, ovarian, or endometrial cancer (which can spread to the colon); ulcerative colitis; Crohn's disease; familial polyposis or adenomas; polyps; or a family history of CRC. Also assess the patient's participation in age-specific cancer screening guidelines. Ask about whether the patient uses tobacco and/or alcohol. Assess the patient's usual physical activity level.

Ask whether vomiting and changes in bowel elimination habits, such as constipation or change in shape of stool with or without blood, have been noted. The patient may also report fatigue (related to anemias), abdominal fullness, vague abdominal pain, or unintentional weight loss. These symptoms suggest advanced disease.

Physical Assessment/Clinical Manifestations.

The clinical manifestations of CRC depend on the location of the tumor. *However, the most common signs are rectal bleeding, anemia, and a change in stool consistency or shape.* Stools may contain microscopic amounts of blood that are not noticeably visible, or the patient may have mahogany (dark)-colored or bright red stools (Fig. 56-4). Gross blood is not usually detected with tumors of the right side of the colon but is common (but not massive) with tumors of the left side of the colon and the rectum.

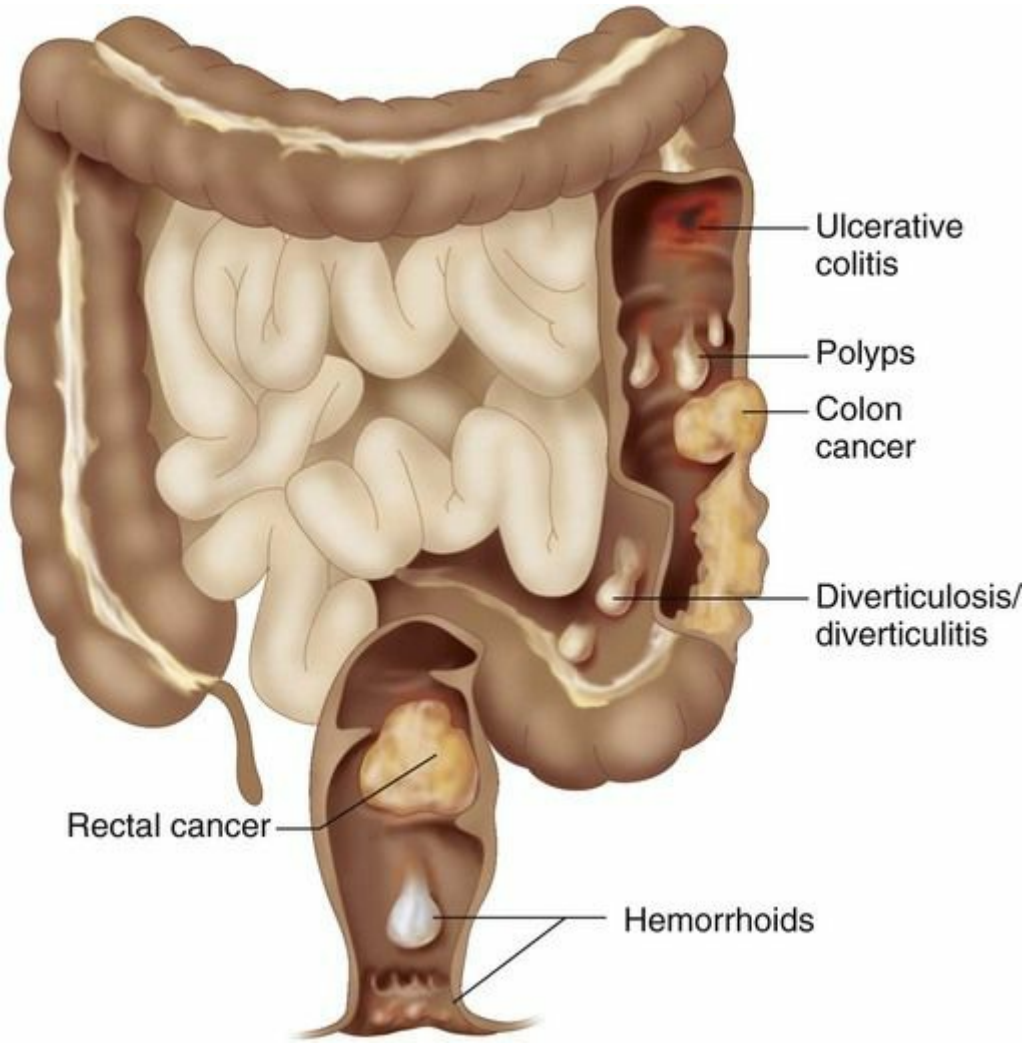

FIG. 56-4 Common causes of lower gastrointestinal bleeding.

Tumors in the transverse and descending colon result in symptoms of

obstruction as growth of the tumor blocks the passage of stool. The patient may report "gas pains," cramping, or incomplete evacuation. Tumors in the rectosigmoid colon are associated with **hematochezia** (the passage of red blood via the rectum), straining to pass stools, and narrowing of stools. Patients may report dull pain. Right-sided tumors can grow quite large without disrupting bowel patterns or appearance because the stool consistency is more liquid in this part of the colon. These tumors ulcerate and bleed intermittently, so stools can contain mahogany (dark)-colored blood. A mass may be palpated in the lower right quadrant, and the patient often has anemia secondary to blood loss.

Examination of the abdomen begins with assessment for obvious distention or masses. Visible peristaltic waves accompanied by high-pitched or "tinkling" bowel sounds may indicate a partial bowel obstruction from the tumor. Total absence of bowel sounds indicates a complete bowel obstruction. Palpation and percussion are performed by the advanced practice nurse or other health care provider to determine whether the spleen or liver is enlarged or whether masses are present along the colon. The examiner may also perform a digital rectal examination to palpate the rectum and lower sigmoid colon for masses. Fecal occult blood screening should not be done with a specimen from a rectal examination because it is not reliable. A positive result could occur as a result of tissue trauma during the examination.

Psychosocial Assessment.

The psychological consequences associated with a diagnosis of colorectal cancer (CRC) are many. Patients must cope with a diagnosis that instills fear and anxiety about treatment, feelings that life has been disrupted, a need to search for ways to deal with the diagnosis, and concern about family. They also have questions about why colon cancer affected them, as well as concerns about pain, possible body changes, and possible death. In addition, if the cancer is believed to have a genetic origin, there is anxiety concerning implications for immediate family members.

Laboratory Assessment.

Hemoglobin and hematocrit values are often decreased as a result of the intermittent bleeding associated with the tumor. For some patients, that may be the first indication that a tumor is present. CRC that has metastasized to the liver causes liver enzymes to be elevated.

A positive test result for occult blood in the stool **(fecal occult blood test [FOBT])** indicates bleeding in the GI tract. These tests can yield false-positive results if certain vitamins or drugs are taken before the

test. Remind the patient to avoid aspirin, vitamin C, and red meat for 48 hours before giving a stool specimen. Also assess whether the patient is taking anti-inflammatory drugs (e.g., ibuprofen, corticosteroids, or salicylates). These drugs should be discontinued for a designated period before the test. Two or three separate stool samples should be tested on 3 consecutive days. Negative results do not completely rule out the possibility of CRC.

Carcinoembryonic antigen (CEA), an oncofetal antigen, is elevated in many people with CRC. The normal value is less than 5 ng/mL (Pagana & Pagana, 2014). This protein is not specifically associated with the colorectal cancer, and it may be elevated in the presence of other benign or malignant diseases and in smokers. CEA is often used to monitor the effectiveness of treatment and to identify disease recurrence.

Imaging Assessment.

A *double-contrast barium enema* (air and barium are instilled into the colon) or colonoscopy provides better visualization of polyps and small lesions than does a barium enema alone. These tests may show an occlusion in the bowel where the tumor is decreasing the size of the lumen.

CT or *MRI* of the chest, abdomen, pelvis, lungs, or liver helps confirm the existence of a mass, the extent of disease, and the location of distant metastases. CT-guided virtual colonoscopy is growing in popularity and may be more thorough than traditional colonoscopy. However, treatments or surgeries cannot be performed when a virtual colonoscopy is used.

Other Diagnostic Assessment.

A *sigmoidoscopy* provides visualization of the lower colon using a fiberoptic scope. Polyps can be visualized, and tissue samples can be taken for biopsy. Polyps are usually removed during the procedure. A *colonoscopy* provides views of the entire large bowel from the rectum to the ileocecal valve. As with sigmoidoscopy, polyps can be seen and removed and tissue samples can be taken for biopsy. *Colonoscopy is the definitive test for the diagnosis of colorectal cancer. These procedures and associated nursing care are discussed in Chapter 52.*

◆ Analysis

The priority NANDA-I nursing diagnoses and collaborative problems for patients with colorectal cancer (CRC) include:

1. Potential for colorectal cancer metastasis
2. Grieving related to cancer diagnosis (NANDA-I)

Planning and Implementation

The primary approach to treating CRC is to remove the entire tumor or as much of the tumor as possible to prevent or slow metastatic spread of the disease. A patient-centered collaborative care approach is essential to meet the desired outcomes.

Preventing or Controlling Metastasis

Planning: Expected Outcomes.

The patient with colorectal cancer (CRC) is expected to not have the cancer spread to vital organs. Thus the patient's life expectancy will be increased and the quality of life will be improved. However, if metastasis is present, the desired outcome is to ensure that the patient is as comfortable as possible and pain is well-managed.

Interventions.

Although surgical resection is the primary method used to control the disease, several adjuvant (additional) therapies are used. Adjuvant therapies are administered before or after surgery to achieve a cure and prevent recurrence, if possible.

Nonsurgical Management.

The type of therapy used is based on the pathologic staging of the disease. Several staging systems may be used.

The administration of preoperative *radiation therapy* has not improved overall survival rates for colon cancer, but it has been effective in providing local or regional control of the disease. Postoperative radiation has not demonstrated any consistent improvement in survival or recurrence. However, as a palliative measure, radiation therapy may be used to control pain, hemorrhage, bowel obstruction, or metastasis to the lung in advanced disease. For rectal cancer, unlike colon cancer, radiation therapy is almost always a part of the treatment plan. Reinforce information about the radiation therapy procedure to the patient and family, and monitor for possible side effects (e.g., diarrhea, fatigue). Chapter 22 describes the general nursing care of patients undergoing radiation therapy.

Adjuvant *chemotherapy* after primary surgery is recommended for

patients with stage II or stage III disease to interrupt the DNA production of cells and destroy them. The drugs of choice are IV 5-fluorouracil (5-FU) with leucovorin (LV) (folinic acid) (5-FU/LV), capecitabine (Xeloda), or a combination of drugs referred to as *FOLFOX4*. The most frequently used FOLFOX4 combination for metastatic CRC is fluorouracil (5-FU), leucovorin (LV), and oxaliplatin (Eloxatin), a platinum analog. These drugs cannot discriminate between cancer and healthy cells. Therefore common side effects are diarrhea, mucositis, leukopenia, mouth ulcers, and peripheral neuropathy (Lilley et al., 2014).

Bevacizumab (Avastin) and panitumumab (Vectibix) are antiangiogenesis drugs, also known as *vascular endothelial growth factor (VEGF) inhibitors*, approved for advanced CRC. These drugs reduce blood flow to the growing tumor cells, thereby depriving them of necessary nutrients needed to grow (Wilkes, 2013). A VEGF inhibitor is usually given in combination with other chemotherapeutic agents.

Cetuximab (Erbitux), a monoclonal antibody known as an *epidermal growth factor receptor (EGFR) antagonist*, may also be given in combination with other drugs for advanced disease (Wilkes, 2013). This drug works by blocking factors that promote cancer cell growth.

Intrahepatic arterial chemotherapy, often with 5-FU, may be administered to patients with liver metastasis. Patients with CRC also receive drugs for relief of symptoms, such as opioid analgesics and antiemetics. Chapter 22 describes care of patients receiving chemotherapy in detail.

Surgical Management.

Surgical removal of the tumor with margins free of disease is the best method of ensuring removal of CRC. The size of the tumor, its location, the extent of metastasis, the integrity of the bowel, and the condition of the patient determine which surgical procedure is performed for colorectal cancer (Table 56-1). Many regional lymph nodes are removed and examined for presence of cancer. The number of lymph nodes that contain cancer is a strong predictor of prognosis. The most common surgeries performed are **colon resection** (removal of the tumor and regional lymph nodes) with reanastomosis, **colectomy** (colon removal) with *colostomy (temporary or permanent) or ileostomy/ileoanal pull-through*, and **abdominoperineal (AP) resection.** A **colostomy** is the surgical creation of an opening of the colon onto the surface of the abdomen. An AP resection is performed when rectal tumors are present. The surgeon removes the sigmoid colon, rectum, and anus through combined

abdominal and perineal incisions.

TABLE 56-1

Surgical Procedures for Colorectal Cancers in Various Locations

Right-Sided Colon Tumors
• Right hemicolectomy for smaller lesions • Right ascending colostomy or ileostomy for large, widespread lesions • Cecostomy (opening into the cecum with intubation to decompress the bowel)
Left-Sided Colon Tumors
• Left hemicolectomy for smaller lesions • Left descending colostomy for larger lesions
Sigmoid Colon Tumors
• Sigmoid colectomy for smaller lesions • Sigmoid colostomy for larger lesions • Abdominoperineal resection for large, low sigmoid tumors (near the anus) with colostomy (the rectum and the anus are completely removed, leaving a perineal wound)
Rectal Tumors
• Resection with anastomosis or pull-through procedure (preserves anal sphincter and normal elimination pattern) • Colon resection with permanent colostomy • Abdominoperineal resection with colostomy

For patients having a colon resection, minimally invasive surgery (MIS) via laparoscopy is commonly performed today. This procedure results in shorter hospital stays, less pain, fewer complications, and quicker recovery compared with the conventional open surgical approach (Kapritsou et al., 2013).

Preoperative Care.

Reinforce the physician's explanation of the planned surgical procedure. The patient is told as accurately as possible what anatomic and physiologic changes will occur with surgery. The location and number of incision sites and drains are also discussed.

Before evaluating the tumor and colon during surgery, the surgeon may not be able to determine whether a colostomy (or less commonly, an ileostomy) will be necessary. The patient is told that a colostomy is a possibility. If a colostomy is planned, the surgeon consults a certified wound, ostomy, continence nurse (CWOCN) to recommend optimal placement of the ostomy. The CWOCN teaches the patient about the rationale and general principles of ostomy care. In many settings, he or she marks the patient's abdomen to indicate a potential ostomy site that will decrease the risk for complications such as interference of the undergarments or a prosthesis with the ostomy appliance. Table 56-2 describes the role of the CWOCN.

TABLE 56-2

Preoperative Assessment by the CWOCN Prior to Ostomy Surgery

Key Points of Psychosocial Assessment
• Patient's and family's level of knowledge of disease and ostomy care • Patient's educational level • Patient's physical limitations (particularly sensory) • Support available to patient • Patient's type of employment • Patient's involvement in activities such as hobbies • Financial concerns regarding purchase of ostomy supplies
Key Points of Physical Assessment
• Before marking the placement for the ostomy, the nurse specialist considers: • Contour of the abdomen in lying, sitting, and standing positions • Presence of skinfolds, creases, bony prominences, and scars • Location of belt line • Location that is easily visible to the patient • Possible location in the rectus muscle

CWOCN, Certified wound, ostomy, continence nurse.

The patient who requires low rectal surgery (e.g., AP resection) is faced with the risk for postoperative sexual dysfunction and urinary incontinence after surgery as a result of nerve damage during surgery. The surgeon discusses the risk for these problems with the patient before surgery and allows him or her to verbalize concerns and questions related to this risk. Reinforce teaching about abdominal surgery performed for the patient under general anesthesia, and review the routines for turning and deep breathing (see Chapter 14). Teach the patient about the method of pain management to be used after surgery such as IV patient-controlled analgesia (PCA), epidural analgesia, or other method.

If the bowel is not obstructed or perforated, elective surgery is planned. The patient may be instructed to thoroughly clean the bowel, or "bowel prep," to minimize bacterial growth and prevent complications. Mechanical cleaning is accomplished with laxatives and enemas or with "whole-gut lavage." The use of bowel preps is controversial, and some surgeons do not recommend it because of patient discomfort. Older adults may become dehydrated from this process.

To reduce the risk for infection, the surgeon may prescribe one dose of oral or IV antibiotics to be given before the surgical incision is made. Teach patients that a nasogastric tube (NGT) may be placed for decompression of the stomach after surgery. A peripheral IV or central venous catheter is also placed for fluid and electrolyte replacement while the patient is NPO after surgery. Patients having minimally invasive surgeries do not need an NGT.

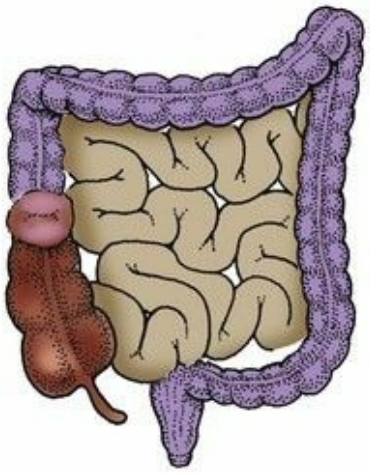
The patient with colorectal cancer faces a serious illness with long-term

consequences of the disease and treatment. A case manager or social worker can be very helpful in identifying patient and family needs, as well as ensuring continuity of care and support.

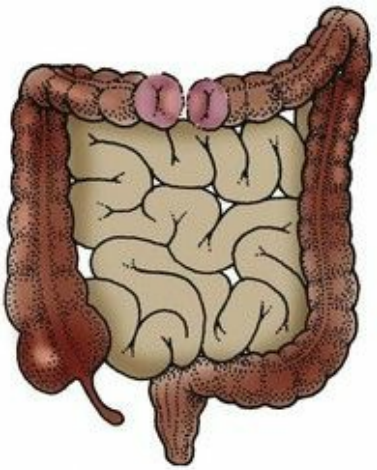
Operative Procedures.

For the conventional open surgical approach, the surgeon makes a large incision in the abdomen and explores the abdominal cavity to determine whether the tumor can be removed. For a colon resection, the portion of the colon with the tumor is excised and the two open ends of the bowel are irrigated before **anastomosis** (reattachment) of the colon. If an anastomosis is not feasible because of the location of the tumor or the bowel is inflamed, a colostomy is created.

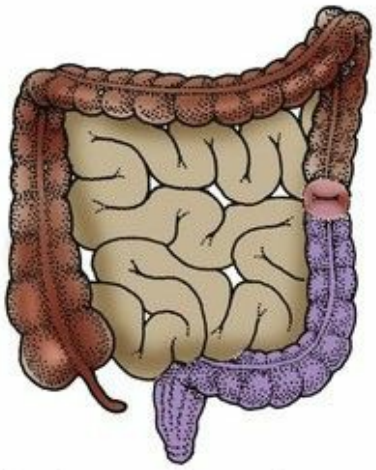
A temporary or permanent colostomy may be created in the ascending, transverse, descending, or sigmoid colon (Fig. 56-5). One of several techniques is used to construct a colostomy. A loop **stoma** (surgical opening) is made by bringing a loop of colon to the skin surface, severing and everting the anterior wall, and suturing it to the abdominal wall. Loop colostomies are usually performed in the transverse colon and are usually temporary. An external rod may be used to support the loop until the intestinal tissue adheres to the abdominal wall. Care must be taken to avoid displacing the rod, especially during appliance changes.



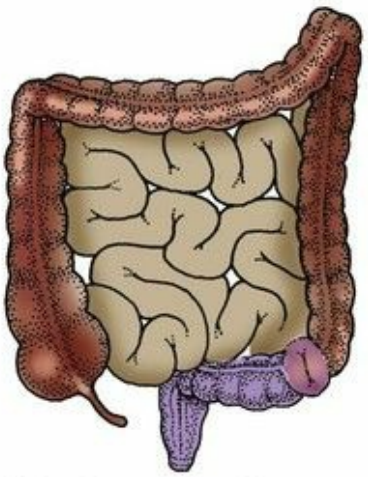
The **ascending colostomy** is done for right-sided tumors.



The **transverse (double-barrel) colostomy** is often used in such emergencies as intestinal obstruction or perforation because it can be created quickly. There are two stomas. The proximal one, closest to the small intestine, drains feces. The distal stoma drains mucus.



The **descending colostomy** is done for left-sided tumors.



The **sigmoid colostomy** is done for rectal tumors.

FIG. 56-5 Different locations of colostomies in the colon.

An end stoma is often constructed, usually in the descending or sigmoid colon, when a colostomy is intended to be permanent. It may also be done when the surgeon oversews the distal stump of the colon and places it in the abdominal cavity, preserving it for future reattachment. An end stoma is constructed by severing the end of the proximal portion of the bowel and bringing it out through the abdominal wall.

The least common colostomy is the **double-barrel stoma,** which is created by dividing the bowel and bringing both the proximal and distal portions to the abdominal surface to create two stomas. The proximal

stoma (closest to the patient's head) is the functioning stoma and eliminates stool. The distal stoma (farthest from the head) is considered nonfunctioning, although it may secrete some mucus. The distal stoma is sometimes referred to as a *mucous fistula.*

MIS colon resection or total colectomy allows complete tumor removal with an adequate surgical margin and removal of associated lymph nodes. Several small incisions are made, and a miniature video camera is placed within the abdomen to help see the area that is involved. This technique takes longer than the conventional procedure and requires specialized training. However, blood loss is less.

Postoperative Care.

Patients who have an *open colon resection* without a colostomy receive care similar to that of those having any abdominal surgery (see Chapter 16). Other patients have surgeries that also require colostomy management. They typically have a nasogastric tube (NGT) after open surgery and receive IV PCA for the first 24 to 36 hours. After NGT removal, the diet is slowly progressed from liquids to solid foods as tolerated. The care of patients with an NGT is found on p. 1159 in the discussion of Interventions in the Intestinal Obstruction section.

By contrast, patients who have *laparoscopic (MIS) surgery* can eat solid foods very soon after the procedure. Because they usually have less pain, they are able to ambulate earlier than those who have the conventional approach. The hospital stay is usually shorter for the patient with MIS—less than 23 hours or 1 to 2 days, depending on the patient's age and general condition.

Colostomy Management.

The patient who has a colostomy may return from surgery with a clear ostomy pouch system in place. A clear pouch allows the health care team to observe the stoma. If no pouch system is in place, a petrolatum gauze dressing is usually placed over the stoma to keep it moist. This is covered with a dry, sterile dressing. In collaboration with the CWOCN, place a pouch system as soon as possible. The colostomy pouch system, also called an *appliance,* allows more convenient and acceptable collection of stool than a dressing does.

Assess the color and integrity of the stoma frequently. A healthy stoma should be reddish pink and moist and protrude about ¾ inch (2 cm) from the abdominal wall (Fig. 56-6). During the initial postoperative period, the stoma may be slightly edematous. A small amount of

bleeding at the stoma is common.

FIG. 56-6 A mature colostomy.

Nursing Safety Priority QSEN

Action Alert

Report any of these problems related to the colostomy to the surgeon:

- Signs of ischemia and necrosis (dark red, purplish, or black color; dry)
- Unusual bleeding
- Mucocutaneous separation (breakdown of the suture line securing the stoma to the abdominal wall)

Also assess the condition of the peristomal skin (skin around the stoma), and frequently check the pouch system for proper fit and signs of leakage. The skin should be intact, smooth, and without redness or excoriation.

The colostomy should start functioning in 2 to 3 days postoperatively. When it begins to function, the pouch may need to be emptied frequently because of excess gas collection. It should be emptied when it is one-third to one-half full of stool. Stool is liquid immediately postoperatively but becomes more solid, depending on where in the colon the stoma was placed. For example, the stool from a colostomy in

the ascending colon is liquid, the stool from a colostomy in the transverse colon is pasty, and the stool from a colostomy in the descending colon is more solid (similar to usual stool expelled from the rectum).

Wound Management.

For an AP resection, the perineal wound is generally surgically closed and two bulb suction drains such as Jackson-Pratt drains are placed in the wound or through stab wounds near the wound. The drains help prevent drainage from collecting within the wound and are usually left in place for several days, depending on the character and amount of drainage. These drains are described in more detail in Chapter 16.

Monitoring drainage from the perineal wound and cavity is important because of the possibility of infection and abscess formation. Serosanguineous drainage from the perineal wound may be observed for 1 to 2 months after surgery. Complete healing of the perineal wound may take 6 to 8 months. This wound can be a greater source of discomfort than the abdominal incision and ostomy, and more care may be required. The patient may experience phantom rectal sensations because sympathetic innervation for rectal control has not been interrupted. Rectal pain and itching may occasionally occur after healing. Interventions may include use of antipruritic drugs, such as benzocaine, and warm compresses. Continually assess for signs of infection, abscess, or other complications, and implement methods for promoting wound drainage and comfort (Chart 56-3).

Chart 56-3 Best Practice for Patient Safety & Quality Care QSEN

Perineal Wound Care

Wound Care

- Place an absorbent dressing (e.g., abdominal pad) over the wound.
- Instruct the patient that he or she may:
  - Use a feminine napkin as a dressing
  - Wear jockey-type shorts rather than boxers

Comfort Measures

- If prescribed, soak the wound area in a sitz bath for 10 to 20 minutes 3 or 4 times per day or use warm/hot compresses or packs.
- Administer pain medication as prescribed, and assess its effectiveness.

- Instruct the patient about permissible activities. The patient should:
  - Assume a side-lying position in bed; avoid sitting for long periods
  - Use foam pads or a soft pillow to sit on whenever in a sitting position
  - Avoid the use of air rings or rubber donut devices

Prevention of Complications

- Maintain fluid and electrolyte balance by monitoring intake and output and by monitoring output from the perineal wound.
- Observe incision integrity, and monitor wound drains; watch for erythema, edema, bleeding, drainage, unusual odor, and excessive or constant pain.

NCLEX Examination Challenge

Physiological Integrity

A nurse is assigned to care for a client who had an open partial colectomy and descending colostomy this morning. What assessment findings are expected for the client? **Select all that apply.**

A The colostomy stoma is purple and dry.
B The nasogastric tube is draining yellowish green fluid.
C The client has pain that is controlled by analgesics.
D The colostomy is not draining any stool.
E The perineal incision is covered with a surgical dressing.

Assisting with the Grieving Process

Planning: Expected Outcomes.

The expected outcomes are that the patient will verbalize feelings about the diagnosis and treatment and progress through the normal stages of grief.

Interventions.

The patient and family are faced with a possible loss of or alteration in body functions. Medical and surgical interventions for the treatment of colorectal cancer may result in cure, disease control, or palliation. Interventions are designed to assist the patient and family in planning effective strategies for expressing feelings of grief and developing coping skills. Families and significant others may request that patients not be informed of the diagnosis of cancer, particularly if the patient is an older adult.

Observe and identify:

- The patient's and family's current methods of coping
- Effective sources of support used in past crises
- The patient's and family's present perceptions of the health problem
- Signs of anticipatory grief, such as denial, crying, anger, and withdrawal from usual relationships

Encourage the patient and family to verbalize feelings about the diagnosis, treatment, and anticipated alteration in body functions if a colostomy is planned. (See discussion of Operative Procedures on p. 1153 in the Surgical Management section.) Denial, sadness, anger, feelings of loss, and depression are normal responses to this change in body function. The patient will need to learn new methods for toileting and how to cope with these changes.

If a colostomy is planned, instruct the patient on what to expect about the appearance and care of the colostomy. Postoperatively, encourage him or her to look at and touch the stoma. When the patient is physically able, ask him or her to participate in colostomy care. Participation helps restore the patient's sense of control over his or her lifestyle and thus facilitates improved self-esteem. If culturally appropriate, encourage participation of family or other caregivers in colostomy care.

Assist the patient in identifying the nature of and reaction to the loss. Encourage the patient and family to verbalize feelings and identify fears to help move them through the appropriate phases of the grief process. Establish a trusting, ongoing relationship with the patient and family, and provide support through the personal grieving stages.

In collaboration with the social worker or chaplain, assist the patient in identifying personal coping strategies. Encourage him or her to implement cultural, religious, and social customs associated with the loss, and identify sources of community support. Modifications in lifestyle are needed for patients with CRC. Help the patient and family identify these changes and how best to make them. The chaplain, social worker, or case manager assists in discussions and decisions with them concerning treatment, the prognosis, and end-of-life decisions as appropriate.

Nursing Safety Priority QSEN

Action Alert

Refer patients who are at risk for or have familial CRC for genetic counseling. Specially trained nurses can discuss the purposes and goals

of genetic testing. Ensure privacy and confidentiality. A review of the family history may provide important information concerning the pattern of colorectal cancer inheritance. To make an informed decision, the patient and family need information about the advantages, risks, and costs of appropriate genetic tests. Monitor the patient's response regarding genetic risk factors.

Community-Based Care

Patients undergoing a colon resection by open approach are typically hospitalized for 2 to 3 days or longer, depending on the age of the patient and any complications or concurrent health problems. Collaborate with the case manager to assist patients and their families in coping with the immediate postoperative phase of recovery. After hospitalization for surgery, the patient is usually managed at home. Radiation therapy or chemotherapy is typically done on an ambulatory care basis. For the patient with advanced cancer, hospice care may be an option (see Chapter 7).

Home Care Management.

Assess all patients for their ability for self-management within limitations. For those requiring assistance with care, home care visits by nurses or assistive nursing personnel can be provided.

For the patient who has undergone a colostomy, review the home situation to aid the patient in arranging for care. Ostomy products should be kept in an area (preferably the bathroom) where the temperature is neither hot nor cold (skin barriers may become stiff or melt in extreme temperatures) to ensure proper functioning. The home care nurse or CWOCN or enterostomal therapist (ET) may serve as a consultant after the patient is discharged home to ensure continuity of care (per The Joint Commission's National Patient Safety Goals).

No changes are needed in sleeping accommodations. A moisture-proof covering may initially be placed over the bed mattress if patients feel insecure about the pouch system. They may consume their usual diet on discharge.

Self-Management Education.

Before discharge, teach the patient to avoid lifting heavy objects or straining on defecation to prevent tension on the anastomosis site. If he or she had the open surgical approach, the patient should avoid driving for 4 to 6 weeks while the incision heals. Patients who have had

laparoscopy can usually return to all usual activities in 1 to 2 weeks.

Nursing Safety Priority QSEN

Action Alert

A stool softener may be prescribed to keep stools at a soft consistency for ease of passage. Teach patients to note the frequency, amount, and character of the stools. In addition to this information, teach those with colon resections to watch for and report clinical manifestations of intestinal obstruction and perforation (e.g., cramping, abdominal pain, nausea, vomiting). Advise the patient to avoid gas-producing foods and carbonated beverages. Four to six weeks may be required to establish the effects of certain foods on bowel patterns.

Colostomy Care.

Rehabilitation after surgery requires that patients and family members learn how to perform colostomy care. Provide adequate opportunity before discharge for patients to learn the psychomotor skills involved in this care. Plan sufficient practice time for learning how to handle, assemble, and apply all ostomy equipment. Teach patients and families or other caregivers about:

- The normal appearance of the stoma
- Signs and symptoms of complications
- Measurement of the stoma
- The choice, use, care, and application of the appropriate appliance to cover the stoma
- Measures to protect the skin adjacent to the stoma
- Nutrition changes to control gas and odor
- Resumption of normal activities, including work, travel, and sexual intercourse

The appropriate pouch system must be selected and fitted to the stoma. Patients with flat, firm abdomens may use either flexible (bordered with paper tape) or nonflexible (full skin barrier wafer) pouch systems. A firm abdomen with lateral creases or folds requires a flexible system. Patients with deep creases, flabby abdomens, a retracted stoma, or a stoma that is flush or concave to the abdominal surface benefit from a convex appliance with a stoma belt. This type of system presses into the skin around the stoma, causing the stoma to protrude. This protrusion helps tighten the skin and prevents leaks around the stoma opening onto the peristomal skin.

Measurement of the stoma is necessary to determine the correct size of the stomal opening on the appliance. The opening should be large enough not only to cover the peristomal skin but also to avoid stomal trauma. The stoma will shrink within 6 to 8 weeks after surgery. Therefore it needs to be measured at least once weekly during this time and as needed if the patient gains or loses weight. Teach the patient and family caregiver to trace the pattern of the stomal area on the wafer portion of the appliance and to cut an opening about $\frac{1}{8}$- to $\frac{1}{16}$-inch larger than the stomal pattern to ensure that stomal tissue will not be constricted.

Skin preparation may include clipping peristomal hair or shaving the area (moving from the stoma outward) to achieve a smooth surface, prevent unnecessary discomfort when the wafer is removed, and minimize the risk for infected hair follicles. Advise the patient to clean around the stoma with mild soap and water before putting on an appliance. He or she should avoid using moisturizing soaps to clean the area because the lubricants can interfere with adhesion of the appliance.

Nursing Safety Priority QSEN

Action Alert

Teach the patient and family to apply a skin sealant (preferably without alcohol) and allow it to dry before application of the appliance (colostomy bag) to facilitate less painful removal of the tape or adhesive. If peristomal skin becomes raw, stoma powder or paste or a combination may also be applied. The paste or other filler cream is also used to fill in crevices and creases to create a flat surface for the faceplate of the colostomy bag. If the patient develops a fungal rash, an antifungal cream or powder should be used.

Control of gas and odor from the colostomy is often an important outcome for patients with new ostomies. Although a leaking or inadequately closed pouch is the usual cause of odor, flatus can also contribute to the odor. Remind the patient that although generally no foods for ostomates are forbidden, certain foods and habits can cause flatus or contribute to odor when the pouch is open. Broccoli, beans, spicy foods, onions, Brussels sprouts, cabbage, cauliflower, cucumbers, mushrooms, and peas often cause flatus, as does chewing gum, smoking, drinking beer, and skipping meals. Crackers, toast, and yogurt can help prevent gas. Asparagus, broccoli, cabbage, turnips, eggs, fish, and garlic

contribute to odor when the pouch is open. Buttermilk, cranberry juice, parsley, and yogurt help prevent odor. Charcoal filters, pouch deodorizers, or placement of a breath mint in the pouch helps eliminate odors. The patient should be cautioned to not put aspirin tablets in the pouch because they may cause ulceration of the stoma. Vents that allow release of gas from the ostomy bag through a deodorizing filter are available and may decrease the patient's level of self-consciousness about odor.

The patient with a sigmoid colostomy may benefit from colostomy irrigation to regulate elimination. However, most patients with a sigmoid colostomy can become regulated through diet. An irrigation is similar to an enema but is administered through the stoma rather than the rectum.

In addition to teaching the patient about the clinical manifestations of obstruction and perforation, ask the patient to report any fever or sudden onset of pain or swelling around the stoma. Other home care assessment is listed in Chart 56-4.

Chart 56-4 Home Care Assessment

The Patient with a Colostomy

Assess gastrointestinal status, including:

- Dietary and fluid intake and habits
- Presence or absence of nausea and vomiting
- Weight gain or loss
- Bowel elimination pattern and characteristics and amount of effluent (stool)
- Bowel sounds

Assess condition of stoma, including:

- Location, size, protrusion, color, and integrity
- Signs of ischemia, such as dull coloring or dark or purplish bruising

Assess peristomal skin for:

- Presence or absence of excoriated skin, leakage underneath drainage system
- Fit of appliance and effectiveness of skin barrier and appliance

Assess the patient's and family's coping skills, including:

- Self-care abilities in the home
- Acknowledgment of changes in body image and function
- Sense of loss

Psychosocial Concerns.

The diagnosis of cancer can be emotionally immobilizing for the patient and family or significant others, but treatment may be welcomed because it may provide hope for control of the disease. Explore reactions to the illness and perceptions of planned interventions.

The patient's reaction to ostomy surgery may include:

- Fear of not being accepted by others
- Feelings of grief related to disturbance in body image
- Concerns about sexuality

Encourage the patient and family to verbalize their feelings. By teaching how to physically manage the ostomy, help them begin to restore self-esteem and improve body image. Inclusion of family and significant others in the rehabilitation process may help maintain relationships and raise self-esteem. Anticipatory instruction includes information on leakage accidents, odor control measures, and adjustments to resuming sexual relationships.

Health Care Resources.

Several resources are available to maintain continuity of care in the home environment and provide for patient needs that the nurse is not able to meet. Make referrals to community-based case managers or social workers, who can provide further emotional counseling, aid in managing financial concerns, or arrange for services in the home or long-term care facility as needed.

Provide information about the United Ostomy Associations of America, Inc. (www.uoaa.org), a self-help group of people who have ostomies. This group has literature such as the organization's publication *(Ostomy Quarterly)* and information about local chapters. The organization conducts a visitor program that sends specially trained visitors (who have an ostomy [ostomate]) to talk with patients. After obtaining consent, make a referral to the visitor program so that the volunteer ostomate can see the patient both preoperatively and postoperatively. A physician's consent for visitation may be necessary.

The local division or unit of the American Cancer Society (ACS) (www.cancer.org) can help provide necessary medical equipment and supplies, home care services, travel accommodations, and other resources for the patient who is having cancer treatment or surgery. Inform the patient and family of the programs available through the local division or unit. Other excellent web resources include Cancer Care (www.cancercare.org), Colon Cancer Alliance (www.ccalliance.org), and the National Cancer Institute (www.nci.gov).

Because of short hospital stays, patients with new ostomies receive

much health teaching from nurses working for home health care agencies. This resource also helps provide physical care needs, medication management, and emotional support. If the patient has advanced colorectal cancer, a referral for hospice services in the home, nursing home, or other long-term care setting may be appropriate. The home health care nurse informs the patient and family about what ostomy supplies are needed and where they can be purchased. Price and location are considered before recommendations are made.

Clinical Judgment Challenge

Prioritization, Delegation, and Supervision

A 56-year-old woman returns from the postanesthesia care unit (PACU) after an open colon resection and colostomy for ascending colon cancer. She has IV fluids running at 100 mL/hr and is receiving morphine PCA. An NGT is in place connected to low suction, and she is NPO. Her abdominal dressing is dry and intact, and her oxygen saturation is 95% on 2 L/min of oxygen via nasal cannula. She is allowed out of bed to the bathroom or chair today. You are assigned to care for this patient for the rest of the day shift.

1. Upon the patient's admission to your unit at 11 am, should you delegate taking the patient's vital signs to an experienced nursing technician? Why or why not?
2. At 5 pm, the patient states that she needs to go to the bathroom. Will you delegate this activity to the nursing technician? Why or why not?
3. While the patient was in the bathroom, her oxygen saturation level decreased to 88%. What is your best action at this time?
4. The patient's husband asks you about his wife's prognosis regarding her cancer survival. What is your best response at this time?

Evaluation: Outcomes

Evaluate the care of the patient with colorectal cancer based on the identified priority patient problems. The expected outcomes are that the patient:

- Adjusts to actual or impending loss
- Is free of complications or metastasis associated with CRC
- States he or she has well-controlled pain and is as comfortable as possible (if metastasis is present)

Intestinal Obstruction

Pathophysiology

Intestinal obstructions can be partial or complete and are classified as mechanical or nonmechanical. In **mechanical obstruction,** the bowel is physically blocked by problems outside the intestine (e.g., adhesions), in the bowel wall (e.g., Crohn's disease), or in the intestinal lumen (e.g., tumors). **Nonmechanical obstruction** (also known as **paralytic ileus** or *adynamic ileus*) does not involve a physical obstruction in or outside the intestine. Instead, peristalsis is decreased or absent as a result of neuromuscular disturbance, resulting in a slowing of the movement or a backup of intestinal contents (McCance et al., 2014).

Intestinal contents are composed of ingested fluid, food, and saliva; gastric, pancreatic, and biliary secretions; and swallowed air. In both mechanical and nonmechanical obstructions, the intestinal contents accumulate at and above the area of obstruction. Distention results from the intestine's inability to absorb the contents and move them down the intestinal tract. To compensate for the lag, peristalsis increases in an effort to move the intestinal contents forward. This increase stimulates more secretions, which then leads to additional distention. The bowel then becomes edematous, and increased capillary permeability results. Plasma leaking into the peritoneal cavity and fluid trapped in the intestinal lumen decrease the absorption of fluid and electrolytes into the vascular space. Reduced circulatory blood volume (hypovolemia) and electrolyte imbalances typically occur. Hypovolemia ranges from mild to extreme (hypovolemic shock).

Specific problems related to fluid and electrolyte balance and acid-base balance result, depending on the part of the intestine that is blocked. An obstruction high in the small intestine causes a loss of gastric hydrochloride, which can lead to *metabolic alkalosis.* Obstruction below the duodenum but above the large bowel results in loss of both acids and bases, so that acid-base balance is usually not compromised. Obstruction at the end of the small intestine and lower in the intestinal tract causes loss of alkaline fluids, which can lead to *metabolic acidosis* (McCance et al., 2014).

If hypovolemia is severe, renal insufficiency or even death can occur. Bacterial peritonitis with or without actual perforation can also result. Bacteria in the intestinal contents lie stagnant in the obstructed intestine. This is not a problem unless the blood flow to the intestine is compromised. However, with *closed-loop obstruction* (blockage in two different areas) or a **strangulated obstruction** (obstruction with

compromised blood flow), the risk for peritonitis is greatly increased. Bacteria without blood supply can form and release an endotoxin into the peritoneal or systemic circulation and cause septic shock. With a strangulated obstruction, major blood loss into the intestine and the peritoneum can occur. Sepsis and bleeding can result in an increased intra-abdominal pressure (IAP) or acute compartment syndrome (Lee, 2012). (See later discussion of IAP on p. 1163 of this chapter.)

Intestinal obstruction is a common and serious disorder caused by a variety of conditions and is associated with significant morbidity. It can occur anywhere in the intestinal tract, although the ileum in the small intestine (the narrowest part of the intestinal tract) is the most common site.

Mechanical obstruction can result from:

- Adhesions (scar tissue from surgeries or pathology)
- Benign or malignant tumor
- Complications of appendicitis
- Hernias
- Fecal impactions (especially in older adults)
- Strictures due to Crohn's disease or previous radiation therapy
- **Intussusception** (telescoping of a segment of the intestine within itself) (Fig. 56-7)

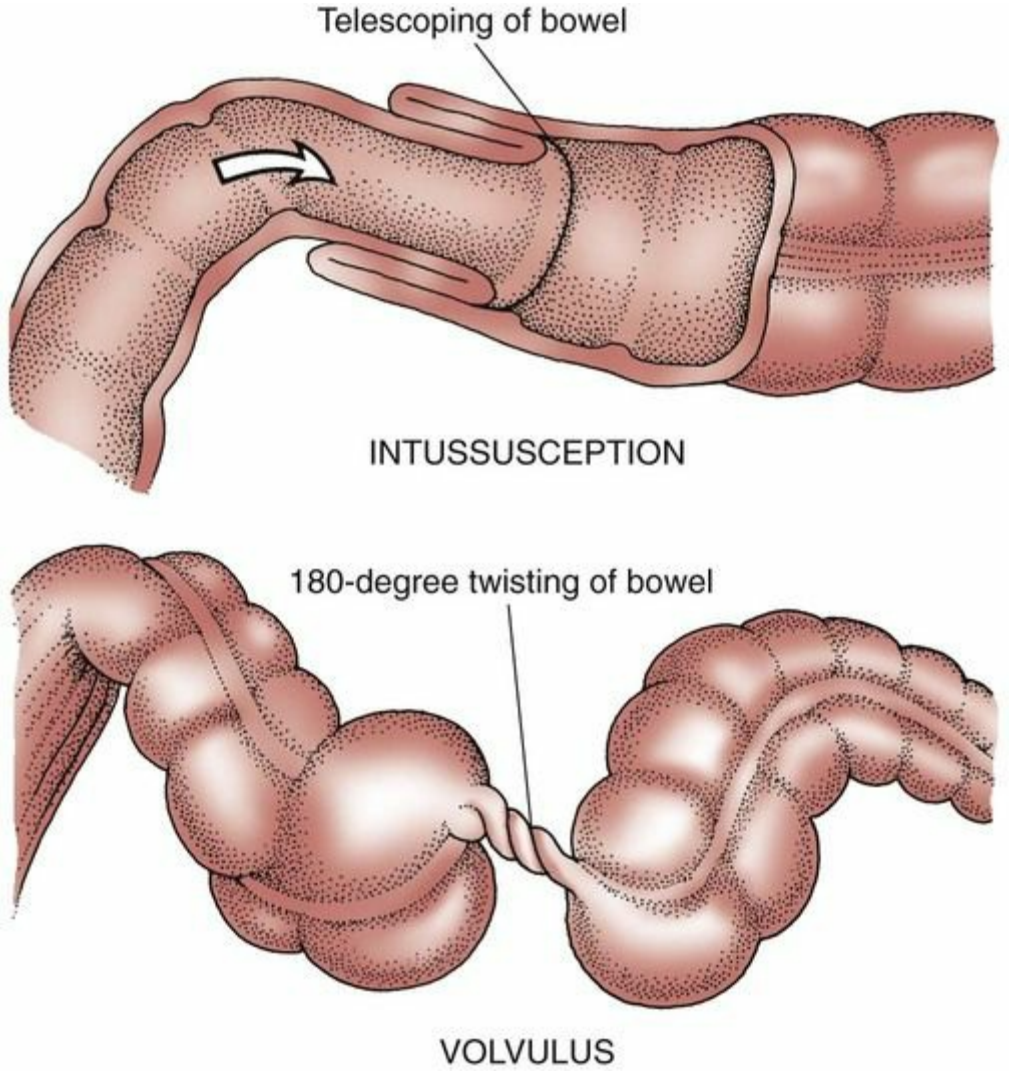


FIG. 56-7 Two major types of mechanical obstruction.

- **Volvulus** (twisting of the intestine) (see Fig. 56-7)
- Fibrosis due to disorders such as endometriosis
- Vascular disorders (e.g., emboli and arteriosclerotic narrowing of mesenteric vessels)

In people ages 65 years or older, diverticulitis, tumors, and fecal impaction are the most common causes of obstruction (McCance et al., 2014).

Postoperative ileus (POI) (paralytic ileus), or *nonmechanical* obstruction, is most commonly caused by handling of the intestines during abdominal surgery. In patients with POI, intestinal function is lost for a few hours to several days. Electrolyte disturbances, especially hypokalemia, predispose the patient to this problem. The ileus can also be a consequence of **peritonitis**, because leakage of colonic contents causes severe irritation and triggers an inflammatory response and infection (see discussion of peritonitis on p. 1170 in Chapter 57). Vascular insufficiency to the bowel, also referred to as *intestinal ischemia*, is another potential cause of an ileus. It results when arterial or venous

thrombosis or an embolus decreases blood flow to the mesenteric blood vessels surrounding the intestines, as in heart failure or severe shock. Severe insufficiency of blood supply can result in infarction of surrounding organs (e.g., bowel infarction).

Patient-Centered Collaborative Care

Assessment

History.

Collect information about a history of gastrointestinal disorders, surgeries, and treatments. Question the patient about recent nausea and vomiting and the color of emesis. Perform a thorough pain assessment with particular attention to the onset, aggravating factors, alleviating factors, and patterns or rhythms of the pain. Severe pain that then stops and changes to tenderness on palpation may indicate perforation and should be reported promptly to the physician. Ask about the passage of flatus and the time, character, and consistency of the last bowel movement. Singultus (hiccups) is common with all types of intestinal obstruction. When an obstruction is suspected, keep the patient NPO and contact the physician promptly for further direction.

Assess for a family history of colorectal cancer (CRC), and ask about blood in the stool or a change in bowel pattern. Body temperature with uncomplicated obstruction is rarely higher than 100° F (37.8° C). A temperature higher than this, with or without guarding and tenderness, and a sustained elevation in pulse could indicate a strangulated obstruction or peritonitis. A fever, tachycardia, hypotension, increasing abdominal pain, abdominal rigidity, or change in color of skin overlying the abdomen should be reported to the attending physician immediately.

Physical Assessment/Clinical Manifestations.

The patient with *mechanical* obstruction in the *small intestine* often has mid-abdominal pain or cramping. The pain can be sporadic, and the patient may feel comfortable between episodes. If strangulation is present, the pain becomes more localized and steady. Vomiting often accompanies obstruction and is more profuse with obstructions in the proximal small intestine. The vomitus may contain bile and mucus or be orange-brown and foul smelling as a result of bacterial overgrowth with low ileal obstruction. Prolonged vomiting can result in a disruption in fluid and electrolyte balance. **Obstipation** (no passage of stool) and failure to pass flatus accompany complete obstruction. Diarrhea may be present in

partial obstruction.

Mechanical colonic obstruction causes a milder, more intermittent colicky abdominal pain than is seen with small-bowel obstruction. Lower abdominal distention and obstipation may be present, or the patient may have ribbon-like stools if obstruction is partial. Alterations in bowel patterns and blood in the stools accompany the obstruction if colorectal cancer or diverticulitis is the cause.

On examination of the abdomen, observe for abdominal distention, which is common in all forms of intestinal obstruction. Peristaltic waves may also be visible. Auscultate for proximal high-pitched bowel sounds **(borborygmi),** which are associated with cramping early in the obstructive process as the intestine tries to push the mechanical obstruction forward. In later stages of mechanical obstruction, bowel sounds are absent, especially distal to the obstruction. Abdominal tenderness and rigidity are usually minimal. The presence of a tense, fluid-filled bowel loop mimicking a palpable abdominal mass may signal a closed-loop, strangulating small-bowel obstruction.

In most types of *nonmechanical* obstruction, the pain is described as a constant, diffuse discomfort. Colicky cramping is not characteristic of this type of obstruction. Pain associated with obstruction caused by vascular insufficiency or infarction is usually severe and constant. On inspection, abdominal distention is typically present. On auscultation of the abdomen, note and document decreased bowel sounds in early obstruction and absent bowel sounds in later stages. Vomiting of gastric contents and bile is frequent, but the vomitus rarely has a foul odor and is rarely profuse. Obstipation may or may not be present. Chart 56-5 compares small-bowel and large-bowel obstructions.

Chart 56-5 Key Features

Small-Bowel and Large-Bowel Obstructions

SMALL-BOWEL OBSTRUCTIONS	LARGE-BOWEL OBSTRUCTIONS
Abdominal discomfort or pain possibly accompanied by visible peristaltic waves in upper and middle abdomen	Intermittent lower abdominal cramping
Upper or epigastric abdominal distention	Lower abdominal distention
Nausea and early, profuse vomiting (may contain fecal material)	Minimal or no vomiting
Obstipation	Obstipation or ribbon-like stools
Severe fluid and electrolyte imbalances	No major fluid and electrolyte imbalances
Metabolic alkalosis	Metabolic acidosis (not always present)

Diagnostic Assessment.

There is no definitive laboratory test to confirm a diagnosis of mechanical or nonmechanical obstruction. *White blood cell (WBC) counts* are normal unless there is a strangulated obstruction, in which case there may be leukocytosis (increased WBCs). *Hemoglobin, hematocrit, creatinine, and blood urea nitrogen (BUN)* values are often elevated, indicating dehydration. Serum sodium, chloride, and potassium are decreased. Elevations in serum amylase levels may be found with strangulating obstructions, which can damage the pancreas.

The health care provider obtains an *abdominal CT scan* as soon as an obstruction is suspected. Distention with fluid and gas in the small intestine with the absence of gas in the colon indicates an obstruction in the small intestine.

The diagnostic examination chosen depends on the suspected location of the obstruction. As an initial assessment, the health care provider may prescribe an *abdominal ultrasound* to evaluate the potential cause of the obstruction. The physician may perform endoscopy (sigmoidoscopy or colonoscopy) to determine the cause of the obstruction, except when perforation or complete obstruction is suspected.

Interventions

Interventions are aimed at uncovering the cause and relieving the obstruction. Intestinal obstructions can be relieved by nonsurgical or surgical means. If the obstruction is partial and there is no evidence of strangulation, nonsurgical management may be the treatment of choice (Chart 56-6).

Chart 56-6 Best Practice for Patient Safety & Quality

Care QSEN

Nursing Care of Patients Who Have an Intestinal Obstruction

- Monitor vital signs, especially blood pressure, for indications of fluid balance.
- Assess the patient's abdomen at least twice a day for bowel sounds, distention, and passage of flatus.
- Monitor fluid and electrolyte status, including laboratory values.
- Manage the patient who has a nasogastric tube (NGT):
  - Monitor drainage.
  - Ensure tube patency.
  - Check tube placement.
  - Irrigate tube as prescribed.
  - Maintain the patient on NPO status.
  - Provide frequent mouth and nares care.
  - Maintain the patient in a semi-Fowler's position.
- Give analgesics for pain as prescribed.
- Give alvimopan (Entereg) as prescribed for patients with a postoperative ileus.
- Maintain parenteral nutrition if prescribed.

Nonsurgical Management.

Paralytic ileus responds well to nonsurgical methods of relieving obstruction. Nonsurgical approaches are also preferred in the treatment of patients with terminal disease associated with bowel obstruction. In addition to being NPO, patients typically have a nasogastric tube (NGT) inserted to decompress the bowel by draining fluid and air. The tube is attached to suction.

Nasogastric Tubes.

Most patients with an obstruction have an NGT unless the obstruction is mild. A **Salem sump tube** is inserted through the nose and placed into the stomach. It is attached to low continuous suction. This tube has a vent ("pigtail") that prevents the stomach mucosa from being pulled away during suctioning. Levin tubes do not have a vent and therefore should be connected to low intermittent suction. They are used much less often than the Salem sump tubes.

Nursing Safety Priority QSEN

Action Alert

At least every 4 hours, assess the patient with an NGT for proper placement of the tube, tube patency, and output (quality and quantity). Monitor the nasal skin around the tube for irritation. Use a device that secures the tube to the nose to prevent accidental removal. Assess for peristalsis by auscultating for bowel sounds with the suction disconnected (suction masks peristaltic sounds).

Question the patient about the passage of flatus, and record flatus and the character of bowel movements daily. Flatus or stool means that peristalsis has returned. Assess for nausea, and ask the patient to report this manifestation.

Monitor any NGT for proper functioning. Occasionally NGTs move out of optimal drainage position or become plugged. In this case, note a decrease in gastric output or stasis of the tube's contents. Assess the patient for nausea, vomiting, increased abdominal distention, and placement of the tube. If the NGT is repositioned or replaced, confirmation of proper placement may be obtained by x-ray before use. After appropriate placement is established, aspirate the contents and irrigate the tube with 30 mL of normal saline every 4 hours or as requested by the health care provider.

Other Nonsurgical Interventions.

Most types of nonmechanical obstruction respond to nasogastric decompression with medical treatment of the primary disorder. Incomplete mechanical obstruction can sometimes be successfully treated without surgery. Obstruction caused by lower fecal impaction usually resolves after disimpaction and enema administration. Intussusception may respond to hydrostatic pressure changes during a barium enema.

For patients with a postoperative ileus (POI), alvimopan (Entereg) may be given for short-term use. This drug is an oral, peripherally acting mu opioid receptor antagonist that increases GI motility (Russell et al., 2012).

IV fluid replacement and maintenance are indicated for all patients with intestinal obstruction because the patient is NPO and fluid and electrolyte balance is lost (particularly potassium) through vomiting and nasogastric suction. On the basis of serum electrolytes and blood urea nitrogen (BUN) levels, the health care provider prescribes aggressive fluid replacement with 2 to 4 L of normal saline or lactated Ringer's solution with potassium added. Use care with patients who are susceptible to

fluid overload (e.g., older adults with a history of heart or kidney failure). Monitor lung sounds, weight, and intake and output daily. Weight is the most reliable indicator of fluid balance. Blood replacement may be indicated in strangulated obstruction because of blood loss into the bowel or peritoneal cavity.

Monitor vital signs and other measures of fluid status (e.g., urine output, skin turgor, mucous membranes) every 2 to 4 hours, depending on the severity of the patient's symptoms. In collaboration with the dietitian, the physician may prescribe parenteral nutrition (PN), especially if the patient has had chronic nutritional problems and has been NPO for an extended period. Chapter 60 discusses the nursing care of patients receiving PN.

The patient with intestinal obstruction is usually thirsty, although some older adults have a decreased thirst response. Delegate frequent mouth care to unlicensed assistive personnel (UAP) to help maintain moist mucous membranes. Be sure to supervise this activity. A few ice chips may be allowed if the patient is not having surgery. Follow agency protocol or the physician's request regarding ice chips.

Abdominal distention can cause a great deal of discomfort, especially when it is severe. The colicky, crampy pain that comes and goes with mechanical obstruction and the nausea, vomiting, dry mucous membranes, and thirst contribute to the patient's discomfort. Continually assess the character and location of the pain, and immediately report any pain that significantly increases or changes from a colicky, intermittent type to a constant discomfort. These changes can indicate perforation of the intestine or peritonitis.

Opioid analgesics may be temporarily withheld in the diagnostic workup period so that clinical manifestations of perforation or peritonitis are not masked. Explain to the patient and family the rationale for not giving analgesics. In addition, if analgesics such as morphine are given, they may slow intestinal motility and can cause vomiting. Be alert to this side effect because nausea and vomiting are also signs of NG tube obstruction or worsening bowel obstruction.

Help the patient obtain a position of comfort with frequent position changes to promote increased peristalsis. A semi-Fowler's position helps alleviate the pressure of abdominal distention on the chest. This position is for comfort and promotion of thoracic excursion to facilitate breathing.

Discomfort is generally less with nonmechanical obstruction than with mechanical obstruction. With both types of obstruction, discomfort is aggravated by taking in food or fluids.

If strangulation is thought to be likely, the health care provider

prescribes IV broad-spectrum antibiotics. In addition, in cases of partial obstruction or paralytic ileus, drugs that enhance gastric motility such as octreotide acetate (Sandostatin) may be used.

Surgical Management.

In patients with complete mechanical obstruction and in some cases of incomplete mechanical obstruction, surgical intervention is necessary to relieve the obstruction. A strangulated obstruction is complete, and surgical intervention is always required. An **exploratory laparotomy** (a surgical opening of the abdominal cavity to investigate the cause of the obstruction) is initially performed for many patients with obstruction. More specific surgical procedures depend on the cause of the obstruction.

Preoperative Care.

Provide general preoperative teaching for both the patient and family as discussed in Chapter 14. In cases of complete obstruction, the patient may feel too ill to want the information. Reinforce the information with the family or other caregiver. Depending on the cause and severity of the obstruction, as well as the expertise of the surgeon, patients have either minimally invasive surgery (MIS) via laparoscopy or a conventional open approach.

Operative Procedures.

In the *conventional open surgical approach*, the surgeon makes a large incision, enters the abdominal cavity, and explores for obstruction and its cause, if possible (exploratory laparotomy). If adhesions are found, they are lysed (cut and released). Obstruction caused by a tumor or diverticulitis requires a colon resection with primary anastomosis or a temporary or permanent colostomy. If obstruction is caused by intestinal infarction, an embolectomy, thrombectomy, or resection of the gangrenous small or large bowel may be necessary. In severe cases a colectomy (removal of the entire colon) may be needed.

For the *MIS* approach, the specially trained surgeon makes several small incisions in the abdomen and places a video camera to view the abdominal contents to determine the extent of the obstruction. A laparoscope (type of endoscope) with a lighted end is inserted along with various surgical instruments to remove the problem. This procedure takes longer than the open approach, but blood loss is less and healing is faster. Robotic assistance may be used, depending on the experience of the surgeon and available equipment.

Postoperative Care.

General postoperative care for the patient undergoing an *exploratory laparotomy* with lysis of adhesions, colon resection, thrombectomy, or embolectomy is similar to that described in Chapter 16. In addition, patients who had an open surgical approach have an NGT in place until peristalsis resumes. A clear liquid diet may be prescribed to encourage peristalsis return. As liquids are started, the NGT can be disconnected from suction and capped for 1 to 2 hours after the patient has taken clear liquids to determine if he or she is able to tolerate them. If the patient vomits after liquids, the suction is resumed. When the patient has return of peristalsis, the NGT suction is discontinued and the tube is clamped for a scheduled amount of time. If the patient does not experience nausea while the NGT is clamped, the tube is removed.

Most patients today have laparoscopic surgery (MIS) for mechanical intestinal obstructions. They usually do *not* have an NGT and can recover more quickly than those with the open surgical approach. The hospital stay for those having MIS to remove tumors, adhesions, and other obstructions may be as short as 1 to 2 days compared with 3 days or longer for the conventional surgical patients. Recovery is much quicker because there is less pain and there are fewer postoperative complications among those who had laparoscopic surgery.

Clinical Judgment Challenge

Patient-Centered Care; Teamwork and Collaboration; Informatics QSEN

An 82-year-old woman had open abdominal surgery 36 hours ago for removal of a large uterine tumor. As her nurse, you note that she continues to have no bowel sounds and has not passed flatus. Her abdomen is moderately distended and hard. She has reported several episodes of severe nausea and has no appetite but states that she has no pain. You suspect that the patient has a postoperative ileus but need more data before calling the surgeon.

1. What questions do you need to ask the patient and her family related to her current problem?
2. What other objective assessment data do you need before contacting the surgeon?
3. Using SBAR and data that you provide, how will you communicate the information about this patient to the surgeon?
4. What evidence-based collaborative interventions are appropriate for

this patient immediately? Support your answer with Internet resources.
5. What information will you document in the electronic health record?
6. What electrolyte imbalances would you expect? How might her presentation be somewhat different from that of a younger adult and why?

Community-Based Care

All patients with intestinal obstruction are hospitalized for monitoring and treatment. The length of stay varies according to the type of obstruction, the treatment, and the presence of complications. Patients who have complicated obstruction, such as strangulation or incarceration, are at greater risk for peritonitis, sepsis, and shock.

Patients with nonmechanical (adynamic) intestinal obstruction are less likely to require a lengthy hospitalization because of the obstruction alone. Adynamic obstruction generally responds to NG suction and possible drug therapy within a few days. However, if the ileus occurs as a complication of an abdominal surgery, the hospital stay could be lengthy.

Home Care Management.

For the patient who has had an intestinal obstruction, preparation for home care depends on the cause of the obstruction and the treatment required. Those who have resolution of obstruction without surgical intervention are assessed for their knowledge of strategies to avoid recurrent obstruction. For example, if fecal impaction was the cause of the obstruction, assess the patient's ability to carry out a bowel regimen independently (Chart 56-7). For those who have had surgery, evaluate their ability to function at home with the added tasks of incision care and possibly colostomy care.

Chart 56-7 Nursing Focus on the Older Adult

Preventing Fecal Impaction

- Teach the patient to eat high-fiber foods, including plenty of raw fruits and vegetables and whole-grain products.
- Encourage the patient to drink adequate amounts of fluids, especially water.
- Do not routinely administer a laxative; teach the patient that laxative abuse decreases abdominal muscle tone and contributes to an atonic colon.

- Encourage the patient to exercise regularly, if possible. Walking every day is an excellent exercise for promoting intestinal motility.
- Use natural foods to stimulate peristalsis, such as warm beverages and prune juice.
- Take bulk-forming products, such as Metamucil, to provide fiber.
- Check the patient's stool for amount and frequency; oozing of soft or diarrheal stool often indicates a fecal impaction.
- Have the patient sit on a toilet or bedside commode rather than on a bedpan for elimination.

Self-Management Education.

Instruct the patient to report any abdominal pain or distention, nausea, or vomiting, with or without constipation, because these symptoms might indicate recurrent obstruction. The patient should be reassured, however, that recurrent paralytic ileus is not common.

Teach the patient who has had surgery about incision care, drug therapy, and activity limitations. Drug therapy consists of an oral opioid analgesic, such as oxycodone hydrochloride with acetaminophen (Tylox, Percocet, Endocet), to be taken as needed for incisional discomfort. As with any opioid therapy, an over-the-counter laxative with a softener (e.g., Docusate with Senna) or polyethylene glycol (MiraLax) may be added to prevent constipation and possible recurrent obstruction.

The patient who had curative treatment of the underlying cause most likely requires less support than one who had treatment of obstruction related to a serious disease that will require further management. Encourage the patient to express fears and concerns about the future. Assess the patient's understanding and needs with regard to treatment plans.

Health Care Resources.

The need for follow-up appointments depends on the cause of the obstruction and the treatment required. In collaboration with the case manager, make arrangements for a home care nurse if the patient needs help with incision or colostomy care.

Abdominal Trauma

Pathophysiology

Abdominal trauma is defined as injury to the structures located between the diaphragm and the pelvis that occurs when the abdomen is subjected to blunt or penetrating forces. Organs injured may include the large or small bowel, liver, spleen, duodenum, pancreas, kidneys, and urinary bladder.

At least one half of all *blunt abdominal traumas* occur from motor vehicle crashes. Other causes of blunt trauma include falls, aggravated assaults, and contact sports. The spleen is the most commonly injured organ from *blunt* abdominal trauma. *Penetrating abdominal trauma* is caused by gunshot wounds (GSWs), stabbing, or impalement with an object. The liver is the most commonly injured organ from penetrating abdominal trauma. *Trauma is the leading cause of death in adults younger than 40 years in the United States.*

Patient-Centered Collaborative Care

Assessment

*First, assess any patient experiencing trauma for **a**irway, **b**reathing, and **c**irculation (ABCs).*

Nursing Safety Priority QSEN

Critical Rescue

Once the patient with abdominal trauma has been assessed for airway, breathing, and circulation, focus on the risks for hemorrhage, shock, and peritonitis. Mental status, vital signs, and skin perfusion are *priority* nursing assessments, with skin perfusion being the most reliable clinical guide in assessing hypovolemic shock:

- In a person with mild shock, the skin is pale, cool, and moist.
- With moderate shock, diaphoresis is more marked and urine output ceases.
- With severe shock, changes in mental status are manifested by agitation, disorientation, and recent memory loss.

Assess for abdominal trauma by asking the patient about the presence, location, and quality of pain. Inspect the abdomen, flanks, back, genitalia, and rectum for contusions, abrasions, lacerations, ecchymosis, penetrating injuries, and asymmetry. All of the patient's

clothes must be removed for this examination.

Inspection of the abdomen may reveal distention. To perform an adequate inspection, turn the patient while maintaining spinal immobilization. *Ecchymosis (bruising) may indicate internal bleeding. Ecchymosis present in the distribution of a lap seat belt should be reported to the health care provider immediately because the bowel or other major organ may be injured.*

Auscultate the abdomen for bowel sounds. Absent or diminished bowel sounds may be caused by the presence of blood, bacteria, or a chemical irritant in the abdominal cavity. Also auscultate for bruits in the abdomen, which could indicate renal artery injury.

Injury to the spleen is present in many people with left lower rib fractures. Liver injury may be present in those with right lower rib fractures. Dullness over hollow organs that normally contain gas, such as the stomach and the large and small intestines, may indicate the presence of blood or fluid. Light abdominal palpation identifies areas of tenderness, rebound tenderness, guarding, rigidity, and spasm. A palpated mass may be blood or a fluid collection.

The patient without obvious significant bleeding or definite signs of peritoneal irritation undergoes abdominal ultrasound, **diagnostic peritoneal lavage (DPL),** and CT. For DPL, the physician inserts a large-bore catheter into the abdomen and allows fluid to enter the abdominal cavity. If the return drainage from the abdomen is pink or grossly bloody, the health care team prepares for surgery. Abdominal ultrasound or *focused abdominal sonography for trauma (FAST)* is used to diagnose blunt abdominal trauma and may replace CT and DPL for diagnosis. Patients with hemodynamic instability or peritonitis are candidates for immediate laparotomy.

Interventions

Nonsurgical and surgical interventions are aimed at preserving or restoring hemodynamic stability, preventing or decreasing blood loss, and preventing complications. Patients with abdominal trauma from a vehicle crash often have other injuries such as multiple fractures. *The priority for care is to establish and maintain the ABCs.*

Emergency Care: Abdominal Trauma.

Nursing interventions include placement of at least two large-bore IV catheters in the upper extremities. IV catheters are not used in the lower

extremities; if the vasculature has been injured, fluid can pool in the abdomen. The health care provider may insert a central venous catheter to assist with rapid fluid volume infusion. IV fluids include saline, crystalloids, and possibly blood. Be sure that the patient is typed and crossmatched for as many as 4 to 8 units of packed red blood cells.

These laboratory values are monitored:

- Arterial blood gases
- Complete blood count (CBC)
- Serum electrolyte, glucose and amylase, and blood urea nitrogen (BUN) determinations
- Liver function tests
- Coagulation studies

Measuring arterial blood gases may help determine the severity of shock. Hemoglobin and hematocrit values do not initially reflect true blood loss; values can be skewed because of hemoconcentration from volume loss or the dilutional effects of IV fluids. Serial hemoglobin and hematocrit measurements may be more accurate in determining true blood loss. An elevated white blood cell (WBC) count may indicate a ruptured spleen or intestinal injury. Elevated levels of serum transaminases may indicate liver injury. Elevation of serum amylase activity may signal injury to the pancreas or the bowel. All laboratory work is compiled so that values can be compared and trended.

Continuous hemodynamic monitoring is begun in the emergency department. Insert an indwelling urinary (Foley) catheter unless there is blood at the urinary meatus. Initially and hourly thereafter, evaluate urine output for bleeding and specific gravity. Laboratory tests indicate the amount of blood and protein in the urine. If there is an open abdominal wound or evisceration, cover it with a sterile dry dressing unless the physician requests otherwise. Unless it is contraindicated, as in the case of a skull fracture, the physician or nurse inserts a nasogastric tube (NGT) to identify bleeding and minimize the risk for vomiting and aspiration. Antibiotics may be administered as prescribed to reduce the risk for peritonitis.

If the patient with known abdominal trauma has no definite clinical manifestations of active bleeding or organ injury, he or she is admitted to the hospital for observation. Many patients are admitted to the critical care unit. Blunt trauma can cause active, but often not obvious, damage.

Nursing Safety Priority QSEN

Critical Rescue

For the patient who has sustained abdominal trauma, assess for abdominal or referred pain and nausea. Every 15 to 30 minutes in the early postinjury period and then hourly, evaluate:

- Mental status
- Vital signs
- Clinical findings, such as vomiting, guarding, rigidity, or rebound tenderness
- Bowel sounds
- Urine output

Report any change immediately to the health care provider! It is more important to recognize the high risk for an active abdominal injury and assess for general signs of organ injury (e.g., hemorrhage and peritonitis) than to identify the exact nature of the abdominal injury. Opioid analgesics are given for pain after the physician's initial assessment is complete. Explain to the patient and family the rationale for delaying analgesics.

Intra-Abdominal Pressure Monitoring.

Some patients are monitored for intra-abdominal pressure (IAP) using a continuous monitoring system. As the name implies, **intra-abdominal pressure** is pressure within the abdominal cavity. The normal IAP in healthy adults is 0 to 5 mm Hg, but obese patients often have a higher normal value (Lee, 2012). Increased IAP commonly occurs in patients with abdominal trauma. Other causes of IAP elevation include sepsis, burns, abdominal hemorrhage, and mechanical intestinal obstruction.

Nursing interventions to help *prevent* increased IAP in high-risk patients include (Lee, 2012):

- Record bowel movements.
- Check daily for fecal impaction.
- Provide measures to prevent constipation (e.g., increased fluids if tolerated, daily stool softener).
- Provide fluid replacement with hypertonic saline, crystalloids (e.g., 0.9% saline), or colloids (e.g., albumin, Dextran) as prescribed to expand plasma volume.
- Document intake and output.
- Monitor residuals for patients being tube-fed.
- Elevate the head of the bed to 20-30 degrees, depending on the patient's condition.
- Manage pain adequately.

When IAP becomes higher than the central venous pressure, the inferior vena cava and other abdominal vessels are compressed. This leads to impaired venous return, increased afterload, and decreased preload. The patient is then at risk for deep vein thrombosis and pulmonary embolism (PE). The patient has tachycardia and hypotension. As the IAP increases further, acidosis and ischemia occur. A sustained or repeated IAP of 12 mm Hg or higher is considered **intra-abdominal hypertension (IAH). Abdominal acute compartment syndrome (AACS)** results when the IAP is sustained at greater than 20 mm Hg. Untreated AACS results in damage to the intestine and increases the risk for sepsis, multiple organ dysfunction syndrome (MODS), and death. Almost every body system can be affected (Lee, 2012).

For patients with abdominal trauma or other high-risk factors, the health care provider may request continuous or intermittent IAP monitoring in the critical care unit using a urinary manometer or transducer system. *Report any increase in IAP immediately to the health care provider.* AACS has a rapid onset after abdominal trauma (especially blunt trauma) and must be treated immediately using either a nonsurgical (vasopressor drugs and fluids) or surgical approach (fasciotomy). Surgery is risky because it increases the chance of embolic stroke and PE.

Surgical Management.

For the patient with severe abdominal trauma, the surgeon performs an *exploratory laparotomy* and repairs abdominal injuries immediately if there are definite signs of peritoneal irritation. These signs include rebound tenderness, significant blood loss, evisceration, or a gunshot wound (GSW) with possible peritoneal involvement. After surgery, many of these patients are admitted to a critical care unit and mechanically ventilated.

Most stab wounds and GSWs require exploratory laparotomy. The surgeon explores and cleans superficial penetrating wounds. The patient does not require an exploratory laparotomy for superficial wounds.

Patients with multiple trauma stay in the hospital for a prolonged period. Before discharge from the hospital, teach the patient and family the signs and symptoms of abdominal bleeding whether or not surgery has been performed. Instruct them to report abdominal pain, nausea, vomiting, bloody or black stools, fever, weakness, and dizziness.

Hemorrhage can occasionally occur weeks after blunt abdominal trauma, despite medical evaluation or treatment. For the patient who has surgery or exploration of wounds, provide instructions on wound care

before discharge from the hospital. Provide additional health teaching as the patient's overall condition requires.

NCLEX Examination Challenge

Physiological Integrity

A client is admitted to the emergency department in severe pain with a gunshot wound to the right upper abdomen. Admitting vital signs are TPR 98-96-28; BP 118/70; oxygen saturation 94%. What is the nurse's priority when monitoring this client?

A Open the airway to improve breathing.
B Give oxygen via nasal cannula at 2 L/min.
C Monitor vital signs frequently.
D Determine how the client was shot and by whom.

Polyps

Pathophysiology

Polyps in the intestinal tract are small growths covered with mucosa and attached to the surface of the intestine. Although most are benign, they are significant because some have the potential to become malignant.

Polyps are identified by their tissue type. Although only a very small number of adenomas progress to cancer, almost all colorectal cancers develop from an adenoma. Adenomas are further classified as villous or tubular. Of these, villous adenomas pose a greater cancer risk.

Familial adenomatous polyposis (FAP) and hereditary nonpolyposis colorectal cancer (HNPCC) are inherited syndromes characterized by progressive development of colorectal adenomas. Unless these syndromes are treated, colorectal cancer (CRC) inevitably occurs by the fourth to fifth decade of life. These conditions were discussed on p. 1149 in the Genetic/Genomic Considerations feature in the Colorectal Cancer section.

Patient-Centered Collaborative Care

Polyps are usually asymptomatic and are discovered during routine colonoscopy screening. However, they can cause gross rectal bleeding, intestinal obstruction, or intussusception (telescoping of the bowel). Biopsy specimens of polyps can be obtained and the entire polyp can be removed (polypectomy) with the use of a snare that fits through the sigmoidoscope or colonoscope. This often eliminates the need for abdominal surgery to remove a suspicious or definitely malignant polyp. The patient with FAP often requires a total colectomy (colon removal) to prevent the development of cancer.

Nursing care focuses on patient education. Instruct the patient about:

- The nature of the polyp
- Clinical manifestations to report to the health care provider
- The need for regular, routine monitoring or screening

If the patient has had a polypectomy, follow-up sigmoidoscopic or colonoscopic examinations are needed because there is an increased risk for developing multiple polyps.

Nursing care of the patient after a polypectomy of the colorectal area includes monitoring for abdominal distention and pain, rectal bleeding, mucopurulent drainage from the rectum, and fever. A small amount of blood might appear in the stool after a polypectomy, but this should be

temporary.

Hemorrhoids

Pathophysiology

Hemorrhoids are unnaturally swollen or distended veins in the anorectal region. The veins involved in the development of hemorrhoids are part of the normal structure in the anal region. With limited distention, the veins function as a valve overlying the anal sphincter that assists in continence. Increased intra-abdominal pressure causes elevated systemic and portal venous pressure, which is transmitted to the anorectal veins. Arterioles in the anorectal region shunt blood directly to the distended anorectal veins, which increases the pressure. With repeated elevations in pressure from increased intra-abdominal pressure and engorgement from arteriolar shunting of blood, the distended veins eventually separate from the smooth muscle surrounding them. The result is prolapse of the hemorrhoidal vessels.

Hemorrhoids can be internal or external (Fig. 56-8). **Internal hemorrhoids,** which cannot be seen on inspection of the perineal area, lie above the anal sphincter. **External hemorrhoids** lie below the anal sphincter and can be seen on inspection of the anal region. Prolapsed hemorrhoids can become thrombosed or inflamed, or they can bleed (McCance et al., 2014).

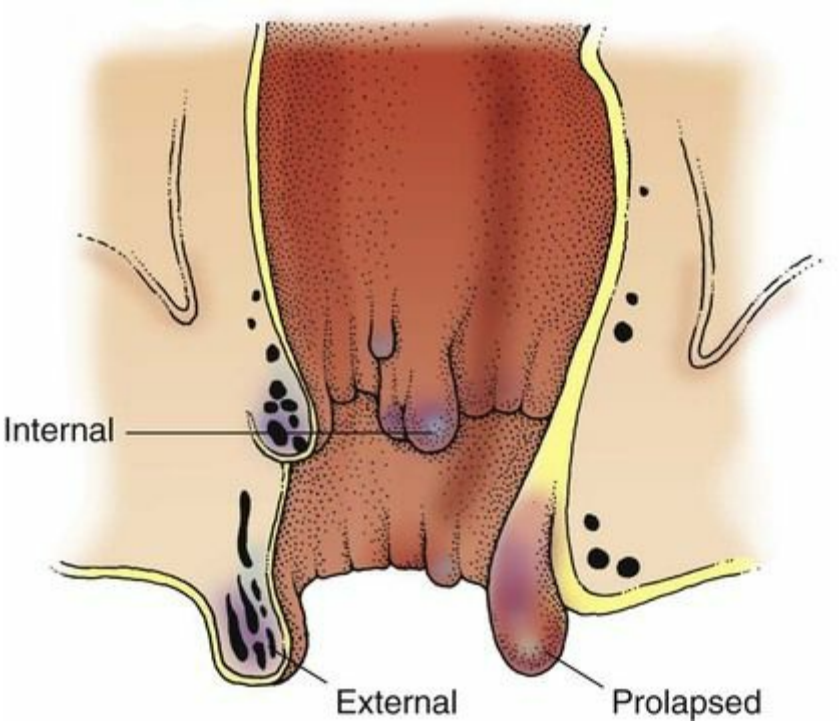

FIG. 56-8 Internal, external, and prolapsed hemorrhoids. *Internal hemorrhoids* lie above the anal sphincter and cannot be seen on inspection of the anal area. *External hemorrhoids* lie below the anal sphincter and can be seen on inspection of the anal region. Hemorrhoids that enlarge, fall down, and protrude through the anus are called *prolapsed hemorrhoids*.

Hemorrhoids are common and not significant unless they cause pain or bleeding. Caused by increased abdominal pressure, the condition worsens during pregnancy, constipation with straining, obesity, heart failure, prolonged sitting or standing, and strenuous exercise and weight lifting. Decreased fluid intake can also cause hemorrhoids because of the development of hard stool and subsequent constipation. Straining while evacuating stool causes them to enlarge.

Health Promotion and Maintenance

Prevention of constipation is the most important preventive measure. It can be prevented by increasing fiber in the diet, such as eating more whole grains and raw vegetables and fruits. Encourage patients to drink plenty of water unless otherwise contraindicated (e.g., kidney disease, heart disease). Remind the patient to avoid straining at stool. Remind him or her to exercise regularly with a gradual buildup in intensity. Maintaining a healthy weight also helps prevent hemorrhoids.

❖ Patient-Centered Collaborative Care

Assessment

The most common symptoms of hemorrhoids are bleeding, swelling, and prolapse (bulging). Blood is characteristically bright red and is present on toilet tissue or streaked in the stool. Pain is a common symptom and is often associated with thrombosis, especially if thrombosis occurs suddenly. Other symptoms include itching and a mucous discharge. Diagnosis is usually made by inspection and digital examination.

Interventions

Interventions are typically conservative and are aimed at reducing symptoms with a minimum of discomfort, cost, and time lost from usual activities. Local treatment and nutrition therapy are used when symptoms begin. Cold packs applied to the anorectal region for a few minutes at a time beginning with the onset of pain and tepid sitz baths 3 or 4 times per day are often enough to relieve discomfort, even if the hemorrhoids are thrombosed.

Topical anesthetics, such as lidocaine (Xylocaine), are useful for severe pain. Dibucaine (Nupercainal) ointment and similar products are available over the counter and may be applied for mild to moderate pain and itching. This ointment should be used only temporarily, however, because it can mask worsening symptoms and delay diagnosis of a severe disorder. If itching or inflammation is present, the health care provider prescribes a steroid preparation, such as hydrocortisone. Cleansing the anal area with moistened cleansing tissues rather than standard toilet tissue helps avoid irritation. The anal area should be cleansed gently by dabbing, rather than by wiping.

Diets high in fiber and fluids are recommended to promote regular bowel movements without straining. Stool softeners, such as docusate sodium (Colace), can be used temporarily. Irritating laxatives are avoided, as are foods and beverages that can make hemorrhoids worse. Spicy foods, nuts, coffee, and alcohol can be irritating. Remind patients to avoid sitting for long periods. The health care provider may prescribe mild oral analgesics for pain if the hemorrhoids are thrombosed.

Conservative treatment should alleviate symptoms in 3 to 5 days. If symptoms continue or recur frequently, the patient may require surgical intervention.

The surgeon can perform several procedures in an ambulatory care setting to remove symptomatic hemorrhoids (**hemorrhoidectomy**). The type of surgery (e.g., ultrasound or laser removal) depends on the degree

of prolapse, whether there is thrombosis, and the overall condition of the patient. Complications of these procedures include pain, thrombosis of other hemorrhoids, infection, bleeding, and abscess formation. If the hemorrhoid is prolapsed, a circular stapling device may be used to excise a band of mucosa above the prolapse and restore the hemorrhoidal tissue back into the anal canal.

Teach patients with hemorrhoids about the need to eat high-fiber, high-fluid diets to promote regular bowel patterns before and after surgery. Advise them to avoid stimulant laxatives, which can be habit forming.

For patients who undergo any type of surgical intervention, monitor for bleeding and pain postoperatively and teach them to report these problems to their health care provider. Using moist heat (e.g., sitz baths or warm compresses) 3 or 4 times per day can help promote comfort.

Nursing Safety Priority QSEN

Action Alert

Tell the patient who has had surgical intervention for hemorrhoids that the first postoperative bowel movement may be very painful. Be sure that someone is with or near the patient when this happens. Some patients become light-headed and diaphoretic and may have syncope ("blackout").

The physician usually prescribes stool softeners such as docusate sodium (Colace) to begin preoperatively and continue after surgery. Analgesics and anti-inflammatory drugs are prescribed. A mild laxative should be administered if the patient has not had a bowel movement by the third postoperative day.

Malabsorption Syndrome

❖ Pathophysiology

Malabsorption is a syndrome associated with a variety of disorders and intestinal surgical procedures. It interferes with the ability to absorb nutrients and is a result of a generalized flattening of the mucosa of the small intestine. With various disorders, physiologic mechanisms limit absorption of nutrients because of one or more of these abnormalities:

- Bile salt deficiencies
- Enzyme deficiencies
- Presence of bacteria
- Disruption of the mucosal lining of the small intestine
- Altered lymphatic and vascular circulation
- Decrease in the gastric or intestinal surface area

The nutrient involved in malabsorption depends on the type and location of the abnormality in the intestinal tract.

Deficiencies of bile salts can lead to malabsorption of fats and fat-soluble vitamins. Bile salt deficiencies can result from decreased synthesis of bile in the liver, bile obstruction, or alteration of bile salt absorption in the small intestine.

Enzymes normally found in the intestine split disaccharides (complex sugars) to monosaccharides (simple sugars). Examples of these enzymes are lactase, sucrase, maltase, and isomaltase. Lactase deficiency is the most common disaccharide enzyme deficiency. Without sufficient amounts of this enzyme, the body is not able to break down lactose. Lactase deficiency can be due to genetic inheritance, injury to intestinal mucosa from viral hepatitis, or excessive bacteria in the intestine. Deficiencies of the other disaccharide enzymes are rare.

Pancreatic enzymes are also necessary for absorption of vitamin B_{12}. With destruction or obstruction of the pancreas or insufficient pancreatic stimulation, this nutrient is not well absorbed. Chronic pancreatitis, pancreatic carcinoma, resection of the pancreas, and cystic fibrosis can cause these malabsorption problems.

Loops of bowel can accumulate intestinal contents, resulting in bacterial overgrowth, when peristalsis is decreased. Bacteria at these sites break down bile salts, and fewer salts are available for fat absorption. They can also ingest vitamin B_{12}, which contributes to vitamin B_{12} deficiency. This process can occur after a gastrectomy.

Obstruction to lymphatic flow in the intestine can lead to loss of plasma proteins along with loss of minerals (e.g., iron, copper, calcium),

vitamin B_{12}, folic acid, and lipids. Lymphatic obstruction can be caused by many conditions. Certain cancers such as lymphoma, inflammatory states, radiation enteritis, Crohn's disease, heart failure, and constrictive pericarditis are causes of lymphatic obstruction.

Interference with blood flow to the intestinal mucosa results in malabsorption. With intestinal surgery, there is loss of the surface area needed to facilitate absorption. Resection of the ileum results in vitamin B_{12}, bile salt, and other nutrient deficiencies. Gastric surgery is one of the most common causes of malabsorption and maldigestion. Other conditions associated with poor digestion and malabsorption include small-bowel ischemia and radiation enteritis.

Patient-Centered Collaborative Care

Assessment

Chronic diarrhea is a classic symptom of malabsorption. It occurs as a result of unabsorbed nutrients, which add to the bulk of the stool, and unabsorbed fat. **Steatorrhea** (greater than normal amounts of fat in the feces) is a common sign. It is a result of bile salt deconjugation, nonabsorbed fats, or bacteria in the intestine. Not all patients with malabsorption have diarrhea. Instead, some have an increased stool mass. Other clinical manifestations include:

- Unintentional weight loss
- Bloating and flatus (carbohydrate malabsorption)
- Decreased libido
- Easy bruising (purpura)
- Anemia (with iron and folic acid or vitamin B_{12} deficiencies)
- Bone pain (with calcium and vitamin D deficiencies)
- Edema (caused by hypoproteinemia)

Serum laboratory studies reveal a decrease in mean corpuscular volume (MCV), mean corpuscular hemoglobin (MCH), and mean corpuscular hemoglobin concentration (MCHC). These decreases indicate hypochromic microcytic anemia resulting from iron deficiency. Increased MCV and variable MCH and MCHC values indicate macrocytic anemia resulting from vitamin B_{12} and folic acid deficiencies. Serum iron levels are low in protein malabsorption because of insufficient gastric acid for use of iron. Serum cholesterol levels may be low from decreased absorption and digestion of fat. Low serum calcium levels may indicate malabsorption of vitamin D and amino acids. Low levels of serum vitamin A (retinol) and carotene, its precursor, indicate a bile salt

deficiency and malabsorption of fat. Serum albumin and total protein levels are low if protein is lost.

A quantitative *fecal fat analysis* is often elevated in either malabsorption or maldigestive disorders (Pagana & Pagana, 2014).

A *lactose tolerance test* is a type of disaccharidase analysis that may show an inability to digest foods and beverages that contain lactose. A hydrogen breath test can also be performed to detect this problem. The d-xylose absorption test can reveal low urine and serum d-xylose levels if malabsorption in the small intestine is present (Pagana & Pagana, 2014).

The *Schilling test* measures urinary excretion of vitamin B_{12} for diagnosis of pernicious anemia and a variety of other malabsorption syndromes. The *bile acid breath test* assesses the absorption of bile salt. If the patient has bacterial overgrowth, the bile salts will become deconjugated and the carbon dioxide level in the breath will peak earlier than expected.

Ultrasonography is used to diagnose pancreatic tumors and tumors in the small intestine that are causing malabsorption. X-rays of the GI tract reveal pancreatic calcifications, tumors, or other abnormalities that cause malabsorption. A CT scan may also be done.

Interventions

Interventions for most malabsorption syndromes focus on (1) avoidance of substances that aggravate malabsorption and (2) supplementation of nutrients. Surgical management of the primary disease may be indicated. Drug therapy may also improve or resolve malabsorption.

Nutrition management includes a low-fat diet for patients who have gallbladder disease, severe steatorrhea, or cystic fibrosis. A low-fat diet may or may not be indicated for pancreatic insufficiency because this disorder improves with enzyme replacement. Some clinicians believe that limitation of fat intake is not necessary with enzyme replacement. Dietary intake of fat is actually beneficial to the patient because it has a high number of calories. After a total gastrectomy, a high-protein, high-calorie diet and small, frequent meals are recommended. Lactose-free or lactose-restricted diets are available for patients with lactase deficiency, and gluten-free diets are available for those with celiac disease, discussed in Chapter 57.

The health care provider prescribes nutritional supplements according to the specific deficiency. Common supplements include:

- Water-soluble vitamins, such as folic acid and vitamin B complex
- Fat-soluble vitamins, such as vitamin A, vitamin D, and vitamin K

- Minerals, such as calcium, iron, and magnesium
- Pancreatic enzymes, such as pancrelipase (Pancrease, Viokase)

Antibiotics are used to treat disorders involving bacterial overgrowth. Bacterial overgrowth can be caused by a variety of disorders but is often treated with tetracycline and metronidazole (Flagyl, Novonidazol).

Drug therapy is used to control the clinical manifestations of malabsorption. Antidiarrheal agents, such as diphenoxylate hydrochloride and atropine sulfate (Lomotil, N-Lomotil), are often used to control diarrhea and steatorrhea. Anticholinergics, such as dicyclomine hydrochloride (Bentyl, Bentylol), may be given before meals to inhibit gastric motility. IV fluids may be necessary to replenish fluid losses associated with diarrhea.

Provide special measures to protect the skin when chronic diarrhea occurs (Chart 56-8). Conduct an ongoing assessment for clinical manifestations of malabsorption, and relate these to activities and dietary intake. For example, patients with steatorrhea are monitored for fluid and electrolyte balance and are encouraged to drink electrolyte-rich liquids liberally. Teach them the rationale for dietary, drug, and surgical management of nutritional deficiencies, and evaluate interventions on the basis of changes in or resolution of clinical manifestations.

Chart 56-8 Best Practice for Patient Safety & Quality Care QSEN

Special Skin Care for Patients with Chronic Diarrhea

- Use medicated wipes or premoistened disposable wipes rather than toilet tissue to clean the perineal area.
- Clean the perineal area well with mild soap and warm water after each stool; rinse soap from the area well.
- If the physician allows, provide a sitz bath several times per day.
- Apply a thin coat of A+D Ointment or other medicated protective barrier, such as aloe products, after each stool.
- Keep the patient off the affected buttock area.
- For open areas, cover with thin DuoDerm or Tegaderm occlusive dressing to promote rapid healing.
- Observe for fungal or yeast infections, which appear as dark red rashes with "satellite" lesions. Obtain prescription for medication if this problem occurs.

Nursing Concepts and Clinical Judgment Review

What might you NOTICE if the patient has impaired absorption and inadequate nutrition as a result of noninflammatory intestinal disorders?

- Rectal bleeding
- Report of change in bowel habits
- Diarrhea or report of constipation
- Fatigue
- Vomiting
- Abdominal pain
- Change in bowel sounds (decreased or increased)
- Weight loss

What should you INTERPRET and how should you RESPOND to a patient with impaired absorption and inadequate nutrition as a result of noninflammatory intestinal disorders?

Perform and interpret focused physical assessment findings, including:

- Vital signs
- Complete pain assessment
- Abdominal assessment
- Current weight compared with previous weight

Respond by:

- Decreasing abdominal pain by placing patient in sitting position
- Starting IV (large-bore catheter) to replace fluids and electrolytes
- Giving blood transfusion as prescribed
- Providing rest
- Providing privacy and dignity
- Assisting with hygiene as needed
- Inserting nasogastric tube and connecting to low suction as needed
- Checking laboratory values of hemoglobin and hematocrit
- Checking stool for occult or frank blood
- Giving antidiarrheal drugs if prescribed
- Recording intake and output
- Assisting with ADLs and ambulation as needed

On what should you REFLECT?

- Continue to monitor for vomiting and diarrhea and for changes in pain.
- Think about what you need to document. Decide when you might need to call the health care provider or Rapid Response Team.
- Determine what health teaching and community resources may be needed for the patient and family.

- Think about what you can do to help prevent complications of the health problem.

Get Ready for the NCLEX® Examination!

Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Prioritize care for patients experiencing abdominal trauma: first assess **a**irway, **b**reathing, and **c**irculation (ABCs), and then monitor vital signs, mental status, and skin perfusion to assess for hypovolemic shock. **Safety** QSEN
- Collaborate with the certified wound, ostomy, continence nurse (CWOCN) or enterostomal therapist (ET) when a patient is scheduled for or has a new colostomy. **Teamwork and Collaboration** QSEN
- Collaborate with the case manager/discharge planner, health care provider, and CWOCN to plan care for the patient with CRC. **Teamwork and Collaboration** QSEN

Health Promotion and Maintenance

- Refer patients with familial CRC syndromes for genetic counseling and testing. **Patient-Centered Care** QSEN
- Refer ostomy patients to the United Ostomy Associations of America, Inc. and the American Cancer Society for additional information and support groups. **Patient-Centered Care** QSEN
- Teach patients with irritable bowel syndrome (IBS) to avoid GI stimulants, such as caffeine, alcohol, and milk and milk products, and to manage stress. **Evidence-Based Practice** QSEN
- Instruct patients on dietary modifications to decrease the occurrence of colorectal cancer (CRC), such as eating a diet high in fiber and avoiding red meat. **Evidence-Based Practice** QSEN
- Teach adults 50 years and older to have routine screening for CRC as listed in Chart 56-2; people with genetic predispositions should have earlier and more frequent screening. **Evidence-Based Practice** QSEN
- Teach people to prevent or manage constipation to help avoid hemorrhoids; teach patients the importance of maintaining a healthy weight to decrease the risk for hemorrhoids. **Evidence-Based Practice** QSEN
- Teach patients and caregivers how to provide colostomy care, including dietary measures, skin care, and ostomy products. **Patient-Centered Care** QSEN

Psychosocial Integrity

- Assist the patient with CRC with the grieving process. **Patient-Centered Care** QSEN
- Be aware that having a colostomy is a life-altering event that can severely impact one's body image; issues related to sexuality and fear of acceptance should be discussed. **Patient-Centered Care** QSEN

Physiological Integrity

- Be aware that minimally invasive inguinal hernia repair is an ambulatory care procedure done via laparoscopy; postoperative management requires health teaching regarding rest for a few days and inspection of incisions for signs of infection (see Chart 56-1). **Evidence-Based Practice** QSEN
- Be aware that a strangulated hernia can cause ischemia and bowel obstruction, requiring immediate intervention. **Safety** QSEN
- Monitor patients who have conventional open herniorrhaphy for ability to void. **Safety** QSEN
- Recall that changes in bowel habits or stool characteristics and/or rectal bleeding are often associated with a diagnosis of CRC. **Safety** QSEN
- Keep the peristomal skin clean and dry; observe for leakage around the pouch seal. **Evidence-Based Practice** QSEN
- Provide meticulous perineal wound care for patients having an abdominoperineal (AP) resection, as described in Chart 56-3. **Safety** QSEN
- Document the characteristics of the colostomy stoma, which should be reddish pink and moist; report abnormalities such as ischemia and necrosis (purplish or black) or unusual bleeding to the surgeon. **Informatics** QSEN
- Recall that bowel sounds are altered in patients with obstruction; absent bowel sounds imply total obstruction. **Safety** QSEN
- Assess the patient's nasogastric tube for proper placement, patency, and output at least every 4 hours. **Safety** QSEN
- Monitor patients with bowel obstruction for signs and symptoms of fluid, electrolyte, and acid-base imbalances; patients with small bowel obstruction are at greater risk for problems with fluid and electrolyte balance. **Safety** QSEN
- Teach patients having hemorrhoid surgery to take stool softeners before and after surgery to decrease discomfort during elimination. **Evidence-Based Practice** QSEN

- Provide comfort measures for the patient who has chronic diarrhea associated with malabsorption as described in Chart 56-8. **Patient-Centered Care** QSEN
- Reinforce teaching regarding supplements or dietary restrictions needed for malabsorption management. **Evidence-Based Practice** QSEN

CHAPTER 57

Care of Patients with Inflammatory Intestinal Disorders

Donna D. Ignatavicius

PRIORITY CONCEPTS

- Elimination
- Inflammation
- Nutrition
- Pain
- Infection
- Fluid and Electrolyte Balance

Learning Outcomes

Safe and Effective Care Environment

1. Describe the importance of collaborating with health care team members to provide care for patients with inflammatory bowel disease (IBD).

Health Promotion and Maintenance

2. Develop a health teaching plan for patients to promote self-management when caring for ileostomy or other surgical diversion.
3. Identify community resources for patients and families regarding IBD.
4. Discuss ways that gastroenteritis can be prevented.

Psychosocial Integrity

5. Identify expected body image changes associated with having an ileostomy or other surgical diversion.

Physiological Integrity

6. Differentiate common types of acute inflammatory bowel disorders.
7. Develop an evidence-based collaborative plan of care for the patient who has appendicitis or peritonitis.
8. Compare and contrast the pathophysiology and clinical manifestations of ulcerative colitis and Crohn's disease.
9. Identify priority problems for patients with ulcerative colitis.
10. Explain the purpose of and nursing implications related to drug therapy for patients with IBD.
11. Plan evidence-based postoperative care for a patient undergoing surgery for IBD.
12. Develop a hospital discharge teaching plan for patients who have IBD.
13. Explain the role of nutrition therapy in managing the patient with diverticular disease.
14. Describe the comfort measures to relieve pain that the nurse can implement for the patient with anal disorders.

 http://evolve.elsevier.com/Iggy/

Inflammatory bowel health problems affect the small intestine, large intestine (colon), or both. Together, these organs are called the *intestinal tract*. Continued digestion of food and absorption of nutrients occur primarily in the small intestine (bowel) to meet the body's needs for energy. Water is reabsorbed in the large intestine to help maintain a fluid balance and promote the passage of waste products. When the intestinal tract and its nearby structures become inflamed, nutrition may be inadequate to meet a patient's needs. Bowel elimination changes, pain, infection, and/or problems with fluid and electrolyte balance can result from inflammatory bowel diseases that are chronic.

Acute Inflammatory Bowel Disorders

Appendicitis, gastroenteritis, and peritonitis are the most common acute inflammatory bowel problems. These disorders are potentially life threatening and can have major systemic complications if not treated promptly.

Appendicitis

Pathophysiology

Appendicitis is an acute inflammation of the vermiform appendix that occurs most often among young adults. It is the most common cause of right lower quadrant (RLQ) pain. The appendix usually extends off the proximal cecum of the colon just below the ileocecal valve. Inflammation occurs when the lumen (opening) of the appendix is obstructed (blocked), leading to infection as bacteria invade the wall of the appendix. The initial obstruction is usually a result of fecaliths (very hard pieces of feces) composed of calcium phosphate–rich mucus and inorganic salts. Less common causes are malignant tumors, helminthes (worms), or other infections (McCance et al., 2014).

When the lumen is blocked, the mucosa secretes fluid, increasing the internal pressure and restricting blood flow, which results in pain. If the process occurs slowly, an abscess may develop, but a rapid process may result in peritonitis (inflammation and infection of the peritoneum). *All complications of peritonitis are serious. Gangrene and sepsis can occur within 24 to 36 hours, are life threatening, and are some of the most common indications for emergency surgery. Perforation may develop within 24 hours, but the risk rises rapidly after 48 hours.* Perforation of the appendix also results in peritonitis with a temperature of greater than 101° F (38.3° C) and a rise in pulse rate.

Considerations for Older Adults

Patient-Centered Care QSEN

Appendicitis is relatively rare at extremes in age. However, perforation is more common in older people, causing a higher mortality rate. The diagnosis of appendicitis is difficult to establish in older adults because symptoms of pain and tenderness may not be as pronounced in this age-group. This difference results in treatment delay and an increased risk for perforation, peritonitis, and death.

Patient-Centered Collaborative Care

Assessment

History taking and tracking the sequence of symptoms are important because nausea or vomiting before abdominal pain can indicate gastroenteritis. Abdominal pain followed by nausea and vomiting can indicate appendicitis. Ask about risk factors such as age, familial tendency, and intra-abdominal tumors. Classically, patients with appendicitis have cramplike pain in the epigastric or periumbilical area. Anorexia is a frequent symptom with nausea and vomiting occurring in many cases.

Perform a complete pain assessment. Initially, pain can present anywhere in the abdomen or flank area. As the inflammation and infection progress, the pain becomes more severe and steady and shifts to the RLQ between the anterior iliac crest and the umbilicus. This area is referred to as *McBurney's point* (Fig. 57-1). *Abdominal pain that increases with cough or movement and is relieved by bending the right hip or the knees suggests perforation and peritonitis.* An advanced practice nurse or other health care provider assesses for muscle rigidity and guarding on palpation of the abdomen. The patient may report pain after release of pressure. This is referred to as "rebound" tenderness.

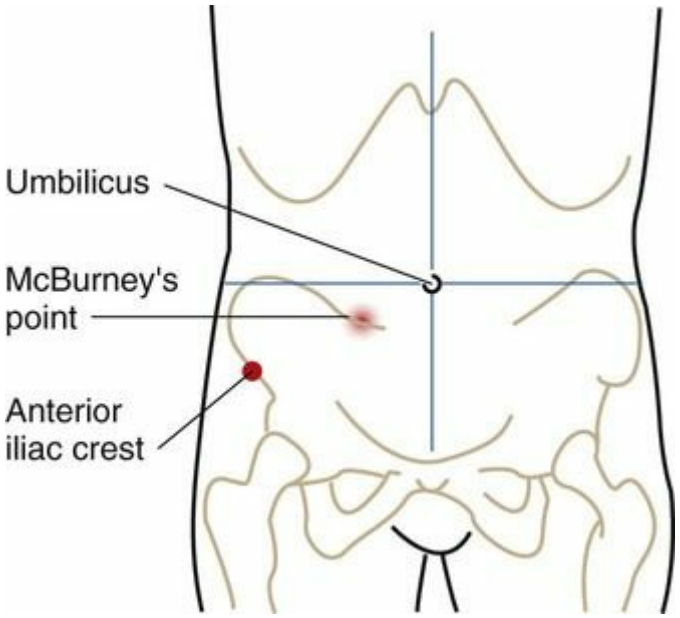

FIG. 57-1 McBurney's point is located midway between the anterior iliac crest and the umbilicus in the right lower quadrant. This is the classic area for localized tenderness during the later stages of appendicitis.

Laboratory findings do not establish the diagnosis, but often there is a moderate elevation of the *white blood cell (WBC) count* (leukocytosis) to 10,000 to 18,000/mm^3 with a "shift to the left" (an increased number of immature WBCs). A WBC elevation to greater than 20,000/mm^3 may indicate a perforated appendix. An *ultrasound* study may show the presence of an enlarged appendix. If symptoms are recurrent or prolonged, a CT scan can be used for diagnosis and may reveal the presence of a fecalith.

Interventions

All patients with suspected or confirmed appendicitis are hospitalized and most have surgery to remove the inflamed appendix.

Nonsurgical Management.

Keep the patient with suspected or known appendicitis on NPO to prepare for the possibility of surgery and to avoid making the inflammation worse.

Nursing Safety Priority QSEN

Action Alert

For the patient with suspected appendicitis, administer IV fluids as prescribed to maintain fluid and electrolyte balance and to replace fluid volume. If tolerated, advise the patient to maintain a semi-Fowler's position so that abdominal drainage, if any, can be contained in the lower abdomen. Once the diagnosis of appendicitis is confirmed and surgery is scheduled, administer opioid analgesics and antibiotics as prescribed. *The patient with suspected or confirmed appendicitis should not receive laxatives or enemas, which can cause perforation of the appendix. Do not apply heat to the abdomen because this may increase circulation to the appendix and result in increased inflammation and perforation!*

Surgical Management.

Surgery is required as soon as possible. An **appendectomy** is the removal of the inflamed appendix by one of several surgical approaches. Uncomplicated appendectomy procedures are done via laparoscopy. A **laparoscopy** is a minimally invasive surgical (MIS) procedure with one or more small incisions near the umbilicus through which a small endoscope is placed. Patients having this type of surgery for appendix removal have few postoperative complications (see Chapter 15). A newer

procedure known as natural orifice transluminal endoscopic surgery (NOTES) (e.g., transvaginal endoscopic appendectomy) does not require an external skin incision. In this procedure the surgeon places the endoscope into the vagina or other orifice and makes a small incision to enter the peritoneal space. Patients having any type of laparoscopic procedures are typically discharged the same day of surgery with less pain and few complications after discharge. Most patients can return to usual activities in 1 to 2 weeks.

If the diagnosis is not definitive but the patient is at high risk for complications from suspected appendicitis, the surgeon may perform an exploratory laparotomy to rule out appendicitis. A **laparotomy** is an open surgical approach with a large abdominal incision for complicated or atypical appendicitis or peritonitis.

Preoperative teaching is often limited because the patient is in pain or may be transferred quickly to the operating suite for emergency surgery. The patient is prepared for general anesthesia and surgery as described in Chapter 14. After surgery, care of the patient who has undergone an appendectomy is the same as that required for anyone who has received general anesthesia (see Chapter 16).

If complications such as peritonitis or abscesses are found during *open* traditional surgery, wound drains are inserted and a nasogastric tube may be placed to decompress the stomach and prevent abdominal distention. Administer IV antibiotics and opioid analgesics as prescribed. Help the patient out of bed on the evening of surgery to help prevent respiratory complications, such as atelectasis. He or she may be hospitalized for as long as 3 to 5 days and return to normal activity in 4 to 6 weeks.

Peritonitis

Peritonitis is a life-threatening, acute inflammation and infection of the visceral/parietal peritoneum and endothelial lining of the abdominal cavity. Primary peritonitis is rare and indicates the peritoneum is infected via the bloodstream. This problem is not discussed here.

❖ Pathophysiology

Normally the peritoneal cavity contains about 50 mL of sterile fluid (transudate), which prevents friction in the abdominal cavity during peristalsis. When the peritoneal cavity is contaminated by bacteria, the body first begins an inflammatory reaction walling off a localized area to fight the infection. This local reaction involves vascular dilation and

increased capillary permeability, allowing transport of leukocytes and subsequent phagocytosis of the offending organisms. If this walling-off process fails, the inflammation spreads and contamination becomes massive, resulting in diffuse (widespread) peritonitis.

Peritonitis is most often caused by contamination of the peritoneal cavity by bacteria or chemicals. Bacteria gain entry into the peritoneum by perforation (from appendicitis, diverticulitis, peptic ulcer disease) or from an external penetrating wound, a gangrenous gallbladder, bowel obstruction, or ascending infection through the genital tract. Less common causes include perforating tumors, leakage or contamination during surgery, and infection by skin pathogens in patients undergoing continuous ambulatory peritoneal dialysis (CAPD). Common bacteria responsible for peritonitis include *Escherichia coli, Streptococcus, Staphylococcus, Pneumococcus,* and *Gonococcus.* Chemical peritonitis results from leakage of bile, pancreatic enzymes, and gastric acid (McCance et al., 2014).

When diagnosis and treatment of peritonitis are delayed, blood vessel dilation continues. The body responds to the continuing infectious process by shunting extra blood to the area of inflammation (hyperemia). Fluid is shifted from the extracellular fluid compartment into the peritoneal cavity, connective tissues, and GI tract *("third spacing").* This shift of fluid can result in a significant decrease in circulatory volume and *hypovolemic shock.* Severely decreased circulatory volume can result in insufficient perfusion of the kidneys, leading to acute kidney injury with impaired fluid and electrolyte balance (McCance et al., 2014). Assess for clinical manifestations of these life-threatening problems.

Peristalsis slows or *stops* in response to severe peritoneal inflammation, and the lumen of the bowel becomes distended with gas and fluid. Fluid that normally flows to the small bowel and the colon for reabsorption accumulates in the intestine in volumes of 7 to 8 L daily. The toxins or bacteria responsible for the peritonitis can also enter the bloodstream from the peritoneal area and lead to bacteremia or **septicemia** (bacterial invasion of the blood).

Respiratory problems can occur as a result of increased abdominal pressure against the diaphragm from intestinal distention and fluid shifts to the peritoneal cavity. Pain can interfere with respirations at a time when the patient has an increased oxygen demand because of the infectious process.

❖ Patient-Centered Collaborative Care

Assessment

Ask the patient about abdominal pain, and determine the character of the pain (e.g., cramping, sharp, aching), location of the pain, and whether the pain is localized or generalized. Ask about a history of a low-grade fever or recent spikes in temperature.

Physical findings of peritonitis (Chart 57-1) depend on several factors: the stage of the disease, the ability of the body to localize the process by walling off the infection, and whether the inflammation has progressed to generalized peritonitis. The patient most often appears acutely ill, lying still, possibly with the knees flexed. Movement is guarded, and he or she may report and show signs of pain (e.g., facial grimacing) with coughing or movement of any type. During inspection, observe for progressive abdominal distention, often seen when the inflammation markedly reduces intestinal motility. Auscultate for bowel sounds, which usually disappear with progression of the inflammation.

Chart 57-1 Key Features

Peritonitis

- Rigid, boardlike abdomen (classic)
- Abdominal pain (localized, poorly localized, or referred to the shoulder or chest)
- Distended abdomen
- Nausea, anorexia, vomiting
- Diminishing bowel sounds
- Inability to pass flatus or feces
- Rebound tenderness in the abdomen
- High fever
- Tachycardia
- Dehydration from high fever (poor skin turgor)
- Decreased urine output
- Hiccups
- Possible compromise in respiratory status

The cardinal signs of peritonitis are abdominal pain, tenderness, and distention. In the patient with *localized* peritonitis, the abdomen is tender on palpation in a well-defined area with rebound tenderness in this area. With *generalized* peritonitis, tenderness is widespread.

Nursing Safety Priority QSEN

Action Alert

For patients with peritonitis, assess for abdominal wall rigidity, which is a classic finding that is sometimes referred to as a "boardlike" abdomen. Monitor the patient for a high fever because of the infectious process. Assess for tachycardia occurring in response to the fever and decreased circulating blood volume. Observe whether he or she has dry mucous membranes and a low urine output seen with third spacing. Nausea and vomiting may also be present. Hiccups may occur as a result of diaphragmatic irritation. Be sure to document all assessment findings.

White blood cell (WBC) counts are often elevated to 20,000/mm^3 with a high neutrophil count. *Blood culture* studies may be done to determine whether septicemia has occurred and to identify the causative organism to enable appropriate therapy. The health care provider requests laboratory tests to assess fluid and electrolyte balance and renal status, including blood urea nitrogen (BUN), creatinine, hemoglobin, and hematocrit. Oxygen saturation and end–carbon dioxide monitoring may be obtained to assess respiratory function and acid-base balance.

Abdominal x-rays can assess for free air or fluid in the abdominal cavity, indicating perforation. The x-rays may also show dilation, edema, and inflammation of the small and large intestines. An *abdominal ultrasound* may also be performed.

Interventions

Patients with peritonitis are hospitalized because of the severe nature of the illness. If complications are extensive, the patients are often admitted to a critical care unit. Nursing interventions focus on the early identification of complications.

Nonsurgical Management.

The health care provider prescribes hypertonic IV fluids and broad-spectrum antibiotics immediately after establishing the diagnosis of peritonitis. IV fluids are used to replace fluids collected in the peritoneum and bowel. Monitor daily weight and intake and output carefully. A nasogastric tube (NGT) decompresses the stomach and the intestine, and the patient is NPO. Apply oxygen as prescribed and according to the patient's respiratory status and oxygen saturation via pulse oximetry (e.g., Spo_2 less than 93%). Administer analgesics, and

monitor for pain control. Document all pain assessments and interventions thoroughly.

Surgical Management.

Abdominal surgery may be needed to identify and repair the cause of the peritonitis. If the patient is so critically ill that surgery would be life threatening, it may be delayed. Surgery focuses on controlling the contamination, removing foreign material from the peritoneal cavity, and draining collected fluid.

Exploratory laparotomy (surgical opening into the abdomen) or laparoscopy is used to remove or repair the inflamed or perforated organ (e.g., appendectomy for an inflamed appendix; a colon resection, with or without a colostomy, for a perforated diverticulum). Before the incision(s) is closed, the surgeon irrigates the peritoneum with antibiotic solutions. Several catheters may be inserted to drain the cavity and provide a route for irrigation after surgery.

The preoperative care is similar to that described in Chapter 14 for patients having general anesthesia. Chapter 16 describes general postoperative care for exploratory laparotomy. Multi-system complications can occur with peritonitis. Loss of fluids and electrolytes from the extracellular space to the peritoneal cavity, NGT suctioning, and NPO status require that the patient receives IV fluid replacement. Be sure that unlicensed assistive personnel (UAP) carefully measure intake and output. Fluid rates may be changed frequently based on laboratory values and patient condition.

Nursing Safety Priority QSEN

Action Alert

Monitor the patient's level of consciousness, vital signs, respiratory status (respiratory rate and breath sounds), and intake and output at least hourly immediately after abdominal surgery. Maintain the patient in a semi-Fowler's position to promote drainage of peritoneal contents into the lower region of the abdominal cavity. This position helps increase lung expansion.

If an open surgical procedure is needed, the infection may slow healing of an incision or the incision may be partially open to heal by second or third intention. These wounds require special care involving manual irrigation or packing as prescribed by the surgeon. If the surgeon

requests peritoneal irrigation through a drain, *maintain sterile technique during manual irrigation.* Assess whether the patient retains the fluid used for irrigation by comparing the amount of fluid returned with the amount of fluid instilled. Fluid retention could cause abdominal distention or pain.

Community-Based Care

The length of hospitalization depends on the extent and severity of the infectious process. Patients who have a localized abscess drained and who respond to antibiotics and IV fluids without multi-system complications are discharged in several days. Others may require mechanical ventilation or hemodialysis with longer hospital stays. Some patients may be transferred to a transitional care unit to complete their antibiotic therapy and recovery. Convalescence is often longer than for other surgeries because of multi-system involvement.

When discharged home, assess the patient's ability for self-management at home with the added task of incision care and a reduced activity tolerance. Provide the patient and family with written and oral instructions to report these problems to the health care provider immediately:

- Unusual or foul-smelling drainage
- Swelling, redness, or warmth or bleeding from the incision site
- A temperature higher than 101° F (38.3° C)
- Abdominal pain
- Signs of wound dehiscence or ileus

Patients with large incisions heal by second or third intention and may require dressings, solution, and catheter-tipped syringes to irrigate the wound. A home care nurse may be needed to assess, irrigate, or pack the wound and change the dressing as needed until the patient and family feel comfortable with the procedure. If the patient needs assistance with ADLs, a home care aide or temporary placement in a skilled care facility may be indicated. Collaborate with the case manager (CM) to determine the most appropriate setting for seamless continuing care in the community.

Review information about antibiotics and analgesics. For patients taking oral opioid analgesics such as oxycodone with acetaminophen (Tylox, Percocet, Endocet) for any length of time, a stool softener such as docusate sodium (Colace, Regulex) may be prescribed. Older adults are especially at risk for constipation from codeine-based drugs. Remind patients to avoid taking additional acetaminophen (Tylenol) to prevent liver toxicity.

Teach patients to refrain from any lifting for *at least* 6 weeks after an open surgical procedure. Other activity limitations are made on an individual basis with the physician's recommendation. Patients who have laparoscopic surgery can resume activities within a week or two and may not have any major restrictions.

NCLEX Examination Challenge

Safe and Effective Care Environment

A client had a bowel resection yesterday for colorectal cancer. Which assessment finding does the nurse report immediately to the surgeon?
A Abdominal discomfort
B Mild abdominal distention
C Distended, board-like abdomen
D Minimal abdominal bowel sounds

Gastroenteritis

Pathophysiology

Gastroenteritis is a very common health problem worldwide that causes diarrhea and/or vomiting as a result of inflammation of the mucous membranes of the stomach and intestinal tract. It affects mainly the small bowel and can be caused by either viral or bacterial infection. Viral gastroenteritis is the most common (Krenzer, 2012). Table 57-1 lists common types of gastroenteritis and their primary characteristics.

TABLE 57-1

Common Types of Gastroenteritis and Their Characteristics

TYPE	CHARACTERISTICS
Viral Gastroenteritis	
Epidemic viral	Caused by many parvovirus-type organisms
	Transmitted by the fecal-oral route in food and water
	Incubation period 10-51 hrs
	Communicable during acute illness
Norovirus (Norwalk viruses)	Transmitted by the fecal-oral route and possibly the respiratory route (vomitus)
	Incubation in 48 hrs
	Affects adults of all ages
	Older adults can become hypovolemic and experience electrolyte imbalances
Bacterial Gastroenteritis	
Campylobacter enteritis	Transmitted by the fecal-oral route or by contact with infected animals or infants
	Incubation period 1-10 days
	Communicable for 2-7 wks
Escherichia coli diarrhea	Transmitted by fecal contamination of food, water, or fomites
Shigellosis	Transmitted by direct and indirect fecal-oral routes
	Incubation period 1-7 days
	Communicable during the acute illness to 4 wk after the illness
	Humans possibly carriers for months

Norovirus (also known as Norwalk-like viruses) is the leading foodborne disease that causes gastroenteritis. It occurs most often between November and April because it is resistant to low temperatures and has a long viral shedding before and after the illness. Norovirus is transmitted (spread) through the fecal-oral route from person to person and from contaminated food and water. Infected people can also contaminate surfaces and objects in the environment. Vomiting causes the virus to become airborne. The incubation time is 1 to 2 days.

In most cases of gastroenteritis, the illness is self-limiting and lasts about 3 days. However, in people who are immunosuppressed or in older adults, dehydration and hypovolemia can occur as complications requiring medical attention and possibly hospitalization.

Health Promotion and Maintenance

Outbreaks of norovirus have occurred in prisons, cruise ships, nursing homes, college dormitories, and other places where large groups of people are in close proximity. Handwashing and sanitizing surfaces and other environmental items help prevent the spread of the illness. Hand

sanitizers are often placed in public areas so that hands can be cleaned when washing with soap and water is inconvenient. Proper food and beverage preparation is also important to prevent contamination.

Patient-Centered Collaborative Care

Assessment

The patient history can provide information related to the potential cause of the illness. Ask about recent travel, especially to tropical regions of Asia, Africa, or Central or South America. Some areas of Mexico may also be the source of gastroenteritis.

Also inquire if the patient has eaten at any restaurant in the past 24 to 36 hours. Some people have acquired gastroenteritis from eating in "fast food" restaurants or from food items purchased at a farmer's market or grocery store. Bacterial infections have caused large outbreaks that resulted from contaminated spinach and lettuce in the United States.

The patient who has gastroenteritis usually looks ill. Nausea and vomiting typically occur first, followed by abdominal cramping and diarrhea.

For patients who are older or for those who have inadequate immune systems, weakness and cardiac dysrhythmias may occur from loss of potassium (hypokalemia) from diarrhea. Monitor for and document manifestations of hypokalemia and hypovolemia (dehydration).

Nursing Safety Priority QSEN

Action Alert

For patients with gastroenteritis, note any abdominal distention and listen for hyperactive bowel sounds. Depending on the amount of fluids and electrolytes lost through diarrhea and vomiting, patients may have varying degrees of dehydration manifested by:

- Poor skin turgor
- Fever (not common in older adults)
- Dry mucous membranes
- Orthostatic blood pressure changes (which can cause falls, especially for older adults)
- Hypotension
- Oliguria (scant urinary output)

In some cases, dehydration may be severe. Dehydration occurs rapidly in older adults. Monitor mental status changes, such as acute confusion,

that result from hypoxia in the older adult. These changes may be the only clinical manifestation of dehydration in older adults.

Interventions

For any type of gastroenteritis, encourage fluid replacement. The amount and route of fluid administration are determined by the patient's hydration status and overall health condition. Teach patients to drink extra fluids to replace fluid lost through vomiting and diarrhea. Oral rehydration therapy (ORT) may be needed for some patients to replace fluids and electrolytes. Examples of ORT solutions include Gatorade, Pedialyte, and Powerade. Depending on the patient's age and severity of dehydration, he or she may be admitted to the hospital for gastroenteritis or may stay in the emergency department or urgent care center until adequate hydration is restored.

Drugs that suppress intestinal motility may not be given for bacterial or viral gastroenteritis. *Use of these drugs can prevent the infecting organisms from being eliminated from the body.* If the health care provider determines that antiperistaltic agents are necessary, an initial dose of loperamide (Imodium) 4 mg can be administered orally, followed by 2 mg after each loose stool, up to 16 mg daily.

Nursing Safety Priority QSEN

Drug Alert

Diphenoxylate hydrochloride with atropine sulfate (Lomotil, Lomanate) reduces GI motility but is used sparingly because of its habit-forming ability. *The drug should not be used for older adults because it also causes drowsiness and could contribute to falls.*

Treatment with antibiotics may be needed if the gastroenteritis is due to bacterial infection with fever and severe diarrhea. Depending on the type and severity of the illness, examples of drugs that may be prescribed include ciprofloxacin (Cipro), levofloxacin (Levaquin), or azithromycin (Zithromax). If the gastroenteritis is due to shigellosis, anti-infective agents such as trimethoprim/sulfamethoxazole (Septra DS, Bactrim DS, Roubac) or ciprofloxacin (Cipro) are prescribed.

Frequent stools that are rich in electrolytes and enzymes, as well as frequent wiping and washing of the anal region, can irritate the skin. Teach the patient to avoid toilet paper and harsh soaps. Ideally, he or she can gently clean the area with warm water or an absorbent material,

followed by thorough but gentle drying. Cream, oil, or gel can be applied to a damp, warm washcloth to remove stool that sticks to open skin. Special prepared skin wipes can also be used. Protective barrier cream can be applied to the skin between stools. Sitz baths for 10 minutes 2 or 3 times daily can also relieve discomfort.

If leakage of stool is a problem, the patient can use an absorbent cotton or panty liner and keep it in place with snug underwear. For patients who are incontinent, remind unlicensed assistive personnel (UAP) to keep the perineal and buttock areas clean and dry. The use of incontinent pads at night instead of briefs allows air to circulate to the skin and prevents irritation.

During the acute phase of the illness, teach the patient and family about the importance of fluid replacement. Teaching the patient and family about reducing the risk for transmission of gastroenteritis is also important (Chart 57-2).

Chart 57-2 Patient and Family Education: Preparing for Self-Management

Preventing Transmission of Gastroenteritis

Advise the patient to:

- Wash hands well for at least 30 seconds with an antibacterial soap, especially after a bowel movement, and maintain good personal hygiene.
- Restrict the use of glasses, dishes, eating utensils, and tubes of toothpaste for his or her own use. In severe cases, disposable utensils may be wise.
- Maintain clean bathroom facilities to avoid exposure to stool.
- Inform the health care provider if symptoms persist beyond 3 days.
- Do not prepare or handle food that will be consumed by others. If you (the patient) are employed as a food handler, the public health department should be consulted for recommendations about the return to work.

Chronic Inflammatory Bowel Disease

Ulcerative colitis and Crohn's disease are the two most common inflammatory bowel diseases (IBDs) that affect adults. Comparisons and differences are listed in Table 57-2. Viral and bacterial gastroenteritis can cause symptoms similar to those of IBD, and other problems must be ruled out before a definitive diagnosis is made.

TABLE 57-2

Differential Features of Ulcerative Colitis and Crohn's Disease

FEATURE	ULCERATIVE COLITIS	CROHN'S DISEASE
Location	Begins in the rectum and proceeds in a continuous manner toward the cecum	Most often in the terminal ileum, with patchy involvement through all layers of the bowel
Etiology	Unknown	Unknown
Peak incidence at age	15-25 yr and 55-65 yr	15-40 yr
Number of stools	10-20 liquid, bloody stools per day	5-6 soft, loose stools per day, non-bloody
Complications	Hemorrhage	Fistulas (common)
	Nutritional deficiencies	Nutritional deficiencies
Need for surgery	Infrequent	Frequent

The approach to each patient is individualized. Encourage patients to self-manage their disease by learning about the illness, treatment, drugs, and complications.

Ulcerative Colitis

Pathophysiology

Ulcerative colitis (UC) creates widespread inflammation of mainly the rectum and rectosigmoid colon but can extend to the entire colon when the disease is extensive. Distribution of the disease can remain constant for years. UC is a disease that is associated with periodic remissions and exacerbations (flare-ups) (McCance et al., 2014). Many factors can cause exacerbations, including intestinal infections. Older adults with UC are at high risk for impaired fluid and electrolyte balance as a result of diarrhea, including dehydration and hypokalemia.

The intestinal mucosa becomes hyperemic (has increased blood flow), edematous, and reddened. In more severe inflammation, the lining can bleed and small erosions, or ulcers, occur. Abscesses can form in these ulcerative areas and result in tissue necrosis (cell death). Continued edema and mucosal thickening can lead to a narrowed colon and possibly a partial bowel obstruction. Table 57-3 lists the categories of the severity of UC.

TABLE 57-3

American College of Gastroenterologists Classification of UC Severity

SEVERITY	STOOL FREQUENCY	SIGNS/SYMPTOMS
Mild	<4 stools/day with/without blood	Asymptomatic
		Laboratory values usually normal
Moderate	>4 stools/day with/without blood	Minimal symptoms
		Mild abdominal pain
		Mild intermittent nausea
		Possible increased C-reactive protein* or ESR†
Severe	>6 bloody stools/day	Fever
		Tachycardia
		Anemia
		Abdominal pain
		Elevated C-reactive protein* and/or ESR†
Fulminant	>10 bloody stools/day	Increasing symptoms
		Anemia may require transfusion
		Colonic distention on x-ray

UC, Ulcerative colitis.

*C-reactive protein is a sensitive acute-phase serum marker that is evident in the first 6 hours of an inflammatory process.

†ESR (erythrocyte sedimentation rate) may be helpful but is less sensitive than C-reactive protein.

The patient's stool typically contains blood and mucus. Patients report **tenesmus** (an unpleasant and urgent sensation to defecate) and lower abdominal colicky pain relieved with defecation. Malaise, anorexia, anemia, dehydration, fever, and weight loss are common. Extraintestinal manifestations such as migratory polyarthritis, ankylosing spondylitis, and erythema nodosum are present in a large number of patients. The common complications of UC, including extraintestinal manifestations, are listed in Table 57-4.

TABLE 57-4

Complications of Ulcerative Colitis and Crohn's Disease

COMPLICATION	DESCRIPTION
Hemorrhage/perforation	Lower gastrointestinal bleeding results from erosion of the bowel wall.
Abscess formation	Localized pockets of infection develop in the ulcerated bowel lining.
Toxic megacolon	Paralysis of the colon causes dilation and subsequent colonic ileus, possibly perforation.
Malabsorption	Essential nutrients cannot be absorbed through the diseased intestinal wall, causing anemia and malnutrition (most common in Crohn's disease).
Nonmechanical bowel obstruction	Obstruction results from toxic megacolon or cancer.
Fistulas	In Crohn's disease in which the inflammation is transmural, fistulas can occur anywhere but usually track between the bowel and bladder resulting in pyuria and fecaluria.
Colorectal cancer	Patients with ulcerative colitis with a history longer than 10 years have a high risk for colorectal cancer. This complication accounts for about one third of all deaths related to ulcerative colitis.
Extraintestinal complications	Complications include arthritis, hepatic and biliary disease (especially cholelithiasis), oral and skin lesions, and ocular disorders, such as iritis. The cause is unknown.
Osteoporosis	Osteoporosis occurs especially in patients with Crohn's disease.

Etiology and Genetic Risk

The exact cause of UC is unknown, but a combination of genetic, immunologic, and environmental factors likely contributes to disease development. A genetic basis of the disease has been supported because it is often found in families and twins. Immunologic causes, including autoimmune dysfunction, are likely the etiology of extraintestinal manifestations of the disease. Epithelial antibodies in the immunoglobulin G (IgG) class have been identified in the blood of some patients with UC (McCance et al., 2014).

With long-term disease, cellular changes can occur that increase the risk for colon cancer. Damage from pro-inflammatory cytokines, such as specific interleukins (ILs) (e.g., IL-1, IL-6, IL-8) and tumor necrosis factor (TNF)–alpha, have cytotoxic effects on the colonic mucosa (McCance et al., 2014).

Incidence and Prevalence

Chronic inflammatory bowel disease (IBD) affects about 1.4 million people in the United States and is split about equally between ulcerative colitis (UC) and Crohn's disease (discussed later). Peak age for being diagnosed with UC is between 30 and 40 years and again at 55 to 65 years.

Women are more often affected than men in their younger years, but men have the disease more often as middle-aged and older adults (McCance et al., 2014).

Cultural Considerations

Patient-Centered Care QSEN

Ulcerative colitis is more common among Jewish persons than among those who are not Jewish and among whites more than non-whites (McCance et al., 2014). The reasons for these cultural differences are not known.

Patient-Centered Collaborative Care

Assessment

History.

Collect data on family history of IBD, previous and current therapy for the illness, and dates and types of surgery. Obtain a nutrition history, including intolerance of milk and milk products and fried, spicy, or hot foods. Ask about usual bowel elimination pattern (color, number, consistency, and character of stools), abdominal pain, tenesmus, anorexia, and fatigue. Note any relationship between diarrhea, timing of meals, emotional distress, and activity. Inquire about recent (past 2 to 3 month) exposure to antibiotics suggesting *Clostridium difficile* infection. Has the patient traveled to or emigrated from tropical areas? Ask about recent use of NSAIDs that can cause a flare-up of the disease. Ask about any extraintestinal symptoms such as arthritis, mouth sores, vision problems, and skin disorders.

Physical Assessment/Clinical Manifestations.

Symptoms vary with an acuteness of onset. Vital signs are usually within normal limits in mild disease. In more severe cases, the patient may have a low-grade fever (99° to 100° F [37.2° to 37.8° C]). The physical assessment findings are usually nonspecific, and in milder cases the physical examination may be normal. Viral and bacterial infections cause symptoms similar to those of UC.

Note any abdominal distention along the colon. Fever associated with tachycardia may indicate peritonitis, dehydration, and bowel perforation. Assess for clinical manifestations associated with extraintestinal

complications, such as inflamed joints and lesions inside the mouth.

Psychosocial Assessment.

Many patients are very concerned about the frequency of stools and the presence of blood. *The inability to control the disease symptoms, particularly diarrhea, can be disruptive and stress producing.* Severe illness may limit the patient's activities outside the home with fear of fecal incontinence resulting in feeling "tied to the toilet." Severe anxiety and depression may result. Eating may be associated with pain and cramping and an increased frequency of stools. Mealtimes may become unpleasant experiences. Frequent visits to health care providers and close monitoring of the colon mucosa for abnormal cell changes can be anxiety provoking.

Assess the patient's understanding of the illness and its impact on his or her lifestyle. Encourage and support the patient while exploring:

- The relationship of life events to disease exacerbations
- Stress factors that produce symptoms
- Family and social support systems
- Concerns regarding the possible genetic basis and associated cancer risks of the disease
- Internet access for reliable education information

Laboratory Assessment.

As a result of chronic blood loss, hematocrit and hemoglobin levels may be low, which indicates anemia and a chronic disease state. *An increased WBC count, C-reactive protein, or erythrocyte sedimentation rate (ESR) is consistent with inflammatory disease.* Blood levels of sodium, potassium, and chloride may be *low* as a result of frequent diarrheal stools and malabsorption through the diseased bowel (Pagana & Pagana, 2014). Hypoalbuminemia (decreased serum albumin) is found in patients with extensive disease from losing protein in the stool.

Other Diagnostic Assessment.

Magnetic resonance enterography (MRE) is the major examination used to study the bowel in patients who have IBD. Teach the patient that he or she will need to fast for 4 to 6 hours prior to the test. To have the test, the patient drinks a contrast medium, which can cause diarrhea. The patient has the opportunity to go to the restroom before positioning on the MRI table. The patient then lies prone while the first of two doses of glucagon are given subcutaneously. This substance helps to slow the bowel's activity and motility (Grossman, 2011).

A *colonoscopy* may be done to aid in diagnosis, but the bowel prep can be especially uncomfortable for patients with inflammatory bowel disease (IBD). Frequent colonoscopies are recommended when patients have longer than a 10-year history of UC involving the entire colon because they are at high risk for colorectal cancer. In some cases, a *CT scan* may be done to confirm the disease or its complications. *Barium enemas* with air contrast can show differences between UC and Crohn's disease and identify complications, mucosal patterns, and the distribution and depth of disease involvement. In early disease, the barium enema may show incomplete filling as a result of inflammation and fine ulcerations along the bowel contour, which appear deeper in more advanced disease.

Analysis

The priority NANDA-I nursing diagnoses and collaborative problems for patients with ulcerative colitis include:
1. Diarrhea related to inflammation of the bowel mucosa (NANDA-I)
2. Acute Pain and Chronic Pain related to inflammation and ulceration of the bowel mucosa and skin irritation (NANDA-I)
3. Potential for lower GI bleeding and resulting anemia

Planning and Implementation

Decreasing Diarrhea

Planning: Expected Outcomes.

The major concern for a patient with ulcerative colitis is the occurrence of frequent, bloody diarrhea and fecal incontinence from tenesmus. Therefore, with treatment, the patient is expected to have decreased diarrhea, formed stools, and control of bowel movements.

Interventions.

Many measures are used to relieve symptoms and to reduce intestinal motility, decrease inflammation, and promote intestinal healing. Nonsurgical and/or surgical management may be needed.

Nonsurgical Management.

Nonsurgical management includes drug and nutrition therapy. The use of physical and emotional rest is also an important consideration. Teach the patient to record color, volume, frequency, and consistency of stools to determine severity of the problem.

Monitor the skin in the perianal area for irritation and ulceration resulting from loose, frequent stools. Stool cultures may be sent for analysis if diarrhea continues. Have the patient weigh himself or herself 1 or 2 times per week. If the patient is hospitalized, remind unlicensed assistive personnel to weigh him or her on admission and daily in the morning before breakfast and document all weights.

NCLEX Examination Challenge

Physiological Integrity

The nurse is caring for an older client who experiences an exacerbation of ulcerative colitis with severe diarrhea. What is the nurse's priority for care?

A Monitor skin for breakdown.
B Monitor heart rate and rhythm.
C Maintain intake and output records.
D Auscultate bowel sounds frequently.

Drug Therapy.

Common drug therapy for UC includes aminosalicylates, glucocorticoids, antidiarrheal drugs, and immunomodulators. Teach patients about side effects and adverse drug events (ADEs) and when to call their health care provider.

The *aminosalicylates* are drugs commonly used to treat mild to moderate UC and/or maintain remission. Several aminosalicylic acid compounds are available. These drugs, also called *5-ASAs,* are thought to have an anti-inflammatory effect by inhibiting prostaglandins and are usually effective in 2 to 4 weeks.

Sulfasalazine (Azulfidine, Azulfidine EN-tabs), the first aminosalicylate approved for UC, is metabolized by the intestinal bacteria into 5-ASA, which delivers the beneficial effects of the drug, and sulfapyridine, which is responsible for unwanted side effects.

Nursing Safety Priority QSEN

Drug Alert

Teach patients taking sulfasalazine to report nausea, vomiting, anorexia, rash, and headache to the health care provider. With higher doses, hemolytic anemia, hepatitis, male infertility, or agranulocytosis

can occur. This drug is in the same family as sulfonamide antibiotics. Therefore assess the patient for an allergy to sulfonamide or other drugs that contain sulfa *before* the patient takes the drug. The use of a thiazide diuretic is also a contraindication for sulfasalazine (Lilley et al., 2014).

Mesalamine (Asacol, Pentasa, Rowasa, Apriso, Canasa) is better tolerated than sulfasalazine because none of its preparations contain sulfapyridine. Asacol is an enteric-coated drug and is released in the terminal ileum and right side of the colon. Pentasa and Apriso are delayed- and extended-release drugs that work throughout the colon and rectum. Rowasa can be given as an enema, and Canasa can be given as a suppository. These preparations have minimal systemic absorption and therefore have fewer side effects. Table 57-5 lists commonly used 5-ASA drugs.

TABLE 57-5

Recommended Doses for 5-ASA Medications

GENERIC NAME	TRADE NAME	DOSAGE AVAILABLE	RECOMMENDED DOSE
Sulfasalazine	Azulfidine Azulfidine En-tabs	500 mg tablets	3-4 g daily in divided doses Children >2 yr: 30 mg/kg/day not to exceed 2 g/day
	Azulfidine oral suspension (50 mg/mL)	250 mg/5 mL liquid	
Mesalamine	Asacol	400 mg tablets	800 mg three times daily
	Pentasa	500 mg tablets	1 g four times daily
	Rowasa enemas	4 g/60 mL	At bedtime
	Rowasa suppository	1000 mg/supp	Twice daily or at bedtime
Olsalazine (rarely used)	Dipentum	250 mg tablets	1 g daily in two divided doses
Balsalazide	Colazal	750 mg tablets	3 tablets three times daily

5-ASA, 5-aminosalicylic acid.

Glucocorticoids, such as prednisone and prednisolone, are corticosteroid therapies prescribed during exacerbations of the disease. Prednisone (Deltasone, Winpred) 40 to 65 mg daily is typically prescribed, but the dose may be increased as acute flare-ups occur. Once clinical improvement occurs, the corticosteroids are tapered because of the adverse effects that commonly occur with long-term steroid therapy (e.g., hyperglycemia, osteoporosis, peptic ulcer disease, increased risk for infection). For patients with rectal inflammation, topical steroids in the form of small retention enemas may be prescribed.

To provide symptomatic management of diarrhea, *antidiarrheal drugs* may be prescribed. These drugs are given very cautiously, however, because they can cause colon dilation and toxic megacolon. Common antidiarrheal drugs include diphenoxylate hydrochloride and atropine sulfate (Lomotil) and loperamide (Imodium).

Immunomodulators are drugs that alter a person's immune response. Alone, they are often not effective in the treatment of ulcerative colitis. However, in combination with steroids, they may offer a synergistic effect to a quicker response, thereby decreasing the amount of steroids needed. Biologic response modifiers (BRMs) used for UC (and Crohn's disease, discussed later in this chapter) include infliximab (Remicade) and adalimumab (Humira). Although not approved as a first-line therapy for ulcerative colitis, *infliximab* (Remicade) may be used for refractory disease or for severe complications, such as **toxic megacolon** (massive dilation of the colon that can lead to gangrene and peritonitis) and extraintestinal manifestations. Remicade is an immunoglobulin G (IgG) monoclonal antibody that reduces the activity of tumor necrosis factor (TNF) to decrease inflammation. Adalimumab (Humira) is another monoclonal antibody approved for refractory (not responsive to other therapies) cases. BRMs are used more commonly in management of Crohn's disease. These drugs cause immunosuppression and should be used with caution. *Teach the patient to report any signs of a beginning infection, including a cold, and to avoid large crowds or others who are sick*!

Several newer monoclonal antibodies are awaiting FDA approval for use in patients with IBD. One of these drugs, vedolizumab, is an intestinal-specific leukocyte traffic inhibitor in that it prevents white blood cells from migrating to inflamed bowel tissue.

Nutrition Therapy and Rest.

Patients with severe symptoms who are hospitalized are kept NPO to ensure bowel rest. The physician may prescribe total parenteral nutrition (TPN) for severely ill and malnourished patients during severe exacerbations. Chapter 60 describes this therapy in detail. Patients with less severe symptoms may drink elemental formulas such as Vivonex PLUS or Vivonex T.E.N, which are absorbed in the small bowel and reduce bowel stimulation.

Diet is not a major factor in the inflammatory process, but some patients with ulcerative colitis (UC) find that caffeine and alcohol increase diarrhea and cramping. For some patients, raw vegetables and other high-fiber foods can cause GI symptoms. Lactose-containing foods may be poorly tolerated and should be reduced or eliminated. Teach patients that carbonated beverages, pepper, nuts and corn, dried fruits, and smoking are common GI stimulants that could cause discomfort. Each patient differs in his or her food and fluid tolerances.

During an exacerbation of the disease, patient activity is generally restricted because rest can reduce intestinal activity, provide comfort, and

promote healing. Ensure that the patient has easy access to a bedpan, bedside commode, or bathroom in case of urgency or tenesmus.

Complementary and Alternative Therapies.

In addition to dietary changes, complementary and alternative therapies may be used to supplement traditional management of ulcerative colitis. Examples include herbs (e.g., flaxseed), selenium, and vitamin C. Biofeedback, hypnosis, yoga, acupuncture, and ayurveda (a combination of diet, yoga, herbs, and breathing exercises) may also be helpful. These therapies need further study to validate their effectiveness, but some patients find them helpful.

Surgical Management.

Some patients with ulcerative colitis require surgery to help manage their disease when medical therapies alone are not effective. In some cases, surgery is performed for complications of UC such as toxic megacolon, hemorrhage, dysplastic biopsy results, and colon cancer.

Preoperative Care.

General preoperative teaching related to abdominal surgery is described in Chapter 14. If a temporary or permanent ileostomy is planned, provide an in-depth explanation to the patient and family. An **ileostomy** is a procedure in which a loop of the ileum is placed through an opening in the abdominal wall **(stoma)** for drainage of fecal material into a pouching system worn on the abdomen. The external pouching system consists of a solid skin barrier (wafer) to protect the skin and a fecal collection device (pouch), similar to the system used for patients with colostomies (discussed in Chapter 56).

If an ileostomy is planned, the surgeon consults with a certified wound, ostomy, continence nurse (CWOCN) before surgery for recommendations on the best location of the stoma. A visit from an **ostomate** (a patient with an ostomy) may be helpful before surgery. Parenteral antibiotics are given within 1 hour of surgical opening based on current best evidence and per The Joint Commission's National Patient Safety Goals.

Operative Procedures.

Any one of several surgical approaches may be used for the patient with UC. Minimally invasive procedures, such as laparoscopic, laparoscopic-assisted, hand-assisted, and robotic-assisted surgery, are common for patients with ulcerative colitis in large tertiary care centers (Kessler et al.,

2011). Laparoscopic surgery usually involves one or several small incisions but often takes longer to perform than the open surgical approach. A newer procedure, natural orifice transluminal endoscopic surgery (NOTES), can be performed via the anus or vagina for selected patients if the surgeon has been trained in the procedure. Patients may have moderate sedation or general anesthesia for minimally invasive surgical procedures and are not typically admitted to critical care units for continuing postoperative care.

Patients who are obese, have had previous abdominal surgeries, or have dense scar tissue (adhesions) may not be candidates for laparoscopic procedures. The conventional open surgical approach involves an abdominal incision and is done under general anesthesia. Patients with open procedures are typically admitted to critical care units for short-term stabilization.

Restorative Proctocolectomy with Ileo Pouch–Anal Anastomosis (RPC-IPAA).

This procedure has become the gold standard for patients with UC. In some centers, the surgery is performed via laparoscopy (laparoscopic RPC-IPAA). It is usually a two-stage procedure that includes the removal of the colon and most of the rectum (Fig. 57-2). The anus and anal sphincter remain intact. The surgeon then surgically creates an internal pouch (reservoir) using the last $1\frac{1}{2}$ feet of the small intestine. The pouch, sometimes called a *J-pouch*, *S-pouch*, or *pelvic pouch*, is then connected to the anus. A temporary ileostomy through the abdominal skin is created to allow healing of the internal pouch and all anastomosis sites. It also allows for an increase in the capacity of the internal pouch. In the *second* surgical stage, the loop ileostomy is closed. The time interval between the first and second stages varies, but many patients have the second surgical stage to close the ileostomy within 1 to 2 months of the first surgery.

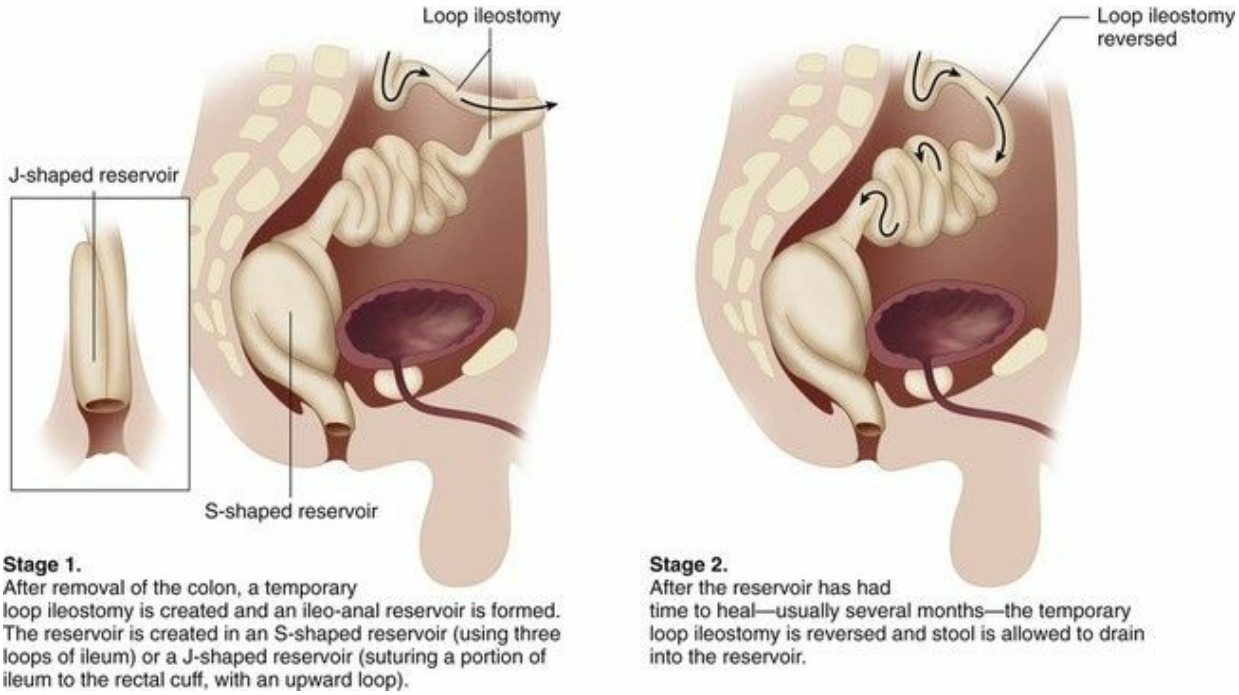

FIG. 57-2 The creation of an ileo-anal reservoir.

Usually bowel continence is excellent after this procedure, but some patients have leakage of stool during sleep. They may take antidiarrheal drugs to help control this problem.

Total Proctocolectomy with a Permanent Ileostomy.

Total proctocolectomy with a permanent ileostomy is done for patients who are not candidates for or do not want the ileo-anal pouch. The procedure involves the removal of the colon, rectum, and anus with surgical closure of the anus (Fig. 57-3, *A*). The surgeon brings the end of the ileum out through the abdominal wall and forms a stoma, or **ostomy.**

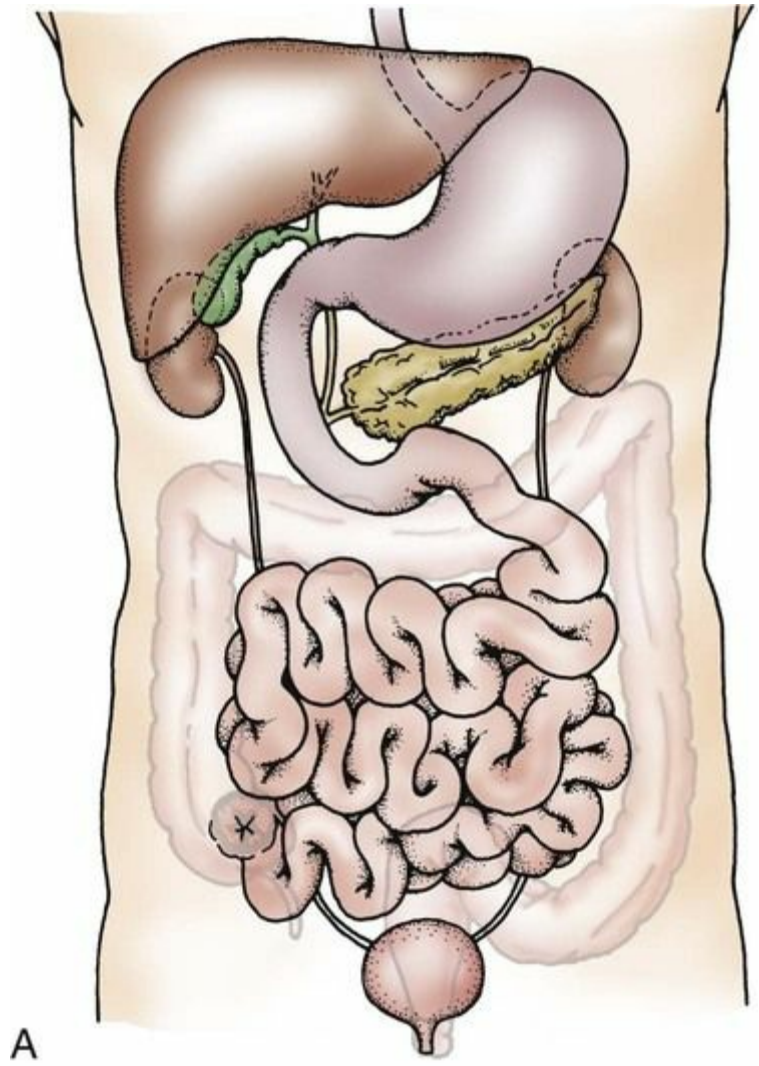

FIG. 57-3 **A,** Total proctocolectomy with a permanent ileostomy. This involved removal of the colon, the rectum, and the anus with closure of the anus. Note the missing colon, rectum, and anus with the resultant stoma (**B**) in the right lower

quadrant.

Nursing Safety Priority QSEN

Critical Rescue

The ileostomy stoma (Fig. 57-3, *B*) is usually placed in the right lower quadrant of the abdomen below the belt line. It should not be prolapsed or retract into the abdominal wall. *Assess the stoma frequently. It should be pinkish to cherry red to ensure an adequate blood supply. If the stoma looks pale, bluish, or dark, report these findings to the health care provider immediately!*

With an ileostomy, initially after surgery the output is a loose, dark green liquid that may contain some blood. Over time, a process called "ileostomy adaptation" occurs. The small intestine begins to perform some of the functions that had previously been done by the colon, including the absorption of increased amounts of sodium and water. Stool volume decreases, becomes thicker (pastelike), and turns yellow-green or yellow-brown. The effluent (fluid material) usually has little odor or a sweet odor. Any foul or unpleasant odor may be a symptom of a problem such as blockage or infection.

The ostomy drains frequently, and the stool is irritating. *The patient must wear a pouch system at all times.* The stool from the small intestine contains many enzymes and bile salts, which can quickly irritate and excoriate the skin. *Skin care around the stoma is a priority!* A pouch system with a skin barrier (gelatin or pectin) provides sufficient protection for most patients. Other products are also available.

Postoperative Care.

Provide general postoperative care after surgery, as described in Chapter 16. The few patients requiring open-approach surgery for ulcerative colitis have a large abdominal incision. At first they are NPO and a nasogastric tube (NGT) is used for suction. The tube is removed in 1 to 2 days as the drainage decreases, and fluids and food are slowly introduced. The patient having minimally invasive surgery (MIS) usually does not have an NGT.

In collaboration with the CWOCN, help the patient adjust and learn the required care. The ileostomy usually begins to drain within 24 hours after surgery at more than 1 L per day. Be sure that fluids are replaced by

adding an additional 500 mL or more each day to prevent dehydration. After about a week of high-volume output, the drainage slows and becomes thicker. During this period, some patients need antidiarrheal drugs.

The hospital stay is usually from 1 to 4 days, depending on whether the patient has laparoscopic or conventional open surgery. Patients having MIS have less pain from surgery and faster restoration of bowel function when compared with other surgical patients, but the incidence of complications is about the same (Fajardo et al., 2010).

For those who have the RPC-IPAA procedure, remind them that the internal pouch can become inflamed. This problem is usually effectively treated with metronidazole (Flagyl) for 7 to 10 days. Teach patients that after the second stage of surgery, they might have burning during bowel elimination because gastric acid cannot be well absorbed by the ileum. Also instruct them to omit foods that can cause odors or gas, such as cabbage, asparagus, Brussels sprouts, and beans. Teach patients to eliminate foods that cannot be well digested, such as nuts and corn. Each patient differs in which foods he or she can tolerate.

Surgery for UC may result in altered body image. However, it may be viewed as positive because the patient will have fewer symptoms and feel more comfortable than before the procedure. Patients have to adjust to having an ostomy before they can resume their presurgery activities.

NCLEX Examination Challenge

Physiological Integrity

The health care provider prescribes prednisone (Deltasone) for a client with ulcerative colitis. What health teaching is most important before the client begins the medication?

A Determine if the client's insurance pays for the drug.
B Teach the client to take the drug at night.
C Ask the client if he has any allergies to sulfa-type drugs.
D Teach the client the importance of avoiding crowds.

Minimizing Pain

Planning: Expected Outcomes.

The desired outcome for the patient is that he or she will verbalize decreased pain as a result of collaborative, evidence-based pain management interventions.

Interventions.

Pain control requires pharmacologic and nonpharmacologic measures. Physical discomfort can contribute to emotional distress. A variety of symptom-reducing interventions and supportive measures are used. Surgery also reduces pain for many patients.

The purpose of pain management is alleviation of pain or a reduction in pain to a level of comfort that is acceptable to the patient. Increases in pain may indicate the development of complications such as peritonitis (see earlier discussion in this chapter). Assist the patient in reducing or eliminating factors that can cause or increase the pain experience. For example, he or she may benefit from nutrition changes to decrease abdominal discomfort such as cramping and bloating.

Antidiarrheal drugs may be needed to control diarrhea, thus reducing the discomfort. However, they must be used with caution and for a short time because toxic megacolon can develop.

Perineal skin can be irritated by contact with loose stools and frequent cleaning. Explain special measures for skin care. Use of medicated wipes is soothing if the rectal area is tender or sensitive from the use of toilet tissue (Chart 57-3). A number of ostomy manufacturers (e.g., Hollister, ConvaTec) produce a system for skin care that may help prevent and heal perineal skin irritation. These systems usually include a skin-cleaning solution, a moisturizing and healing cream, and a petroleum jelly–like barrier that prevents contact of moisture and stool with the skin.

Chart 57-3 Best Practice for Patient Safety & Quality Care QSEN

Pain Control and Skin Care for Patients with Inflammatory Bowel Disease

PATIENT PROBLEM	INTERVENTIONS
Abdominal pain (particularly with exacerbations of the disease)	Administer analgesics. Assist with frequent positioning. Identify foods that increase pain. Perform a comprehensive pain assessment. Observe for signs and symptoms of peritonitis. Evaluate effectiveness of pain management. Teach music therapy, guided imagery.
Skin excoriation and/or irritation from frequent bowel movements	Encourage good skin care with a mild soap and water after each bowel movement. Gently pat the area dry. Identify foods that increase diarrhea. Sitz baths may be of benefit. Apply a thin coat of A+D Ointment or aloe cream. Use medicated wipes instead of tissue. Ensure appropriate ostomy supplies that fit well. Antidiarrheal medications may help, but use with caution. Observe for symptoms related to megacolon (fever, leukocytosis, tachycardia, distended abdomen with 3-view abdominal x-ray noting an enlarged colon).

Planning: Expected Outcomes.

For patients who experience GI bleeding, the patient with UC is expected to have a reduction in or cessation of bleeding with prompt collaborative care. If possible, patients are expected to remain free of complications of the disease that can cause bleeding, such as perforation.

Interventions.

The primary nursing priority is to monitor the patient closely for signs and symptoms of GI bleeding resulting from the disease or its complications.

Nursing Safety Priority QSEN

Critical Rescue

For the patient with ulcerative colitis, monitor stools for blood loss. The blood may be bright red (frank bleeding) or black and tarry (melena). Monitor hematocrit, hemoglobin, and electrolyte values, and assess vital signs. Prolonged slow bleeding can lead to anemia. Observe for fever, tachycardia, and signs of fluid volume depletion. Changes in mental status may occur, especially among older adults, and may be the first indication of dehydration or anemia.

If symptoms of GI bleeding begin, notify the health care provider immediately. Blood products are often prescribed for patients with severe anemia. Prepare for the blood transfusion by inserting a large-bore IV catheter if it is not already in place. Chapter 40 outlines nursing actions during blood transfusion.

If the patient has lower GI bleeding of more than 0.5 mL per minute, a *GI bleeding scan* may be useful to localize the site of the bleeding (Pagana & Pagana, 2014). This test cannot indicate the cause of the bleeding, however, and may take several hours to administer. Patients in the critical care unit are not candidates for the test because they must leave the unit for the test.

Community-Based Care

Home Care Management.

The patient with ulcerative colitis provides self-management at home but

may require hospitalization during severe exacerbations or surgery. In addition, those who have extraintestinal problems often need ongoing collaborative care for joint and/or skin problems.

Home care management focuses on controlling clinical manifestations and monitoring for complications. For patients returning home or transferring to nursing home or transitional care after surgery, ongoing respiratory care, incision care (if applicable), ostomy care, and pain management should be continued.

Self-Management Education.

Teach the patient about the nature of ulcerative colitis, including its acute episodes, remissions, and symptom management. Also stress that even though the cause is unknown, relapses can be prevented with proper health care. Teach patients taking immunosuppressive drugs, such as corticosteroids and biologic response modifiers (monoclonal antibodies), to report signs of possible infection, such as sore throat, to the health care provider. Remind them to avoid crowds and anyone who has an infection. Review the purpose of drug therapy, when drugs should be taken, side effects, and adverse drug events.

Instruct the patient about measures to reduce or control abdominal pain, cramping, and diarrhea. Also teach the patient and family about symptoms associated with disease exacerbation that should be reported to the health care provider, such as fever higher than 101° F (38.3° C), tachycardia, palpitations, and an increase in diarrhea, abdominal pain, or nausea/vomiting. Provide written information and contact numbers for the health care provider.

There is no special diet for a patient with an ileostomy. However, teach the patient to avoid any foods that cause gas. Examples include high-fiber foods like nuts, raw cabbage, corn, celery, apples with peels, and popcorn. The patient needs to learn what foods he or she tolerates best and adjust the diet accordingly.

If the patient has undergone a temporary or permanent surgical diversion, collaborate with the CWOCN to explain and demonstrate required care so that the patient can self-manage or the family/caregiver can assist. Also teach the importance of including adequate amounts of salt and water in the diet because the ileostomy increases the loss of these substances. Urge the patient to be cautious in situations that lead to heavy sweating or fluid loss, such as strenuous physical activity, high environmental heat, and episodes of diarrhea and vomiting.

Finding the best ostomy pouching system is a major issue for many patients. An effective system is one that:

- Protects the skin
- Contains the effluent (drainage) and reduces odor, if any
- Remains securely attached to the skin for a dependable period of time

Most patients desire an adhesive barrier that will last for 3 to 7 days. The barrier must create a solid seal to prevent the enzymes in the drainage from irritating the skin. Solid barriers are classified as "regular wear" or "extended wear." A person with a high output may want an extended-wear barrier. A special cream can be used to help fill any uneven skin surfaces and provide a consistent seal. Pouches are also individualized by the patient. Large pouches can hold more but are heavy when full. Patients also have to consider the costs of the various systems and if or how much their insurance will pay for them. Chart 57-4 describes the main aspects of ileostomy care, including skin care.

Chart 57-4 Patient and Family Education: Preparing for Self-Management

Ileostomy Care

Skin Protection

- Use a skin barrier to protect your skin from contact with contents from the ostomy.
- Use skin care products, such as skin sealants and ostomy skin creams. If your skin continues to come into contact with ostomy contents, select a product to fill in problem areas and provide an even skin surface.
- Watch your skin for any irritation or redness.

Pouch Care

- Empty your pouch when it is one-third to one-half full.
- Change the pouch during inactive times, such as before meals, before retiring at night, on waking in the morning, and 2 to 4 hours after eating.
- Change the entire pouch system every 3 to 7 days.

Nutrition

- Chew food thoroughly.
- Be cautious of high-fiber and high-cellulose foods. You may need to eliminate these from the diet if they cause severe problems (diarrhea, constipation, or blockage). Examples include corn, peanuts, coconut, Chinese vegetables, string beans, tough-fiber meats, shrimp and

lobster, rice, bran, and vegetables with skins (tomatoes, corn, and peas).

Drug Therapy

- Avoid taking enteric-coated and capsule medications.
- Inform any health care provider who is prescribing medications for you that you have an ostomy. Before having prescriptions filled, inform your pharmacist that you have an ostomy.
- Do not take any laxative or enemas. You should usually have loose stool and should contact a physician if no stool has passed in 6 to 12 hours.

Symptoms to Watch for

- Report any drastic increase or decrease in drainage to your health care provider.
- If stomal swelling, abdominal cramping, or distention occurs or if ileostomy contents stop draining:
  - Remove the pouch with faceplate.
  - Lie down, assuming a knee-chest position.
  - Begin abdominal massage.
  - Apply moist towels to the abdomen.
  - Drink hot tea.
  - If none of these maneuvers is effective in resuming ileostomy flow or if abdominal pain is severe, call your health care provider right away.

A patient with an ileostomy may have many concerns about management at home and about sexual and social adjustments. Considering possible sexual issues helps the patient identify and discuss these concerns with the sex partner. For example, a change in positioning during intercourse may alleviate apprehension. Social situations may cause anxiety related to decreased self-esteem and a disturbance in body image. Encourage the patient to discuss possible concerns in addressing and resolving these potentially stressful events. Clinical depression is common among patients with ulcerative colitis. Refer patients to appropriate mental health resources if depression is suspected.

Some hospitals provide community support groups for their patients with inflammatory bowel disease (IBD). These groups help patients and their families cope with the psychological impact of IBD and educate them about nutrition and complementary and alternative therapies (see the Evidence-Based Practice box).

Evidence-Based Practice QSEN

Is a Support Group for Patients with Inflammatory Bowel Disease Helpful?

McMaster, K., Aguinaldo, L., & Parekh, N.K. (2012). Evaluation of an ongoing psychoeducational inflammatory bowel disease support group in an adult outpatient setting. *Gastroenterology Nursing, 35*(6), 383-390.

In this study, researchers evaluated the use of an ongoing open psychoeducational support group for adult patients with inflammatory bowel disease (IBD) in an outpatient tertiary care setting. The sample was 18 adults who attended more than two meetings of the support group. The support group focused on diet and nutrition, psychological impact of IBD, and complementary and alternative medicine. Subjects completed several tools, including the Client Satisfaction Questionnaire, Multidimensional Support Scale, demographic data tool, and a brief open-ended qualitative questionnaire developed by the researchers.

The results showed that the participants in the support group were very satisfied with the support group and the peer support they received. The study demonstrated that the support group for IBD clients was effective.

Level of Evidence: 5

This study was a very small descriptive study that collected both quantitative and qualitative data.

Commentary: Implications for Practice and Research

Patients who have IBD need ongoing support and education in the community to cope with their disease. Nurses are in a prime position to facilitate these groups and help patients gain knowledge as well as emotional support as they learn to cope with their disease. This research was a small pilot study that needs a larger sample in a multi-setting research design.

Health Care Resources.

If the patient needs assistance with self-management at home, collaborate with the case manager or social worker to arrange the services of a home care aide or nurse. A home care nurse can provide assessment and guidance in integrating ostomy care into the patient's lifestyle. The nurse may also teach about wound care, including the monitoring of wound healing, if needed (Chart 57-5). The patient and family need to know where to purchase ostomy supplies, along with the name, size, and manufacturer's order number.

Chart 57-5 Home Care Assessment

The Patient with Inflammatory Bowel Disease

Assess gastrointestinal function and nutritional status, including:

- Abdominal cramping or pain
- Bowel elimination pattern, specifically frequency, characteristics, and amount of stools and presence or absence of blood in stools
- Food and fluid intake (include relationship of specific foods to cramping and stools)
- Weight gain or loss
- Signs and symptoms of dehydration
- Presence or absence of fever, rectal tenesmus, or urgency
- Bowel sounds
- Condition of perianal skin, including presence or absence of perianal fistula or abscess

Assess patient's and family's coping skills, including:

- Current and ongoing stress level and coping style
- Availability of support system

Assess home environment, including:

- Adequacy and availability of bathroom facilities
- Opportunity for rest and relaxation

Assess ability to self-manage therapeutic regimen, including:

- Drug therapy
- Signs and symptoms to report
- Nutrition therapy
- Availability of community resources
- Importance of follow-up care

For patients with a permanent ileostomy, locate a community ostomy support group by contacting the United Ostomy Associations of America (www.uoaa.org). The United Ostomy Association of Canada serves the needs of Canadian patients (www.ostomycanada.ca). A local support group or the Crohn's and Colitis Foundation of America (www.ccfa.org) may be helpful in obtaining supplies and providing education for ostomates. Inform the patient and family of available ostomy ambulatory care clinics and ostomy specialists. If the patient agrees, a visit from an ostomate can be continued after discharge to home.

Evaluation: Outcomes

Evaluate the care of the patient with ulcerative colitis based on the

identified priority patient problems. Expected outcomes may include that the patient will:

- Verbalize decreased pain
- Gain control over bowel elimination
- Not experience lower GI bleeding
- Self-manage the ileostomy (temporary or permanent)
- Maintain peristomal skin integrity
- Demonstrate behaviors that integrate ostomy care into his or her lifestyle if a permanent ileostomy is performed

Crohn's Disease

Pathophysiology

Crohn's disease (CD) is a chronic inflammatory disease of the small intestine (most often), the colon, or both. It can affect the GI tract from the mouth to the anus but most commonly affects the terminal ileum. CD is a slowly progressive and unpredictable disease with involvement of multiple regions of the intestine with normal sections in between (called "skip lesions" on x-rays). Like ulcerative colitis (UC), this disease is recurrent with remissions and exacerbations.

Crohn's disease presents as inflammation that causes a thickened bowel wall. Strictures and deep ulcerations (cobblestone appearance) also occur, which put the patient at risk for developing bowel **fistulas** (abnormal openings between two organs or structures). The result is severe diarrhea and malabsorption of vital nutrients. Anemia is common, usually from iron deficiency or malabsorption issues (McCance et al., 2014).

The complications associated with Crohn's disease are similar to those of ulcerative colitis (see Table 57-4). Hemorrhage is more common in ulcerative colitis, but it can occur in CD as well. Severe malabsorption by the small intestine is more common in patients with CD because UC may not involve the small bowel to any significant extent. *Therefore patients with CD can become very malnourished and debilitated.*

Rarely, cancer of the small bowel and colon develop but can occur after the disease has been present for 15 to 20 years. Fistula formation is a common complication of CD but is rare in UC. Fistulas can occur between segments of the intestine or manifest as cutaneous fistulas (opening to the skin) or perirectal abscesses. They can also extend from the bowel to other organs and body cavities, such as the bladder or vagina (Fig. 57-4). Some patients develop intestinal obstruction, which at first is secondary to inflammation and edema. Over time, fibrosis and scar

tissue develop and obstruction results from a narrowing of the bowel. Most patients with CD require surgery at some time.

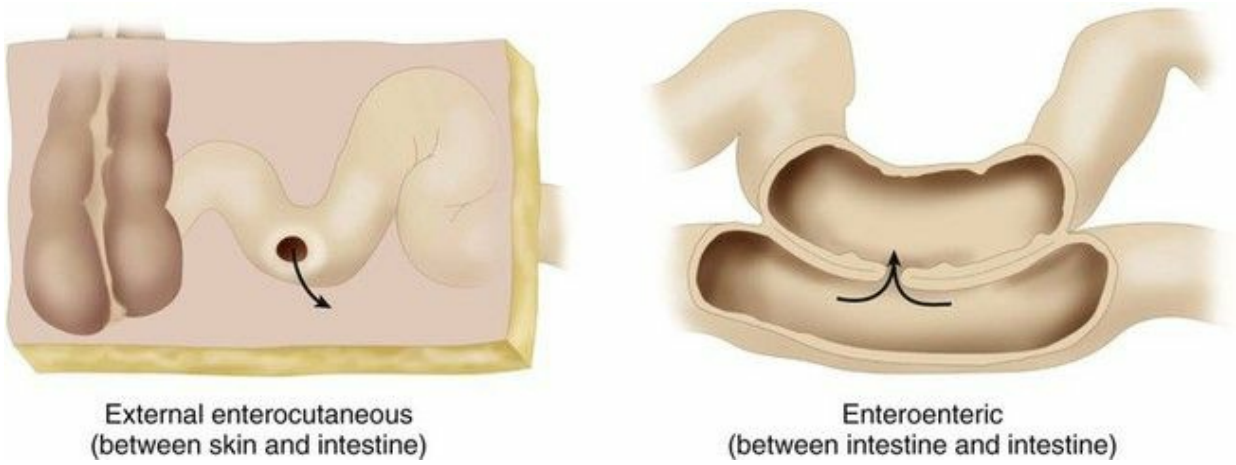

FIG. 57-4 The types of fistulas that are complications of Crohn's disease.

Genetic/Genomic Considerations

Patient-Centered Care QSEN

The exact cause of CD is unknown. A combination of genetic, immune, and environmental factors may contribute to its development. About 10% to 20% of patients have a positive family history for the disease (Nussbaum et al., 2007). The discovery of a mutation in the *NOD2/CARD15* gene on chromosome 16 seems to be associated with some patients who have CD. This gene is found in monocytes that normally recognize and destroy bacteria.

Pro-inflammatory cytokines, such as tumor necrosis factor–alpha (TNF-alpha) and interleukins (ILs) (e.g., IL-6 and IL-8), are immunologic factors that contribute to the etiology of CD (McCance et al., 2014). Many of the drugs used for the disease inhibit or block one or more of these factors.

Other risk factors include tobacco use, Jewish ethnicity, and living in urban areas (McCance et al., 2014). CD is more common in people of Ashkenazi Jewish background than in any other group (Nussbaum et al., 2007). The reasons for these factors have not been established. It was once thought that stress and nutrition play a role in the *development* of CD, but these factors have not been proven. However, inadequate nutrition can worsen the patient's symptoms.

Almost a million people in the United States have Crohn's disease. Most have symptoms and are diagnosed as adolescents or young adults.

Patient-Centered Collaborative Care

Assessment

Crohn's disease is made worse by bacterial infection. A detailed history is needed to identify manifestations specific to the disease. Ask about recent unintentional weight loss, the frequency and consistency of stools, the presence of blood in the stool, fever, and abdominal pain.

Perform a thorough abdominal assessment. Assess for manifestations of the disease, and evaluate the patient's nutrition and hydration status.

When inspecting the abdomen, assess for distention, masses, or visible peristalsis. Inspection of the perianal area may reveal ulcerations, fissures, or fistulas. During auscultation, bowel sounds may be decreased or absent with severe inflammation or obstruction. An increase in high-pitched or rushing sounds may be present over areas of narrowed bowel loops. Muscle guarding, masses, rigidity, or tenderness may be noted on palpation by the advanced practice nurse or other health care provider.

The clinical presentation of Crohn's disease varies greatly from person to person. Most patients report diarrhea, abdominal pain, and low-grade fever. Fever is common with fistulas, abscesses, and severe inflammation. If the disease occurs in only the ileum, diarrhea occurs 5 or 6 times per day, often with a soft, loose stool. **Steatorrhea** (fatty diarrheal stools) is common. Rarely, stools may contain bright red blood.

Abdominal pain from the inflammatory process is usually constant and often located in the right lower quadrant. The patient also may have pain around the umbilicus before and after bowel movements. If the lower colon is diseased, pain is common in both lower abdominal quadrants.

Most patients with Crohn's disease have *weight loss.* Nutritional problems are the result of increased catabolism from chronic inflammation, anorexia, malabsorption, or self-imposed dietary restrictions. These problems result in impaired fluid and electrolyte balance and vital nutrient deficiencies.

The inflammatory bowel changes decrease the small bowel's ability to absorb nutrients, which may be made worse by surgery and fistulas.

Nursing Safety Priority QSEN

Action Alert

For the patient with Crohn's disease, be especially alert for manifestations of peritonitis (discussed earlier in this chapter), small-bowel obstruction, and nutritional and fluid imbalances. Early detection of a change in the patient's status helps reduce these life-threatening complications.

The patient who has Crohn's disease (CD) needs a complete psychosocial assessment. The chronic nature of the problem and the associated complications can greatly affect patients and their families. Lifestyle changes are necessary to cope with such a disruptive and painful chronic illness. Assess the patient's coping skill, and help identify support systems. Similar to problems associated with other chronic diseases, clinical depression and severe anxiety disorders are common among patients with CD.

The health care provider requests many laboratory studies for patients with Crohn's disease. The results of laboratory tests often indicate the extent and severity of inflammation or complications that occur with the disease.

Anemia is common as a result of slow bleeding and poor nutrition. Serum levels of folic acid and vitamin B_{12} are generally low because of malabsorption, further contributing to anemia. Amino acid malabsorption and protein-losing enteropathy may result in *decreased albumin* levels. C-reactive protein and ESR may be elevated to indicate inflammation. White blood cells (WBCs) in the urine may show infection (pyuria), which is caused by ureteral obstruction or an enterovesical (bowel to bladder) fistula. If severe diarrhea or fistula is present, the patient may have fluid and electrolyte losses, particularly potassium and magnesium. Assess the patient for clinical manifestations that can occur as a result of electrolyte losses (see Chapter 11).

X-rays show the narrowing, ulcerations, strictures, and fistulas common with Crohn's disease. *Magnetic resonance enterography (MRE)* is performed to determine bowel activity and motility as discussed on p. 1175 in this chapter. An *abdominal ultrasound or CT* scan may also be performed. In acute illness, these tests may be deferred until the risk for perforation lessens. If the patient has lower GI bleeding of more than 0.5 mL per minute, a *GI bleeding scan* may be useful to localize the site of the bleeding (Pagana & Pagana, 2014).

Interventions

Collaborative care for patients with Crohn's disease is similar to that described on p. 1175 in the Nonsurgical Management discussion in the

Ulcerative Colitis section. Specific interventions vary with the severity of disease and the complications that are present.

Drug Therapy.

Drugs used to manage Crohn's disease (CD) are similar to those used in the treatment of ulcerative colitis (UC). For mild to moderate disease, 5-ASA drugs may be very effective (see p. 1183 in the Drug Therapy discussion in the Ulcerative Colitis section).

Most patients have moderate to severe disease and need stronger drug therapy to control their symptoms. Two agents that may be prescribed for CD are azathioprine (Imuran) and mercaptopurine (Purinethol). These drugs suppress the immune system and can lead to serious infections. Methotrexate (MTX) may also be given to suppress immune activity of the disease.

A group of biologic response modifiers (BRMs), also known as *monoclonal antibody drugs,* have been approved for use in Crohn's disease when other drugs have been ineffective. These drugs inhibit tumor necrosis factor (TNF)–alpha, which decreases the inflammatory response. Examples of commonly used drugs for patients with CD include infliximab (Remicade), adalimumab (Humira), natalizumab (Tysabri), and certolizumab pegol (Cimzia). These agents are not given to patients with a history of cancer, heart disease, or multiple sclerosis.

Nursing Safety Priority QSEN

Drug Alert

Both infliximab and certolizumab pegol must be given in a health care setting, such as a physician's office, via parenteral routes. Adalimumab (Humira) is self-administered by subcutaneous injection every other week. If needed, instruct patients on how to give themselves a subcutaneous injection. Teach patients to report injection site reactions, including redness and swelling. Remind them that headache, abdominal pain, and nausea and vomiting are common side effects. Teach them to avoid crowds, such as malls and large shopping centers, and people with infection. Reinforce the need to report any infection, including a cold or sore throat, to the health care provider immediately.

Natalizumab is given IV under medical supervision every 4 weeks for moderate to severe CD and is given when other drugs are not effective. Although the use of this drug has decreased the length of hospital stays (Dudley-Brown et al., 2009), natalizumab can cause **progressive**

multifocal leukoencephalopathy (PML), a deadly infection that affects the brain. Before giving the drug, be sure that the patient is free of all infections. Teach patients the importance of reporting any cognitive, motor, or sensory changes immediately to the health care provider.

Although glucocorticoids can be effective for patients with Crohn's disease, sepsis can result from abscesses or fistulas that may be present. These drugs mask the symptoms of infection. Therefore they must be used with caution. Monitor the patient closely for signs of infection. Metronidazole (Flagyl, Novonidazol) has been helpful in patients with fistulas.

Nutrition Therapy.

Long-standing nutritional deficits can have severe consequences for the patient with Crohn's disease. Poor nutrition can lead to inadequate fistula and wound healing, loss of lean muscle mass, decreased immune responses, and increased morbidity and mortality. During severe exacerbations of the disease, the patient may be hospitalized to provide bowel rest and nutritional support with total parenteral nutrition (TPN). For less severe exacerbations, an elemental or semi-elemental product such as Vivonex PLUS may be prescribed to induce remission. These products are absorbed in the jejunum and therefore permit the distal small intestine and colon to rest. Nutritional supplements such as Ensure or Sustacal can be added then to provide nutrients and more calories. Teach the patient to avoid GI stimulants, such as caffeinated beverages and alcohol.

Fistula Management.

Fistulas (abnormal tracts between two or more body areas) are common with acute exacerbations of Crohn's disease. They can be between the bowel and bladder (enterovesical), between two segments of bowel (enteroenteric), between the skin and bowel (enterocutaneous), or between the bowel and vagina (enterovaginal) (see Fig. 57-4). The patient with one or more fistulas often has complications such as systemic infections, skin problems, malnutrition, and impaired fluid and electrolyte balance. Treatment of the patient with a fistula is complicated and includes nutrition and electrolyte therapy, skin care, and prevention of infection.

Nursing Safety Priority QSEN

Action Alert

Adequate nutrition and fluid and electrolyte balance are priorities in the care of the patient with a fistula. GI secretions are high in volume and rich in electrolytes and enzymes. The patient is at high risk for malnutrition, dehydration, and hypokalemia (decreased serum potassium). Assess for these complications, and collaborate with the health care team to manage them. Monitor urinary output and daily weights. A decrease indicates possible dehydration, which should be treated immediately by providing additional fluids.

The patient requires at least 3000 calories daily to promote healing of the fistula. If he or she cannot take adequate oral fluids and nutrients, total enteral nutrition (TEN) or TPN may be prescribed. For patients who do not require TEN or TPN, collaborate with the dietitian to:

- Carefully monitor the patient's tolerance to the prescribed diet.
- Assist the patient in selecting high-calorie, high-protein, high-vitamin, low-fiber meals.
- Offer enteral supplements, such as Ensure and Vivonex PLUS.
- Record food intake for accurate calorie counts.

Providing enteral supplements, recording intake and output, and taking daily weights may be delegated to unlicensed assistive personnel (UAP) under the supervision of the RN.

Collaborate with the certified wound, ostomy, and continence nurse (CWOCN) to select the most appropriate wound management for each patient.

Nursing Safety Priority QSEN

Action Alert

For patients with fistulas, preserving and protecting the skin is the nursing priority. Be sure that wound drainage is not in direct contact with skin because intestinal fluid enzymes are caustic! Clean the skin promptly to prevent skin breakdown or fungal infection, which can cause major discomfort for the patient.

Enzymes and bile in the stool contribute to the problem of skin irritation and excoriation. Skin irritation needs to be prevented. This may be accomplished through the use of skin barriers, pouching systems, and insertion of drains (Fig. 57-5). Skin barriers or dressings are used when the fistula drainage is less than 100 mL in 24 hours. A pouch is used for

heavily draining fistulas to reduce the risk for skin breakdown and measure the **effluent** (drainage). However, they are very challenging because of location and drainage amount. Treatment with an antifungal powder applied to the skin around the fistula is often very helpful to prevent or treat *Candida* infection.

FIG. 57-5 Skin barriers, such as wafers **(A)** are cut to fit ⅛ inch around the fistula. A drainable pouch **(B)** is applied over the wafer and clamped **(C)** until the pouch is to be emptied. Effluent should drain into the bag and not contact the skin.

For some fistulas, pouching may not be possible because of their location. Drainage may need to be managed using regulated wall suction or a negative-pressure wound therapy device. Continuous low wall suction is attached to a suction catheter in the wound bed of the fistula, not into the fistula tract. These systems are not meant for long-term management.

Negative-pressure wound therapy (e.g., VAC therapy) promotes wound healing by secondary intention as it prepares the wound bed for closure, reduces edema, promotes granulation and perfusion, and removes exudate and infectious material. It should not be used for patients who are at risk for bleeding or only for the purpose of drainage containment. Chapter 25 describes this therapy in detail.

Patients with fistulas are also at high risk for intra-abdominal abscesses and sepsis. Antibiotic therapy is commonly prescribed. Observe for signs of sepsis (systemic infection), such as fever, abdominal pain, or a change in mental status. Monitor for increased WBC levels that could indicate a systemic infection.

Other helpful interventions for the patient with CD are those that relax the patient and soothe the GI tract. Such therapies may include naturopathy, herbs (e.g., ginger), acupuncture, hypnotherapy, and ayurveda (a combination of diet, herbs, yoga, breathing exercises). The evidence supporting the use of these substances for CD is lacking, but

many patients find them helpful for overall physical and emotional health. Teach patients about the availability of these therapies, and recommend that they include them in their collaborative plan of care.

Clinical Judgment Challenge

Patient-Centered Care; Teamwork and Collaboration; Informatics QSEN

A young woman has an exacerbation of Crohn's disease with multiple diarrheal stools each day. She has been taking adalimumab (Humira) for the past 2 years to control the disease. However, she has been especially stressed in her doctoral program because she is applying for an internship for clinical psychology. The process is very competitive, and she is concerned that she may not be successful in finding a suitable internship site. She is worried that her flare-up will put her behind in her program.

1. What is your best response to the patient at this time?
2. What patient assessments will you perform on admission and why?
3. Based on the patient data provided, what priority problems do you identify?
4. Using best current evidence, how will you plan care with other members of the health care team? What members of the health care team will be involved in this patient's care and why?

Surgical Management.

Surgery for Crohn's disease may be performed for those patients who have not improved with medical management or for those who have complications from the disease. Surgery to manage CD is not as successful as that for ulcerative colitis because of the extent of the disease. The patient with a fistula may undergo resection of the diseased area. Other indications for surgical treatment include perforation, massive hemorrhage, intestinal obstruction or strictures, abscesses, or cancer.

In some cases, a resection (removal of part of the small bowel) can be performed as minimally invasive surgery (MIS) via laparoscopy. This surgery involves one or more small incisions, less pain, and a quicker surgical recovery when compared with traditional open surgery. Both small-bowel resection (usually the ileum) and ileocecal resection can be done using this procedure. For other patients, an open surgical approach is used to allow for better visual access to the bowel.

Stricturoplasty may be performed for bowel strictures related to Crohn's disease. This procedure increases the bowel diameter. Care before and after each of these surgical procedures is similar to care for patients undergoing other types of abdominal surgery (see Chapters 14 and 16).

Community-Based Care

The discharge care plan for the patient with Crohn's disease is similar to that for the patient with ulcerative colitis (see p. 1180 in the discussion of Community-Based Care in the Ulcerative Colitis section). Collaborate with the case manager and CWOCN or wound nurse to help the patient plan self-management.

The interventions that were started to manage the disease are continued. Reinforce measures to control the disease and related symptoms and manage nutrition. Teach the patient and family to make arrangements for the patient to have easy access to the bathroom, as well as privacy to perform fistula care, if needed.

The health teaching plan for Crohn's disease is similar to that for the patient with ulcerative colitis. Teach the patient about the usual course of the disease, symptoms of complications, and when to notify the health care provider. Provide health teaching for drug therapy, including purpose, dose, and side effects. In addition to other drugs, vitamin supplements, including monthly vitamin B_{12} injections, may be needed because of the inability of the ileum to absorb these nutrients. In collaboration with the dietitian, instruct the patient to follow a low-residue, high-calorie diet and to avoid foods that cause discomfort, such as milk, gluten (wheat products), and other GI stimulants like caffeine.

Remind the patient to take rest periods, especially during exacerbations of the disease. If stress appears to increase symptoms of the disease, recommend stress management techniques, counseling, and/or physical activity to improve quality of life (Crumbock et al., 2009). For long-term follow-up, teach the patient about the increased risk for bowel cancer and the importance of having frequent colonoscopies.

If a patient has a fistula, explain and demonstrate wound care. Provide the opportunity for the patient to practice this care in the hospital. Ideally, he or she should be independent in fistula care before leaving the hospital. However, because of location of the fistula (perirectal or vaginal) or a large abdomen, assistance may be needed. If this is the case, teach a family member or other caregiver how to manage the wound. Patients may be transferred to a transitional or skilled nursing unit for collaborative care.

Patients who are discharged to home after undergoing resection and anastomosis may require visits from a home care nurse to assess the surgical wound and monitor for complications (see Chart 57-5). Assess the patient's and family's ability to monitor the progress of fistula healing and to watch for indications of infection and sepsis. A home care aide or other service might be helpful for the patient who cannot meet nutritional needs or who needs help with grocery shopping and meal preparation.

In collaboration with the CM, assist with obtaining the equipment and supplies for fistula care, such as skin barriers and wound drainage bags. A support group sponsored by the United Ostomy Associations of America (www.uoaa.org) or a local hospital in the community may also be available to help with meeting physical and psychosocial needs.

Diverticular Disease

Diverticula are pouchlike herniations of the mucosa through the muscular wall of any portion of the gut but most commonly the colon. **Diverticulosis** is the presence of many abnormal pouchlike herniations (diverticula) in the wall of the intestine. Acute **diverticulitis** is the inflammation of diverticula.

Pathophysiology

Diverticula can occur in any part of the small or large intestine but usually occur in the sigmoid colon (Fig. 57-6). The muscle of the colon hypertrophies, thickens, and becomes rigid, and herniation of the mucosa and submucosa through the colon wall is seen. Diverticula seem to occur at points of weakness in the intestinal wall, often at areas where blood vessels interrupt the muscle layer. Muscle weakness develops as part of the aging process or as a result of a lack of fiber in the diet.

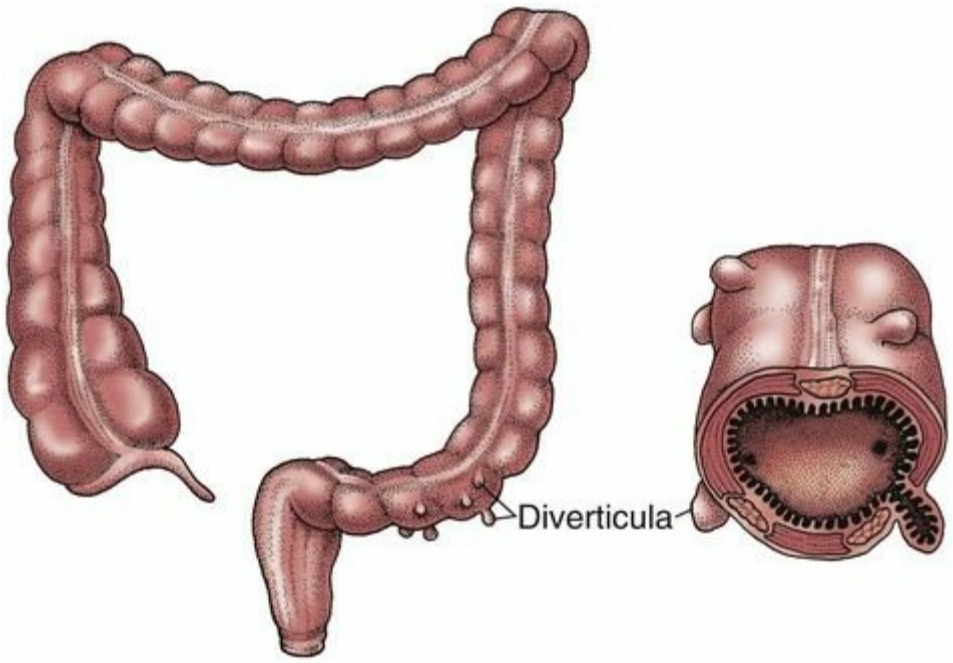

FIG. 57-6 Several abnormal outpouchings, or herniations, in the wall of the intestine, which are diverticula. These can occur anywhere in the small or large intestine but are found most often in the colon. Diverticulitis is the inflammation of a diverticulum that occurs when undigested food or bacteria become trapped in the diverticulum.

Without inflammation, diverticula cause few problems. If undigested food or bacteria become trapped in a diverticulum, however, blood supply to that area is reduced. Bacteria invade the diverticulum, resulting in diverticulitis, which then can perforate and develop a local abscess. A perforated diverticulum can progress to an intra-abdominal perforation with peritonitis (inflammation of the peritoneum). Lower GI bleeding may also occur.

High intraluminal pressure forces the formation of a pouch in the weakened area of the mucosa, frequently near blood vessels. Diets low in fiber that cause less bulky stool and constipation have been implicated in the formation of diverticula. Retained undigested food in diverticula is suggested to be one cause of diverticulitis. The retained food reduces blood flow to that area and makes bacterial invasion of the sac easier (McCance et al., 2014).

The exact incidence of diverticulosis is unknown, but millions of people are affected by the problem. It is found in two thirds of adults older than 80 years, with more men than women affected. African Americans have more diverticular disease than do Caucasians (Hall, 2011). The causes for these differences are not known.

❖ Patient-Centered Collaborative Care

Assessment

The patient with *diverticulosis* usually has no symptoms. Unless pain or bleeding develops, the condition may go undiagnosed. Diverticula are most often diagnosed during routine colonoscopy. Occasionally, diverticulosis will cause symptoms. For the patient with uncomplicated diverticulosis, ask about intermittent pain in the left lower quadrant and a history of constipation. If diverticulitis is suspected, ask about a history of low-grade fever, nausea, and abdominal pain. Inquire about recent bowel elimination patterns because constipation may develop as a result of intestinal inflammation. Also ask about any bleeding from the rectum.

The patient with *diverticulitis* may have abdominal pain, most often localized to the left lower quadrant. It is intermittent at first but becomes progressively steady. Occasionally, pain may be just above the pubic bone or may occur on one side. Abdominal pain is generalized if peritonitis has occurred. Nausea and vomiting are common. The patient's temperature is elevated, ranging from a low-grade fever to 101° F (38.3° C). Chills may be present. Often an increased heart rate (tachycardia) occurs with fever.

Considerations for Older Adults

Patient-Centered Care QSEN

The first sign of peritonitis in older adults may be a sudden change in mental status (e.g., acute confusion). For those who have dementia, the confusion worsens. Fever and chills may not be present due to normal physiologic changes associated with aging.

On examination of the abdomen, observe for distention. The patient may report tenderness over the involved area. Localized muscle spasm, guarded movement, and rebound tenderness may be present with peritoneal irritation. If generalized peritonitis is present, profound guarding occurs; rebound tenderness is more widespread; and sepsis, hypotension, or hypovolemic shock can occur. If the perforated diverticulum is close to the rectum, the health care provider may palpate a tender mass during the rectal examination. Blood pressure checks may show orthostatic changes. *If bleeding is massive, the patient may have hypotension and dehydration that result in shock.*

For the patient with uncomplicated diverticulosis, laboratory studies are not indicated. The patient with diverticulitis, however, has an *elevated white blood cell (WBC) count. Decreased hematocrit and hemoglobin* values are

common if chronic or severe bleeding occurs. Stool tests for occult blood, if requested, are sometimes positive. Abdominal x-rays may be done to evaluate for free air and fluid indicating perforation. A CT scan may be performed to diagnose an abscess or thickening of the bowel related to diverticulitis.

Abdominal ultrasonography, a noninvasive test, may also reveal bowel thickening or an abscess. The health care provider may recommend a colonoscopy 4 to 8 weeks *after the acute phase* of the illness to rule out a tumor in the large intestine, particularly if the patient has rectal bleeding.

Interventions

Patients are managed on an ambulatory care basis if the symptoms are mild. Monitor the patient for any prolonged or increased fever, abdominal pain, or blood in the stool. The patient with moderate to severe diverticulitis may be hospitalized, especially if the patient is older or has complications. Manifestations suggesting the need for admission are a temperature higher than 101° F (38.3° C), persistent and severe abdominal pain for more than 3 days, and/or lower GI bleeding.

Nonsurgical Management.

A combination of drug and nutrition therapy with rest is used to decrease the inflammation associated with diverticular disease. Broad-spectrum antimicrobial drugs, such as metronidazole (Flagyl) plus trimethoprim/sulfamethoxazole (TMZ) (Bactrim or Bactrim DS, Septra) or ciprofloxacin (Cipro), are often prescribed. A mild analgesic may be given for pain. Chart 57-6 lists nursing interventions needed for care of older adults with diverticulitis.

Chart 57-6 Nursing Focus on the Older Adult

Diverticulitis

- Provide antibiotics, analgesics, and anticholinergics as prescribed. Observe older patients carefully for side effects of these drugs, especially confusion (or increased confusion), urinary retention or failure, and orthostatic hypotension.
- Do not give laxatives or enemas. Teach the patient and the family about the importance of avoiding these measures.
- Encourage the patient to rest and to avoid activities that may increase intra-abdominal pressure, such as straining and bending.

- While diverticulitis is active, provide a *low*-fiber diet. When the inflammation resolves, provide a *high*-fiber diet. Teach the patient and family about these diets and when they are appropriate.
- Because older patients do not always experience the typical pain or fever expected, observe carefully for other signs of active disease, such as a sudden change in mental status.
- Perform frequent abdominal assessments to determine distention and tenderness on palpation.
- Check stools for occult or frank bleeding.

The patient with more severe pain may be admitted to the hospital for IV fluids to correct dehydration and IV drug therapy. For patients with moderate to severe diverticulitis, an opioid analgesic may alleviate pain.

Laxatives and enemas are avoided because they increase intestinal motility. Assess the patient on an ongoing basis for manifestations of impaired fluid and electrolyte balance.

Teach the patient to rest during the acute phase of illness. Remind him or her to refrain from lifting, straining, coughing, or bending to avoid an increase in intra-abdominal pressure, which can result in perforation of the diverticulum. Nutrition therapy should be restricted to low fiber or clear liquids based on symptoms. The patient with more severe symptoms is NPO. A nasogastric tube (NGT) is inserted if nausea, vomiting, or abdominal distention is severe. Infuse IV fluids as prescribed for hydration. In collaboration with the dietitian, the patient increases dietary intake slowly as symptoms subside. When inflammation has resolved and bowel function returns to normal, a fiber-containing diet is introduced gradually.

Surgical Management.

Diverticulitis can result in rupture of the diverticulum with peritonitis, pelvic abscess, bowel obstruction, fistula, persistent fever or pain, or uncontrolled bleeding. The surgeon performs emergency surgery if peritonitis, bowel obstruction, or pelvic abscess is present. Colon resection, with or without a colostomy, is the most common surgical procedure for patients with diverticular disease. Chapter 56 discusses the nursing care for patients with this procedure.

Community-Based Care

The length of stay for patients hospitalized for diverticulitis ranges from 1 to 4 days, depending on the response to treatment and if surgery is performed. Discharge plans vary according to the treatment. The patient

who has surgical intervention has the added responsibilities of incision care and possibly colostomy care with temporary limitations placed on activities.

Patients with diverticular disease need education regarding a high-fiber diet. Encourage the patient with *diverticulosis* to eat a diet high in cellulose and hemicellulose types of fiber. These substances can be found in wheat bran, whole-grain breads, and cereals. Teach the patient to eat at least 25 to 35 g of fiber per day. Fresh fruits and vegetables with high fiber content are added to provide bulk to stools.

If not accustomed to eating high-fiber foods, teach the patient to add them to the diet gradually to avoid flatulence and abdominal cramping. If he or she cannot tolerate the recommended fiber requirement, a bulk-forming laxative, such as psyllium hydrophilic mucilloid (Metamucil), can be taken to increase fecal size and consistency. Teach the patient to drink plenty of fluids to help prevent bloating that may occur with a high-fiber diet. Alcohol should be avoided because it irritates the bowel. Foods containing seeds or indigestible material that may block a diverticulum, such as nuts, corn, popcorn, cucumbers, tomatoes, figs, and strawberries, may be eliminated. Teach the patient that dietary fat intake should not exceed 30% of the total daily caloric intake.

Teach the patient to avoid all fiber when symptoms of *diverticulitis* are present, because high-fiber foods are then irritating. As inflammation resolves, fiber can gradually be added until progression to a high-fiber diet is established. The patient who has undergone surgery is usually taking solid food by the time of discharge from the hospital.

Provide oral and written instructions on incision care and the signs and symptoms to report to the health care provider for the patient who had abdominal surgery. If a colostomy was created, reinforce ostomy care as needed. Encourage the patient to express concerns about body image. Allow time and address sexual concerns regarding the changed body image.

Instruct the patient with any type of diverticular disease, orally and in writing, about the manifestations of acute diverticulitis, including fever, abdominal pain, and bloody, mahogany, or tarry stools. Advise patients to avoid the use of laxatives (other than bulk-forming types) and enemas. Reassure them that this disorder should not cause problems if a proper diet is followed.

In collaboration with the case manager, arrange for a home care nurse, if needed, to assess wound healing and proper functioning of the ostomy and the appliance. If the patient is interested, arrange for a visit from an ostomy volunteer (ostomate) or an ostomy nurse. For information about

other community resources, remind the patient to contact the United Ostomy Associations of America (www.uoaa.org).

NCLEX Examination Challenge

Physiological Integrity

The nurse is teaching a client about nutrition and diverticulitis. Which statement by the client indicates a need for further teaching?
A "I should eat more foods low in fiber."
B "I will not drink any alcohol."
C "I can have any fruits that I want."
D "I need to avoid nuts and corn."

Celiac Disease

Celiac disease (CD) was once thought to be a rare disease, but many cases in adults between 30 and 50 years old have been diagnosed in the past 10 years. CD is a multi-system autoimmune disease with an estimated incidence of about 3 million Americans; most are not diagnosed (Strauch & Cotter, 2011). Patients who have other autoimmune diseases, such as rheumatoid arthritis and diabetes mellitus type 1, are at the highest risk for the disease.

CD is a chronic inflammation of the small intestinal mucosa that can cause bowel wall atrophy and malabsorption. Like many inflammatory disorders, it is thought to be caused by a combination of genetic, immunologic, and environmental factors. The primary complication of CD is cancer, specifically non-Hodgkin's lymphoma or GI cancers.

Patients with CD have varying clinical manifestations with cycles of remission and exacerbation (flare-up). Classic symptoms include anorexia, diarrhea and/or constipation, steatorrhea (fatty stools), abdominal pain, abdominal bloating and distention, and weight loss. Some patients have no symptoms. Still others have atypical symptoms that affect every body system (Chart 57-7).

Chart 57-7 Key Features

Celiac Disease

Classic Symptoms

- Weight loss
- Anorexia

- Diarrhea and/or constipation
- Steatorrhea
- Abdominal pain and distention
- Vomiting

Atypical Symptoms

- Osteoporosis
- Joint pain and inflammation
- Lactose intolerance
- Iron deficiency anemia
- Depression
- Migraines
- Epilepsy
- Autoimmune disorders
- Stomatitis
- Early menopause
- Protein-calorie malnutrition

Dietary management is the only available treatment for achieving disease remission. In most cases, a gluten-free diet (GFD) results in healing the intestinal mucosa after about 2 years (Strauch & Cotter, 2011). Gluten is the primary substance in wheat and wheat-based products. Teach patients to carefully check for hidden sources of gluten that are in foods, food additives, drugs, and cosmetics. Patients often take vitamin and mineral supplements to replace those lost in avoiding gluten foods.

Anal Disorders

Anorectal Abscess

Anorectal abscess is a localized area of induration and pus caused by inflammation of the soft tissue near the rectum or anus. It is most often the result of obstruction of the ducts of glands in the anorectal region. Feces, foreign bodies, or trauma can be the cause of the obstruction and stasis, leading to infection that spreads into nearby tissue.

Rectal pain is often the first symptom. There may be no other manifestations at first, but local swelling, redness, and tenderness are present within a few days after the onset of pain. If the abscess becomes chronic, discharge, bleeding, and pruritus (itching) may exist. Fever occurs if larger abscesses are present.

Anorectal abscesses are managed by surgical incision and drainage (I&D). The physician can often excise (surgically remove) simple perianal and ischiorectal abscesses using a local anesthetic. For patients with more extensive abscesses, a regional or general anesthetic may be needed. Systemic antibiotics are given only for patients who are immunocompromised, are diabetic, have valvular disease or a prosthetic valve, or are obese.

Nursing Safety Priority QSEN

Action Alert

For patients with an anorectal abscess, nursing interventions are focused on comfort and helping the patient maintain optimal perineal hygiene. Encourage the use of warm sitz baths, analgesics, bulk-producing agents, and stool softeners after the surgery until healing occurs. *Stress the importance of good perineal hygiene after all bowel movements and the maintenance of a regular bowel pattern with a high-fiber diet.*

Patients are often embarrassed about having anal problems. Provide privacy and maintain the patient's dignity during the examination and treatment.

Anal Fissure

An **anal fissure** is a tear in the anal lining, which can be very painful. Smaller fissures occur with straining to have a stool, such as with diarrhea or constipation. Larger, deeper fissures may occur as a result of

another disorder (e.g., Crohn's disease, tuberculosis, leukemia, neoplasm) or from trauma (e.g., from a foreign body, anal intercourse, perirectal surgery).

An *acute* anal fissure is superficial and usually resolves on its own or heals quickly with conservative treatment. *Chronic* fissures recur, and surgical treatment may be needed. Pain during and after defecation and bright red blood in the stool are the most common symptoms. Other manifestations include pruritus, urinary frequency or retention, dysuria, and **dyspareunia** (painful intercourse).

The diagnosis is made by stretching and inspecting the perianal skin. If the patient is having pain at the time of the examination, diagnostic testing is usually limited to inspection. If he or she is not in severe pain, a digital examination and possibly a sigmoidoscopy are performed. When painless or multiple fissures are present, a colonoscopy may be performed to rule out any inflammatory bowel disorder.

Management of an acute fissure is usually aimed at local pain relief and softening of stools to reduce trauma to the area. Teach the patient to use warm sitz baths, analgesics, and bulk-producing agents (e.g., psyllium hydrophilic mucilloid [Metamucil]) to help minimize the pain from defecation. Topical anti-inflammatory agents (hydrocortisone creams and suppositories) may be helpful for some patients.

Explain pain control measures to the patient. Remind him or her to notify the health care provider if pain is not relieved within a few days. If fissures do not respond to management within several days to weeks, surgical repair under a local anesthetic may be needed. Teach the patient to report any drainage or bleeding from the rectum to the health care provider.

Anal Fistula

An anal fistula, or *fistula in ano,* is an abnormal tract leading from the anal canal to the perianal skin. Most anal fistulas result from anorectal abscesses, which are caused by obstruction of anal glands (see Anorectal Abscess, p. 1188). Fistulas can also occur with tuberculosis, Crohn's disease, or cancer. Intermittent discharge is usually noted over the perianal area.

The patient with an anal fistula has pruritus (itching), purulent discharge, and tenderness or pain that is worsened by bowel movements. A proctoscope may be used to identify the source of symptoms and to locate the fistula. Because fistulas do not heal spontaneously, surgery is necessary. To perform a fistulotomy, the surgeon opens the tissue over

the tract and scrapes the base. The incision site then heals by secondary intention. For a fistula higher in the anus, a special surgical technique is used to preserve important sphincters. After surgery, instruct the patient about sitz baths, analgesics, and the use of bulk-producing agents or stool softeners to reduce pain.

Parasitic Infection

Pathophysiology

Parasites can enter and invade the GI tract and cause infection. They commonly enter through the mouth (oral-fecal transmission) from contaminated food or water, oral-anal sexual practices, or contact with feces from a contaminated person. Common parasites that cause infection in humans are *Giardia lamblia,* which causes giardiasis; *Entamoeba histolytica,* which causes amebiasis (amebic dysentery); and *Cryptosporidium. Handwashing is the best way to prevent the spread of parasitic infections.*

G. lamblia is a protozoal parasite that causes superficial invasion, destruction, and inflammation of the mucosa in the small intestine. This organism occurs in cysts and trophozoites (sporozoan parasites). Trophozoites die rapidly after they leave the body in stool. Cysts, however, can remain alive in the right type of environment for weeks or months. Humans who eliminate cysts are infectious. Flies can spread the cysts, and the problem is more common in areas that use human excrement for fertilizer. Humans are hosts to this organism, but beavers and dogs may be reservoirs for infection.

Giardiasis is a well-recognized problem in international travelers, campers, and immunosuppressed patients. In the United States, giardiasis is prevalent and is the most common parasitic infection. This disorder affects only the intestinal system, causing acute diarrhea, chronic diarrhea, or malabsorption syndrome. The acute phase usually is self-limiting, lasting days or weeks. The chronic phase can last for years. Diarrhea is usually mild in both forms, but it can be severe. As stools increase in frequency, they become more watery, greasy, frothy, and malodorous with mucus. Weight loss and weakness are also common. Malabsorption can occur with diarrhea that continues for longer than 3 weeks. Manifestations result from malabsorption of fat, protein, and vitamin B_{12} and lactase deficiency.

Humans are the only known hosts for *E. histolytica* (also known as *amebiasis*). This organism also occurs in cysts and trophozoites. Amebiasis occurs worldwide, but it is most common in tropical areas. Prevalence rates are high in areas with poor sanitation, crowding, and poor nutrition. Amebiasis causes tens of thousands of deaths annually worldwide. The disease causes less severe symptoms and often goes undiagnosed in temperate climates.

E. histolytica either feeds on bacteria in the intestine or invades and

ulcerates the mucosa of the large intestine. The parasite can be limited to the GI tract (intestinal amebiasis), or it can extend outside the intestines (extraintestinal amebiasis). People can have intestinal amebiasis without having any symptoms, or symptoms can range from mild to severe.

Cryptosporidium is manifested by diarrhea. This infection occurs most commonly in immunosuppressed patients, particularly those with human immune deficiency virus (HIV). It can also occur in children and older adults from contaminated swimming pools. (See Chapter 19 for a discussion of HIV infection.)

Chagas disease is caused by the *Trypanosoma cruzi* parasite, which is most commonly transmitted to people in poverty areas of Latin America by the triatomine (kissing) bug. Patients first develop an acute infection, followed by an intermediate asymptomatic period and a chronic infection. Patients with chronic Chagas disease often develop cardiac dysrhythmias or heart failure, as well as colon or esophagus dilation causing impaired digestion and bowel elimination. An estimated 300,000 people in the United States have the disease (most in the southern areas of the United States), which can be transmitted through blood transfusions and organ transplantations. The CDC has targeted Chagas disease as one of five neglected parasitic infections that require public health action as the number of cases is expected to increase (CDC, 2014).

Patient-Centered Collaborative Care

Assessment

A thorough history can help determine potential sources of exposure to parasitic infection. A history of travel to parts of the world where such infections are prevalent increases suspicion for infection with parasites. GI symptoms related to travel may be delayed as long as 1 to 2 weeks after the return home. Immigrants (newcomers) may have the infection upon entering a new country. A nutrition history is especially helpful if several people in a group become ill. Common water supplies or bodies of water may be infected with *Giardia* or *Cryptosporidium.* Trichinosis should be considered if the patient has eaten pork products.

Mild to moderate *E. histolytica* infestation causes the daily passage of several strongly foul-smelling stools, possibly with mucus but without blood, accompanied by abdominal cramping, flatulence (gas), fatigue, and weight loss.

The infected patient usually experiences remissions and recurrences. Severe amebic dysentery is manifested by frequent, more liquid, and foul-smelling stools with mucus *and* blood. Fever up to 104° F (40° C),

tenesmus (feeling the urge to defecate), generalized abdominal tenderness, and vomiting can also occur. The ulcerations of invading amebiasis that occur in the colon can cause pain, bleeding, and obstruction. Ulcerations can also occur in the rectum, resulting in formed stool with blood. Complications are rare but include appendicitis and bowel perforation.

Extraintestinal amebiasis can occur without symptoms of intestinal infection. The most common form is amebic liver abscess, which causes symptoms of fever, pain, and an enlarged liver. The abscess can rupture, and death can result if the infection and complications are not treated.

The diagnosis of *amebiasis* is made by examining the stool for parasites. Because *E. histolytica* is difficult to detect, serial stool examinations are needed if the disease is suspected. The use of sigmoidoscopy may detect ulcerations in the rectum or colon. Exudate obtained during sigmoidoscopic examination is studied for the parasite. The white blood cell (WBC) count can be very high when severe dysentery is present.

The diagnosis of *giardiasis* is also confirmed by the presence of parasites in the stool. Because organisms may not be detected for at least 1 week after symptoms appear, multiple stool samples should be examined.

Interventions

Treatment for all types of *amebiasis* involves the use of amebicide drugs. Metronidazole (Flagyl, Novonidazol) and diloxanide furoate (Entamide) or diloxanide furoate and tetracycline hydrochloride (Sumycin) followed by chloroquine are commonly prescribed. The patient with severe dysentery requires IV fluid replacement and possibly opiates, such as diphenoxylate hydrochloride and atropine sulfate (Lomotil), to control bowel motility. The patient with extraintestinal amebiasis or severe dehydration is hospitalized, especially the older adult. The patient with asymptomatic, mild, or moderate disease is treated with drug therapy on an ambulatory care basis. Therapy effectiveness is based on the examination of at least three stools at 2- to 3-day intervals, starting 2 to 4 weeks after drug therapy has been completed. *Teach patients the importance of keeping their follow-up appointments and taking all drugs as prescribed.*

Treatment for *giardiasis* is drug therapy. Metronidazole is the drug of choice, 250 mg orally 3 times daily for 5 days. Tinidazole (Fasigyn) can be used as an alternative. Stools are examined 2 weeks after treatment to assess for drug effectiveness.

Nursing Safety Priority QSEN

Action Alert

Explain modes of transmission of parasitic infections and means to avoid the spread of infection and recurrent contact with parasitic organisms. *Inform the patient that the infection can be transmitted to others until amebicides effectively kill the parasites. Teach the patient to:*

- Avoid contact with stool.
- Keep toilet areas clean.
- Wash hands meticulously with an antimicrobial soap after bowel movements.
- Maintain good personal hygiene by bathing or showering daily.
- Avoid stool from dogs and beavers.

Advise the patient to avoid sexual practices that allow rectal contact until drug therapy is completed. *All household and sexual partners should have stool examinations for parasites.* If the water supply is suspected as the source, a sample is obtained and sent for analysis. Multiple infections are common in households, often as a result of contaminated water supplies. Well water and water from areas with inadequate or no filtration equipment can be sources of contamination.

Infection with *Cryptosporidium* is usually self-limiting in people who have normal immune function. Drug therapy for patients who are immunosuppressed may include paromomycin (Paromycin), an aminoglycoside antibiotic. Teach patients that this drug can cause dizziness.

Nursing Concepts and Clinical Judgment Review

What might you NOTICE if the patient has impaired digestion and inadequate nutrition as a result of inflammatory intestinal problems?

- Report of nausea
- Vomiting
- Report of epigastric or abdominal pain
- Diarrhea (sometimes bloody)
- Elevated temperature
- Weakness

What should you INTERPRET and how should you RESPOND to a patient with impaired digestion and inadequate nutrition as a result of inflammatory intestinal problems?

Perform and interpret focused physical assessment findings, including:

- Vital signs
- Complete pain assessment
- Skin turgor and mucous membrane dryness
- Abdominal assessment
- Current and previous weight
- History of recent food intake
- History of recent travel

Respond by:

- Preventing pain and aspiration by placing the patient in a sitting position
- Placing an IV catheter (large-bore) to replace fluids
- Providing privacy, and assisting with hygiene
- Providing rest
- Checking laboratory values for hemoglobin and hematocrit (anemia)
- Checking serum electrolytes (dehydration, hypokalemia)
- Giving antidiarrheal drugs if prescribed
- Recording intake and output
- Assisting with ADLs and ambulation as needed

On what should you REFLECT?

- Continue to monitor for vomiting and diarrhea and changes in pain level.
- Think about what you need to document.
- Decide when you might need to call the health care provider or Rapid Response Team (for hospitalized patients).
- Determine what health teaching and community resources may be needed for this patient and family.
- Think about what you can do to help prevent complications of the health problem.

Get Ready for the NCLEX® Examination!

Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Collaborate with a CWOCN, health care provider, and case manager to plan care for patients with IBD. **Teamwork and Collaboration** QSEN

Health Promotion and Maintenance

- Teach patients to use infection control measures to prevent transmission of gastroenteritis as stated in Chart 57-2.
- Teach patients how to self-manage an ileostomy or other surgical diversion, including skin care, pouch management, and stoma assessment (see Chart 57-4).
- Remind patients and families about community resources for IBD, including the United Ostomy Associations of America and the Crohn's and Colitis Foundation of America.

Psychosocial Integrity

- Be aware that all inflammatory bowel diseases (acute and chronic) are very disruptive to one's daily routine; living with IBD requires a lifetime of modifications.
- Recognize that having a chronic bowel disease or an ileostomy impacts the patient's body image and self-esteem; assess for coping strategies that the patient has previously used, and identify personal support systems, such as family members, to assist in coping.

Physiological Integrity

- Assess for the classic clinical manifestations of appendicitis, which include abdominal pain, nausea and vomiting, and abdominal tenderness upon palpation (McBurney's point); some patients also have leukocytosis.
- Recognize that perforation (rupture) of the appendix requires prompt intervention and can result in peritonitis.
- Assess for the key features of peritonitis as listed in Chart 57-1.
- Assess for signs and symptoms of dehydration in patients who have acute and chronic inflammatory bowel disorders.
- Administer antidiarrheal medications as prescribed to decrease stools

and therefore prevent dehydration in patients with acute and chronic inflammatory bowel disorders.
- Be aware that there are two major types of chronic inflammatory bowel disease (IBD): ulcerative colitis (UC) and Crohn's disease; both have similarities but also have differences (see Table 57-2).
- Be alert for GI bleeding in the patient with chronic inflammatory bowel disease (IBD).
- Be aware that patients with Crohn's disease are at high risk for malnutrition as a result of an inability to absorb nutrients via the small intestine.
- Priority problems for patients with ulcerative colitis include diarrhea, pain, and potential for lower GI bleeding.
- Monitor for complications of UC as listed in Table 57-4.
- Provide nursing interventions for patients with IBD as listed in Chart 57-3.
- Teach patients with IBD to avoid GI stimulants, such as alcohol and caffeine; each patient's response to foods differs.
- Administer 5-aminosalicylic acid (5-ASA) drugs as prescribed (e.g., Pentasa) to decrease inflammation in patients with UC; most of these same drugs are also used for Crohn's disease management.
- Administer infliximab (Remicade) or other monoclonal antibody agent as prescribed for patients with Crohn's disease; these drugs may also be useful for those with UC in selected cases.
- Observe for manifestations of lower GI bleeding in patients with chronic inflammatory and diverticular disease.
- Teach patients with diverticulosis to eat a high-fiber diet; diverticulitis requires a low-fiber diet.
- Teach older patients how to self-manage diverticulitis as outlined in Chart 57-6.
- Instruct patients with diverticulosis about nutrition modifications, such as avoiding nuts, foods with seeds, and GI stimulants.
- Be aware that patients with celiac disease (CD) vary in their clinical manifestations; some have no symptoms, some have classic symptoms, and some have atypical symptoms (see Chart 57-7).
- Teach patients with CD about the need to consume a strict gluten-free diet, which avoids wheat and wheat-based products.
- Be aware that GI problems, including diarrhea, may also be caused by parasites and food poisoning.
- Instruct patients with anorectal disorders to use sitz baths, bulk-forming agents (e.g., Metamucil), and stool softeners to decrease pain.

CHAPTER 58

Care of Patients with Liver Problems

Jennifer Powers and Lara Carver

PRIORITY CONCEPTS

- Inflammation
- Infection
- Pain
- Fluid and Electrolyte Balance

Learning Outcomes

Safe and Effective Care Environment

1. Describe the need to collaborate with health care team members to provide care for patients with liver inflammation and necrosis.
2. Identify community resources for patients with chronic liver disease.

Health Promotion and Maintenance

3. Develop a health teaching plan for patients and families to prevent hepatitis and its spread to others.
4. Develop a health teaching plan for patients and families to prevent or slow the progress of alcohol-induced cirrhosis.

Psychosocial Integrity

5. Explain the psychosocial needs of patients with liver problems.

Physiological Integrity

6. Identify risk factors for developing hepatic cirrhosis.
7. Interpret laboratory test findings commonly seen in patients with

cirrhosis.

8. Analyze assessment data from patients with cirrhosis to determine priority patient problems.
9. Develop an evidence-based collaborative plan of care for the patient with late-stage cirrhosis.
10. Describe the role of the nurse in monitoring for and managing potentially life-threatening complications of cirrhosis.
11. Identify emergency interventions for the patient with bleeding esophageal varices.
12. Explain the role of the nurse when assisting with a paracentesis procedure.
13. Describe treatment options for patients with cancer of the liver.
14. Describe the interventions to prevent complications that result from liver transplantation, including infection.

 http://evolve.elsevier.com/Iggy/

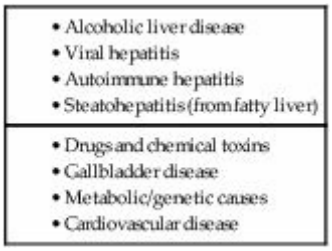
The liver is the largest and one of the most vital internal organs, performing more than 400 functions and affecting every system in the body. When the liver is diseased or damaged, it cannot accomplish these functions. As a result, *digestion, nutrition, and metabolism* can be severely affected. Liver diseases range in severity from mild hepatic inflammation to chronic end-stage cirrhosis.

Cirrhosis

Cirrhosis is extensive, irreversible scarring of the liver, usually caused by a chronic reaction to hepatic inflammation and necrosis. The disease typically develops slowly and has a progressive, prolonged, destructive course resulting in end-stage liver disease. The most common causes for cirrhosis in the United States are chronic alcoholism, chronic viral hepatitis, nonalcoholic steatohepatitis (NASH), bile duct disease, and genetic diseases (Table 58-1).

TABLE 58-1

Common Causes of Cirrhosis



Pathophysiology

Cirrhosis is characterized by widespread fibrotic (scarred) bands of connective tissue that change the liver's normal makeup. inflammation caused by either toxins or disease results in extensive degeneration and destruction of **hepatocytes** (liver cells). As cirrhosis develops, the tissue becomes nodular. These nodules can block bile ducts and normal blood flow throughout the liver. Impairments in blood and lymph flow result from compression caused by excessive fibrous tissue. In early disease, the liver is usually enlarged, firm, and hard. As the pathologic process continues, the liver shrinks in size, resulting in decreased liver function, which can occur in weeks to years. Some patients with cirrhosis have no symptoms until serious complications occur. The impaired liver function results in elevated serum liver enzymes (Pagana & Pagana, 2014).

Cirrhosis of the liver can be divided into several common types, depending on the cause of the disease (McCance et al., 2014):

- Postnecrotic cirrhosis (caused by viral hepatitis [especially hepatitis C] and certain drugs or other toxins)
- Laennec's or alcoholic cirrhosis (caused by chronic alcoholism)
- Biliary cirrhosis (also called *cholestatic;* caused by chronic biliary obstruction or autoimmune disease)

Complications of Cirrhosis

Common problems and complications associated with hepatic cirrhosis depend on the amount of damage sustained by the liver. In **compensated cirrhosis,** the liver is scarred but can still perform essential functions without causing major symptoms. In **decompensated cirrhosis,** liver function is impaired with obvious manifestations of liver failure.

The loss of hepatic function contributes to the development of metabolic abnormalities. Hepatic cell damage may lead to these common complications:

- Portal hypertension
- Ascites and esophageal varices
- Coagulation defects
- Jaundice
- Portal-systemic encephalopathy (PSE) with hepatic coma
- Hepatorenal syndrome
- Spontaneous bacterial peritonitis

Portal Hypertension.

Portal hypertension, a persistent increase in pressure within the portal vein greater than 5 mm Hg, is a major complication of cirrhosis (Minano & Garcia-Tsao, 2010). It results from increased resistance to or obstruction (blockage) of the flow of blood through the portal vein and its branches. The blood meets resistance to flow and seeks collateral (alternative) venous channels around the high-pressure area.

Blood flow backs into the spleen, causing **splenomegaly** (spleen enlargement). Veins in the esophagus, stomach, intestines, abdomen, and rectum become dilated. Portal hypertension can result in ascites (excessive abdominal [peritoneal] fluid), esophageal varices (distended veins), prominent abdominal veins (caput medusae), and hemorrhoids.

Ascites and Gastroesophageal Varices.

Ascites is the collection of free fluid within the peritoneal cavity caused by increased hydrostatic pressure from portal hypertension (McCance et al., 2014). The collection of plasma protein in the peritoneal fluid reduces the amount of circulating plasma protein in the blood. When this decrease is combined with the inability of the liver to produce albumin because of impaired liver cell functioning, the serum colloid osmotic pressure is decreased in the circulatory system. The result is a fluid shift from the vascular system into the abdomen, a form of "third spacing." As a result, the patient may have hypovolemia and edema at

the same time.

Massive ascites may cause renal vasoconstriction, triggering the renin-angiotensin system. This results in sodium and water retention, which increases hydrostatic pressure and the vascular volume and leads to more ascites.

As a result of portal hypertension, the blood backs up from the liver and enters the esophageal and gastric veins. **Esophageal varices** occur when fragile, thin-walled esophageal veins become distended and tortuous from increased pressure. The potential for varices to bleed depends on their size; size is determined by direct endoscopic observation. Varices occur most often in the distal esophagus but can be present also in the stomach and rectum.

Bleeding esophageal varices is a life-threatening medical emergency. Severe blood loss may occur, resulting in shock from hypovolemia. The bleeding may be either **hematemesis** (vomiting blood) or **melena** (black, tarry stools). Loss of consciousness may occur before any observed bleeding. Variceal bleeding can occur spontaneously with no precipitating factors. However, any activity that increases abdominal pressure may increase the likelihood of a variceal bleed, including heavy lifting or vigorous physical exercise. In addition, chest trauma or dry, hard food in the esophagus can cause bleeding.

Patients with portal hypertension may also have **portal hypertensive gastropathy.** This complication can occur with or without esophageal varices. Slow gastric mucosal bleeding occurs, which may result in chronic slow blood loss, occult-positive stools, and anemia.

Splenomegaly (enlarged spleen) results from the backup of blood into the spleen. The enlarged spleen destroys platelets, causing thrombocytopenia (low serum platelet count) and increased risk for bleeding. Thrombocytopenia is often the first clinical sign that a patient has liver dysfunction.

Biliary Obstruction.

In patients with cirrhosis, the production of bile in the liver is decreased. This prevents the absorption of fat-soluble vitamins (e.g., vitamin K). Without vitamin K, clotting factors II, VII, IX, and X are not produced in sufficient quantities and the patient is susceptible to bleeding and easy bruising. These abnormalities are confirmed by coagulation studies. Some patients have a genetic predisposition to obstruction of the bile duct that leads to biliary cirrhosis—usually from gallbladder disease or an autoimmune form of the disease called *primary biliary cirrhosis (PBC).*

Jaundice (yellowish coloration of the skin) in patients with cirrhosis is

caused by one of two mechanisms: hepatocellular disease or intrahepatic obstruction (Fig. 58-1). *Hepatocellular* jaundice develops because the liver cells cannot effectively excrete bilirubin. This decreased excretion results in excessive circulating bilirubin levels. *Intrahepatic obstructive* jaundice results from edema, fibrosis, or scarring of the hepatic bile channels and bile ducts, which interferes with normal bile and bilirubin excretion. Patients with jaundice often report pruritus (itching).

FIG. 58-1 Jaundice as a result of liver dysfunction such as cirrhosis and hepatitis.

Hepatic Encephalopathy.

Hepatic encephalopathy (also called **portal-systemic encephalopathy [PSE]**) is a complex cognitive syndrome that results from liver failure and cirrhosis. Patients report sleep disturbance, mood disturbance, mental status changes, and speech problems early as this complication begins. Hepatic encephalopathy may be reversible with early intervention. Later neurologic symptoms include an altered level of consciousness, impaired thinking processes, and neuromuscular problems.

Hepatic encephalopathy may develop slowly in patients with chronic

liver disease and go undetected until the late stages. Symptoms develop rapidly in acute liver dysfunction. Four stages of development have been identified (Table 58-2). The patient's symptoms may gradually progress to coma or fluctuate among the four stages.

TABLE 58-2

Stages of Hepatic Encephalopathy

Stage I
• Subtle manifestations that may not be recognized immediately • Personality changes • Behavior changes (agitation, belligerence) • Emotional lability (euphoria, depression) • Impaired thinking • Inability to concentrate • Fatigue, drowsiness • Slurred or slowed speech • Sleep pattern disturbances
Stage II
• Continuing mental changes • Mental confusion • Disorientation to time, place, or person • Asterixis (hand flapping)
Stage III
• Progressive deterioration • Marked mental confusion • Stuporous, drowsy but arousable • Abnormal electroencephalogram tracing • Muscle twitching • Hyperreflexia • Asterixis (hand flapping)
Stage IV
• Unresponsiveness, leading to death in most patients progressing to this stage • Unarousable, obtunded • Usually no response to painful stimulus • No asterixis • Positive Babinski's sign • Muscle rigidity • Fetor hepaticus (characteristic liver breath—musty, sweet odor) • Seizures

The exact mechanisms causing hepatic encephalopathy are not clearly understood but probably are the result of the shunting of portal venous blood into the central circulation so that the liver is bypassed. As a result, substances absorbed by the intestine are not broken down or detoxified and may lead to metabolic abnormalities, such as elevated serum ammonia and gamma-aminobutyric acid (GABA). Elevated serum ammonia results from the inability of the liver to detoxify protein by-products and is common in patients with hepatic encephalopathy. However, it is not a clear indicator of the presence of encephalopathy. Some patients may have major impairment without high elevations of serum ammonia, and elevations of ammonia can occur without evidence of encephalopathy.

Factors that may lead to hepatic encephalopathy in patients with cirrhosis include:

- High-protein diet
- Infection
- Hypovolemia (decreased fluid volume)
- Hypokalemia (decreased serum potassium)
- Constipation
- GI bleeding (causes a large protein load in the intestines)
- Drugs (e.g., hypnotics, opioids, sedatives, analgesics, diuretics, illicit drugs)

The prognosis depends on the severity of the underlying cause, the precipitating factors, and the degree of liver dysfunction.

Other Complications.

The development of **hepatorenal syndrome (HRS)** indicates a poor prognosis for the patient with liver failure. It is often the cause of death in these patients. This syndrome is manifested by:

- A sudden decrease in urinary flow (<500 mL/24 hr) (oliguria)
- Elevated blood urea nitrogen (BUN) and creatinine levels with abnormally decreased urine sodium excretion
- Increased urine osmolarity

HRS often occurs after clinical deterioration from GI bleeding or the onset of hepatic encephalopathy. It may also complicate other liver diseases, including acute hepatitis and fulminant liver failure.

Patients with cirrhosis and ascites may develop acute *spontaneous bacterial peritonitis (SBP)*. Those who are particularly susceptible are patients with very advanced liver disease. This may be the result of low concentrations of proteins; proteins normally provide some protection against bacteria.

The bacteria responsible for SBP are typically from the bowel and reach the ascitic fluid after migrating through the bowel wall and transversing the lymphatics. Clinical manifestations vary but may include fever, chills, and abdominal pain and tenderness. However, manifestations can also be minimal with only mild symptoms in the absence of fever. Worsening encephalopathy and increased jaundice may also be present without abdominal symptoms.

The diagnosis of SBP is made when a sample of ascitic fluid is obtained by paracentesis for cell counts and culture. An ascitic fluid leukocyte count of more than 250 polymorphonuclear (PMN) leukocytes may indicate the need for treatment.

Etiology and Genetic Risk

Hepatitis C is the second leading cause of cirrhosis and liver failure in the United States. It is an infectious bloodborne illness that usually causes chronic disease. Inflammation caused by infection over time leads to progressive scarring of the liver. It usually takes decades for cirrhosis to develop, although alcohol use in combination with hepatitis C may speed the process.

Hepatitis B and hepatitis D are the most common causes of cirrhosis worldwide. Hepatitis B also causes inflammation and low-grade damage over decades that can ultimately lead to cirrhosis. Hepatitis D virus can infect the liver but only in people who already have hepatitis B (see discussion of hepatitis on p. 1203).

Cirrhosis may also occur as a result of nonalcoholic fatty liver disease (NAFLD), a rapidly growing health care concern. NAFLD is associated with obesity, diabetes mellitus type 2, and metabolic syndrome. It is the most common cause of liver disease in the world (World Gastroenterology Organisation, 2012). This disease can progress to liver cancer, cirrhosis, or failure, causing a premature death. Up to 25% of Americans may have NAFLD (American Liver Foundation, 2010) (see p. 1208). The Patatin-like phospholipase domain-containing 3 gene (PNPLA3) has been identified as a risk gene for the disease. Hispanics have this gene more often than other ethnic groups and are therefore at the highest risk for NAFLD (Houghton-Rahrig et al., 2014).

Another common cause of cirrhosis is excessive and prolonged alcohol use. Alcohol has a direct toxic effect on the hepatocytes and causes liver inflammation **(alcoholic hepatitis).** The liver becomes enlarged, with cellular degeneration and infiltration by fat, leukocytes, and lymphocytes. Over time, the inflammatory process decreases and the destructive phase increases. Early scar formation is caused by fibroblast infiltration and collagen formation. Damage to the liver tissue progresses as malnutrition and repeated exposure to the alcohol continue. If alcohol is withheld, the fatty infiltration and inflammation are reversible. If alcohol use continues, widespread scar tissue formation and fibrosis infiltrate the liver as a result of cellular necrosis. The long-term use of illicit drugs, such as cocaine, has similar effects on the liver.

Gender Health Considerations

Patient-Centered Care QSEN

The amount of alcohol necessary to cause cirrhosis varies widely from

person to person, and there are gender differences. In women, it may take as few as two or three drinks per day over a minimum of 10 years. In men, perhaps six drinks per day over the same time period may be needed to cause disease. However, a smaller amount of alcohol over a long period of time can increase memory loss from alcohol toxicity of the cerebral cortex. Binge drinking can increase risk for hepatitis and fatty liver.

Incidence and Prevalence

The American Liver Foundation (2011) released the following statistics on the prevalence of liver disease in the United States:

- More than 30 million people in the United States have liver disease—or 1 in 10 Americans.
- Four million Americans have hepatitis C, and more than 1 million Americans have hepatitis B.

Combined, the incidence of chronic liver disease and cirrhosis are the twelfth most common cause of death in the United States, and about 28,000 adults die from them each year.

Patient-Centered Collaborative Care

Assessment

History.

Obtain data from patients with suspected cirrhosis, including age, gender, and employment history, especially history of exposure to alcohol, drugs (prescribed and illicit), and chemical toxins. Keep in mind that all exposures are important regardless of how long ago they occurred. Determine whether there has ever been a needle stick injury. Sexual history and orientation may be important in determining an infectious cause for liver disease, because men having sex with men (MSM) are at high risk for hepatitis A, hepatitis B, and hepatitis C. People with hepatitis can develop cirrhosis (American Liver Foundation, 2011).

Inquire about whether there is a family history of alcoholism and/or liver disease. Ask the patient to describe his or her alcohol intake, including the amount consumed during a given period. Is there a history of illicit drug use, including oral, IV, and intranasal forms? Is there a history of tattoos? If so, when and where were they done? Has the patient been in the military or in prison? Is the patient a health care worker, firefighter, or police officer? For patients previously or currently in an alcohol or drug recovery program, how long have they been sober? This

information is sensitive and often difficult for the patient to answer. Be sure to establish why you are asking these questions, and accept answers in a nonjudgmental manner. Provide privacy during the interview. For many people, the behaviors causing the liver disease occurred years before the onset of their current illness and they are regretful and often embarrassed.

Ask the patient about previous medical conditions, such as an episode of jaundice or acute viral hepatitis, biliary tract disorders (such as cholecystitis), viral infections, surgery, blood transfusions, autoimmune disorders, obesity, altered lipid profile, heart failure, respiratory disorders, or liver injury.

Physical Assessment/Clinical Manifestations.

Because cirrhosis has a slow onset, many of the *early* manifestations are vague and nonspecific. Assess for:

- Fatigue
- Significant change in weight
- GI symptoms, such as anorexia and vomiting
- Abdominal pain and liver tenderness (both of which may be ignored by the patient)

Liver function problems are often found during a routine physical examination or when laboratory tests are completed for an unrelated illness or problem. The patient with *compensated cirrhosis* may be completely unaware that there is a liver problem. The first sign may present before the onset of symptoms when routine laboratory tests, presurgical evaluations, or life and health insurance assessments show abnormalities. These tests could indicate abnormal liver function or thrombocytopenia, requiring a more thorough diagnostic workup.

The development of late signs of *advanced cirrhosis* (also called "end-stage liver failure") usually cause the patient to seek medical treatment. GI bleeding, jaundice, ascites, and spontaneous bruising indicate poor liver function and complications of cirrhosis.

Thoroughly assess the patient with liver dysfunction or failure because it affects every body system. The clinical picture and course vary from patient to patient depending on the severity of the disease. Assess for:

- Obvious yellowing of the skin (jaundice) and sclerae (icterus)
- Dry skin
- Rashes
- Purpuric lesions, such as **petechiae** (round, pinpoint, red-purple lesions) or **ecchymoses** (large purple, blue, or yellow bruises)
- Warm and bright red palms of the hands (palmar erythema)

- Vascular lesions with a red center and radiating branches, known as **"spider angiomas"** (telangiectases, spider nevi, or vascular spiders), on the nose, cheeks, upper thorax, and shoulders
- Ascites (abdominal fluid)
- Peripheral dependent edema of the extremities and sacrum
- Vitamin deficiency (especially fat-soluble vitamins A, D, E, and K)

Abdominal Assessment.

Massive ascites can be detected as a distended abdomen with bulging flanks (Fig. 58-2). The umbilicus may protrude, and dilated abdominal veins (caput medusae) may radiate from the umbilicus. Ascites can cause physical problems. For example, orthopnea and dyspnea from increased abdominal distention can interfere with lung expansion. The patient may have difficulty maintaining an erect body posture, and problems with balance may affect walking. Inspect and palpate for the presence of inguinal or umbilical hernias, which are likely to develop because of increased intra-abdominal pressure. *Minimal* ascites is often more difficult to detect, especially in the obese patient.

FIG. 58-2 Patient with abdominal ascites in late-stage cirrhosis.

When performing an assessment of the abdomen, keep in mind that **hepatomegaly** (liver enlargement) occurs in many cases of early cirrhosis. Splenomegaly is common in nonalcoholic causes of cirrhosis. As the liver deteriorates, it may become hard and small.

Measure the patient's abdominal girth to evaluate the progression of ascites (see Fig. 58-2). To measure abdominal girth, the patient lies flat while the nurse or other examiner pulls a tape measure around the largest diameter (usually over the umbilicus) of the abdomen. The girth is measured at the end of exhalation. Mark the abdominal skin and flanks to ensure the same tape measure placement on subsequent readings. *Taking daily weights, however, is the most reliable indicator of fluid retention.*

Other Physical Assessment.

Observe vomitus and stool for blood. This may be indicated by frank blood in the excrement or by a positive fecal occult blood test (FOBT) (Hema-Check, Hematest). Gastritis, stomach ulceration, or oozing esophageal varices may be responsible for the blood in the stool. Note the presence of **fetor hepaticus,** which is the distinctive breath odor of chronic liver disease and hepatic encephalopathy and is characterized by a fruity or musty odor.

Amenorrhea (no menstrual period) may occur in women, and men may exhibit testicular atrophy, **gynecomastia** (enlarged breasts), and impotence as a result of inactive hormones. Patients with problems of the hematologic system caused by hepatic failure may have bruising and petechiae (small, purplish hemorrhagic spots on the skin).

Continually assess the patient's neurologic function. Subtle changes in mental status and personality often progress to coma—a late complication of encephalopathy. Monitor for **asterixis**—a coarse tremor characterized by rapid, nonrhythmic extensions and flexions in the wrists and fingers (hand-flapping).

Psychosocial Assessment.

The patient with hepatic cirrhosis may undergo subtle or obvious personality, cognitive, and behavior changes, such as agitation. He or she may experience sleep pattern disturbances or may exhibit signs of emotional lability (fluctuations in emotions), euphoria (a very elevated mood), or depression. A psychosocial assessment identifies needs and helps guide care.

Repeated hospitalizations are common for patients with cirrhosis. It is a life-altering chronic disease, impacting not only the patient but also the immediate and extended family members and significant others. There are significant emotional, physical, and financial changes. Substance use may continue even as health worsens. It is important, whenever possible, to use resources available to these patients and their families. Collaborate with social workers, substance use counselors, and mental

health/behavioral health care professionals as needed for patient assessment and management.

Part of the psychosocial assessment is determining if the patient is alcohol-dependent. If this is the case, observe and prepare for alcohol withdrawal (Donnelly et al., 2012). Care of the patient experiencing withdrawal can be a medical emergency. Consult mental health textbooks or references for this chapter for more information about caring for the alcohol-dependent patient.

NCLEX Examination Challenge

Physiological Integrity

A client previously diagnosed with liver cirrhosis visits the medical clinic. What assessment findings does the nurse expect in this client? **Select all that apply.**

A Ecchymosis
B Soft abdomen
C Moist, clammy skin
D Jaundice
E Ankle edema
F Fever

Laboratory Assessment.

Laboratory study abnormalities are common in patients with liver disease (Table 58-3). Serum levels of *aspartate aminotransferase* (AST), *alanine aminotransferase* (ALT), and *lactate dehydrogenase* (LDH) are typically elevated because these enzymes are released into the blood during hepatic inflammation. However, as the liver deteriorates, the hepatocytes may be unable to create an inflammatory response and the AST and ALT may be normal. ALT levels are more specific to the liver, whereas AST can be found in muscle, kidney, brain, and heart. An AST/ALT ratio greater than 2 is usually found in alcoholic liver disease (Pagana & Pagana, 2014).

TABLE 58-3

Assessment of Abnormal Laboratory Findings in Liver Disease

ABNORMAL FINDING	SIGNIFICANCE
Serum Enzymes	
Elevated serum aspartate aminotransferase (AST)	Hepatic cell destruction, hepatitis
Elevated serum alanine aminotransferase (ALT)	Hepatic cell destruction, hepatitis (most specific indicator)
Elevated lactate dehydrogenase (LDH)	Hepatic cell destruction
Elevated serum alkaline phosphatase	Obstructive jaundice, hepatic metastasis
Elevated gamma-glutamyl transpeptidase (GGT)	Biliary obstruction, cirrhosis
Bilirubin	
Elevated serum total bilirubin	Hepatic cell disease
Elevated serum direct conjugated bilirubin	Hepatitis, liver metastasis
Elevated serum indirect unconjugated bilirubin	Cirrhosis
Elevated urine bilirubin	Hepatocellular obstruction, viral or toxic liver disease
Elevated urine urobilinogen	Hepatic dysfunction
Decreased fecal urobilinogen	Obstructive liver disease
Serum Proteins	
Increased serum total protein	Acute liver disease
Decreased serum total protein	Chronic liver disease
Decreased serum albumin	Severe liver disease
Elevated serum globulin	Immune response to liver disease
Other Tests	
Elevated serum ammonia	Advanced liver disease or portal-systemic encephalopathy (PSE)
Prolonged prothrombin time (PT) or international normalized ratio (INR)	Hepatic cell damage and decreased synthesis of prothrombin

Increased *alkaline phosphatase* and gamma-glutamyl transpeptidase (GGT) levels are caused by biliary obstruction and therefore may increase in patients with cirrhosis. Alkaline phosphatase is a nonspecific bone, intestinal, and liver enzyme. However, alkaline phosphatase also increases when bone disease, such as osteoporosis, is present. Total serum *bilirubin* levels also rise. Indirect bilirubin levels increase in patients with cirrhosis because of the inability of the failing liver to excrete bilirubin. Therefore bilirubin is present in the urine (urobilinogen) in increased amounts. Fecal urobilinogen concentration is decreased in patients with biliary tract obstruction. These patients have light- or clay-colored stools.

Total serum *protein* and *albumin* levels are decreased in patients with severe or chronic liver disease as a result of decreased synthesis by the liver (Pagana & Pagana, 2014). Loss of osmotic "pull" proteins like albumin promotes the movement of intravascular fluid into the interstitial tissues (e.g., ascites). Prothrombin time/*international normalized ratio* (PT/INR) is prolonged because the liver decreases the

production of prothrombin. The platelet count is low, resulting in a characteristic thrombocytopenia of cirrhosis. Anemia may be reflected by decreased red blood cell (RBC), hemoglobin, and hematocrit values. The white blood cell (WBC) count may also be decreased. *Ammonia* levels are usually elevated in patients with advanced liver disease. Serum creatinine may be elevated in patients with deteriorating kidney function. Dilutional hyponatremia (low serum sodium) may occur in patients with ascites.

Imaging Assessment.

Plain x-rays of the abdomen may show hepatomegaly, splenomegaly, or massive ascites. A CT scan may be requested.

MRI is another test used to diagnose the patient with liver disease. It can reveal mass lesions, giving additional specific information. This information is helpful in determining whether the condition is malignant or benign.

Other Diagnostic Assessment.

Ultrasound (US) of the liver is often the first assessment for a person with suspected liver disease to detect ascites, hepatomegaly, and splenomegaly. It can also determine the presence of biliary stones or biliary duct obstruction. Liver US is useful in detecting portal vein thrombosis and evaluating whether the direction of portal blood flow is normal.

Some patients being assessed for liver disease require biopsies to determine the exact pathology and the extent of disease progression. This procedure can be problematic because a large number of patients are at risk for bleeding. Even a **percutaneous** (through the skin) biopsy can pose a significant risk to the patient. To minimize this risk, an interventional radiologist can perform a liver biopsy using a long sheath through a jugular vein that then is threaded into the hepatic vein and liver. A tissue sample is obtained for microscopic evaluation. If a biopsy procedure is not possible, a radioisotope liver scan may be used to identify cirrhosis or other diffuse disease.

The physician may request *arteriography* if US is not conclusive in finding portal vein thrombosis. To evaluate the portal vein and its branches, a portal venogram may be performed instead, by passing a catheter into the liver and into the portal vein. This procedure is described on p. 1200 in the Transjugular Intrahepatic Portal-Systemic Shunt section.

The physician may perform an **esophagogastroduodenoscopy (EGD)** to directly visualize the upper GI tract to detect complications of liver

failure. These complications may include bleeding or oozing esophageal varices, stomach irritation and ulceration, or duodenal ulceration and bleeding. EGD is performed by introducing a flexible fiberoptic endoscope into the mouth, esophagus, and stomach while the patient is under moderate sedation. A camera attached to the scope permits direct visualization of the mucosal lining of the upper GI tract. An **endoscopic retrograde cholangiopancreatography (ERCP)** uses the endoscope to inject contrast material via the sphincter of Oddi to view the biliary tract and allow for stone removals, sphincterotomies, biopsies, and stent placements if required. These procedures are described in more detail in Chapter 52.

Analysis

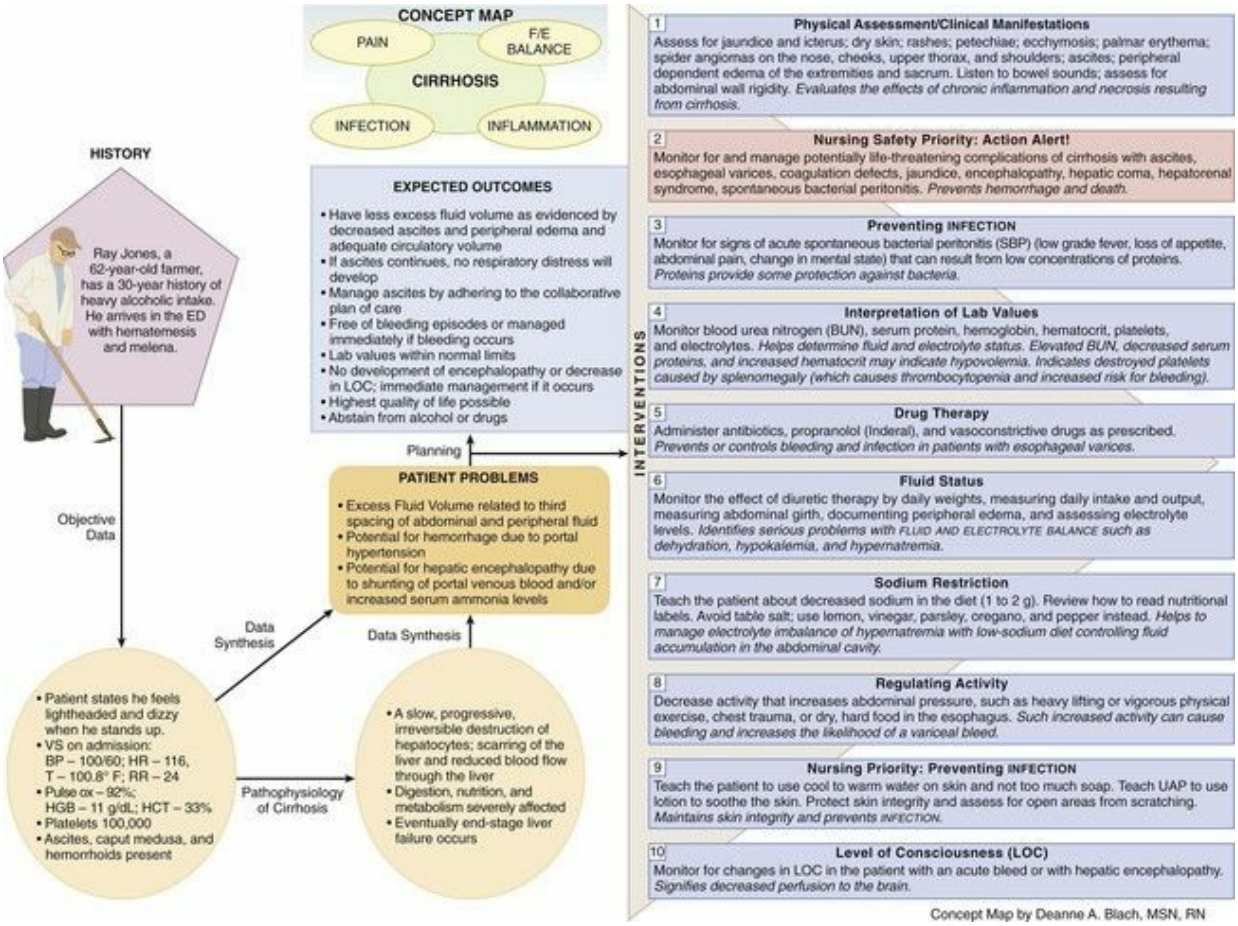
The priority NANDA-I nursing diagnoses and collaborative problems for patients with cirrhosis include:
1. Excess Fluid Volume related to third spacing of abdominal and peripheral fluid (NANDA-I)
2. Potential for hemorrhage due to portal hypertension
3. Potential for hepatic encephalopathy due to shunting of portal venous blood and/or increased serum ammonia levels

Planning and Implementation

Managing Fluid Volume

Planning: Expected Outcomes.

The patient with cirrhosis is expected to have less excess fluid volume as evidenced by decreased ascites and peripheral edema and adequate circulatory volume. If ascites continues, the patient will not have respiratory distress and will manage ascites by adhering to the collaborative plan of care (see the Concept Map for liver failure due to cirrhosis on p. 1198).



Interventions.

Fluid accumulations are minimal during the early stages of ascites. Therefore interventions are aimed at preventing the accumulation of additional fluid and moving the existing fluid collection. Nonsurgical treatment measures are used to treat ascites in most cases.

Supportive measures to control abdominal ascites include nutrition therapy, drug therapy, paracentesis, and respiratory support. The patient's fluid and electrolyte balance is also carefully monitored. If the patient is jaundiced, he or she will likely scratch the skin because the excess bilirubin products cause irritation and pruritus (itching).

Nursing Safety Priority QSEN

Action Alert

For skin irritation and pruritus associated with jaundice, teach the patient to use cool rather than warm water on the skin and to not use an excessive amount of soap. Teach unlicensed assistive personnel to use lotion to soothe the skin. Assess for open skin areas from scratching, which could become infected.

Nutrition Therapy.

The health care provider usually places the patient with abdominal ascites on a low-sodium diet as an initial means of controlling fluid accumulation in the abdominal cavity. The amount of daily sodium (Na^+) intake restriction varies, but a 1- to 2-gram (2000 mg) Na^+ restriction may be tried first. In collaboration with the dietitian, explain the purpose of the restriction and advise the patient and family to read the sodium content labels on all food and beverages. Table salt should be completely excluded. Low-sodium diets may be distasteful, so suggest alternative flavoring additives such as lemon, vinegar, parsley, oregano, and pepper. Remind the patient that seasoned and salty food is an acquired taste; in time, he or she will become used to the decrease in dietary sodium.

In general, patients with late-stage cirrhosis are malnourished and have multiple dietary deficiencies. Vitamin supplements such as thiamine (due to alcohol withdrawal), folate, and multivitamin preparations are typically added to the IV fluids because the liver cannot store vitamins. For patients with biliary cirrhosis, bile may not be available for fat-soluble vitamin transport and absorption. Oral vitamins are prescribed when IV fluid administration is discontinued.

Drug Therapy.

The health care provider usually prescribes a *diuretic* to reduce fluid accumulation and to prevent cardiac and respiratory problems. Monitor the effect of diuretic therapy by weighing the patient daily, measuring daily intake and output, measuring abdominal girth, documenting peripheral edema, and assessing electrolyte levels. Serious fluid and electrolyte imbalances, such as dehydration, hypokalemia (decreased potassium), and hyponatremia (decreased sodium), may occur with loop diuretic therapy. Depending on the diuretic selected, the provider may prescribe an oral or IV potassium supplement. Some clinicians prescribe furosemide (Lasix) and spironolactone (Aldactone) as a combination diuretic therapy for the treatment of ascites. Because these drugs work differently, they are used for maintenance of sodium and potassium balance. For example, furosemide causes potassium loss, whereas spironolactone conserves it in the body.

All patients with ascites have the potential to develop **spontaneous bacterial peritonitis (SBP)** from bacteria in the collected ascitic fluid. In some patients, mild symptoms such as low-grade fever and loss of appetite occur. In others, there may be abdominal pain, fever, and change in mental status. When performing an abdominal assessment, listen for

bowel sounds and assess for abdominal wall rigidity. Quinolones such as norfloxacin (Noroxin) are the drugs of choice for SBP. If the patient is allergic to this class of *antibiotics*, combination antibiotics like trimethoprim-sulfamethoxazole (Bactrim) are given.

Paracentesis.

For some patients, abdominal **paracentesis** may be needed. Nursing implications associated with this procedure are described in Chart 58-1. The procedure is performed at the bedside, in an interventional radiology department, or in an ambulatory care setting. The physician inserts a trocar catheter or drain into the abdomen to remove the ascitic fluid from the peritoneal cavity. This procedure is done using ultrasound for added safety. In some situations, a short-term ascites drain catheter may be placed while the patient is awaiting surgical intervention, or tunneled ascites drains (e.g., PleurX drains) can allow a patient or family caregiver to drain ascitic fluid at home.

Chart 58-1 Best Practice for Patient Safety & Quality Care QSEN

The Patient with Paracentesis

- Explain the procedure, and answer patient questions.
- Obtain vital signs, including weight.
- *Ask the patient to void before the procedure to prevent injury to the bladder!*
- Position the patient in bed with the head of the bed elevated.
- Monitor vital signs per protocol or physician's request.
- Measure the drainage, and record accurately.
- Describe the collected fluid.
- Label and send the fluid for laboratory analysis; document in the patient record that specimens were sent.
- After the physician removes the catheter, apply a dressing to the site; assess for leakage.
- Maintain bedrest per protocol.
- Weigh the patient after the paracentesis; document in the patient record weight both before and after paracentesis.

If SBP is suspected, a sample of fluid is withdrawn and sent for cell count and culture. If the patient has symptoms of infection, the physician may prescribe antibiotics while awaiting the culture results.

Respiratory Support.

Excessive ascitic fluid volume may cause the patient to have respiratory problems. He or she may develop *hepatopulmonary syndrome.* Dyspnea develops as a result of increased intra-abdominal pressure, which limits thoracic expansion and diaphragmatic excursion. Auscultate lungs every 4 to 8 hours for crackles that could indicate pulmonary complications, depending on the patient's overall condition.

Nursing Safety Priority QSEN

Action Alert

For the patient with hepatopulmonary syndrome, monitor his or her oxygen saturation with pulse oximetry. If needed, apply oxygen therapy to ease breathing. Elevate the head of the bed to at least 30 degrees or as high as the patient wants to improve breathing. This position, with his or her feet elevated to decrease dependent ankle edema, often relieves dyspnea. Weigh the patient daily, or delegate and supervise this activity.

fluid and electrolyte balance problems are common as a result of the disease or treatment. Laboratory tests, such as blood urea nitrogen (BUN), serum protein, hematocrit, and electrolytes, help determine fluid and electrolyte status. An elevated BUN, decreased serum proteins, and increased hematocrit may indicate hypovolemia.

If medical management fails to control ascites, the physician may choose to divert ascites into the venous system by creating a shunt. Patients with ascites are poor surgical risks. The transjugular intrahepatic portal-systemic shunt (TIPS) is a nonsurgical procedure that is used to control long-term ascites and to reduce variceal bleeding. This procedure is described in the discussion of Interventions in the Preventing or Managing Hemorrhage section that follows.

NCLEX Examination Challenge

Psychosocial Integrity

The nurse is providing teaching for a client scheduled for a paracentesis. Which statement by the client indicates the teaching has been successful?

A "I must not use the bathroom prior to the procedure."
B "I will lie on my stomach while the procedure is performed."
C "I will not be allowed to eat or drink anything the night before

surgery."

D "The physician will likely remove 2 to 3 liters of fluid from my abdomen."

Preventing or Managing Hemorrhage

Planning: Expected Outcomes.

The patient is expected to be free of bleeding episodes. However, if he or she has a hemorrhage, it is expected to be controlled by prompt, evidence-based interdisciplinary interventions. Esophageal variceal bleeds are the most common type of upper GI bleeding.

Interventions.

All patients with cirrhosis should be screened for esophageal varices by endoscopy to detect them early *before they bleed.* If patients have varices, they are placed on preventive therapy. If acute bleeding occurs, early interventions are used to manage it. *Because massive esophageal bleeding can cause rapid blood loss, emergency interventions are needed.*

Drug Therapy.

The role of early drug therapy is to *prevent* bleeding and infection in patients who have varices. A nonselective *beta-blocking agent* such as propranolol (Inderal) is usually prescribed to prevent bleeding. By decreasing heart rate and the hepatic venous pressure gradient, the chance of bleeding may be reduced (Felicilda-Reynaldo, 2012b).

Up to 20% of cirrhotic patients who are admitted to the hospital due to upper GI bleeding have bacterial infections, and even more patients develop health care–associated infections, usually urinary tract infections or pneumonia (McCance et al., 2014). Infection is one of the most common indicators that patients will have an acute variceal bleed (AVB). Therefore cirrhotic patients with GI bleeding should receive *antibiotics* when admitted to the hospital.

If bleeding occurs, the health care team intervenes quickly to control it by combining vasoactive drugs with endoscopic therapies. *Vasoactive* drugs, such as vasopressin and octreotide acetate (Sandostatin), reduce blood flow through vasoconstriction to decrease portal pressure. Octreotide also suppresses secretion of gastrin, serotonin, and intestinal peptides, which decreases GI blood flow to help with pressure reduction within the varices (Felicilda-Reynaldo, 2012b).

Endoscopic Therapies.

Endoscopic therapies include ligation of the bleeding veins or sclerotherapy. Both procedures have been very effective in controlling bleeding and improving patient survival rates. Esophageal varices may be managed with **endoscopic variceal ligation (EVL) (banding).** This procedure involves the application of small "0" bands around the base of the varices to decrease the blood supply to the varices. The patient is unaware of the bands, and they cause no discomfort.

Endoscopic sclerotherapy (EST), also called **injection sclerotherapy**, may be done to stop bleeding. The varices are injected with a sclerosing agent via a catheter. This procedure is associated with complications such as mucosal ulceration, which could result in further bleeding.

Rescue Therapies.

If rebleeding occurs, rescue therapies are used. These procedures include a second endoscopic procedure, balloon tamponade and esophageal stents, and shunting procedures. Short-term esophagogastric balloon tamponade using a Minnesota or **Sengstaken-Blakemore tube** with esophageal stents is a very effective way to control bleeding. However, the procedure can cause potentially life-threatening complications, such as aspiration, asphyxia, and esophageal perforation (Augustin et al., 2010). Similar to a nasogastric tube, the tube is placed through the nose and into the stomach. An attached balloon is inflated to apply pressure to the bleeding variceal area. Before this tamponade, the patient is usually intubated and placed on a mechanical ventilator to protect the airway. This therapy is used if the patient is not able to have a second endoscopy or TIPS procedure.

Transjugular Intrahepatic Portal-Systemic Shunt.

The transjugular intrahepatic portal-systemic shunt (TIPS) is a nonsurgical procedure performed in interventional radiology departments. This procedure is used for patients who have not responded to other modalities for hemorrhage or long-term ascites. If time permits, patients have a Doppler ultrasound to assess jugular vein anatomy and patency. The patient receives heavy IV sedation or general anesthesia for this procedure. The radiologist places a large sheath through the jugular vein. A needle is guided through the sheath and pushed through the liver into the portal vein. A balloon enlarges this tract, and a stent keeps it open. Most patients also have a Doppler ultrasound study of the liver after the TIPS procedure to record the blood flow through the shunt.

Serious complications of TIPS are not common. Patients are usually

discharged in 1 or 2 days and are followed up with ultrasounds for the first year after the shunt is placed. Some shunts require re-opening at least once during the first year as an ambulatory care procedure.

Other Interventions.

Depending on the procedure done to control esophageal bleeding, patients usually have a nasogastric tube (NGT) inserted to detect any new bleeding episodes. Patients often receive packed red blood cells, fresh frozen plasma, dextran, albumin, and platelets through large-bore IV catheters.

Monitor vital signs every hour, and check coagulation studies, including prothrombin time (PT), partial thromboplastin time (PTT), platelet count, and international normalized ratio (INR). Additional interventions for upper GI bleeding are discussed in Chapter 55.

Preventing or Managing Hepatic Encephalopathy

Planning: Expected Outcomes.

The patient is expected to be free of encephalopathy. However, if it occurs, it is expected that the interdisciplinary team will intervene early to prevent further health problems or death.

Interventions.

The poorly functioning liver cannot convert ammonia and other by-products of protein metabolism to a less toxic form. They are carried by the circulatory system to the brain, where they affect cerebral function. Interventions are planned around the management of slowing or stopping the accumulation of ammonia in the body.

Because ammonia is formed in the GI tract by the action of bacteria on protein, nonsurgical treatment measures to decrease ammonia production include dietary limitations and drug therapy to reduce bacterial breakdown.

Nutrition Therapy.

Patients with cirrhosis have increased nutritional requirements—high-carbohydrate, moderate-fat, and high-protein foods. However, the diet may be changed for those who have elevated serum ammonia levels with signs of encephalopathy. Patients should have a moderate amount of protein and fat foods and simple carbohydrates. Strict protein restrictions are not required because patients need protein for healing. In collaboration with the dietitian, be sure to include family members or

significant others in nutrition counseling. The patient is often weak and unable to remember complicated guidelines. Brief, simple directions regarding dietary dos and don'ts are recommended. Keep in mind any financial, cultural, or personal preferences when discussing food choices, as well as the patient's food allergies.

Drug Therapy.

Drugs are used sparingly because they are difficult for the failing liver to metabolize. In particular, opioid analgesics, sedatives, and barbiturates should be restricted, especially for the patient with a history of encephalopathy.

Several types of drugs, however, may eliminate or reduce ammonia levels in the body. These include lactulose (e.g., Evalose, Heptalac) or lactitol and nonabsorbable antibiotics (Felicilda-Reynaldo, 2012a). The health care provider may prescribe *lactulose* (or lactitol) to promote the excretion of ammonia in the stool. This drug is a viscous, sticky, sweet-tasting liquid that is given either orally or by NG tube. The purpose is to obtain a laxative effect. Cleansing the bowels may rid the intestinal tract of the toxins that contribute to encephalopathy. It works by increasing osmotic pressure to draw fluid into the colon and prevents absorption of ammonia in the colon. The drug may be prescribed to the patient who has manifested signs of encephalopathy, regardless of the stage. The desired effect of the drug is production of two or three soft stools per day and a decrease in patient confusion caused by this complication.

Observe for response to lactulose. The patient may report intestinal bloating and cramping. Serum ammonia levels may be monitored but do not always correlate with symptoms. Hypokalemia and dehydration may result from excessive stools. Remind unlicensed nursing personnel to help the patient with skin care if needed to prevent breakdown caused by excessive stools.

Several *nonabsorbable antibiotics* may be given if lactulose does not help the patient meet the desired outcome or if he or she cannot tolerate the drug. These drugs should not be given together. Older adults can become weak and dehydrated from having multiple stools. Neomycin sulfate (Mycifradin) or rifaximin (Xifaxan), both broad-spectrum antibiotics, may be given to act as an intestinal antiseptic (Felicilda-Reynaldo, 2012a). These drugs destroy the normal flora in the bowel, diminishing protein breakdown and decreasing the rate of ammonia production. Maintenance doses of neomycin are given orally but may also be administered as a retention enema. Long-term use has the potential for kidney toxicity and therefore is not commonly used. It cannot be used for patients with

existing kidney disease.

Metronidazole (Flagyl, Novonidazol) is another broad-spectrum antibiotic with similar action to neomycin, but it can cause peripheral neuropathy. Vancomycin (Vancocin) may also be given, but its long-term use can lead to resistance (Felicilda-Reynaldo, 2012a).

Frequently assess for changes in level of consciousness and orientation. Check for asterixis (liver flap) and fetor hepaticus (liver breath). These signs suggest worsening encephalopathy. Thiamine supplements and benzodiazepines may be needed if the patient is at risk for alcohol withdrawal.

Clinical Judgment Challenge

Safety; Evidence-Based Practice QSEN

A 60-year-old man is admitted to the emergency department (ED) with a report of vomiting bright red blood. He has had liver cirrhosis for the past 10 years and states that he has been drinking heavily since his wife died last year. His blood pressure is 106/68, and his pulse rate is 94. His abdomen is distended, and he is having some difficulty breathing; his respirations are 34 per minute. You are assigned to care for this patient.

1. For what complications is this patient at risk and why? What causes these complications?
2. In what position will you place the patient and why? What evidence supports your answer? Why do you think he has tachypnea?
3. The physician suspects that he has bleeding gastroesophageal varices. What laboratory tests will he likely request and why?
4. Vasopressin is prescribed for the patient, and several large-bore IV lines are inserted. What is the purpose of this drug for this patient?
5. How will you know if the drug was effective?
6. If the drug is not effective in treating the patient, what other options are available for his management?

Community-Based Care

If the patient with late-stage cirrhosis survives life-threatening complications, he or she is usually discharged to the home or to a long-term care facility after treatment measures have managed the acute medical problems. A home care referral may be needed if the patient is discharged to the home. These chronically ill patients are often readmitted multiple times, and community-based care is aimed at optimizing comfort, promoting independence, supporting caregivers,

and preventing rehospitalization. Patients with end-stage disease may benefit from hospice care. Collaborate with the case manager (CM) or other discharge planner to coordinate interdisciplinary continuing care.

Home Care Management.

In collaboration with the patient, family, and case manager, assess physical adaptations needed to prepare the patient's home for recovery. Referrals for physical therapy, nutrition therapy, and transportation for physician and laboratory follow-up may be needed. The patient's rest area needs to be close to a bathroom because diuretic and/or lactulose therapy increases the frequency of urination and stools. If the patient has difficulty reaching the toilet, additional equipment (e.g., bedside commode) is necessary. Special adult-size incontinence pads or briefs may be helpful if the patient has an altered mental status and has incontinence. If the patient has shortness of breath from massive ascites, elevating the head of the bed and maintaining the patient in a semi-Fowler's to high-Fowler's position may help alleviate respiratory distress. Alternatively, a reclining chair with an elevated foot rest may be used.

Self-Management Education.

The patient is discharged to the home setting with an individualized teaching plan (Chart 58-2) that includes nutrition therapy, drug therapy, and alcohol abstinence, if needed. The patient who has a tunneled ascites drain (e.g., PleurX drain) will need to be taught how to access the drain and remove excess fluid. *Review the home care instructions that are provided with the drainage system with both the patient and family/caregiver. Remind them to not remove more than 2000 mL from the abdomen at one time to prevent hypovolemic shock.*

Chart 58-2 Patient and Family Education: Preparing for Self-Management

Cirrhosis

Nutrition Therapy

- Consume a diet that adheres to the guidelines set by your physician, nurse, or dietitian.
- If you have excessive fluid in your abdomen, follow the low-sodium diet prescribed for you.
- Eat small, frequent meals that are nutritionally well balanced.

- Include in your diet daily supplemental liquids (e.g., Ensure or Ensure Plus) and a multivitamin.

Drug Therapy

- Take the diuretic or preventive beta blocker prescribed for you. If you experience muscle weakness, irregular heartbeat, or light-headedness, contact your health care provider right away.
- Take the medication prescribed for you that helps prevent gastrointestinal bleeding.
- Take the lactulose syrup as prescribed to maintain two or three bowel movements every day.
- Do *not* take any other medication (prescribed or over the counter) unless specifically prescribed by your health care provider.

Alcohol Abstinence

- Do not consume any alcohol.
- Seek support services for help if needed.

The patient with encephalopathy often finds that small, frequent meals are best tolerated. If the patient's nutritional intake or albumin/pre-albumin is decreased after discharge, multivitamin supplements and supplemental liquid feedings (e.g., Ensure, Boost) are usually needed. Teach patients to avoid excessive vitamins and minerals that can be toxic to the liver, such as fat-soluble vitamins, excessive iron supplements, and niacin. Remind patients to check with their health care provider before taking any vitamin supplement.

The patient is often discharged while receiving diuretics. Provide instructions regarding the health care provider's prescription for the diuretic. Teach about side effects of therapy, such as hypokalemia. The patient may need to take a potassium supplement if he or she is taking a diuretic that is not potassium-sparing.

If the patient has had problems with bleeding from gastric ulcers, the primary care provider may prescribe an H_2-receptor antagonist agent or proton pump inhibitor to reduce acid reflux (see Chapter 55). Patients who have had episodes of spontaneous bacterial peritonitis (SBP) may be on a daily maintenance antibiotic.

Teach family members how to recognize signs of encephalopathy and to contact the health care provider if these signs develop. Reinforce that constipation, bleeding, and infections can increase the risk for encephalopathy.

Advise the patient to avoid all over-the-counter drugs, especially

NSAIDs and hepatic toxic herbs, vitamins, and minerals. Reinforce the need to keep appointments for follow-up medical care. Remind the patient and family to notify the health care provider immediately if any GI bleeding (overt bleeding or melena) is noted so that re-evaluation can begin quickly.

Nursing Safety Priority QSEN

Action Alert

One of the most important aspects of ongoing care for the patient with cirrhosis is to stress the need to avoid acetaminophen (Tylenol), alcohol, and illicit drugs. By avoiding these substances, the patient may:

- Prevent further fibrosis of the liver from scarring
- Allow the liver to heal and regenerate
- Prevent gastric and esophageal irritation
- Reduce the incidence of bleeding
- Prevent other life-threatening complications

Health Care Resources.

The patient with chronic cirrhosis may require a home care nurse for several visits after hospital discharge. The home care nurse can monitor the effectiveness of treatment in controlling ascites. The encephalopathic patient may need to be monitored for adherence to drug therapy and alcohol abstinence, if appropriate. Individual and group therapy sessions may be arranged to assist patients in dealing with alcohol abstinence if they are too ill to attend a formal treatment program. Because some patients may have alienated relatives over the years because of substance use, it may be necessary to help them identify a friend, neighbor, or person in their recovery group for support. If needed, refer the patient and family to self-help groups, such as Alcoholics Anonymous and Al-Anon.

The patient with cirrhosis may also desire spiritual or other psychosocial support. Finances are frequently a problem for the chronically ill patient and family; social support and community services need to be identified. The American Liver Foundation (www.liverfoundation.org) and American Gastroenterological Association (www.gastro.org) are excellent sources for more information about liver disease.

For patients who are not candidates for liver transplantation, address end-of-life issues. Discuss options such as hospice care with patients and

their families (see Chapter 7). Be aware that they will go through a grieving process and will perhaps be in denial or very angry.

Evaluation: Outcomes

Evaluate the care of the patient with cirrhosis based on the identified priority patient problems. The expected outcomes include that the patient will:

- Have a decrease in or have no ascites
- Have electrolytes within normal limits (WNL)
- Not have hemorrhage or will be managed immediately if bleeding occurs
- Not develop encephalopathy or will be managed immediately if it occurs
- Have the highest quality of life possible
- Successfully abstain from alcohol or drugs (if disease is caused by these substances)

NCLEX Examination Challenge

Physiological Integrity

Which intervention will the nurse include in the plan of care for a client with severe liver disease?

A Encourage the client to eat a low-protein, high-carbohydrate diet.
B Administer Kayexalate enemas.
C Instruct the client to eat a high-protein, low-carbohydrate diet.
D Teach the client to participate in frequent, vigorous physical activities.

Hepatitis

❖ Pathophysiology

Hepatitis is the widespread inflammation of liver cells. *Viral* hepatitis is the most common type and can be either acute or chronic. Less common types of hepatitis are caused by chemicals, drugs, and some herbs. This section discusses hepatitis caused by a virus. **Viral hepatitis** results from an infection caused by one of five major categories of viruses:

- Hepatitis A virus (HAV)
- Hepatitis B virus (HBV)
- Hepatitis C virus (HCV)
- Hepatitis D virus (HDV)
- Hepatitis E virus (HEV)

Some cases of viral hepatitis are not caused by any of these viruses. These patients have non–A-E hepatitis.

Liver injury with inflammation can develop after exposure to a number of drugs and chemicals by inhalation, ingestion, or parenteral (IV) administration. **Toxic and drug-induced hepatitis** can result from exposure to hepatotoxins (e.g., industrial toxins, alcohol, and drugs). Hepatitis may also occur as a secondary infection during the course of infections with other viruses, such as Epstein-Barr, herpes simplex, varicella-zoster, and cytomegalovirus.

After the liver has been exposed to any causative agent (e.g., a virus), it becomes enlarged and congested with inflammatory cells, lymphocytes, and fluid, resulting in right upper quadrant pain and discomfort. As the disease progresses, the liver's normal lobular pattern becomes distorted as a result of widespread inflammation, necrosis, and hepatocellular regeneration. This distortion increases pressure within the portal circulation, interfering with the blood flow into the hepatic lobules. Edema of the liver's bile channels results in obstructive **jaundice** (yellowing of the skin).

Classification of Hepatitis and Etiologies

The five major types of acute viral hepatitis vary by mode of transmission, manner of onset, and incubation periods. Hepatitis cases must be reported to the local public health department, which then notifies the Centers for Disease Control and Prevention (CDC).

Hepatitis A.

The causative agent of **hepatitis A,** hepatitis A virus (HAV), is a

ribonucleic acid (RNA) virus of the enterovirus family. *It is a hardy virus and survives on human hands.* The virus is resistant to detergents and acids but is destroyed by chlorine (bleach) and extremely high temperatures.

Hepatitis A usually has a mild course similar to that of a typical flu-like infection and often goes unrecognized. It is spread most often by the fecal-oral route by fecal contamination either from person-to-person contact (e.g., oral-anal sexual activity) or by consuming contaminated food or water. Common sources of infection include shellfish caught in contaminated water and food contaminated by food handlers infected with HAV. The incubation period of hepatitis A is usually 15 to 50 days, with a peak of 25 to 30 days. The disease is usually not life threatening, but its course may be more severe in people older than 40 years and those with pre-existing liver disease such as hepatitis C (McCance et al., 2014).

In a small percentage of hepatitis A cases, severe illness with extrahepatic manifestations can occur. Advanced age and conditions such as chronic liver disease may cause widespread damage that requires a liver transplant. In some cases, death may occur. The incidence of hepatitis A is particularly high in non-affluent countries in which sanitation is poor. However, over 35,000 cases are diagnosed each year in the United States (American Liver Foundation, 2010). Some adults have hepatitis A and do not know it. The course is similar to that of a GI illness, and the disease and recovery are usually uneventful.

Hepatitis B.

The **hepatitis B** virus (HBV) is not transmitted like HAV. It is a double-shelled particle containing DNA composed of a core antigen (HBcAg), a surface antigen (HBsAg), and another antigen found within the core (HBeAg) that circulates in the blood. HBV may be spread through these common modes of transmission (Lok & McMahon, 2009):

- Unprotected sexual intercourse with an infected partner
- Sharing needles
- Accidental needle sticks or injuries from sharp instruments primarily in health care workers (low incidence)
- Blood transfusions (that have not been screened for the virus, before 1992)
- Hemodialysis
- Close person-to-person contact by open cuts and sores

In addition, patients who are immunosuppressed either by disease or drug therapy are more likely to develop hepatitis B.

The clinical course of hepatitis B may be varied. Symptoms usually

occur within 25 to 180 days of exposure and include (McCance et al., 2014):

- Anorexia, nausea, and vomiting
- Fever
- Fatigue
- Right upper quadrant pain
- Dark urine with light stool
- Joint pain
- Jaundice

Blood tests confirm the disease, although many people with hepatitis B have no symptoms.

Most adults who get hepatitis B recover, clear the virus from their body, and develop immunity. However, a small percentage of people do not develop immunity and become carriers. **Hepatitis carriers** can infect others even though they are not sick and have no obvious signs of hepatitis B. Chronic carriers are at high risk for cirrhosis and liver cancer. Because of the high number of newcomers from endemic areas, the incidence of hepatitis B has increased in the United States.

Hepatitis C.

The causative virus of **hepatitis C** (HCV) is an enveloped, single-stranded RNA virus. Transmission is blood to blood. The rate of sexual transmission is very low in a single-couple relationship but increases with multiple sex partners.

HCV is spread most commonly by:

- Illicit IV drug needle sharing (highest incidence)
- Blood, blood products, or organ transplants received before 1992
- Needle stick injury with HCV-contaminated blood (health care workers at high risk)
- Unsanitary tattoo equipment
- Sharing of intranasal cocaine paraphernalia

The disease is **not** transmitted by casual contact or by intimate household contact. However, those infected are advised not to share razors, toothbrushes, or pierced earrings because microscopic blood may be on these items.

The average incubation period is 7 weeks. Acute infection and illness are not common. Most people are completely unaware that they have been infected. They are asymptomatic and not diagnosed until many months or years after the initial exposure when an abnormality is detected during a routine laboratory evaluation or when liver problems occur. Unlike with hepatitis B, most people infected with hepatitis C do

not clear the virus and a chronic infection develops.

HCV usually does its damage over decades by causing a chronic inflammation in the liver that eventually causes the liver cells to scar. This scarring may progress to cirrhosis (McCance et al., 2014).

Hepatitis D.

Hepatitis D (delta hepatitis) is caused by a defective RNA virus that needs the helper function of HBV. It occurs only with HBV to cause viral replication. This usually develops into chronic disease. The incubation period is about 14 to 56 days. As with hepatitis B, the disease is transmitted primarily by parenteral routes, especially in patients who are IV drug users. Having sexual contact with a person with HDV is also a high risk factor (McCance et al., 2014).

Hepatitis E.

The **hepatitis E** virus (HEV) causes a waterborne infection associated with epidemics in the Indian subcontinent, Asia, Africa, the Middle East, Mexico, and Central and South America. Many large outbreaks have occurred after heavy rains and flooding. Like hepatitis A, hepatitis E is caused by fecal contamination of food and water.

In the United States, hepatitis E has been found only in international travelers. It is transmitted via the fecal-oral route, and the clinical course resembles that of hepatitis A. Hepatitis E has an incubation period of 15 to 64 days. There is no evidence at this time of a chronic form of the disease. The disease tends to be self-limiting and resolves on its own (McCance et al., 2014).

Complications of Hepatitis

Failure of the liver cells to regenerate, with progression of the necrotic process, results in a severe acute and often fatal form of hepatitis known as **fulminant hepatitis.** Hepatitis is considered to be chronic when liver inflammation lasts longer than 6 months. **Chronic hepatitis** usually occurs as a result of hepatitis B or hepatitis C. Superimposed infection with hepatitis D virus (HDV) in patients with chronic hepatitis B may also result in chronic hepatitis. Chronic hepatitis can lead to cirrhosis and liver cancer. Many patients have multiple infections, especially the combination of HBV with either HCV, HDV, or HIV infections (McCance et al., 2014).

Incidence and Prevalence

The incidence of hepatitis A and hepatitis B is declining as a result of CDC recommendations for vaccination. However, hepatitis B and hepatitis C are a concern because of their association with cirrhosis and liver cancer. Although exact numbers are not known, it is estimated that about 200 million people worldwide have the hepatitis C virus (HCV), making this type of hepatitis the most common type. Currently there is no vaccine for HCV. Therefore it is expected that the cases of HCV will rise over the next several decades as a result of increasing illicit drug use. This increase will require a major increase in transplantations and lead to many more deaths (Lok & McMahon, 2009).

Health Promotion and Maintenance

Hepatitis vaccines for infants, children, and adolescents have helped decrease the incidence of hepatitis A and hepatitis B. Some adults also are advised to receive these immunizations.

Measures for preventing hepatitis A in adults include:

- Proper handwashing, especially after handling shellfish
- Avoiding contaminated food or water (including tap water in countries with high incidence)
- Receiving immunoglobulin within 14 days if exposed to the virus
- Receiving the HAV vaccine before traveling to areas where the disease is common (e.g., Mexico, Caribbean)
- Receiving the vaccine if living or working in enclosed areas with others, such as college dormitories, correctional institutions, day-care centers, and long-term care facilities

Several HAV vaccines are available (e.g., Havrix and Vaqta). Both of these vaccines are made of inactivated hepatitis A virus and are given in the deltoid muscle.

Several vaccines can also provide protection against hepatitis B (HBV) infection (e.g., Engerix-B and Recombivax-HB). Twinrix is a combination HAV and HBV vaccine that is also available for adults. Examples of groups for whom immunization against HBV should be used include (Lok & McMahon, 2009):

- People who have sexual intercourse with more than one partner
- People with sexually transmitted disease (STD) or a history of STD
- Men having sex with men (MSM)
- People with any chronic liver disease (such as hepatitis C or cirrhosis)
- Patients with human immune deficiency virus (HIV) infection
- People who are exposed to blood or body fluids in the workplace, including health care workers, firefighters, and police

- People in correctional facilities
- Patients needing immunosuppressant drugs
- Family members, household members, and sexual contacts of people with HBV infection

Additional measures to prevent viral hepatitis for health care workers and others in contact with infected patients are listed in Charts 58-3 and 58-4.

Chart 58-3 Best Practice for Patient Safety & Quality Care QSEN

Prevention of Viral Hepatitis in Health Care Workers

- Use Standard Precautions to prevent the transmission of disease between patients or between patients and health care staff (see Chapter 23).
- Eliminate needles and other sharp instruments by substituting needleless systems. (Needle sticks are the major source of hepatitis B transmission in health care workers.)
- Take the hepatitis B vaccine (e.g., Recombivax HB), which is given in a series of three injections. This vaccine also prevents hepatitis D by preventing hepatitis B.
- For postexposure prevention of hepatitis A, seek medical attention immediately for immunoglobulin (Ig) administration.
- Report all cases of hepatitis to the local health department.

Chart 58-4 Patient and Family Education: Preparing for Self-Management

Health Practices to Prevent Viral Hepatitis

- Maintain adequate sanitation and personal hygiene. Wash your hands before eating and after using the toilet.
- Drink water treated by a water purification system.
- If traveling in underdeveloped or non-industrialized countries, drink only bottled water. Avoid food washed or prepared with tap water, such as raw vegetables, fruits, and soups. Avoid ice.
- Use adequate sanitation practices to prevent the spread of the disease among family members.
- Do not share bed linens, towels, eating utensils, or drinking glasses.
- Do not share needles for injection, body piercing, or tattooing.
- Do not share razors, nail clippers, toothbrushes, or Waterpiks.

- Use a condom during sexual intercourse, or abstain from this activity.
- Cover cuts or sores with bandages.
- If ever infected with hepatitis, never donate blood, body organs, or other body tissue.

Patient-Centered Collaborative Care

Assessment

History.

Begin by asking the patient whether he or she has had known exposure to a person with hepatitis. For the patient who presents with few or no symptoms of liver disease but has abnormal laboratory tests (e.g., elevated alanine aminotransferase [ALT] or aspartate aminotransferase [AST] level), the history may need to include additional questions regarding risk factors such as:

- Exposure to either inhaled or ingested chemical
- Use of herbal supplements
- Use of any new prescribed drug or over-the-counter (OTC) medication
- Recent ingestion of shellfish
- Exposure to a possibly contaminated water source
- Travel to another country
- Sexual activities with men, women, or both and whether it was protected or unprotected
- Illicit drug use, IV or intranasal
- For health care workers, recent needle stick exposure
- Body piercing or tattooing
- Close living accommodations (e.g., military barracks, correctional institutions, overcrowded dormitories, long-term care facilities, day-care centers) or employment in any such setting
- Blood or blood products or organ transplants received before 1992
- Military service
- Place of birth (United States or other country) and parents' place of birth
- History of alcohol use (how many drinks each day or week)
- Human immune deficiency virus (HIV)

Physical Assessment/Clinical Manifestations.

Assess whether the patient has:

- Abdominal pain
- Changes in skin or sclera (icterus)

- **Arthralgia** (joint pain) or **myalgia** (muscle pain)
- Diarrhea/constipation
- Changes in color of urine or stool
- Fever
- Lethargy
- Malaise
- Nausea/vomiting
- Pruritus (itching)

Lightly palpate the right upper abdominal quadrant to assess for liver tenderness. The patient may report right upper quadrant pain with jarring movements. Inspect the skin, sclerae, and mucous membranes for jaundice. He or she may present for medical treatment only after jaundice appears, believing that other vague symptoms are related to a flu-like syndrome.

Jaundice in hepatitis results from intrahepatic obstruction and is caused by edema of the liver's bile channels. Dark urine and clay-colored stools are often reported by the patient. If possible, obtain a urine and stool specimen for visual inspection and laboratory analysis. The patient may also have skin abrasions from scratching because of pruritus (itching).

Psychosocial Assessment.

Viral hepatitis has various presentations, but for most infected people the initial course is mild with few or no symptoms. The long-term complications of fibrosis and cirrhosis cause the more serious problem. This is especially true for patients who have chronic HBV and HCV infection.

Emotional problems for affected patients may center on their feeling sick and fatigued. General malaise, inactivity, and vague symptoms contribute to depression. Some patients often feel guilty and are remorseful about decisions made that caused the disease. These feelings are most likely to occur when the source of infection is from drug use. Family members may be angry that the patient caused the disease.

Infectious diseases such as hepatitis continue to have a social stigma. The patient may feel embarrassed by the precautions that are imposed in the hospital and continue to be necessary at home. This embarrassment may cause the patient to limit social interactions. Patients may be afraid that they will spread the virus to family and friends.

Family members are sometimes afraid of getting the disease and may distance themselves from the patient. Allow them to verbalize these feelings, and explore the reasons for these fears. Educate the patient and

family members about modes of transmission, and clarify information as needed.

Patients may be unable to return to work for several weeks during the acute phases of illness. The loss of wages and the cost of hospitalization for a patient without insurance coverage may produce great anxiety and financial burden. This situation may last for months or years if hepatitis becomes chronic.

Laboratory Assessment.

Hepatitis A, hepatitis B, and hepatitis C are usually confirmed by acute elevations in levels of liver enzymes, indicating liver cellular damage, and by specific serologic markers.

Levels of ALT and AST may possibly rise into the thousands in acute or fulminant cases of hepatitis. Alkaline phosphatase levels may be normal or elevated. Serum total bilirubin levels are elevated and are consistent with the clinical appearance of jaundice. Elevated levels of bilirubin are also present in the urine (Pagana & Pagana, 2014).

The presence of *hepatitis A* is established when hepatitis A virus (HAV) antibodies (anti-HAV) are found in the blood. Ongoing inflammation of the liver by HAV is indicated by the presence of immunoglobulin M (IgM) antibodies, which persist in the blood for 4 to 6 weeks. Previous infection is identified by the presence of immunoglobulin G (IgG) antibodies. These antibodies persist in the serum and provide permanent immunity to HAV.

The presence of the *hepatitis B* virus (HBV) is established when serologic testing confirms the presence of hepatitis B antigen-antibody systems in the blood and a detectable viral count (HBV polymerase chain reaction [PCR] DNA). Antigens located on the surface (shell) of the virus (HBsAg) and IgM antibodies to hepatitis B core antigen (anti-HBcAg IgM) are the most significant serologic markers. The presence of these markers establishes the diagnosis of hepatitis B. *The patient is infectious as long as hepatitis B surface antigen (HBsAg) is present in the blood.* Persistence of this serologic marker after 6 months or longer indicates a carrier state or chronic hepatitis. HBsAg levels normally decline and disappear after the acute hepatitis B episode. The presence of antibodies to HBsAb in the blood indicates recovery and immunity to hepatitis B. *People who have been vaccinated against HBV have a positive HBsAg because they also have immunity to the disease* (Pagana & Pagana, 2014).

Enzyme-linked immunosorbent assay (ELISA) is the initial screening test for patients suspected of being infected with *hepatitis C* virus (HCV). It is also the most commonly used enzyme test for HCV antibodies (anti-

HCV). The antibodies can be detected within 4 weeks of the infection (Pagana & Pagana, 2014). A more specific assay called the *recombinant immunoblot assay (RIBA)* can be used as a confirmatory test. These tests show that the patient has been exposed to HCV and has developed the antibody. To identify the actual circulating virus, the HCV PCR RNA test is used. This confirms active virus and can measure the viral load. A newer diagnostic tool called the *OraQuick HCV Rapid Antibody Test* was approved by the Food and Drug Administration in the United States in 2010. It has the advantage of providing a quick diagnosis of the disease as a point-of-care test.

The presence of *hepatitis D* virus (HDV) can be confirmed by the identification of intrahepatic delta antigen or, more often, by a rise in the hepatitis D virus antibodies (anti-HDV) titer. This increase can be seen within a few days of infection (Pagana & Pagana, 2014).

Hepatitis E virus (HEV) testing is usually reserved for travelers in whom hepatitis is present but the virus cannot be detected. Hepatitis E antibodies (anti-HEV) are found in people infected with the virus.

Other Diagnostic Assessment.

Liver biopsy may be used to confirm the diagnosis of hepatitis and to establish the stage and grade of liver damage. Characteristic changes help the pathologist distinguish among a virus, drug, toxin, fatty liver, iron, and other disease. It is usually performed in an ambulatory care setting as a percutaneous procedure (through the skin) after a local anesthetic is given. If coagulation is abnormal, however, it may be done using either a CT-guided or transjugular route to reduce the risk for pneumothorax or hemothorax. *Ultrasound* also may be used.

Interventions

The patient with viral hepatitis can be mildly or acutely ill depending on the severity of the inflammation. Most patients are not hospitalized, although older adults and those with dehydration may be admitted for a short-term stay. The plan of care for all patients with viral hepatitis is based on measures to rest the liver, promote cellular regeneration, and prevent complications, if possible.

During the acute stage of viral hepatitis, interventions are aimed at resting the inflamed liver to promote hepatic cell regeneration. *Rest* is an essential intervention to reduce the liver's metabolic demands and increase its blood supply. Collaborative care is generally supportive. The patient is usually tired and expresses feelings of general malaise.

Complete bedrest is usually not required, but rest periods alternating with periods of activity are indicated and are often enough to promote hepatic healing. Individualize the patient's plan of care and change it as needed to reflect the severity of symptoms, fatigue, and the results of liver function tests and enzyme determinations. Activities such as self-care and ambulating are gradually added to the activity schedule as tolerated.

The diet should be high in carbohydrates and calories with moderate amounts of fat and protein after nausea and anorexia subside. Small, frequent meals are often preferable to three standard meals. Ask the patient about food preferences because favorite foods are tolerated better than randomly selected foods. Encourage the patient to eat foods that are appealing. High-calorie snacks may be needed. Supplemental vitamins are often prescribed.

Drugs of any kind are used sparingly for patients with hepatitis to allow the liver to rest. An antiemetic to relieve nausea may be prescribed. However, due to the life-threatening nature of chronic hepatitis B and hepatitis C, a number of drugs are given, including antiviral and immunomodulating drugs (Table 58-4). Similar to patients with other chronic diseases, patients with hepatitis often use complementary and alternative therapies to promote general well-being and improve quality of life (see the Evidence-Based Practice box). Be sure to ask patients about their use of these therapies and incorporate them into the collaborative plan of care.

TABLE 58-4

Drug Therapy for Chronic Hepatitis B and Hepatitis C

MEDICATION	NURSING IMPLICATIONS	COMMENTS
Chronic Hepatitis B		
Tenofovir (Viread)	Monitor kidney function. Can cause bone de-mineralization. Teach risk for falls to prevent fractures.	Purpose of treatment is to achieve sustained suppression of hepatitis B virus (HBV) replication and remission of liver disease.
Adefovir (Hepsera)	Monitor kidney function.	
Lamivudine (Epivir-HBV)	Monitor kidney function. Dose is altered if co-infection with human immune deficiency virus (HIV) present.	
Entecavir (Baraclude)	Monitor kidney function.	
Chronic Hepatitis C		
Telaprevir (Incivek)	Monitor complete blood count (CBC) for anemia.	As a result of shared routes of transmission, co-infection with HIV is common.
Boceprevir (Victrelis) in combination with HIV medications if co-infection present	Monitor chemistry panel for impaired kidney and liver function, along with electrolytes abnormalities.	
PegIFN/RBV (interferon/ribavirin)	Peg/IFN administered subcutaneously. Instruct patients that they cannot miss a dose.	

Evidence Based Practice QSEN

Do Patients with Chronic Hepatitis C Use Complementary and Alternative Therapies?

Richmond, J.A., Bailey, D.E. Jr., McHutchinson, J.G., & Muir, A.J. (2010). The use of mind-body medicine and prayer among adult patients with hepatitis C. *Gastroenterology Nursing, 33*(3), 201-216.

The researchers studied the use of mind-body therapies and prayer as part of a larger, exploratory, descriptive study on the use of complementary and alternative medicine by patients with hepatitis C who were treated at one tertiary care center. According to a self-administered survey of 105 participants and semi-structured interviews of 28 participants in the study, most had used mind-body medicine in the past 12 months. The most commonly used therapies were prayer, deep breathing, and meditation to promote general well-being and relieve tension and anxiety.

Level of Evidence: 4

This study did not use an experimental design.

Commentary: Implications for Practice and Research

This exploratory descriptive study showed that patients with chronic hepatitis C use complementary and alternative medicine (CAM) in their everyday lives to promote their health and increase their quality of life. Nurses need to ensure that they ask patients about the use of CAM and which therapies are most helpful so that they can be continued as part of the patient's plan of care.

This research was the first to explore the use of CAM with this population of patients and serves as a pilot study for further research using larger sample sizes of diverse patients in multiple health care settings.

Clinical Judgment Challenge

Patient-Centered Care; Safety QSEN

You are a nurse working in the emergency department (ED) of the local community hospital. You receive report from the night nurse regarding a 50-year-old man who has just returned to the United States from a month-long trip to the southern parts of Africa. For the past 2 weeks, he has been experiencing fevers on and off, malaise, anorexia,

and mild abdominal discomfort. He has been taking acetaminophen (Tylenol) for fevers and abdominal discomfort. His past medical history is significant for elevated cholesterol for which he takes only atorvastatin (Lipitor) every day. While reviewing his social history, you note that the patient reported that he is a nonsmoker, drinks 6 or 7 alcoholic drinks daily, is married, and has three children. He had his gallbladder removed when he was 43 years old.

His current vital signs are: blood pressure 126/82 mm Hg; heart rate 100 beats/min; respirations 22 breaths/min; temperature 101° F orally; pulse oximetry reading 98% on room air. The ED physician orders the following:

Diet: nothing by mouth

Laboratory studies: complete blood count and chemistry panel, urinalysis, blood cultures

STAT electrocardiogram (ECG) and chest x-ray

Start: 0.9% normal saline intravenously to run at 100 mL/hr

The results of his recent laboratory work are:

	Laboratory Result	**Normal Range**
White blood cells	13,000/mm^3	(4,000-12,000/mm^3)
Red blood cells	7.0 million/mm^3	(3.5-5.5 million/mm^3)
Hemoglobin	18 g/dL	(12-16 g/dL)
Hematocrit	52%	(36-46%)
Sodium	135 mEq/L	(135-145 mEq/L)
Potassium	3.5 mEq/L	(3.5-4.5 mEq/L)
Magnesium	1.5 mEq/L	(1.5-2.5 mEq/L)
Serum aspartate aminotransferase (AST)	780 IU/L	(10-34 IU/L)
Serum alanine aminotransferase (ALT)	922 IU/L	(10-40 IU/L)
Blood urea nitrogen (BUN)	30 mg/dL	(8-24 mg/dL)
Creatinine	2.0 mg/dL	0.6-1.1 mg/dL
Urinalysis	Negative for blood, protein, glucose	
Blood culture	Negative for any bacterial growth	
ECG	Sinus tachycardia	
Chest x-ray	Lung fields without any noted infiltrates or masses	

1. In reviewing Mr. Goldman's laboratory values, which findings indicate abnormal liver function?
2. While reviewing Mr. Goldman's medical history, what information most likely increases his risk for abnormal liver function?
3. With further medical workup in the ED, the physician determines that

Mr. Goldman is suffering from acute hepatitis A. The patient asks you how he contracted the virus. What is your best response?

4. You are educating the patient's family about receiving vaccinations against hepatitis. What information will you provide to promote their safety?

Community-Based Care.

Home care management varies according to the type of hepatitis and whether the disease is acute or chronic. A primary focus in any case is preventing the spread of the infection. For hepatitis transmitted by the fecal-oral route, careful handwashing and sanitary disposal of feces are important. Education is therefore very important. Collaborate with the certified infection control practitioner and infectious disease specialist if needed in caring for these patients. These experts can also suggest resources for the patient and family.

Nursing Safety Priority QSEN

Action Alert

Teach the patient with viral hepatitis and the family to use measures to prevent infection transmission (see Chart 58-4). *In addition, instruct the patient to avoid alcohol and to check with the health care provider before taking any medication or vitamin, supplement, or herbal preparation.*

Encourage the patient to increase activity gradually to prevent fatigue. Suggest that he or she eat small, frequent meals of high-carbohydrate foods (Chart 58-5).

Chart 58-5 Patient and Family Education: Preparing for Self-Management

Viral Hepatitis

- Avoid all medications, including over-the-counter drugs such as acetaminophen (Tylenol, Exdol), unless prescribed by your physician.
- Avoid all alcohol.
- Rest frequently throughout the day, and get adequate sleep at night.
- Eat small, frequent meals with a high-carbohydrate, moderate-fat, and moderate-protein content.

- Avoid sexual intercourse until antibody testing results are negative.
- Follow the guidelines for preventing transmission of the disease (see Chart 58-4).

Fatty Liver (Steatosis)

Fatty liver is caused by the accumulation of fats in and around the hepatic cells. It may be caused by alcohol use or other factors. Nonalcoholic fatty liver disease (NAFLD) and nonalcoholic steatohepatitis (NASH) are types of fatty liver disease. Causes include:

- Diabetes mellitus
- Obesity
- Elevated lipid profile

Fatty infiltration of the liver may result from faulty fat metabolism in the liver and the movement of fatty acids from adipose tissue (fat). Many patients are asymptomatic. The most common and typical finding is an elevated ALT and AST or normal ALT and elevated AST (part of a group of liver function tests [LFTs]).

MRI, ultrasound, and nuclear medicine examinations can be used to confirm excessive fat in the liver. A percutaneous biopsy can also confirm the diagnosis. Interventions are aimed at removing the underlying cause of the infiltration. Weight loss, glucose control, and aggressive treatment using lipid-lowering agents are recommended. Monitoring liver function tests is essential in disease management.

Liver Trauma

The liver is one of the most common organs to be injured in patients with abdominal trauma. Damage or injury should be suspected whenever any upper abdominal or lower chest trauma is sustained. The liver is often injured by steering wheels in vehicular crashes. Common injuries include simple lacerations, multiple lacerations, avulsions (tears), and crush injuries.

The liver is a highly vascular organ and receives almost a third of the body's cardiac output. When hepatic trauma occurs, blood loss can be massive. *Observe for early signs of hypovolemic shock* (Chart 58-6).

Chart 58-6 Key Features

Liver Trauma

- Right upper quadrant pain with abdominal tenderness
- Abdominal distention and rigidity
- Guarding of the abdomen
- Increased abdominal pain exaggerated by deep breathing and referred to the right shoulder (Kehr's sign)
- Indicators of hemorrhage and hypovolemic shock:
  - Hypotension
  - Tachycardia
  - Tachypnea
  - Pallor
  - Diaphoresis
  - Cool, clammy skin
  - Confusion or other change in mental state

An ultrasound or CT scan of the abdomen is often done to determine the presence of a hematoma (blood clot). A decreased hematocrit may confirm suspected blood loss. Clinical manifestations include right upper quadrant pain with abdominal tenderness, distention, guarding, and rigidity. Abdominal pain exaggerated by deep breathing and referred to the right shoulder may indicate diaphragmatic irritation.

Liver trauma is managed in a conservative manner through new diagnostic and therapeutic modalities such as enhanced critical care monitoring and damage control surgery (Ahmed & Vernick, 2011). Patients with hepatic trauma may require multiple blood products such as packed red blood cells and fresh frozen plasma, as well as massive volume infusion to maintain adequate hydration. After surgery, the

patient is admitted to a critical care unit. Monitor the patient for persistent or new bleeding. Closely monitor complete blood count and coagulation studies for trends in changes.

Cancer of the Liver

Pathophysiology

Cancers may be *primary* tumors (hepatocellular carcinoma) starting in the liver, or they may be *metastatic* cancers that spread from another organ to the liver. They are most often seen in regions of Asia and the Mediterranean area. Worldwide, the disease kills about 1 million people each year and affects Vietnamese men more than any other group. Black and Hispanic populations have twice the rate of the disease as Euro-Americans, and older adults are affected more than other age-groups (Rossi et al., 2010). In the United States and worldwide, the incidence of liver cancer is increasing because there is an increase in cases of hepatitis C.

Chronic infection with HBV and HCV frequently lead to cirrhosis, which is a risk factor for developing liver cancer. It is important to remember that cirrhosis from any cause, including alcoholic liver disease, increases the risk for cancer.

Patient-Centered Collaborative Care

Assessment

In the early stage of cancer, most patients are without symptoms. Later in the disease, they report weight loss, anorexia, and weakness. Ask the patient if he or she has or has had recent abdominal pain, the most common concern. It is most often felt in the right upper quadrant before jaundice, bleeding, ascites, and edema develop. Palpation may reveal an enlarged, nodular liver.

Elevated serum *alpha-fetoprotein* (AFP) (a tumor marker for cancers of the liver, testis, and ovary) and increased *alkaline phosphatase* are also common (Pagana & Pagana, 2014). Ultrasound (US) and contrast-enhanced CT are both useful in detecting metastasis. If the primary tumor site is not known, a CT- or ultrasound-guided liver biopsy can confirm the diagnosis, although this procedure is risky because of possible bleeding and spread of the cancer cells.

Interventions

Surgical resection and liver transplantation offer the only treatments for long-term survival from liver cancer. Unfortunately, most patients are not candidates for surgical removal because their tumors are unresectable. Tunneled abdominal drains, such as the PleurX drainage system, may be

used at home by the patient and family to remove excess ascitic fluid. *Teach them how to empty the drain and maintain the system. Remind them not to remove more than 2000 mL of fluid at one time to prevent hypovolemic shock.*

Selective internal radiation therapy (SIRT) has been successful for some patients. Other palliative approaches include hepatic artery embolization, ablation techniques, and drug therapy. *Hepatic artery embolization* causes cell death by blocking blood supply to the tumor in the liver. It is performed under moderate sedation by an interventional radiologist who threads a catheter through the femoral artery to inject small beads into the hepatic artery to block blood flow. The patient usually stays overnight in the hospital for observation in case of bleeding. This procedure may be followed by infusing a chemotherapy agent directly into the hepatic artery (chemoembolization).

Common *ablation* procedures include radiofrequency ablation (RFA), percutaneous ethanol injection, and cryotherapy. RFA uses energy waves to heat cancer cells and kill them. It is most often performed as an ambulatory care procedure using a percutaneous laparoscopic approach. Ethanol may also be injected directly into the tumor to destroy tumor cells, although this procedure is not as commonly done as RFA (Rossi et al., 2010). Cryotherapy uses liquid nitrogen to freeze and destroy liver tumors. The general nursing care for patients having these procedures is described in Chapter 22.

Chemotherapy may be administered orally or IV. However, it is not effective in many cases. Examples of drugs used are doxorubicin (Adriamycin), 5-fluorouracil (5-FU), and cisplatin. Sorafenib (Nexavar) is a kinase inhibitor that is approved for inoperable liver cancer. Other drugs are targeted therapies that are being investigated and used with some success.

Another drug route is a catheter-directed method directly into the hepatic artery, a procedure called *hepatic arterial infusion (HAI).* The interventional radiologist places a catheter into the artery that supplies the tumor and injects a mixture of chemotherapy and contrast agent into the tumor. This procedure has the unique effect of depositing chemotherapeutic drugs directly into the tumor without causing major systemic effects. Chapter 22 describes the general nursing care for patients receiving chemotherapy.

Patients with advanced liver cancer usually need end-of-life care and hospice services. Collaborate with the case manager to help patients and their families find the best community resources that meet their needs. Chapter 7 describes end-of-life care and hospice services in detail.

Liver Transplantation

❖ Pathophysiology

Liver transplantation has become a common procedure worldwide. The patient with end-stage liver disease or acute liver failure who has not responded to conventional medical or surgical intervention is a potential candidate for liver transplantation. Many diseases can cause liver failure. Cirrhosis (scarring of the liver) is the most common reason for liver transplants. Other common reasons for liver transplants are chronic hepatitis B and hepatitis C, bile duct diseases, autoimmune liver disease, primary liver cancer, alcoholic liver disease, and fatty liver disease (American Liver Foundation, 2012).

Transplantation Considerations

The patient for potential transplantation has extensive physiologic and psychological assessment and evaluation by physicians and transplant coordinators. Alternative treatment should be extensively explored before committing a patient for a liver transplant. Patients who are *not* considered candidates for transplantation are those with:

- Severe cardiovascular instability with advanced cardiac disease
- Severe respiratory disease
- Metastatic tumors
- Inability to follow instructions regarding drug therapy and self-management

Liver transplantation has become the most effective treatment for an increasing number of patients with acute and chronic liver diseases. Inclusion and exclusion criteria vary among transplantation centers and are continually revised as treatment options change and surgical techniques improve.

Donor livers are obtained primarily from trauma victims who have not had liver damage. They are distributed through a nationwide program—the United Network of Organ Sharing (UNOS). This system distributes donor livers based on regional considerations and patient acuity. Candidates with the highest level of acuity receive highest priority.

The donor liver is transported to the surgery center in a solution that preserves the organ for up to 8 hours. The diseased liver is removed through an incision made in the upper abdomen. The new liver is carefully put in its place and is attached to the patient's blood vessels and bile ducts. The procedure can take many hours to complete and requires a highly specialized team and large volumes of fluid and blood

replacement.

Living donors have also been used and are usually close family members or spouse. This is done on a voluntary basis after careful psychological and physiologic preparation and testing. The donor's liver is resected (usually removal of one lobe) and implanted into the recipient after removal of the diseased liver. In both the donor and the recipient, the liver regenerates and grows in size to meet the demands of the body.

Transplantation Complications

Although liver transplantations are commonly done, complications can occur. Some problems can be medically managed, whereas others require removal of the transplant. The two most common complications are acute graft rejection and infection.

The success rate for transplantations has greatly improved since the introduction many years ago of cyclosporine (cyclosporin A), an immunosuppressant drug. Today, many other anti-rejection drugs are used. (See Chapter 20 for a complete discussion of rejection and preventive drug therapy.)

Nursing Safety Priority QSEN

Action Alert

For the patient who has undergone liver transplantation, monitor for clinical manifestations of rejection, which may include tachycardia, fever, right upper quadrant or flank pain, decreased bile pigment and volume, and increasing jaundice. Laboratory findings include elevated serum bilirubin, rising ALT and AST levels, elevated alkaline phosphatase levels, and increased prothrombin time/international normalized ratio (PT/INR).

Transplant rejection is treated aggressively with immunosuppressive drugs. As with all rejection treatments, the patient is at a greater risk for infection. If therapy is not effective, liver function rapidly deteriorates. Multi-system organ failure, including respiratory and renal involvement, develops along with diffuse coagulopathies and portal-systemic encephalopathy (PSE). The only alternative for treatment is emergency retransplantation.

Infection is another potential threat to the transplanted graft and the patient's survival. Vaccinations and prophylactic antibiotics are helpful in prevention. Immunosuppressant therapy, which must be used to prevent

and treat organ rejection, significantly increases the patient's risk for infection. Other risk factors include the presence of multiple tubes and intravascular lines, immobility, and prolonged anesthesia.

In the early post-transplantation period, common infections include pneumonia, wound infections, and urinary tract infections. Opportunistic infections usually develop after the first postoperative month and include cytomegalovirus, mycobacterial infections, and parasitic infections. Latent infections such as tuberculosis and herpes simplex may be reactivated.

The physician prescribes broad-spectrum antibiotics for prophylaxis during and after surgery. Obtain culture specimens from all lines and tubes and collect specimens for culture at predetermined time intervals as dictated by the agency's policy. If an infection is detected, the physician prescribes organism-specific anti-infective agents.

The biliary anastomosis is susceptible to breakdown, obstruction, and infection. If leakage occurs or if the site becomes necrotic or obstructed, an abscess can form or peritonitis, bacteremia, and cirrhosis may develop. Observe for potential complications, which are listed in Table 58-5.

TABLE 58-5

Assessment and Prevention of Common Postoperative Complications Associated with Liver Transplantation

ASSESSMENT	PREVENTION
Acute Graft Rejection	
Occurs from the 4th to 10th postoperative day Manifested by tachycardia, fever, right upper quadrant (RUQ) or flank pain, diminished bile drainage or change in bile color, or increased jaundice Laboratory changes: (1) increased levels of serum bilirubin, transaminases, and alkaline phosphatase; (2) prolonged prothrombin time	Prophylaxis with immunosuppressant agents, such as cyclosporine Early diagnosis to treat with more potent anti-rejection drugs
Infection	
Can occur at any time during recovery Manifested by fever or excessive, foul-smelling drainage (urine, wound, or bile); other indicators depend on location and type of infection	Antibiotic prophylaxis; vaccinations Frequent cultures of tubes, lines, and drainage Early removal of invasive lines Good handwashing Early diagnosis and treatment with organism-specific anti-infective agents
Hepatic Complications (Bile Leakage, Abscess Formation, Hepatic Thrombosis)	
Manifested by decreased bile drainage, increased RUQ abdominal pain with distention and guarding, nausea or vomiting, increased jaundice, and clay-colored stools Laboratory changes: increased levels of serum bilirubin and transaminases	If present, keep T-tube in dependent position and secure to patient; empty frequently, recording quality and quantity of drainage Report manifestations to physician immediately May necessitate surgical intervention
Acute Renal Failure	
Caused by hypotension, antibiotics, cyclosporine, acute liver failure, or hypothermia Indicators of hypothermia: shivering, hyperventilation, increased cardiac output, vasoconstriction, and alkalemia Early indicators of renal failure: changes in urine output, increased blood urea nitrogen (BUN) and creatinine levels, and electrolyte imbalance	Monitor all drug levels with nephrotoxic side effects Prevent hypotension Observe for early signs of renal failure, and report them immediately to the physician

❖ Patient-Centered Collaborative Care

Care of the patient undergoing liver transplantation requires an interdisciplinary team approach. Receiving a transplant has a major psychosocial impact. Transplant complications cause patients to be very anxious. In collaboration with the members of the health care team, assure them and their families that these problems are common and usually successfully treated.

After the patient is identified as a candidate and a donor organ is procured, the actual liver transplantation surgical procedure usually takes many hours. The length of the procedure can vary greatly.

In the immediate postoperative period, the patient is managed in the critical care unit and requires aggressive monitoring and care. Assess for signs and symptoms of complications of surgery, and immediately report them to the surgeon (see Table 58-5).

Nursing Safety Priority QSEN

Action Alert

For the patient who has had a liver transplantation, monitor the temperature frequently per hospital protocol, and report elevations, increased abdominal pain, distention, and rigidity, which are indicators of peritonitis. Nursing assessment also includes monitoring for a change in neurologic status that could indicate encephalopathy from a nonfunctioning liver. Report signs of clotting problems (e.g., bloody oozing from a catheter, petechiae, ecchymosis) to the surgeon immediately because they may indicate impaired function of the transplanted liver.

Post–liver transplant patients are living longer today than ever. Teach patients to be aware of side effects of immunosuppressive drugs, such as hypertension, nephrotoxicity, and gastrointestinal disturbances. Remind them that long-term management of care includes surveillance for malignancy, metabolic syndrome, and diabetes. Teaching the patient self-examination for skin, breast, and testicular malignancies is important as well as reminders for annual Papanicolaou (Pap) smears and other cancer screening tests. Post-transplant patients need to maintain lifestyle changes to increase their longevity after surgery (Clayton, 2011; Lucey et al., 2013).

What might you NOTICE if the patient is experiencing inadequate digestion, nutrition, and metabolism as a result of impaired liver function?

- Jaundice
- Icterus
- Report of nausea and anorexia
- Vomiting
- Weight loss
- Bruising or bleeding
- Ascites

What should you INTERPRET and how should you RESPOND to a patient experiencing inadequate digestion, nutrition, and metabolism as a result of impaired liver function?

Perform and interpret physical assessment findings, including:

- Assessing respiratory status to check for dyspnea or shallow breathing
- Checking level of consciousness and cognition
- Taking vital signs (looking for fever or decreased BP) and oxygen saturation
- Checking for blood in the vomitus
- Performing an abdominal assessment, including measuring girth
- Checking urine for dark color and stool for clay-colored appearance
- Taking current weight, and comparing with previous weight
- Assessing skin for open areas
- Checking most recent laboratory values for coagulation studies and LFTs

Respond by:

- Applying oxygen to assist in ease of breathing
- Keeping head of bed elevated to at least 30 degrees
- Maintaining rest
- Collaborating with dietitian and pharmacist as needed
- Prioritizing and pacing activities to prevent fatigue
- Monitoring patient closely for complications, such as bleeding; calling the Rapid Response Team if bleeding occurs

On what should you REFLECT?

- Monitor the patient for restored digestion and nutrition, such as

increased appetite.
- Think about what may have caused the liver problem.
- Consider for what complications the patient is at risk.
- Think about what members of the health care team need to provide care for this patient.

Get Ready for the NCLEX® Examination!

Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- When caring for patients with cirrhosis, collaborate with the dietitian, physician, and pharmacist. **Teamwork and Collaboration** QSEN
- Refer patients with liver disorders to the American Liver Foundation; refer dying patients to hospice and other community resources as needed. **Patient-Centered Care** QSEN

Health Promotion and Maintenance

- Follow the guidelines listed in Chart 58-3 to prevent viral hepatitis in the workplace. **Evidence-Based Practice** QSEN
- Teach patients to take precautions to prevent viral hepatitis in the community as described in Chart 58-4. **Evidence-Based Practice** QSEN
- For patients with viral hepatitis, instruct them to follow the guidelines listed in Chart 58-5. **Safety** QSEN
- Teach patients to avoid alcohol and illicit drugs to prevent or slow the progression of alcohol-induced cirrhosis; remind them not to take any medication (including over-the-counter drugs) without checking with their health care provider. **Safety** QSEN

Psychosocial Integrity

- Recognize that patients with cirrhosis have mental and emotional changes due to hepatic encephalopathy. **Patient-Centered Care** QSEN
- Be aware that patients with cirrhosis and/or chronic hepatitis may feel guilty about their disease because of past habits such as drug and alcohol use. **Patient-Centered Care** QSEN
- Be aware that family members and friends may fear getting hepatitis from the patient. **Patient-Centered Care** QSEN
- Be aware that patients having liver transplantation have major concerns about the possibility of complications, such as organ rejection. **Patient-Centered Care** QSEN

Physiological Integrity

- Be aware that cirrhosis has many causes other than alcohol use (see

Table 58-1). **Patient-Centered Care** QSEN

- Observe for clinical manifestations of hepatic encephalopathy (PSE) as listed in Table 58-2. **Safety** QSEN
- Monitor laboratory values of patients suspected of or diagnosed with cirrhosis of the liver as listed in Table 58-3. **Informatics** QSEN
- Monitor the patient with cirrhosis for bleeding and neurologic changes. **Safety** QSEN
- Provide care for the patient having a paracentesis as described in Chart 58-1. **Safety** QSEN
- Administer drug therapy to decrease ammonia levels (which cause PSE) in patients with cirrhosis, such as lactulose and nonabsorbable antibiotics. **Safety** QSEN
- Differentiate the five major types of hepatitis: A, B, C, D, and E. Hepatitis D occurs only with Hepatitis B and is transmitted most commonly by blood and body fluid exposure. Hepatitis A is transmitted via the fecal-oral route. Hepatitis C is the most common type and is also transmitted via blood and body fluids. **Evidence-Based Practice** QSEN
- Be aware that patients with chronic viral hepatitis often develop cirrhosis and cancer of the liver. **Evidence-Based Practice** QSEN
- Recognize that potent immunomodulators and antivirals are given to treat hepatitis B and hepatitis C; teach patients on immunomodulators to avoid large crowds and people who have infections. **Safety** QSEN
- Monitor for bleeding in the patient with liver trauma; assume that any abdominal trauma has damaged the liver. **Safety** QSEN
- Monitor the patient having a liver transplantation for complications, such as those described in Table 58-5. **Safety** QSEN
- Report and document elevated temperature, increased abdominal pain and rigidity, bleeding, and/or neurologic status changes as possible indicators of liver transplantation complications. **Evidence-Based Practice** QSEN

CHAPTER 59

Care of Patients with Problems of the Biliary System and Pancreas

Lara Carver and Jennifer Powers

PRIORITY CONCEPTS

- Pain
- Nutrition
- Inflammation

Learning Outcomes

Safe and Effective Care Environment

1. Collaborate with health care team members to provide care for patients with pancreatic disorders.
2. Identify community-based resources for patients with pancreatic disorders.

Health Promotion and Maintenance

3. Teach people about health promotion practices to prevent gallbladder disease.
4. Teach people about evidence-based health promotion practices to prevent pancreatitis.

Psychosocial Integrity

5. Describe the psychosocial needs of patients with pancreatic cancer and their families.

Physiological Integrity

6. Identify risk factors for gallbladder disease.
7. Interpret diagnostic test results associated with gallbladder disease.
8. Compare postoperative care of patients undergoing a traditional cholecystectomy with that of patients having laparoscopic cholecystectomy.
9. Compare and contrast the pathophysiology of acute and chronic pancreatitis.
10. Interpret laboratory test results associated with acute pancreatitis.
11. Interpret common assessment findings associated with acute and chronic pancreatitis.
12. Prioritize nursing care for patients with acute pancreatitis and patients with chronic pancreatitis.
13. Explain the use and precautions associated with enzyme replacement for chronic pancreatitis.
14. Develop a postoperative plan of care for patients having a Whipple procedure.

 http://evolve.elsevier.com/Iggy/

The biliary system (liver and gallbladder) and pancreas secrete enzymes and other substances that promote food digestion in the stomach and small intestine. When these organs do not work properly, the person has impaired *digestion,* which may result in inadequate nutrition. Collaborative care for patients with problems of the biliary system and pancreas includes the need to promote nutrition for healthy cellular function. This chapter focuses on problems of the gallbladder and pancreas. Liver disorders are described in Chapter 58.

Because of the close anatomic location of these organs, disorders of the gallbladder and pancreas may extend to other organs if the primary health problem is not treated early. inflammation is caused by **obstruction** (blockage) in the biliary system from gallstones, edema, stricture, or tumors. For example, gallstones in the cystic duct cause cholecystitis. Gallstones lodged in the ampulla of Vater block the flow of bile and pancreatic secretions, which can result in pancreatitis. These problems frequently cause the patient to have moderate to severe abdominal pain.

Cholecystitis

Pathophysiology

Cholecystitis is an inflammation of the gallbladder that affects many people, most commonly in affluent countries. It may be either acute or chronic, although most patients have the acute type.

Acute Cholecystitis

Two types of acute cholecystitis can occur: calculous and acalculous cholecystitis. The most common type is **calculous cholecystitis,** in which chemical irritation and inflammation result from gallstones **(cholelithiasis)** that obstruct the cystic duct (most often), gallbladder neck, or common bile duct (choledocholithiasis) (Fig. 59-1). When the gallbladder is inflamed, trapped bile is reabsorbed and acts as a chemical irritant to the gallbladder wall. Reabsorbed bile, in combination with impaired circulation, edema, and distention of the gallbladder, causes ischemia and infection. The result is tissue sloughing with necrosis and gangrene within the gallbladder itself. The gallbladder wall may eventually perforate (rupture). If the perforation is small and localized, an abscess may form. **Peritonitis,** infection of the peritoneum, may result if the perforation is large.

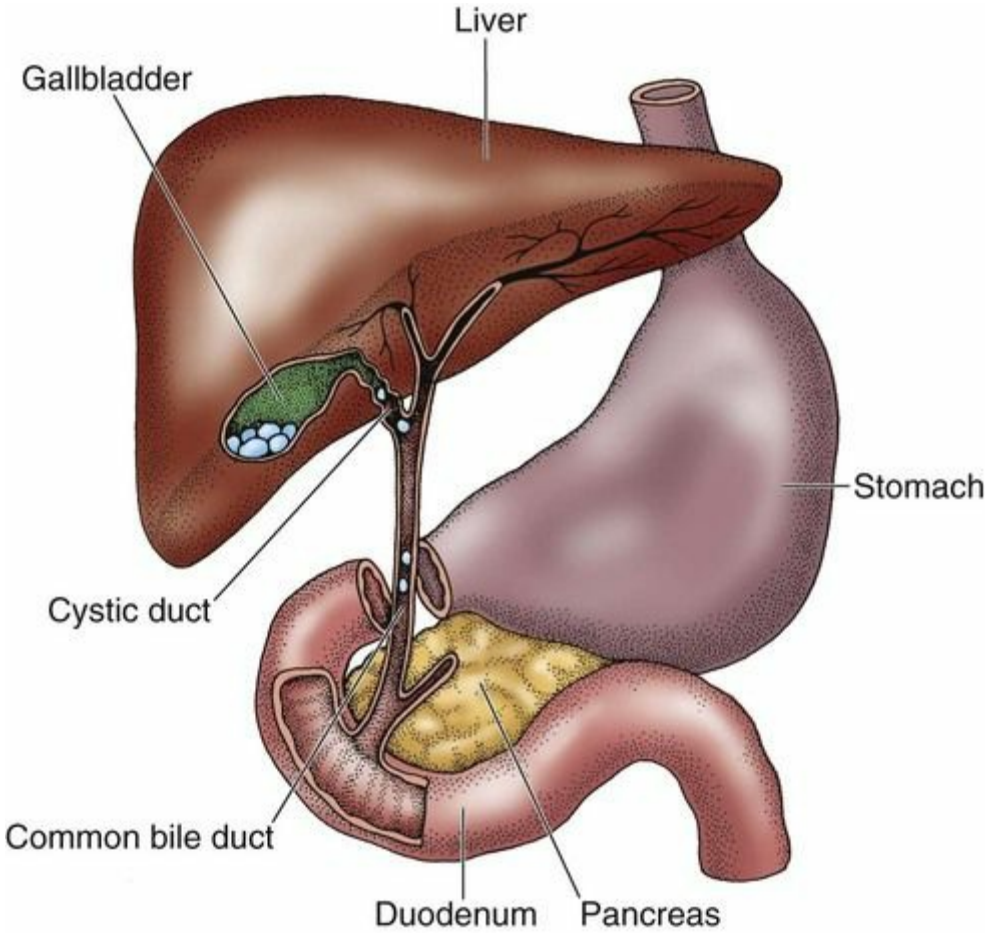


FIG. 59-1 Gallstones within the gallbladder and obstructing the common bile and cystic ducts.

The exact pathophysiology of gallstone formation is not clearly understood, but abnormal metabolism of cholesterol and bile salts plays an important role in their formation. The gallbladder provides an excellent environment for the production of stones because it only occasionally mixes its normally abundant mucus with its highly viscous, concentrated bile. Impaired gallbladder motility can lead to stone formation by delaying bile emptying and causing biliary stasis.

Gallstones are composed of substances normally found in bile, such as cholesterol, bilirubin, bile salts, calcium, and various proteins. They are classified as either cholesterol stones or pigment stones. Cholesterol calculi form as a result of metabolic imbalances of cholesterol and bile salts. They are the most common type found in people in the United States (McCance et al., 2014).

Bacteria can collect around the stones in the biliary system. Severe bacterial invasion can lead to life-threatening *suppurative* cholangitis when symptoms are not recognized quickly and pus accumulates in the ductal system.

Acalculous cholecystitis (inflammation occurring without gallstones) is typically associated with biliary stasis caused by any condition that

affects the regular filling or emptying of the gallbladder. For example, a decrease in blood flow to the gallbladder or anatomic problems such as twisting or kinking of the gallbladder neck or cystic duct can result in pancreatic enzyme reflux into the gallbladder, causing inflammation. Sphincter of Oddi dysfunction (SOD) can also occur to cause reflux and inflammation (Pfadt & Carlson, 2011). Most cases of this type of cholecystitis occur in patients with:

- Sepsis
- Severe trauma or burns
- Long-term total parenteral nutrition
- Multi-system organ failure
- Major surgery
- Hypovolemia

Chronic Cholecystitis

Chronic cholecystitis results when repeated episodes of cystic duct obstruction cause chronic inflammation. Calculi are almost always present. In chronic cholecystitis, the gallbladder becomes fibrotic and contracted, which results in decreased motility and deficient absorption.

Pancreatitis and cholangitis (bile duct inflammation) can occur as chronic complications of cholecystitis. These problems result from the backup of bile throughout the biliary tract. Bile obstruction leads to jaundice.

Jaundice (yellow discoloration of the skin and mucous membranes) and **icterus** (yellow discoloration of the sclera) can occur in patients with acute cholecystitis but are most commonly seen in those with the *chronic* form of the disease. Obstructed bile flow caused by edema of the ducts or gallstones contributes to *extrahepatic* **obstructive jaundice.** Jaundice in cholecystitis may also be caused by direct liver involvement. Inflammation of the liver's bile channels or bile ducts may cause *intrahepatic* obstructive jaundice, resulting in an increase in circulating levels of bilirubin, the major pigment of bile.

In a person with obstructive jaundice, the normal flow of bile into the duodenum is blocked, allowing excessive bile salts to accumulate in the skin. This accumulation of bile salts leads to **pruritus** (itching) or a burning sensation. The bile flow blockage also prevents bilirubin from reaching the large intestine, where it is converted to urobilinogen. Because urobilinogen accounts for the normal brown color of feces, clay-colored stools result. Water-soluble bilirubin is normally excreted by the kidneys in the urine. When an excess of circulating bilirubin occurs, the urine becomes dark and foamy because of the kidneys' effort to clear the

bilirubin.

Etiology and Genetic Risk

A familial or genetic tendency appears to play a role in the development of cholelithiasis, but this may be partially related to familial nutrition habits (excessive dietary cholesterol intake) and sedentary lifestyles. Genetic-environment interactions may contribute to gallstone production. For example, current studies are investigating DNA expression sequences that program some people to make and secrete more cholesterol into bile, leading to the increase in cholesterol-containing gallstones. The main risk factors for developing gallstones are obesity, type 2 diabetes, dyslipidemia, and insulin resistance. Independent risk factors for developing gallstones are increase in age, female gender, and family history (Agostino et al., 2013). Also, people who experience rapid weight loss and certain intestinal diseases affecting the normal absorption of nutrients, such as Crohn's disease, are at risk for gallstones. The highest frequency of gallstone production lies among the American-Indian and Mexican-American populations (McCance, et al., 2014). Risk factors for cholecystitis are listed in Table 59-1.

TABLE 59-1

Risk Factors for Cholecystitis

• Women • Aging • American Indian, Mexican American, or Caucasian • Obesity • Rapid weight loss or prolonged fasting • Increased serum cholesterol • Women on hormone replacement therapy (HRT)	• Cholesterol-lowering drugs • Family history of gallstones • Prolonged total parenteral nutrition • Crohn's disease • Gastric bypass surgery • Sickle cell disease • Glucose intolerance/diabetes mellitus • Pregnancy • Genetic factors

Gender Health Considerations

Patient-Centered Care QSEN

Women who are between 20 and 60 years of age are twice as likely to develop gallstones as are men. Obesity is a major risk factor for gallstone formation, especially in women. Pregnancy and drugs such as hormone replacements and birth control pills alter hormone levels and delay muscular contraction of the gallbladder, decreasing the rate of bile emptying. The incidence of gallstones is higher in women who have had multiple pregnancies. Combinations of causative factors increase the

incidence of stone formation, especially in women. Therefore some clinicians refer to the patient most at risk for acute cholecystitis and gallstones by the four **F**s:

- **F**emale
- **F**orty
- **F**at
- **F**ertile

The incidence of chronic cholecystitis is increased in young, thin women, especially those who are athletic (e.g., ballerinas and gymnasts). These women have chronic pain that is often misdiagnosed as gastritis.

Patient-Centered Collaborative Care

Assessment

Physical Assessment/Clinical Manifestations.

Obtain the patient's height, weight, and vital signs, or delegate these activities to unlicensed assistive personnel (UAP). Ask about food preferences, and determine whether excessive fat and cholesterol are part of the diet. Typically, diets high in fat, high in calories, low in fiber, and high in refined white carbohydrates place patients at higher risk for developing gallstones. Inquire if any foods cause pain. Question whether any GI symptoms occur when fatty food is eaten: **flatulence** (gas), **dyspepsia** (indigestion), **eructation** (belching), anorexia, nausea, vomiting, and abdominal pain or discomfort.

Patients with cholecystitis present with abdominal pain, although clinical manifestations vary in intensity and frequency (Chart 59-1). Ask the patient to describe the pain, including its intensity and duration, precipitating factors, and any measures that relieve it. Pain may be described as indigestion of varying intensity, ranging from a mild, persistent ache to a steady, constant pain in the right upper abdominal quadrant. It may radiate to the right shoulder or scapula. In some cases the abdominal pain of chronic cholecystitis may be vague and nonspecific. The usual pattern is episodic. Patients often refer to acute pain episodes as “gallbladder attacks.”

Chart 59-1 Key Features

Cholecystitis

- Episodic or vague upper abdominal pain or discomfort that can radiate to the right shoulder
- Pain triggered by a high-fat or high-volume meal
- Anorexia
- Nausea and/or vomiting
- Dyspepsia (indigestion)
- Eructation (belching)
- Flatulence (gas)
- Feeling of abdominal fullness
- Rebound tenderness (Blumberg's sign)
- Fever
- Jaundice, clay-colored stools, dark urine, steatorrhea (most common with chronic cholecystitis)

Considerations for Older Adults

Patient-Centered Care QSEN

Older adults and patients with diabetes mellitus may have atypical manifestations of cholecystitis, including the absence of pain and fever. Localized tenderness may be the only presenting sign. The older patient may become acutely confused (delirium) as the first manifestation of gallbladder disease.

The severe pain of **biliary colic** is produced by obstruction of the cystic duct of the gallbladder or movement of one or more stones. When a stone is moving through or is lodged within the duct, tissue spasm occurs in an effort to get the stone through the small duct.

Nursing Safety Priority QSEN

Critical Rescue

Biliary colic may be so severe that it occurs with tachycardia, pallor, diaphoresis, and prostration (extreme exhaustion). Assess the patient for possible shock caused by biliary colic. Notify the health care provider or Rapid Response Team if these manifestations occur. Stay with the patient, and keep the head of the bed flat.

Ask patients to describe their daily activity or exercise routines to determine whether they are sedentary. Sedentary lifestyle, rapid weight loss, prolonged fasting, and pregnancy are risk factors for developing

gallstones. Question whether there is a family history of gallbladder disease. Ask the patient about taking current or previous hormone replacement therapy (HRT). If the patient is female, ask if she is taking or has recently been on oral contraceptives (birth control pills).

Assessment for rebound tenderness **(Blumberg's sign)** and deep palpation are performed only by physicians and advanced practice nurses. To elicit rebound tenderness, the health care provider pushes his or her fingers deeply and steadily into the patient's abdomen and then quickly releases the pressure. Pain that results from the rebound of the palpated tissue may indicate peritoneal inflammation. Deep palpation below the liver border in the right upper quadrant may reveal a sausage-shaped mass, representing the distended, inflamed gallbladder. Percussion over the posterior rib cage worsens localized abdominal pain.

In *chronic* cholecystitis, patients may have slowly developing symptoms and may not seek medical treatment until late symptoms such as jaundice (yellowing of the skin), clay-colored stools, and dark urine occur from biliary obstruction. Yellowing of the sclera (icterus) and oral mucous membranes may also be present. **Steatorrhea** (fatty stools) occurs because fat absorption is decreased because of the lack of bile. Bile is needed for the absorption of fats and fat-soluble vitamins in the intestine. As with any inflammatory process, the patient may have an elevated temperature of 99° to 102° F (37.2° to 38.9° C), tachycardia, and dehydration from fever and vomiting.

Considerations for Older Adults

Patient-Centered Care QSEN

Older adults become dehydrated much quicker than other age-groups, and they may not present with a fever. Monitor for a new onset of disorientation or acute confusion due to decreased blood volume available to oxygenate the cells of the brain (hypoxia).

Diagnostic Assessment.

A differential diagnosis rules out other diseases that may cause similar symptoms, such as peptic ulcer disease, hepatitis, and pancreatitis. An increased *white blood cell* (WBC) count indicates inflammation. Serum levels of *alkaline phosphatase, aspartate aminotransferase (AST),* and *lactate dehydrogenase (LDH)* may be elevated, indicating abnormalities in liver function in patients with severe biliary obstruction. The direct (conjugated) and indirect (unconjugated) *serum bilirubin levels* are also

elevated. If the pancreas is involved, serum amylase and lipase levels are elevated.

Calcified gallstones are easily viewed on abdominal x-ray. Stones that are not calcified cannot be seen. *Ultrasonography (US) of the right upper quadrant is the best initial diagnostic test for cholecystitis.* It is safe, accurate, and painless. Acute cholecystitis is seen as edema of the gallbladder wall and pericholecystic fluid.

A hepatobiliary scan (sometimes called a HIDA scan) can be performed to visualize the gallbladder and determine patency of the biliary system. In this nuclear medicine test, a radioactive tracer or chemical is injected intravenously. About 20 minutes after the injection, a gamma camera tracks the flow of the tracer from the gallbladder to determine the ejection rate of bile into the biliary duct. A decreased bile flow indicates gallbladder disease with obstruction. Teach patients having this test to have nothing by mouth before the procedure. Remind the patient that the camera is large and close to the body for most of the procedure.

When the cause of cholecystitis or cholelithiasis is not known or the patient has manifestations of biliary obstruction (e.g., jaundice), an *endoscopic retrograde cholangiopancreatography* (ERCP) may be performed. Some patients have the less invasive and safer *magnetic resonance cholangiopancreatography* (MRCP), which can be performed by an interventional radiologist. For this procedure, the patient is given oral or IV contrast material (gadolinium) before having an MRI scan (Griffin et al., 2011). Before the test, ask the patient about any history of urticaria (hives) or other allergy. MRI is also contraindicated in patients with pacemaker or other incompatible devices. Gadolinium does not contain iodine, which decreases the risk for an allergic response. Chapter 52 discusses these tests in more detail.

Interventions

Acute cholecystitis is diagnosed on the basis of clinical findings, laboratory tests, and abdominal imaging. If acute infection of the gallbladder is diagnosed, emergency cholecystectomy is usually performed the same or the following day. Laparoscopic cholecystectomy is the treatment of choice for patients with acute and long-term chronic cholecystitis. This minimally invasive procedure achieves the desired outcomes of shorter recovery time, decreased expense, less postoperative pain, and minimal scarring after surgery.

Nonsurgical Management.

Many people with gallstones have no symptoms. Acute pain is present when gallstones partially or totally obstruct the cystic or common bile duct. Most patients find that they need to avoid fatty foods to prevent further episodes of biliary colic. Withhold food and fluids if nausea and vomiting occur. IV therapy is used for hydration.

Drug Therapy.

Acute biliary pain requires opioid analgesia, such as morphine or hydromorphone (Dilaudid). All opioids may cause some degree of sphincter of Oddi spasm.

Ketorolac (Toradol, Acular), an NSAID, may be used for mild to moderate pain. Be sure to monitor the patient for signs and symptoms of GI distress and pain because the drug can cause GI bleeding. The health care provider prescribes antiemetics to control nausea and vomiting. IV antibiotic therapy may also be given, depending on the cause of cholecystitis or as a one-time dose for surgery.

An option for a small number of patients with cholelithiasis (gallstones) is the use of oral bile acid dissolution or gallstone stabilizing agents. Drugs such as ursodiol (Actigall) and chenodiol (Chenodal) may be given for up to 2 years to dissolve or stabilize gallstones. A gallbladder ultrasound is required every 6 months for the first year of therapy to determine the effectiveness of the drug. Teach patients on this type of drug therapy to report diarrhea, vomiting, or severe abdominal pain, especially if it radiates to the shoulders, to their health care provider immediately. Remind them to take the medication with food and milk (Felicilda-Reynaldo, 2012).

Other Nonsurgical Interventions.

For some patients with small stones or for those who are not good surgical candidates, a treatment that is commonly used for kidney stones can be used to break up gallstones—*extracorporeal shock wave lithotripsy (ESWL).* This procedure can be used only for patients who have a normal weight, cholesterol-based stones, and good gallbladder function. The patient lies on a water-filled pad, and shock waves break up the large stones into smaller ones that can be passed through the digestive system. During the procedure, he or she may have pain from the movement of the stones or duct or gallbladder spasms. A therapeutic bile acid, such as ursodeoxycholic acid (UDCA), may be used after the procedure to help dissolve the remaining stone fragments.

Another treatment option in people who cannot have surgery is the insertion of a percutaneous transhepatic biliary catheter (drain) using CT

or ultrasound guidance to open the blocked duct(s) so that bile can flow (cholecystostomy). Catheters can be placed several ways, depending on the condition of the biliary ducts, in an internal, external, or internal/external drain. Biliary catheters usually divert bile from the liver into the duodenum to bypass a stricture. When all of the bile enters the duodenum, it is called an *internal* drain. However, in some cases a patient has an *internal/external* drain in which part of the bile empties into a drainage bag. Patients who need this drain for an extended period may have the external drain capped. If jaundice or leakage around the catheter site occurs, teach the patient to reconnect the catheter to a drainage bag and have a follow-up cholangiogram injection done by an interventional radiologist. An *external* only catheter is connected either temporarily or permanently to a drainage bag. A reduction in bile drainage indicates that the drain is no longer working.

Surgical Management.

Cholecystectomy is a surgical removal of the gallbladder. One of two procedures is performed: the laparoscopic cholecystectomy and, far less often, the traditional open approach cholecystectomy.

Laparoscopic Cholecystectomy.

Laparoscopic cholecystectomy, a minimally invasive surgery (MIS), is the "gold standard" and is performed far more often than the traditional open approach. The advantages of MIS when compared with the open approach include:

- Complications are not common.
- The death rate is very low.
- Bile duct injuries are rare.
- Patient recovery is quicker.
- Postoperative pain is less severe.

The laparoscopic procedure (often called a "lap chole") is commonly done on an ambulatory care basis in a same-day surgery suite. The surgeon explains the procedure, and the nurse answers questions and reinforces the instructions. Reinforce what to expect after surgery, and review pain management, deep-breathing exercises, incisional care, and leg exercises to prevent deep vein thrombosis. There is no special preoperative preparation other than the routine preparation for surgery under general anesthesia described in Chapter 14. An IV antibiotic is usually given immediately before or during surgery (Society of American Gastrointestinal and Endoscopic Surgeons [SAGES], 2013).

During the surgery the surgeon makes a very small midline puncture

at the umbilicus. Additional small incisions may be needed, although single-incision laparoscopic cholecystectomy (SILC) using a flexible endoscope is often done (Salam, 2010). The abdominal cavity is insufflated with 3 to 4 liters of carbon dioxide. Gasless laparoscopic cholecystectomy using abdominal wall lifting devices is a more recent innovation in some centers. This technique results in improved pulmonary and cardiac function. A trocar catheter is inserted, through which a laparoscope is introduced. The laparoscope is attached to a video camera, and the abdominal organs are viewed on a monitor. The gallbladder is dissected from the liver bed, and the cystic artery and duct are closed. The surgeon aspirates the bile and crushes any large stones, if present, and then extracts the gallbladder through the umbilical port.

Removing the gallbladder with the laparoscopic technique reduces the risk for wound complications. Some patients have mild to severe discomfort from carbon dioxide retention in the abdomen, which may be felt throughout the thorax and shoulders.

Nursing Safety Priority QSEN

Action Alert

After a laparoscopic cholecystectomy, assess the patient's oxygen saturation level frequently until the effects of the anesthesia have passed. Remind the patient to perform deep-breathing exercises every hour.

Other postoperative care for the patient after a laparoscopic procedure is similar to that for any patient having minimally invasive endoscopic surgery (see Chapter 16). Offer the patient food and water when fully awake, and monitor for the nausea and/or vomiting that often results from anesthesia. If needed, administer an antiemetic drug, such as ondansetron hydrochloride (Zofran), either IV push or as a disintegrating tablet. Several drug doses may be needed. Maintain an IV line to administer fluids until nausea and/or vomiting subside. Be sure to have the head of the bed elevated in the same-day surgery unit to prevent aspiration from vomiting. After nausea subsides, assist the patient to the bathroom to void. Early ambulation also promotes absorption of the carbon dioxide, which can decrease postoperative discomfort.

Administer an oral or IV push opioid as needed immediately after surgery. Continuous IV pain control is usually not required because there is only one or a few small incisions, which are covered with Steri-Strips

and small adhesive bandages (e.g., Band-Aids) or are surgically glued. The glue or Steri-Strips lose their adhesiveness in about a week to 10 days and can be removed or fall off as the incision heals.

The patient is usually discharged from the hospital or surgery center the same day, although older and obese patients may stay overnight. Provide postoperative teaching regarding pain management, incision care, and follow-up appointments. Teach the patient to use ice and oral opioids for incisional pain, if needed, for a few days. For abdominal or thoracic discomfort from carbon dioxide retention, many patients report that heat application is helpful. The patient is typically allowed to bathe or shower the day after surgery.

After laparoscopic surgery, the patient can return to usual activities much sooner than those having an open cholecystectomy. Instruct the patient to rest for the first 24 hours and then begin to resume usual activities Most patients are able to resume usual activities within a week.

Some patients are able to return to their usual diet after surgery, while others must carefully monitor their diet to avoid high-fat foods. A large intake of fatty foods may result in abdominal pain and diarrhea, which could result in a mild post-cholecystectomy syndrome (PCS) (see later discussion of PCS on p. 1218). Teach patients to introduce foods high in fat one at a time to determine which foods are best tolerated.

A new minimally invasive surgical procedure is *natural orifice transluminal endoscopic surgery* (NOTES) for removal of or repair of organs. Surgery can be performed on many body organs through the mouth, vagina, and rectum. For removal of the gallbladder, the vagina is used most often in women because it can be easily decontaminated with Betadine or other antiseptic and allows easy access into the peritoneal cavity. The surgeon makes a small internal incision through the cul-de-sac of Douglas between the rectum and uterine wall to access the gallbladder. The main advantages of this procedure are the lack of visible incisions and minimal, if any, postoperative complications (Navarra et al., 2010).

Traditional Cholecystectomy.

Use of the open surgical approach (abdominal laparotomy) has greatly declined during the past 25 years. Patients who have this type of surgery usually have severe biliary obstruction and the ducts are explored to ensure patency.

The surgical nurse provides the usual preoperative care and teaching in the operating suite on the day of surgery (see Chapter 14). The surgeon removes the gallbladder through an incision and explores the

biliary ducts for the presence of stones or other cause of obstruction. The surgeon usually inserts a drainage tube such as a Jackson-Pratt (JP) drain. This tube is placed in the gallbladder bed to prevent fluid accumulation. The drainage is usually serosanguineous (serous fluid mixed with blood) and is stained with bile in the first 24 hours after surgery. Antibiotic therapy is given to prevent infection.

Patient care for a patient who has had a traditional open cholecystectomy is similar to the care for any patient who has had abdominal surgery under general anesthesia as described in Chapter 16. Postoperative incisional pain after a traditional cholecystectomy is controlled with opioids using a patient-controlled analgesia (PCA) pump. Encourage the patient to use coughing and deep-breathing exercises when pain is controlled and the incision is splinted.

Antiemetics may be necessary for episodes of postoperative nausea and vomiting. Administer the antiemetic early, as prescribed, to prevent retching associated with vomiting and thus to decrease pain related to muscle straining.

Provide care for the incision and the surgical drain. The surgeon typically removes the surgical dressing and drain within 24 hours after surgery.

The patient is NPO until fully awake postoperatively. Document the patient's level of consciousness, vital signs, and pain level. Assess the surgical incision for signs of infection, such as excessive redness or purulent drainage. Report changes to the surgeon immediately. Begin ambulation as soon as possible to prevent deep vein thrombosis and promote peristalsis.

Advance the diet from clear liquids to solid foods as peristalsis returns. The patient usually resumes solid foods and is discharged to home 1 to 2 days after surgery, depending on any complications and the patient's general condition. In the early postoperative period, if bile flow is reduced, a low-fat diet may reduce discomfort and prevent nausea. For most patients, a special diet is not required. Advise them to eat nutritious meals and avoid excessive intake of fatty foods, especially fried food, butter, and “fast food.” If the patient is obese, recommend a weight-reduction program.

Teach the patient to keep the incision clean and report any changes that may indicate infection. Remind him or her to report repeated abdominal or epigastric pain with vomiting and/or diarrhea that may occur several weeks to months after surgery. These symptoms indicate possible **postcholecystectomy syndrome (PCS)**. There are multiple causes of PCS, some of which are related to the biliary system and others

are not. Common causes of PCS are listed in Table 59-2. Not all patients experience PCS. Often the pain returns because of one of the underlying conditions listed in Table 59-2, not as a result of the cholecystectomy itself (Girometti et al., 2010).

TABLE 59-2

Common Causes of Postcholecystectomy Syndrome

Biliary	Non-Biliary
• Pseudocyst • Common bile duct (CBD) leak • CBD or pancreatic duct stricture or obstruction • Sphincter of Oddi dysfunction • Retained or new CBD gallstone • Pancreatic or liver mass • Primary sclerosing cholangitis • Diverticular compression	• Coronary artery disease • Intercostal neuritis • Unexplained pain syndrome • Psychiatric or neurologic disorder

Management depends on the exact cause but usually involves the use of endoscopic retrograde cholangiopancreatography (ERCP) to find the cause of the problem and repair it. This procedure and related nursing care are described in Chapter 52. Collaborative care includes pain management, antibiotics, nutrition and hydration therapy (possibly short-term parenteral nutrition), and control of nausea and vomiting.

NCLEX Examination Challenge

Physiological Integrity

The nurse is providing discharge instructions for a client who has undergone a laparoscopic cholecystectomy. Which instruction will the nurse include in the discharge teaching?

A Keep dressings in place for 4 weeks.
B Report bile-colored drainage from any of the incisions.
C Expect dark, tarry stools after surgery.
D Be aware that no dietary changes will be necessary.

Acute Pancreatitis

Pathophysiology

Acute pancreatitis is a serious and, at times, life-threatening inflammation of the pancreas. This process is caused by a premature activation of excessive pancreatic enzymes that destroy ductal tissue and pancreatic cells, resulting in autodigestion and fibrosis of the pancreas. The pathologic changes occur in different degrees. The severity of pancreatitis depends on the extent of inflammation and tissue damage. Pancreatitis can range from mild involvement evidenced by edema and inflammation to **necrotizing hemorrhagic pancreatitis (NHP).** NHP is diffusely bleeding pancreatic tissue with fibrosis and tissue death.

The pancreas is unusual in that it functions as both an exocrine gland and an endocrine gland. The primary *endocrine* disorder is diabetes mellitus and is discussed in Chapter 64. The *exocrine* function of the pancreas is responsible for secreting enzymes that assist in the breakdown of starches, proteins, and fats. These enzymes are normally secreted in the inactive form and become activated once they enter the small intestine. Early activation (i.e., activation within the pancreas rather than the intestinal lumen) results in the inflammatory process of pancreatitis. Direct toxic injury to the pancreatic cells and the production and release of pancreatic enzymes (e.g., trypsin, lipase, elastase) result from the obstructive damage. After pancreatic duct obstruction, increased pressure may contribute to ductal rupture allowing spillage of trypsin and other enzymes into the pancreatic parenchymal tissue. Autodigestion of the pancreas occurs as a result (Fig. 59-2). In *acute* pancreatitis, four major pathophysiologic processes occur: lipolysis, proteolysis, necrosis of blood vessels, and inflammation.

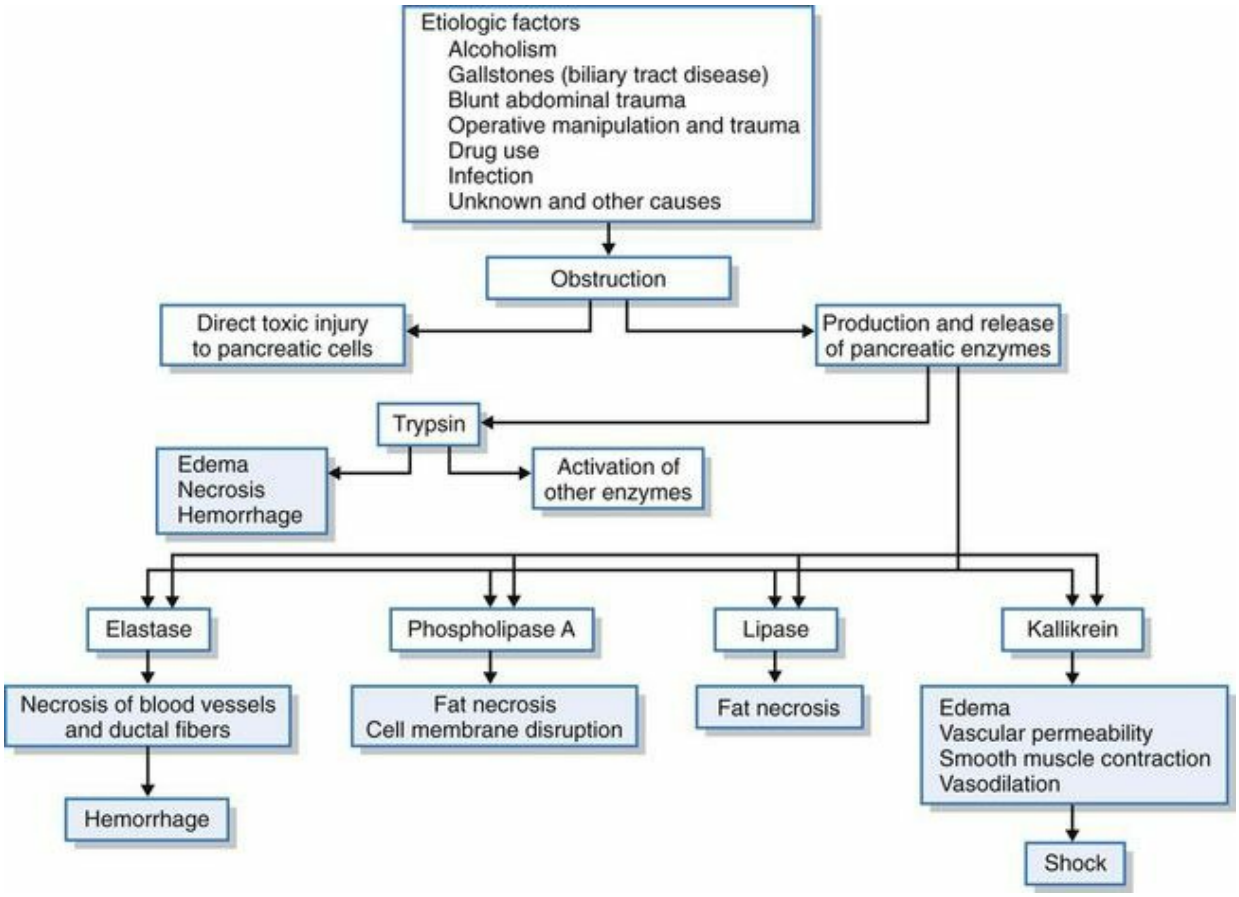

FIG. 59-2 The process of autodigestion in acute pancreatitis.

The hallmark of pancreatic necrosis is enzymatic fat necrosis of the endocrine and exocrine cells of the pancreas caused by the enzyme *lipase.* Fatty acids are released during this *lipolytic process* and combine with ionized calcium to form a soap-like product. The initial rapid lowering of serum calcium levels is not readily compensated for by the parathyroid gland. Because the body needs ionized calcium and cannot use bound calcium, hypocalcemia occurs (McCance et al., 2014).

Proteolysis involves the splitting of proteins by hydrolysis of the peptide bonds, resulting in the formation of smaller polypeptides. Proteolytic activity may lead to thrombosis and gangrene of the pancreas. Pancreatic destruction may be localized and confined to one area or may involve the entire organ.

Elastase is activated by trypsin and causes elastic fibers of the blood vessels and ducts to dissolve. The *necrosis of blood vessels* results in bleeding, ranging from minor bleeding to massive hemorrhage of pancreatic tissue. Another pancreatic enzyme, kallikrein, causes the release of vasoactive peptides, bradykinin, and a plasma kinin known as *kallidin.* These substances contribute to vasodilation and increased vascular permeability, further compounding the hemorrhagic process. This massive destruction of blood vessels by necrosis may lead to

generalized hemorrhage with blood escaping into the retroperitoneal tissues. *The patient with hemorrhagic pancreatitis is critically ill, and extensive pancreatic destruction and shock may lead to death. The majority of deaths in patients with acute pancreatitis result from irreversible shock.*

The *inflammatory stage* occurs when leukocytes cluster around the hemorrhagic and necrotic areas of the pancreas. A secondary bacterial process may lead to suppuration (pus formation) of the pancreatic parenchyma or the formation of an abscess. (See discussion of Pancreatic Abscess on p. 1226.) Mild infected lesions may be absorbed. When infected lesions are severe, calcification and fibrosis occur. If the infected fluid becomes walled off by fibrous tissue, a pancreatic pseudocyst is formed. (See discussion of Pancreatic Pseudocyst on p. 1226.)

Complications of Acute Pancreatitis

Acute pancreatitis may result in severe, life-threatening complications (Table 59-3). Jaundice occurs from swelling of the head of the pancreas, which slows bile flow through the common bile duct. The bile duct may also be compressed by calculi (stones) or a pancreatic pseudocyst. The resulting total bile flow obstruction causes severe jaundice. Intermittent hyperglycemia occurs from the release of glucagon, as well as the decreased release of insulin due to damage to the pancreatic islet cells. Total destruction of the pancreas may occur, leading to type 1 diabetes mellitus (McCance et al., 2014).

TABLE 59-3

Potential Complications of Acute Pancreatitis

- Pancreatic infection (causes septic shock)
- Hemorrhage (necrotizing hemorrhagic pancreatitis [NHP])
- Acute kidney failure
- Paralytic ileus
- Hypovolemic shock
- Pleural effusion
- Acute respiratory distress syndrome (ARDS)
- Atelectasis
- Pneumonia
- Multi-organ system failure
- Disseminated intravascular coagulation (DIC)
- Type 2 diabetes mellitus

Left lung pleural effusions frequently develop in the patient with acute pancreatitis. *Atelectasis and pneumonia may occur also, especially in older patients.*

Multi-system organ failure is caused by necrotizing hemorrhagic pancreatitis (NHP). The patient is at risk for acute respiratory distress syndrome (ARDS). This severe form of pulmonary edema is caused by

disruption of the alveolar-capillary membrane and is a serious complication of acute pancreatitis. (See Chapter 32 for a discussion of ARDS.) In acute pancreatitis, pulmonary failure accounts for more than half of all deaths that occur in the first week of the disease.

Coagulation defects are another major potential complication and may result in death. Complex physiologic changes in the pancreas cause the release of necrotic tissue and enzymes into the bloodstream, resulting in altered coagulation. Disseminated intravascular coagulation (DIC) involves hypercoagulation of the blood, with consumption of clotting factors and the development of microthrombi.

Shock in acute pancreatitis results from peripheral vasodilation from the released vasoactive substances and the retroperitoneal loss of protein-rich fluid from proteolytic digestion. Hypovolemia may result in decreased renal perfusion and acute renal failure. Paralytic (adynamic) ileus results from peritoneal irritation and seepage of pancreatic enzymes into the abdominal cavity.

NCLEX Examination Challenge

Physiological Integrity

The nurse closely monitors the client with acute pancreatitis for which complication?

A Duodenal ulcer
B Infection
C Pneumonia
D Heart failure

Etiology and Genetic Risk

In many cases the cause of pancreatitis is not known, but many factors can injure the pancreas. The most common cause is biliary tract disease, with gallstones accounting for almost half of the cases of obstructive pancreatitis (McCance et al., 2014). Acute pancreatitis may occur as a result of trauma from surgical manipulation after biliary tract, pancreatic, gastric, and duodenal procedures, such as cholecystectomy, the Whipple procedure, and partial gastrectomy. The trauma may also occur as a complication of the diagnostic procedure *endoscopic retrograde cholangiopancreatography (ERCP)*, although this rarely occurs.

Other causative factors include:

- Trauma: external (blunt trauma, stab wounds, gunshot wounds [GSWs])

- Pancreatic obstruction: tumors, cysts, or abscesses; abnormal organ structure
- Metabolic disturbances: hyperlipidemia, hyperparathyroidism, or hypercalcemia
- Renal disturbances: failure or transplantation
- Familial, inherited pancreatitis
- Penetrating gastric or duodenal ulcers, resulting in peritonitis
- Viral infections, such as coxsackievirus B and human immune deficiency virus [HIV] infection
- Alcoholism
- Toxicities of drugs, including opiates, sulfonamides, thiazides, steroids, and oral contraceptives (less common)
- Cigarette smoking
- Cystic fibrosis
- Gallstones
- Abdominal surgery

Incidence and Prevalence

Pancreatic "attacks" are especially common during holidays and vacations when alcohol consumption may be high, especially in men. Women are affected most often after cholelithiasis and biliary tract problems. They are also most at risk for pancreatitis within several months after childbirth.

Death occurs in a small percentage of patients with acute pancreatitis, but with early diagnosis and treatment, mortality can be reduced. It occurs at a higher rate in *older adults* and in patients with postoperative pancreatitis. The prognosis for recovery is usually good for pancreatitis associated with biliary tract disease and poor if pancreatitis accompanies alcoholism.

❖ Patient-Centered Collaborative Care

◆ Assessment

History.

Most often the patient reports severe and constant abdominal pain. Conduct the interview *after pain is controlled.* Ask whether the abdominal pain occurs when drinking alcohol or eating a high-fat meal. Obtain information about alcohol usage, including the amount of alcohol consumed during what period of time (i.e., years of consumption, how much usually consumed over a particular period). Question the patient

about a family or personal history of alcoholism, pancreatitis, trauma, or biliary tract disease. Ask whether any abdominal surgical interventions, such as cholecystectomy, or diagnostic procedures, such as ERCP, have been performed recently.

Ask about other medical problems known to cause pancreatitis, including peptic ulcer disease, renal failure, vascular disorders, hyperparathyroidism, and hyperlipidemia. Inquire about recent viral infections. Ask the patient or family member to list all prescription and over-the-counter (OTC) drugs taken recently, including nutritional and herbal supplements.

Physical Assessment/Clinical Manifestations.

The diagnosis of pancreatitis is made based on the clinical presentation combined with the results of diagnostic studies—both laboratory and imaging assessments. Clinical manifestations of acute pancreatitis vary widely and depend on the severity of the inflammation. Typically, a patient is diagnosed after presenting with severe abdominal pain in the mid-epigastric area or left upper quadrant. Assess the intensity and quality of pain. The patient often states that the pain had a sudden onset and radiates to the back, left flank, or left shoulder. The pain is described as intense, **boring** (feeling that it is going through the body), and continuous and is worsened by lying in the supine position. Often the patient finds relief by assuming the fetal position (with the knees drawn up to the chest and the spine flexed) or by sitting upright and bending forward. He or she may report weight loss resulting from nausea and vomiting. Obtain the patient's weight.

When performing an abdominal assessment, inspect for:

- Generalized jaundice
- Gray-blue discoloration of the abdomen and periumbilical area
- Gray-blue discoloration of the flanks, caused by pancreatic enzyme leakage to cutaneous tissue from the peritoneal cavity

Listen for bowel sounds; absent or decreased bowel sounds usually indicate paralytic (adynamic) ileus. On light palpation, note abdominal tenderness, rigidity, and guarding as a result of peritonitis. A palpable mass may be found if a pancreatic pseudocyst is present. Pancreatic ascites creates a dull sound on percussion.

Monitor and record vital signs frequently to assess for elevated temperature, tachycardia, and decreased blood pressure, or delegate and supervise this activity. Respiratory problems, such as left lung pleural effusions, atelectasis, and pneumonia, are common in patients with acute pancreatitis. Auscultate the lung fields for adventitious sounds or

diminished breath sounds, and observe for dyspnea or orthopnea.

Nursing Safety Priority QSEN

Critical Rescue

For the patient with acute pancreatitis, monitor for significant changes in vital signs that may indicate the life-threatening complication of shock. Hypotension and tachycardia may result from pancreatic hemorrhage, excessive fluid volume shifting, or the toxic effects of abdominal sepsis from enzyme damage. Observe the patient for changes in behavior and level of consciousness (LOC) that may be related to alcohol withdrawal, hypoxia, or impending sepsis with shock.

Psychosocial Assessment.

If excessive alcohol is a causative factor, tactfully explore the patient's alcohol intake history. Provide patient privacy, and establish a trusting relationship. Discuss the intake of alcohol and the reasons for overindulging. Using the CAGE questionnaire to assist with determining alcohol use may be beneficial. Ask him or her when increased drinking episodes occur and, in particular, whether binges occur during holidays, vacations, or weekends or revolve around particular activities, such as television viewing. Question the patient about any recent traumatic or stressful event that may have contributed to increased alcohol consumption, such as the death of a family member or a job loss.

Laboratory Assessment.

Diagnostic laboratory abnormalities are typical in patients with acute pancreatitis (Table 59-4). A variety of pancreatic and non-pancreatic disorders can cause increased serum amylase levels. In patients with pancreatitis, *amylase* levels usually increase within 12 to 24 hours and remain elevated for 2 to 3 days. Persistent elevations may be an indicator of pancreatic abscess or pseudocyst (Pagana & Pagana, 2014).

TABLE 59-4

Causes of Diagnostic Laboratory Abnormalities in Acute Pancreatitis

ABNORMAL FINDING	CAUSE
Cardinal Diagnostic Tests	
Increased *serum* amylase	Pancreatic cell injury
Elevated *serum* lipase	Pancreatic cell injury
Elevated *serum* trypsin	Pancreatic cell injury
Elevated *serum* elastase	Pancreatic cell injury
Other Diagnostic Tests	
Elevated serum glucose	Pancreatic cell injury, resulting in impaired carbohydrate metabolism; decreased insulin release
Decreased serum calcium and magnesium	Fatty acids combined with calcium; seen in fat necrosis
Elevated bilirubin	Hepatobiliary obstructive process
Elevated alanine aminotransferase (ALT)	Hepatobiliary involvement
Elevated aspartate aminotransferase (AST)	Hepatobiliary involvement
Elevated leukocyte count	Inflammatory response

Lipase also helps determine the presence of acute pancreatitis. Serum levels may rise later than amylase and remain elevated for up to 2 weeks. Because these levels stay elevated for such a long time, the health care provider may find this test useful in diagnosing patients who are not examined until several days after the initial onset of symptoms. An increase in lipase and amylase in the urine is also expected (Pagana & Pagana, 2014).

If pancreatitis is accompanied by biliary dysfunction (biliary pancreatitis), serum *bilirubin* and *alkaline phosphatase* levels are usually elevated. A sensitive indicator of biliary obstruction in acute pancreatitis is serum *alanine aminotransferase (ALT)*. A threefold or greater rise in concentration indicates that the diagnosis of acute biliary pancreatitis is valid. Elevated *white blood cell (WBC) count and differential, erythrocyte sedimentation rate (ESR),* and serum *glucose* levels are also common in acute pancreatitis. The levels often correlate with disease severity.

Decreased serum *calcium* and *magnesium* levels are seen with fat necrosis. Calcium levels may fall and remain decreased for 7 to 10 days. Those that consistently remain below 8 mg/dL are associated with a poor prognosis. Other tests include the basic metabolic panel (BMP), complete blood count (CBC), triglycerides, serum total protein, and albumin. The blood urea nitrogen (BUN), serum glucose, and triglycerides are usually elevated. Hemoconcentration is common as a result of third-space fluid loss. Leukocytosis (elevated WBCs) and thrombocytopenia (decreased platelets) are common (Pagana & Pagana, 2014). Albumin levels are decreased because cytokines (e.g., tumor necrosis factor [TNF]) released

as part of the inflammatory response allow it to move from the bloodstream into the extravascular space. The presence of C-reactive protein suggests possible pancreatic inflammation and necrosis.

Imaging Assessment.

Abdominal ultrasound is the most sensitive test to diagnose causes of pancreatitis, such as gallstones, and can be performed at the bedside. However, it is not helpful in viewing the pancreas because of overlying bowel gas. Therefore *contrast-enhanced computed tomography (CT)* provides a more reliable image and diagnosis of acute pancreatitis. This noninvasive technique may also be used to rule out pancreatic pseudocyst or ductal calculi.

An abdominal x-ray may also reveal gallstones. A chest x-ray may show elevation of the left side of the diaphragm or pleural effusion. Pancreatic stones are best diagnosed through ERCP.

Analysis

The priority NANDA-I nursing diagnoses and collaborative problems for patients with acute pancreatitis include:

1. Acute Pain related to pancreatic inflammation and enzyme leakage (NANDA-I)
2. Inadequate nutrition related to the inability to ingest food and absorb nutrients

Planning and Implementation

Managing Acute Pain

Planning: Expected Outcomes.

The patient with acute pancreatitis is expected to state that he or she has a decrease in or absence of abdominal pain, as evidenced by a pain intensity scale measurement.

Interventions.

The priorities for patient care are to provide supportive care by relieving symptoms, to decrease inflammation, and to anticipate or treat complications. *As for any patient, continually assess for and support the ABCs (**a**irway, **b**reathing, and **c**irculation)*. In collaboration with the respiratory therapist, if available, provide oxygen and other respiratory support as needed. The collaborative plan of care depends on the severity

of the illness.

Abdominal pain is the most common symptom of pancreatitis. The main focus of nursing care is aimed at controlling pain by interventions that decrease GI tract activity, thus decreasing pancreatic stimulation. Pain assessment to measure the effectiveness of these interventions is an essential part of nursing care.

Nonsurgical Management.

Mild pancreatitis requires hydration with IV fluids, pain control, and drug therapy. The health care team initially attempts to relieve pain with nonsurgical interventions, which include fasting and rest, drug therapy, and comfort measures. If the patient has a life-threatening complication or requires frequent assessment, he or she is admitted to a critical care unit for invasive hemodynamic monitoring.

To rest the pancreas and reduce pancreatic enzyme secretion, withhold food and fluids (NPO) during the acute period. The health care provider prescribes IV isotonic fluid administration to maintain hydration. IV replacement of calcium and magnesium may also be needed. Measure and document intake and output. Some patients have an indwelling urinary catheter to obtain accurate measurements.

Nasogastric drainage and suction are reserved for more *severely ill* patients who have continuous vomiting or biliary obstruction. Gastric decompression using a nasogastric tube (NGT) prevents gastric juices from flowing into the duodenum.

Nursing Safety Priority QSEN

Action Alert

Because paralytic (adynamic) ileus is a common complication of acute pancreatitis, prolonged nasogastric intubation may be necessary. Assess frequently for the return of peristalsis by asking the patient if he or she has passed flatus or had a stool. The return of bowel sounds is not reliable as an indicator of peristalsis return; passage of flatus or a bowel movement is the most reliable indicator. See the discussion of intestinal obstructions in Chapter 57 on p. 1157.

To decrease pain, the primary drug class used is opioid. Other drugs may also be prescribed. Pain management for acute pancreatitis typically begins with the administration of opioids by patient-controlled analgesia (PCA). Drugs such as morphine or hydromorphone (Dilaudid) are

typically used because meperidine (Demerol) can cause seizures, especially in older adults. Other options that have been used successfully to manage acute pain include IV or transdermal fentanyl and epidural analgesia.

In *mild* pancreatitis, the pain usually subsides in 2 to 3 days. However, with *severe* acute pancreatitis, the abdominal pain and tenderness may persist for up to 2 weeks. The dosages and intervals of drug administration are individualized according to the severity of the disease and the symptoms.

Histamine receptor antagonists (e.g., ranitidine [Zantac]) and proton pump inhibitors (e.g., omeprazole [Prilosec]) help decrease gastric acid secretion. Antibiotics may be used, but they are indicated primarily for patients with acute necrotizing pancreatitis. The health care provider will prescribe appropriate antibiotics, if needed.

Helping the patient assume a side-lying position (with the legs drawn up to the chest) may decrease the abdominal pain of pancreatitis ("fetal position"). Sitting with the knees flexed toward the chest is also helpful.

If the patient is NPO or has an NGT, remind assistive nursing personnel to implement frequent oral and nares hygiene measures to keep mucous membranes moist and free of inflammation or crusting. Because of the drying effect of drugs and the absence of oral fluids, the mouth and oral cavity may be extremely dry, resulting in considerable discomfort and possibly parotitis (inflammation of the parotid [salivary] glands).

Nursing Safety Priority QSEN

Action Alert

For the patient with acute pancreatitis, monitor his or her respiratory status every 4 to 8 hours or more often as needed, and provide oxygen to promote comfort in breathing. Respiratory complications such as pleural effusions increase patient discomfort. Fluid overload can be detected by assessing for weight gain, listening for crackles, and observing for dyspnea. Carefully monitor for signs of respiratory failure.

Observe for signs and symptoms of hypocalcemia by assessing for Chvostek's and Trousseau's signs. These tests cause muscle spasms after stimulating the associated nerves. Chapter 11 discusses assessment and interventions for patients with hypocalcemia in more detail.

Lowering the patient's anxiety level may also substantially reduce pain.

Explain all procedures and other aspects of patient care thoroughly. Provide reassurance, offer diversional activities such as music and reading material, and encourage visitors to direct attention away from the pain.

If pancreatitis was caused by gallstones, an ERCP with a **sphincterotomy** (opening of the sphincter of Oddi) may be performed on an urgent or emergent basis. If this procedure is not successful, surgery is required. ERCP is described in detail in Chapter 52.

Surgical Management.

Surgical intervention for acute pancreatitis is usually not indicated. However, if an ERCP is not successful in removing gallstones, a laparoscopic cholecystectomy may be performed as described on p. 1217 in the discussion of Surgical Management in the Cholecystitis section.

Complications of pancreatitis, such as pancreatic pseudocyst and abscess, may also require surgical intervention. Laparoscopy (minimally invasive surgery [MIS]) may be done to drain an abscess or pseudocyst. For patients who are high surgical risks, pseudocysts or abscesses can be treated by percutaneous drainage under CT guidance.

Promoting Nutrition

Planning: Expected Outcomes.

The patient with acute pancreatitis is expected to have adequate nutrition to meet his or her metabolic needs.

Interventions.

The patient is maintained on NPO status in the early stages of pancreatitis. Antiemetics for nausea and vomiting are prescribed as needed. Patients who have severe pancreatitis and are unable to eat for 24 to 48 hours after illness onset may begin jejunal tube feeding unless paralytic ileus is present. *Early* nutritional intervention enhances immune system functioning and may prevent complications and worsening inflammation. Enteral feeding is preferred over total parenteral nutrition (TPN) because it causes fewer episodes of glucose elevation and other complications associated with TPN. Be sure that the patient is weighed every day. Collaborate with the health care provider, dietitian, and pharmacist to plan and implement the most appropriate nutritional intervention. Chapter 60 describes collaborative care of patients receiving enteral feeding and TPN.

When food is tolerated during the healing phase, the health care

provider prescribes small, frequent, moderate- to high-carbohydrate, high-protein, low-fat meals. Foods should be bland with little spice. GI stimulants such as caffeine-containing foods (tea, coffee, cola, and chocolate), as well as alcohol, should be avoided. Monitor the patient beginning to resume oral food intake for nausea, vomiting, and diarrhea. *If any of these symptoms occur, notify the health care provider immediately.*

To boost caloric intake, commercial liquid nutritional preparations supplement the diet. The health care provider may also prescribe fat-soluble and other vitamin and mineral replacement supplements. Glutamine, omega-3 fatty acids, fiber, antioxidants, and/or nucleotides may be added to the patient's nutrition plan.

Community-Based Care

Home care preparation is individualized for each patient's circumstances. Some patients may be severely weakened from their acute illness and need to confine activity to one floor, limiting stair climbing and other strenuous activities until they regain their strength. Collaborate with the case manager to plan the best place for the patient to recover and resources that may be needed.

Education needs to be started early in the hospitalization period—as soon as the acute episodes of pain have subsided. Assess the patient's and family's knowledge of the disease.

The desired outcomes for discharge planning and education are to avoid further episodes of pancreatitis and prevent progression to a chronic disease. If the patient uses alcohol, instruct him or her to abstain from drinking to prevent further pain attacks and extension of inflammation and pancreatic insufficiency. Tell the patient that if alcohol is consumed, acute pain will return and further autodigestion of the pancreas may lead to chronic pancreatitis.

Teach the patient to notify the health care provider after discharge to home if acute abdominal pain or biliary tract disease (as evidenced by jaundice, clay-colored stools, or darkened urine) occurs. These signs and symptoms are possible indicators of complications or disease progression.

Patients with acute pancreatitis may require several visits by a home care nurse if the hospital course was complicated. In these cases, home care may be needed for wound care and assistance with ADLs. The patient requires medical follow-up with the primary care physician or nurse practitioner to monitor the disease process. For those with alcoholism, provide information about groups such as Alcoholics

Anonymous (AA). Family members may attend support groups such as Al-Anon and Alateen.

Evaluation: Outcomes

Evaluate the care of the patient with acute pancreatitis based on the identified priority patient problems. The expected outcomes include that the patient will:

- Have control of abdominal pain, as indicated by self-report
- Have adequate nutrition available to meet metabolic needs

Clinical Judgment Challenge

Patient-Centered Care; Evidence-Based Practice; Teamwork and Collaboration; Informatics QSEN

A 78-year-old man is admitted from home to the medical unit with acute pancreatitis secondary to a history of gallstones, hypertension, osteoarthritis, and type 2 diabetes mellitus. He has lost 20 pounds (9 kg) in the past 2 months and reports severe boring-like abdominal pain, fatigue, and weakness. On physical assessment, he has decreased bowel sounds in all quadrants, crackles in the bases of his lungs, and signs of dehydration. Vital signs are: T, 100° F; P, 110; R, 36; and BP, 102/58.

What is the priority for this patient's care at this time? What current evidence supports your answer? Where would you look for current evidence that would help you answer this question? (Be specific in your answer.)

1. What laboratory findings would you expect him to have? Why?
2. With whom should you collaborate to meet the desired outcomes for his care?
3. What community support and health teaching is he going to require when he is discharged?

Chronic Pancreatitis

Pathophysiology

Chronic pancreatitis is a progressive, destructive disease of the pancreas that has remissions and exacerbations ("flare-ups"). Inflammation and fibrosis of the tissue contribute to pancreatic insufficiency and diminished function of the organ.

Chronic pancreatitis can be classified into several categories. *Alcoholism* is the primary risk factor for **chronic calcifying pancreatitis (CCP),** the most common type. In the early stages of the disease, pancreatic secretions precipitate as insoluble proteins that plug the pancreatic ducts and flow of pancreatic juices. As the protein plugs become more widespread, the cellular lining of the ducts changes and ulcerates. This inflammatory process causes fibrosis of the pancreatic tissue. Intraductal calcification and marked pancreatic tissue destruction (necrosis) develop in the late stages. The organ becomes hard and firm as a result of cell atrophy and pancreatic insufficiency.

Chronic calcifying pancreatitis is found predominantly in men, but the incidence in women is increasing. In women, chronic pancreatitis occurs more commonly among those with biliary tract disease (cholecystitis and cholelithiasis).

Chronic obstructive pancreatitis develops from inflammation, spasm, and obstruction of the sphincter of Oddi, often from cholelithiasis (gallstones). Inflammatory and sclerotic lesions occur in the head of the pancreas and around the ducts, causing an obstruction and backflow of pancreatic secretions. (See Complications of Acute Pancreatitis, p. 1219.)

Autoimmune pancreatitis is a chronic inflammatory process in which immunoglobulins invade the pancreas. Other organs may also be infiltrated, including the lungs and liver. Whereas other types of chronic pancreatitis may predispose the patient to pancreatic cancer, there is no evidence that autoimmune pancreatitis is a risk factor (Novotny et al., 2010).

Idiopathic and **hereditary chronic pancreatitis** may be associated with *SPINK1* and *CFTR* gene mutations (Midha et al., 2010). The protein encoded by the *SPINK1* gene is a trypsin inhibitor. The *CFTR* gene is associated with cystic fibrosis. Research on these gene mutations can help develop targeted drug therapy for treatment of these diseases.

Pancreatic insufficiency in any type of chronic pancreatitis causes loss of *exocrine* function. Most patients with chronic pancreatitis have decreased pancreatic secretions and bicarbonate. Pancreatic enzyme secretion must be greatly reduced to produce steatorrhea resulting from

severe malabsorption of fats. These characteristic stools are pale, bulky, and frothy and have an offensive odor. The action of colonic bacteria on unabsorbed lipids and proteins is responsible for the extremely foul odor. On inspection of the stools, the fat content is visible. In severe chronic pancreatitis, stool fat output may be more than 40 g/day.

Fat malabsorption also contributes to weight loss and muscle wasting (a decrease in muscle mass) and leads to general debilitation. Protein malabsorption results in a "starvation" edema of the feet, legs, and hands caused by decreased levels of circulating albumin.

The loss of pancreatic *endocrine* function is responsible for the development of diabetes mellitus in patients with chronic pancreatic insufficiency. (See Chapter 64 for a complete discussion of diabetes mellitus.)

The patient with chronic pancreatitis may have pulmonary complications, such as pleuritic pain, pleural effusions, and pulmonary infiltrates. Pancreatic ascites may decrease diaphragmatic excursion and lung expansion, resulting in impaired ventilation. In the ill patient with chronic pancreatitis, acute respiratory distress syndrome (ARDS) may develop.

Patient-Centered Collaborative Care

Assessment

Many of the clinical manifestations of chronic pancreatitis differ from those of an acute inflammation. Abdominal pain is the major clinical manifestation for most types of pancreatitis (Chart 59-2). For those with chronic pancreatitis, pain is typically described as a continuous burning or gnawing dullness with periods of acute exacerbation (flare-ups). The pain is very intense and relentless. The frequency of acute exacerbations may increase as the pancreatic fibrosis develops.

Chart 59-2 Key Features

Chronic Pancreatitis

- Intense abdominal pain (major clinical manifestation) that is continuous and burning or gnawing
- Abdominal tenderness
- Ascites
- Possible left upper quadrant mass (if pseudocyst or abscess is present)
- Respiratory compromise manifested by adventitious or diminished

breath sounds, dyspnea, or orthopnea
- Steatorrhea; clay-colored stools
- Weight loss
- Jaundice
- Dark urine
- Polyuria, polydipsia, polyphagia (diabetes mellitus)

Perform an abdominal assessment. Abdominal tenderness is less intense in patients with chronic pancreatitis than in those with acute pancreatitis. A mass may be palpated in the left upper quadrant, which may suggest a pancreatic pseudocyst or abscess. Massive pancreatic ascites may be present, producing dullness on abdominal percussion. Because respiratory complications can occur, auscultate the lung fields for adventitious sounds or decreased aeration and observe for dyspnea or orthopnea.

Ask the patient to collect a random stool specimen if able, or ask him or her to describe the stools. The specimen may show **steatorrhea** (foul-smelling fatty stools that may increase in volume as pancreatic insufficiency progresses and lipase production decreases). Assess for unintentional weight loss, muscle wasting, jaundice, dark urine, and the manifestations of diabetes mellitus, such as polyuria (increased urinary output), polydipsia (excessive thirst), and polyphagia (increased appetite).

Diagnosis is based on the patient's clinical manifestations and laboratory and imaging assessment. *Endoscopic retrograde cholangiopancreatography* (ERCP) is done to visualize the pancreatic and common bile ducts. *Imaging studies* such as CT scanning, contrast-enhanced MRI, abdominal ultrasound (US), and endoscopic ultrasound (EUS) are also useful in making the diagnosis. In chronic pancreatitis, laboratory findings include normal or moderately elevated serum *amylase* and *lipase* levels. Obstruction of the intrahepatic bile duct can cause elevated serum *bilirubin* and *alkaline phosphatase* levels. Intermittent elevations in serum *glucose* levels are common and can be detected by blood glucose monitoring, both fasting and non-fasting.

Interventions

The focus of caring for the patient with chronic pancreatitis is to manage pain, assist in maintaining sufficient nutrition, and prevent recurrence.

Nonsurgical Management.

Nonsurgical interventions include primarily drug and nutrition therapy. The major intervention for the pain of chronic pancreatitis is drug therapy. Medicate the patient as prescribed according to the assessment of the intensity of pain. Evaluate the effectiveness of the drug intervention. Opioid analgesia is most frequently used initially, but dependency may occur. Non-opioid analgesics may be tried to relieve pain. (See Chapter 3 for other interventions for chronic pain.)

Pancreatic-enzyme replacement therapy (PERT) is the standard of care to prevent malnutrition, malabsorption, and excessive weight loss (Chart 59-3). Pancrelipase is usually prescribed in capsule or tablet form and contains varying amounts of amylase, lipase, and protease. Teach patients not to chew or crush pancrelipase delayed-release capsules (Creon) or enteric tablets, and teach them to take the medications with all meals and snacks.

Chart 59-3 Patient and Family Education: Preparing for Self-Management

Enzyme Replacement for the Patient with Chronic Pancreatitis

- Take pancreatic enzymes with meals and snacks and follow with a glass of water.
- Administer enzymes after antacid or H_2 blockers. (Decreased pH inactivates drug.)
- Swallow the tablets or capsules without chewing to minimize oral irritation and to allow the drug to be released slowly.
- If you cannot swallow the capsule, pierce the gelatin casing and place contents in applesauce.
- Do not mix enzyme preparations in protein-containing foods.
- Wipe your lips after taking enzymes to avoid skin irritation.
- Do not crush enteric-coated preparations.
- Follow up on all scheduled laboratory testing. (Pancrelipase can cause an increase in uric acid levels.)

The dosage of pancreatic enzymes depends on the severity of the malabsorption. Record the number and consistency of stools per day to monitor the effectiveness of enzyme therapy. If pancreatic enzyme treatment is effective, the stools should become less frequent and less fatty.

Nursing Safety Priority QSEN

Action Alert

If the patient has diabetes, the health care provider prescribes insulin or oral hypoglycemic agents for glucose control. Patients maintained on total parenteral nutrition (TPN) are particularly susceptible to elevated glucose levels and usually require regular insulin additives to the solution. Closely monitor blood glucose so that hyperglycemia is controlled. Check finger-stick blood glucose (FSBG) or sugar (FSBS) levels every 2 to 4 hours. Chapter 60 describes in detail the care associated with TPN.

The health care provider may also prescribe drug therapy to decrease gastric acid. Gastric acid destroys the lipase needed to break down fats. Controlling the acidity of the stomach with H_2 blockers or proton pump inhibitors or neutralizing stomach acid with oral sodium bicarbonate may enhance the effectiveness of PERT.

Protein and fat malabsorption result in significant weight loss and decreased muscle mass in the patient with chronic pancreatitis. Therefore the nutritional interventions for acute pancreatitis are also used for chronic pancreatitis. The patient often limits food intake to avoid increased pain. For this reason, nutrition maintenance is often difficult to achieve. Patients receive either total parenteral nutrition (TPN) or total enteral nutrition (TEN), including vitamin and mineral replacement.

Collaborate with the dietitian to teach the patient about long-term dietary management. He or she needs an increased number of calories, up to 4000 to 6000 calories/day, to maintain weight. Those foods high in carbohydrates and protein also assist in the healing process. Foods high in fat are avoided because they cause or increase diarrhea. Teach all patients to avoid alcohol. Alcohol-cessation programs may be recommended.

Surgical Management.

Surgery is not a primary intervention for the treatment of chronic pancreatitis. However, it may be indicated for ongoing abdominal pain, incapacitating relapses of pain, or complications such as abscesses and pseudocysts.

The underlying pathologic changes determine the procedure indicated. Using laparoscopy, the surgeon incises and drains an abscess or

pseudocyst. Laparoscopic cholecystectomy or choledochotomy (incision of the common bile duct) may be indicated if biliary tract disease is an underlying cause of pancreatitis. If the pancreatic duct sphincter is fibrotic, the surgeon performs a sphincterotomy (incision of the sphincter) to enlarge it. Endoscopic sphincterotomy may be used for patients who are poor surgical candidates.

In some cases laparoscopic distal pancreatectomy may be appropriate for resection of the distal pancreas or pancreas head. Endoscopic pancreatic necrosectomy and natural orifice transluminal endoscopic surgery (NOTES) are becoming more common for removing necrosed pancreatic tissue. Both procedures are performed through the GI wall without a visible skin incision. The NOTES procedure is discussed in Surgical Management on p. 1217 in the Cholecystitis section.

In a few cases, pancreas transplantation may be done. However, this procedure is performed most often for patients with severe, uncontrolled diabetes. Chapter 64 discusses pancreas transplantation.

Community-Based Care

Collaborate with the hospital-based case manager (CM) or discharge planner about home care or follow-up in another setting. A community-based CM may continue to follow the patient after hospital discharge. If the patient is discharged to home, the living area should be limited to one floor until he or she regains strength and can increase activity. Teach patients and families that toilet facilities must be easily accessible because of chronic steatorrhea and frequent defecation. If they are not easily accessible, a bedside commode is obtained for the home.

Because there is no known cure for chronic pancreatitis, patient and family education is aimed at preventing acute episodes of the disease, providing long-term care, and promoting health maintenance (Chart 59-4). Teach the patient to avoid known irritating substances, such as caffeinated beverages (stimulates the GI system) and alcohol. Collaborate with the dietitian in diet teaching, which focuses on eating bland, low-fat, frequent meals and avoiding rich, fatty foods. Stress the importance of adhering to the nutritional recommendations. Written instructions are essential, with consideration of personal and cultural food preferences.

Chart 59-4 Patient and Family Education: Preparing for Self-Management

Prevention of Exacerbations of Chronic Pancreatitis

- Avoid things that make your symptoms worse, such as drinking caffeinated beverages.
- Avoid alcohol ingestion; refer to self-help group for assistance.
- Avoid nicotine.
- Eat bland, low-fat, high-protein, and moderate-carbohydrate meals; avoid gastric stimulants, such as spices.
- Eat small meals and snacks high in calories.
- Take the pancreatic enzymes that have been prescribed for you with meals.
- Rest frequently; restrict your activity to one floor until you regain your strength.

Remind the patient and family members or significant others of the importance of adhering to pancreatic enzyme replacement. The patient must take the prescribed enzymes with meals and snacks to aid in the digestion of food and promote the absorption of fats and proteins. Teach the patient to take the enzymes before or at the beginning of the meal. Instruct him or her to report any increase in abdominal distention, cramping, and foul-smelling, frothy, fatty stools to the health care provider so that these supplements may be increased as needed. Remind the patient to report any skin breakdown so that therapeutic interventions to promote skin integrity can be started. Abdominal fistulas are common and present a difficult challenge because pancreatic secretions irritate the skin.

The frequency of defecation (whether continent or incontinent) poses challenging skin care problems. Instruct the patient to keep the skin dry and free of the abrasive fatty stools, which damage the skin. The skin should be cleaned thoroughly after each stool and a moisture barrier applied to prevent breakdown and maintain skin integrity. Many products on the market actively repel stool from the skin.

If the patient develops diabetes mellitus as a result of chronic pancreatitis, management of elevated glucose levels after discharge from the hospital may require oral antidiabetic agents or insulin injections. If this is the case, collaborate with the certified diabetic educator (CDE) to provide in-depth teaching concerning diabetes, its signs and symptoms, medical management, drug therapy, nutrition therapy, blood glucose monitoring, and general care.

Chronic illnesses are devastating for families. The high costs of medical insurance, medical treatment, and drug therapy cause serious

financial problems. Often the patient with chronic pancreatitis is unable to work. Collaborate with the CM about ways to assist the patient with resources for financial help.

The patient may require several home visits by nurses, depending on the severity of the chronic health problems and home maintenance and support needs. The nurse assesses the patient for pain, enzyme therapy, and psychosocial adaptation to a chronic illness. Refer him or her and the family to a counselor or a self-help group, such as Alcoholics Anonymous (www.aa.org) and Al-Anon (www.al-anon.org), if appropriate.

NCLEX Examination Challenge

Physiological Integrity

Which foods will the nurse teach the client with chronic pancreatitis to avoid? **Select all that apply.**

A Blueberries
B Green beans
C Bacon
D Baked fish
E Fried potatoes

Pancreatic Abscess

Pancreatic abscesses are the most serious complication of acute necrotizing pancreatitis. If untreated, they are always fatal. After surgery, the recurrence rate is high. The abscesses form from collections of purulent liquefaction of the necrotic pancreas.

Patients with pancreatic abscesses often appear more seriously ill than those with pseudocysts. Clinical manifestations are similar. However, the temperature in patients with abscesses may spike to as high as 104° F (40° C). Drainage via the percutaneous method or laparoscopy should be performed as soon as possible to prevent sepsis. Antibiotic treatment alone does not resolve the abscess. Death rates remain high even after surgical drainage. Many patients require multiple drainage procedures for repeated abscesses.

Pancreatic Pseudocyst

Pathophysiology

Pancreatic pseudocysts, or false cysts, are so named because, unlike true cysts, they do not have an epithelial lining. They are encapsulated, saclike structures that form on or surround the pancreas. The pseudocyst wall is inflamed, vascular, and fibrotic. It may contain up to several liters of straw-colored or dark brown viscous fluid, the enzymatic exudate of the pancreas (McCance et al., 2014). Risk factors for pseudocysts are acute pancreatitis, abdominal trauma, and chronic pancreatitis.

Patient-Centered Collaborative Care

Assessment

A pseudocyst can be palpated as an epigastric mass in about half of all cases. The primary presenting symptom is epigastric pain radiating to the back. Other common clinical manifestations include abdominal fullness, nausea, vomiting, and jaundice. Pseudocysts are diagnosed and their growth and resolution monitored by serial pancreatic diagnostic testing. Complications of pseudocyst formation include:

- Hemorrhage
- Infection
- Obstruction of the bowel, biliary tract, or splenic vein
- Abscess
- Fistula formation
- Pancreatic ascites

Interventions

Pseudocysts may spontaneously resolve, or they may rupture and produce hemorrhage. Surgical intervention is necessary if the pseudocyst does not resolve within 6 to 8 weeks or if complications develop. To provide external drainage, the surgeon inserts a sump drainage tube to remove pancreatic secretions and exudate. Pancreatic fistulas are common after surgery, and skin breakdown from corrosive pancreatic enzymes in patients who have external drainage presents a major nursing care challenge.

Pancreatic Cancer

Pathophysiology

Cancer of the pancreas is a leading cause of cancer deaths each year in the United States. It is difficult to diagnose early because the pancreas is hidden and surrounded by other organs. Treatment has limited results, and 5-year survival rates are low (American Cancer Society [ACS], 2013).

Pancreatic tumors usually originate from epithelial cells of the pancreatic ductal system. If the tumor is discovered in the early stages, the tumor cells may be localized within the glandular organ. However, this is highly unlikely. Most often, the tumor is discovered in the late stages of development and may be a well-defined mass or is diffusely spread throughout the pancreas.

The tumor may be a primary cancer, or it may result from metastasis from cancers of the lung, breast, thyroid, kidney, or skin. Primary tumors are generally adenocarcinomas and grow in well-differentiated glandular patterns. They grow rapidly and spread to surrounding organs (stomach, duodenum, gallbladder, and intestine) by direct extension and invasion of lymphatic and vascular systems. This highly metastatic lesion may eventually invade the lung, peritoneum, liver, spleen, and lymph nodes.

Clinical manifestations depend on the site of origin or metastasis. The head of the pancreas is the most common site. The tumors are usually small lesions with poorly defined margins. Jaundice results from tumor compression and obstruction of the common bile duct and from gallbladder dilation, causing the organ to enlarge.

Cancers of the body and tail of the pancreas are usually large and invade the entire tail and body. These tumors may be palpable abdominal masses, especially in the thin patient. Through metastatic spread via the splenic vein, metastasis to the liver may cause **hepatomegaly** (enlargement of the liver up to 2 to 3 times its normal size). Cancers of the body and tail spread more extensively than do pancreatic head carcinomas, with invasion of the retroperitoneum, vertebral column, spleen, adrenal glands, colon, or stomach. Regardless of where it originates, it spreads rapidly through the lymphatic and venous systems to other organs.

Venous thromboembolism is a common complication of pancreatic cancer. Necrotic products of the pancreatic tumor are believed to have thromboplastic properties resulting in the blood's hypercoagulable state. In addition, the patient is at high risk because of decreased mobility and extensive surgical manipulation.

The exact cause of pancreatic cancer is unknown. High-risk

populations are those in their sixth to eighth decades of life and those with a personal history of smoking.

Genetic/Genomic Considerations

Patient-Centered Care QSEN

A small number of those with pancreatic cancer have an inherited risk. Mutations in certain oncogenes have been identified. Mutations have also been revealed in tumor suppressor genes, such as *p16* and *BRCA2* —the same mutation that makes some women susceptible to breast and ovarian cancer. Genes responsible for hereditary nonpolyposis colorectal cancer can also increase a person's risk for pancreatic cancer (ACS, 2013).

Other risk factors associated with the disease include:

- Diabetes mellitus
- Chronic pancreatitis
- Cirrhosis
- High intake of red meat, especially processed meat like steak
- Long-term exposure to chemicals such as gasoline and pesticides
- Obesity
- Older age
- Male gender
- Cigarette smoking
- Family history
- Genetic syndromes

Patient-Centered Collaborative Care

Assessment

Pancreatic cancer often presents in a slow and vague manner. The presenting symptoms depend somewhat on the location of the tumor. The first sign may be jaundice, which suggests late, advanced disease (Chart 59-5). Jaundice occurs because the gallbladder and liver are commonly involved. As the tumor spreads, the yellow skin color associated with obstructive jaundice progressively worsens. Ask the patient whether the color of the stool and urine has changed. As a result of the obstructive process, the stool is clay colored and the urine is dark and frothy. Inspect the skin for dryness and scratch marks, indicating pruritus from jaundice caused by bile salt collection. Assess the sclera for icterus (yellowing) and the mucous membranes for signs of jaundice.

Chart 59-5 Key Features

Pancreatic Cancer

- Jaundice
- Clay-colored (light) stools
- Dark urine
- Abdominal pain: usually vague, dull, or nonspecific that radiates into the back
- Weight loss
- Anorexia
- Nausea or vomiting
- Glucose intolerance
- Splenomegaly (enlarged spleen)
- Flatulence
- Gastrointestinal bleeding
- Ascites (abdominal fluid)
- Leg or calf pain (from thrombophlebitis)
- Weakness and fatigue

The enlarged gallbladder and liver may be palpable. In advanced cases of pancreatic carcinoma, the tumor may be felt as a firm, fixed mass in the left upper abdominal quadrant or epigastric region.

The most common concern is fatigue, which is described as a diminished energy level and an increased need for rest relative to the level of activity. The patient notices an inability to perform usual physical or intellectual activities.

Question the patient about abdominal pain, which is usually described as a vague, constant dullness in the upper abdomen and nonspecific in nature. Pain also indicates advanced stages of the disease and may be related to eating or activity. Ask whether the patient has pain in other areas of the body. Referred back pain may be caused by pressure on the nerve plexus. Some patients have leg or calf pain with swelling and redness as a result of deep vein thrombosis or thrombophlebitis.

Weigh the patient to determine the extent of weight loss and whether it has occurred rapidly. Ask about food intake and intolerances. Anorexia accompanied by early satiety, nausea, flatulence (gas), and vomiting is common. GI bleeding may develop from esophageal or gastric varices caused by the tumor pressing on the portal vein. A new diagnosis of diabetes is found in some patients.

In addition to the focused history, perform a general abdominal

assessment. In particular, observe for distention and swelling, which may be **ascites** (abdominal fluid). Percussion over the ascitic abdomen elicits dullness, seen in the advanced stages of the disease process.

No specific blood tests diagnose pancreatic cancer. Serum *amylase* and *lipase* levels, as well as *alkaline phosphatase* and *bilirubin* levels, are increased. The degree of elevation depends on the acuteness or chronicity of the pancreatic and biliary damage. Elevated *carcinoembryonic antigen* (CEA) levels occur in most patients with pancreatic cancer. This test may provide early information about the presence of tumor cells. Other tumor markers such as CA 19-9 and CA 242 have been found to be useful serologic tests for monitoring a proven diagnosis and for continuing surveillance for potential spread or recurrence (Pagana & Pagana, 2014).

Abdominal *ultrasound* and *contrast-enhanced CT* are the most commonly used imaging techniques for confirming a tumor and can differentiate the tumor from a cyst. Endoscopic ultrasonography can also be performed to sample tissue for diagnosis and provide information on tumor type and size (Tonolini et al., 2012). Contrast harmonic echo-endoscopic ultrasound increases the accuracy of diagnosing solid pancreatic masses (Fusaroli et al., 2010).

Endoscopic retrograde cholangiopancreatography (ERCP) also provides visual diagnostic data. An alternative to ERCP is a percutaneous transhepatic biliary cholangiogram with placement of a percutaneous transhepatic biliary drain (PTBD). This drain decompresses the blocked biliary system by draining bile, either internally, externally, or both. Aspiration of pancreatic ascitic fluid by abdominal paracentesis may reveal cancer cells and elevated amylase levels.

Interventions

Management of the patient with pancreatic cancer is geared toward preventing tumor spread and decreasing pain. These measures are not curative, only palliative. The cancers are often metastatic and recur despite treatment.

Nonsurgical Management.

As in other types of cancer, chemotherapy or radiation is used to relieve pain by shrinking the tumor. It may be used before, after, or instead of surgery. *Chemotherapy* has had limited success in increasing survival time. In most cases, combining agents has been more successful than single-agent chemotherapy. 5-Fluorouracil (5-FU), a commonly used drug, may

be given alone or with gemcitabine (Gemzar) for locally advanced, or unresectable, pancreatic cancers. Gemcitabine may also be given with capecitabine (Xeloda), docetaxel (Taxotere), and/or erlotinib (Tarceva), a targeted agent for unresectable or metastatic tumors. Some patients receive three or four drugs and have had more tumor shrinkage as a result. Observe for adverse drug effects, such as fatigue, rash, anorexia, and diarrhea. Chapter 22 discusses nursing implications of chemotherapy in more detail.

Other targeted therapies being investigated include growth factor inhibitors, anti-angiogenesis factors, and kinase inhibitors (also known as *tyrosine kinase inhibitors*). Kinase inhibitors are a newer group of drugs that focus on cancer cells with little or no effect on healthy cells. Chapter 22 describes general nursing interventions associated with chemotherapy.

To control pain, the patient takes high doses of opioid analgesics (usually morphine) as prescribed and uses other comfort measures before the pain escalates and peaks. Because of the poor prognosis, drug dependency is not a consideration. Chapter 3 describes in detail the care of the patient with chronic cancer pain.

Intensive external beam *radiation* therapy to the pancreas may offer pain relief by shrinking tumor cells, alleviating obstruction, and improving food absorption. It does not improve survival rates. Implantation of radioactive iodine (^{125}I) seeds, in combination with systemic or intra-arterial administration of floxuridine (FUDR), has also been used. The patient may experience discomfort during and after the radiation treatments. Chapter 22 describes radiation therapy in more detail.

For patients experiencing biliary obstruction who are high surgical risks, **biliary stents** placed percutaneously (through the skin) can ensure patency to relieve pain. These stents are devices made of plastic materials that keep the ducts of the biliary system open. Using another approach, self-expandable stents may be inserted endoscopically to relieve obstruction.

Surgical Management.

Complete surgical resection of the pancreatic tumor offers the patient with pancreatic cancer the only effective treatment, but it is done only in patients with small tumors. *Partial pancreatectomy* is the preferred surgery for tumors smaller than 3 centimeters in diameter (Grützmann et al., 2011). Recent technologic advances have expanded the role of **minimally invasive surgery (MIS)** via laparoscopy in the staging,

palliation, and removal of pancreatic cancers. The procedure selected depends on the purpose of the surgery and stage of the disease. For example, if the patient has a biliary obstruction, a laparoscopic procedure to relieve the obstruction is performed. This procedure diverts bile drainage into the jejunum.

For larger tumors, the surgeon may perform either a *radical pancreatectomy* or the *Whipple procedure (pancreaticoduodenectomy).* These procedures have traditionally been done using an open surgical approach. Because of new advances in laparoscopic technology using a hand-assist device, this method is beginning to replace the conventional method. Some surgeons are not yet trained in how to perform this technique. Therefore the traditional open surgical approach remains the most common method of performing these surgeries.

Preoperative Care.

The patient with pancreatic cancer may be a poor surgical risk because of malnutrition and debilitation. Specific care depends on the type of surgical approach being used.

Often, in the late stages of pancreatic cancer or before the Whipple procedure, the physician inserts a small catheter into the jejunum **(jejunostomy)** so that enteral feedings may be given. This feeding method is preferred to prevent reflux and to facilitate absorption. Feedings are started in low concentrations and volumes and are gradually increased as tolerated. Provide feedings using a pump to maintain a constant volume, and assess for diarrhea frequency to determine tolerance. Chapter 60 provides additional information about enteral feeding.

For optimal nutrition, TPN may be necessary in addition to tube feedings or as a single measure to provide nutrition. When central venous access is required, a peripherally inserted central catheter (PICC) or other type of IV catheter may be necessary. Meticulous IV line care is an important nursing measure to prevent catheter sepsis. Sterile dressing changes and site observation are extremely important. Additional nursing care measures for the patient receiving TPN are given in Chapter 60. Monitor nutrition indicators such as serum prealbumin and albumin.

For the laparoscopic procedure, no bowel preparation is needed. However, either approach requires that the patient have nothing by mouth (NPO) for at least 6 to 8 hours before surgery. Surgeon preference and agency policy determine the preferred protocol for preoperative preparation.

Operative Procedures.

The **Whipple procedure (radical pancreaticoduodenectomy)** involves extensive surgical manipulation and is used most often to treat cancer of the head of the pancreas. The procedure entails removal of the proximal head of the pancreas, the duodenum, a portion of the jejunum, the stomach (partial or total **gastrectomy**), and the gallbladder, with anastomosis of the pancreatic duct **(pancreaticojejunostomy)**, the common bile duct **(choledochojejunostomy)**, and the stomach **(gastrojejunostomy)** to the jejunum (Fig. 59-3). In addition, the surgeon may remove the spleen **(splenectomy)**.

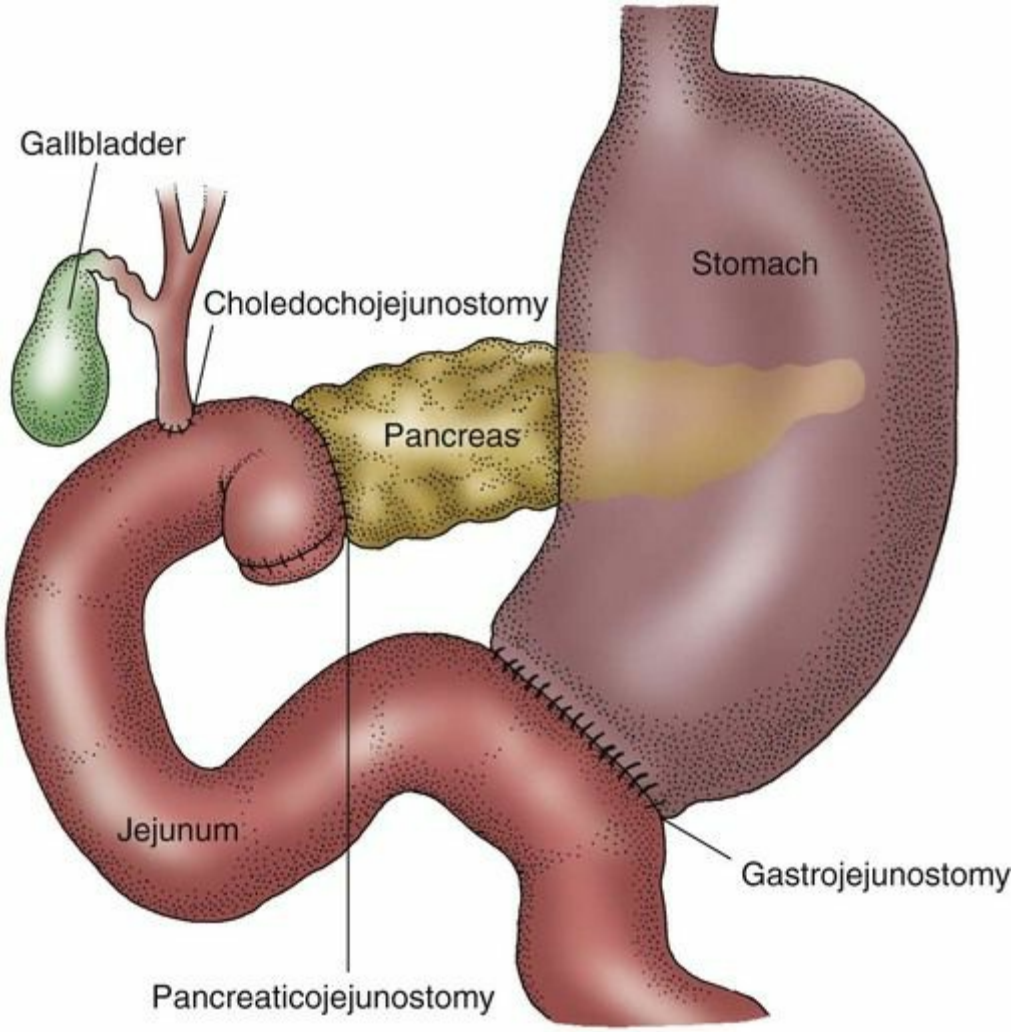

FIG. 59-3 The three anastomoses that constitute the Whipple procedure: choledochojejunostomy, pancreaticojejunostomy, and gastrojejunostomy.

Postoperative Care.

In addition to routine postoperative care measures, the patient who has

undergone an open radical pancreaticoduodenectomy requires intensive nursing care and is usually admitted to a surgical critical care unit. Observe for multiple potential complications of the open Whipple procedure as listed in Table 59-5.

TABLE 59-5

Potential Complications of the Whipple Procedure

Cardiovascular Complications
• Hemorrhage at anastomosis sites with hypovolemia • Myocardial infarction • Heart failure • Thrombophlebitis
Pulmonary Complications
• Atelectasis • Pneumonia • Pulmonary embolism • Acute respiratory distress syndrome • Pulmonary edema
Metabolic Complications
• Unstable diabetes mellitus • Renal failure
Gastrointestinal Complications
• Adynamic (paralytic) ileus • Gastric retention • Gastric ulceration • Bowel obstruction from peritonitis • Acute pancreatitis • Hepatic failure • Thrombosis to mesentery
Wound Complications
• Infection • Dehiscence • Fistulas: pancreatic, gastric, and biliary

The patient's primary benefits of MIS are a shorter postoperative recovery and less pain than with traditional open procedures. The patient having the laparoscopic Whipple surgery or radical pancreatectomy is also less at risk for severe complications. For patients having one of these procedures, observe for and implement preventive measures for these surgical complications:

- Diabetes (Check blood glucose often.)
- Hemorrhage (Monitor pulse, blood pressure, skin color, and mental status [e.g., LOC].)
- Wound infection (Monitor temperature, and assess wounds for redness and induration [hardness].)
- Bowel obstruction (Check bowel sounds and stools.)
- Intra-abdominal abscess (Monitor temperature and patient's report of severe pain.)

Immediately after surgery the patient is NPO and usually has a nasogastric tube (NGT) to decompress the stomach. Monitor GI drainage and tube patency. In open surgical approaches, biliary drainage tubes are placed during surgery to remove drainage and secretions from the area and to prevent stress on the anastomosis sites. Assess the tubes and drainage devices for tension or kinking, and maintain them in a dependent position.

Monitor the drainage for color, consistency, and amount. The drainage should be serosanguineous. The appearance of clear, colorless, bile-tinged drainage or frank blood with an increase in output may indicate disruption or leakage of an anastomosis site. Most of the disruptions of the site occur within 7 to 10 days after surgery. Hemorrhage can occur as an early or late complication.

Place the patient in the semi-Fowler's position to reduce tension on the suture line and anastomosis site as well as to optimize lung expansion. Stress can be decreased by maintaining NGT drainage at a low or high intermittent suction level to keep the remaining stomach (if a partial gastrectomy is done) or the jejunum (if a total gastrectomy is done) free of excessive fluid buildup and pressure. The NGT also reduces stimulation of the remaining pancreatic tissue.

The development of a fistula (an abnormal passageway) is the most common and most serious postoperative complication. Biliary, pancreatic, or gastric fistulas result from partial or total breakdown of an anastomosis site. The secretions that drain from the fistula contain bile, pancreatic enzymes, or gastric secretions, depending on which site is ruptured. *These secretions, particularly pancreatic fluid, are corrosive and irritating to the skin, and internal leakage causes chemical peritonitis.* **Peritonitis** (inflammation and infection of the peritoneum causing boardlike abdominal rigidity) requires treatment with multiple antibiotics. *If you suspect any postoperative complications resulting from MIS or open surgical approaches, call the surgeon immediately and provide assessment findings that support your concerns.*

Because the *open* Whipple procedure is extensive and can take many hours to complete, maintaining fluid and electrolyte balance can be difficult. Patients often have significant intraoperative blood loss and postoperative bleeding. The intestine is exposed to air for long periods, and fluid evaporates. Significant losses of fluid and electrolytes occur from the NGT and other drainage tubes. In addition, these patients may be malnourished and have low serum levels of protein and albumin, which maintain colloid osmotic pressure within the circulating system. Reduction in the serum osmotic pressure makes the patient likely to

develop third spacing of body fluids, with fluid moving from the vascular to the interstitial space, resulting in shock. These problems are less likely to occur when MIS is used. Therefore, when possible, the trained surgeon prefers to perform laparoscopic Whipple procedures to shorten operating time and prevent the many complications that can occur.

Nursing Safety Priority QSEN

Action Alert

To detect early signs of hypovolemia and prevent shock, closely monitor vital signs for decreased blood pressure and increased heart rate, decreased vascular pressures with a pulmonary artery catheter (Swan-Ganz catheter) (in ICU setting), and decreased urine output. Be alert for pitting edema of the extremities, dependent edema in the sacrum and back, and an intake that far exceeds output. Maintain sequential compression devices to prevent deep vein thrombosis.

Maintenance of prescribed IV isotonic fluid replacement with colloid replacements is important. Monitor hemoglobin and hematocrit values to assess for blood loss and the need for blood transfusions. Review electrolyte values for decreased serum levels of sodium, potassium, chloride, and calcium. IV fluid concentrations must be altered to correct these electrolyte imbalances. The physician prescribes replacement of electrolytes as needed.

Immediately after the Whipple procedure, the patient may have hyperglycemia or hypoglycemia as a result of stress and surgical manipulation of the pancreas. Most of the endocrine cells (responsible for insulin and glucagon secretion) are located in the body and tail of the pancreas. In some patients, up to half of the gland remains and diabetes does not develop. However, a large number of patients are diabetic before surgery. For patients having a radical pancreatectomy, administer insulin as prescribed because the entire pancreas is removed. Monitor glucose levels frequently during the early postoperative period, and administer insulin injections as prescribed.

NCLEX Examination Challenge

Physiological Integrity

A client had an open Whipple procedure yesterday for pancreatic cancer. Which nursing interventions are appropriate for this client?

Select all that apply.
A Monitor and document the client's nasogastric tube drainage.
B Place the client in a side-lying position to promote wound drainage.
C Assess the abdomen for signs of peritonitis.
D Monitor the client's hemoglobin and hematocrit.
E Check the client's blood glucose frequently.

Community-Based Care

The patient with pancreatic cancer is usually followed by a case manager (CM), both in the hospital and in the home or other community-based setting. Collaborate with the CM to ensure that the patient receives cost-effective treatment and that his or her needs are met.

Home Care Management.

The stage of progression of pancreatic cancer and available home care resources determine whether the patient can be discharged to home or whether additional care is needed in a skilled nursing facility or with a hospice provider. Home care preparations depend on the patient's physical and activity limitations and should be tailored to his or her needs. Coordinate care with the patient, family, or whoever will be providing care after discharge from the hospital—home care provider, hospice care provider, or extended-care provider.

The patient and family need compassionate emotional support to deal with issues related to this illness. The diagnosis of pancreatic cancer can frighten and overwhelm the patient and family. Assist family members in looking realistically and objectively at the amount of physical care required. Tell family members that their own physical and emotional health are at risk during this stressful period and that supportive counseling may be needed. If the family does not have a religious affiliation or a spiritual leader (e.g., a minister or a rabbi) to provide support, suggest alternative counseling options. Refer patients and families to the certified hospital chaplain if desired. It is appropriate for the nurse to make the initial contact or appointment according to the patient's or family's wishes.

Self-Management Education.

When the patient is discharged to home, many interventions are palliative and aimed at managing symptoms such as pain. In many cases the diagnosis of pancreatic cancer is made a few months before death occurs. The patient needs time to adjust to the diagnosis, which is

usually made too late for cure or prolonged survival. Help the patient identify what needs to be done to prepare for death, including end-of-life care. For example, he or she may want to write a will or see family members and friends whom he or she has not seen recently. The patient needs to make known to family members or others his or her specific requests for the funeral or memorial service. These actions help prepare for death in a dignified manner. Chapter 7 discusses in detail anticipatory grieving and preparation for death, as well as symptom management during the end of life.

Health Care Resources.

Regular home care nursing and assistive nursing personnel visits may be scheduled to assist the patient and family by providing physical, psychological, and supportive care. Supply information about local palliative and hospice care (see Chapter 7) and cancer support groups.

Nursing Concepts and Clinical Judgment Review

What might you NOTICE if the patient is experiencing inadequate digestion and nutrition as a result of gallbladder and pancreatic disorders?

- Report of intense abdominal pain
- Report of nausea, especially after food
- Report of anorexia
- Vomiting
- Jaundice
- Report of weight loss
- Dark urine
- Clay-colored stools

What should you INTERPRET and how should you RESPOND to a patient experiencing inadequate digestion and nutrition as a result of gallbladder and pancreatic disorders?

Perform and interpret physical assessment, including:

- Taking vital signs to assess for hypovolemia and fever
- Assessing respiratory status, including breath sounds
- Conducting a complete pain assessment if possible
- Weighing the patient
- Checking laboratory values, especially enzyme levels like amylase and lipase, liver function studies, and CBC
- Assessing vomitus for quality and amount

Respond by:

- Keeping the patient's head of the bed elevated and knees flexed
- Providing pain management by comfort measures and analgesia
- Providing oxygen if the patient is having dyspnea or adventitious breath sounds
- Reassuring the patient who may be concerned about possible cancer

On what should you REFLECT?

- Observe the patient for improvement in signs and symptoms, including pain control.
- Think about what could have caused the health problem.
- Think about what else you could do to help the patient meet desired outcomes.
- Plan health teaching for patient discharge.

Get Ready for the NCLEX® Examination!

Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Collaborate with the dietitian, pharmacist, health care provider, and case manager when planning care for patients with pancreatic cancer. **Teamwork and Collaboration** QSEN
- Refer patients with end-stage pancreatic cancer for palliative and hospice care.
- Refer patients with pancreatitis who use excessive alcohol to community resources such as Alcoholics Anonymous. **Patient-Centered Care** QSEN

Health Promotion and Maintenance

- Recognize that obese, middle-aged women are most likely to have gallbladder disease. **Patient-Centered Care** QSEN
- Teach patients to avoid losing weight too quickly and to keep weight under control to help prevent gallbladder disease. **Evidence-Based Practice** QSEN
- Teach patients to avoid excessive alcohol consumption to help prevent alcohol-induced acute pancreatitis.
- Instruct patients about ways to prevent exacerbations of chronic pancreatitis as outlined in Chart 59-4.

Psychosocial Integrity

- Refer patients with pancreatic cancer for support services such as spiritual leaders and counselors for coping strategies and facilitation of the grieving process.
- Help prepare the pancreatic cancer patient and family for the death and dying process.

Physiological Integrity

- Be aware that autodigestion of the pancreas causes severe pain in patients with acute pancreatitis (see Fig. 59-2).
- Monitor serum laboratory values, especially amylase and lipase (both elevated), in patients with pancreatitis (see Table 59-4).
- Assess for common clinical manifestations of cholecystitis as listed in

Chart 59-1.

- For patients with acute pancreatitis, provide pain management including opioid analgesia. **Patient-Centered Care** QSEN
- Recognize that acute pain relief is the first priority for patients with acute pancreatitis. **Evidence-Based Practice** QSEN
- Be aware that patients with biliary and pancreatic disorders are at high risk for biliary obstruction, a serious and painful complication.
- Assess for common clinical manifestations of chronic pancreatitis as listed in Chart 59-2.
- Document health teaching about enzyme replacement therapy as described in Chart 59-3. **Informatics** QSEN
- Assess patients with presenting clinical manifestations of pancreatic cancer as described in Chart 59-5.
- Observe for and implement interventions to prevent life-threatening complications of the Whipple procedure as outlined in Table 59-5. **Safety** QSEN

CHAPTER 60

Care of Patients with Malnutrition

Undernutrition and Obesity

Cherie R. Rebar, Nicole Heimgartner and Laura Willis

PRIORITY CONCEPTS

- Nutrition
- Fluid and Electrolyte Balance

Learning Outcomes

Safe and Effective Care Environment

1. Collaborate with the health care team members when providing care for patients with malnutrition or obesity.
2. Protect bariatric patients from injury.
3. Select appropriate activities to delegate to unlicensed assistive personnel to promote a patient's nutrition.

Health Promotion and Maintenance

4. Provide care that meets the special nutrition needs of older adults.
5. Recall the *2010 Dietary Guidelines for Americans* recommendations.
6. Teach overweight and obese patients the importance of lifestyle changes to promote health.
7. Perform a nutrition screening for all patients to determine if they are at high risk for nutrition health problems.

Psychosocial Integrity

8. Assess patient responses to being obese.

9. Explain how to reduce the psychological impact for the patient who is having bariatric surgery.

Physiological Integrity

10. Interpret findings of a nutrition screening and assessment.
11. Calculate body mass index (BMI), and interpret findings.
12. Describe the risk factors for malnutrition, especially for older adults.
13. Explain why serum visceral protein levels indicate change in nutrition status.
14. Identify the role of supplements in restoring or maintaining nutrition.
15. Explain how to prevent complications of total parenteral nutrition (TPN).
16. Explain how to maintain enteral tube patency.
17. Describe evidence-based practices to prevent aspiration for patients with nasoenteric tubes.
18. Explain the medical complications associated with obesity.
19. Identify the role of drug therapy in the management of obesity.
20. Prioritize nursing care for patients having bariatric surgery.
21. Develop a discharge teaching plan for patients having bariatric surgery.

 http://evolve.elsevier.com/Iggy/

Carbohydrates, protein, and fat are nutrients in food that supply the body with energy. In healthy people, most of this energy undergoes digestion and is absorbed from the GI tract. Food energy is used to maintain body temperature, respiration, cardiac output, muscle function, protein synthesis, and the storage and metabolism of food sources. Therefore proper nutrition plays a major role in promoting and maintaining health.

Energy balance refers to the relationship between energy used and energy stored. Weight loss occurs when energy used is more than intake. If food intake is more than energy used, weight is gained. Body proteins are used for energy when calorie intake is insufficient. The body attempts to meet its calorie requirements even if it is at the expense of protein needs.

Nutrition Standards for Health Promotion and Maintenance

The role of nutrition in disease has been a subject of interest for many years. The current focus is on health promotion and the prevention of disease by healthy eating and exercise. The Institute of Medicine of The National Academies (2014) has developed the **Dietary Reference Intakes (DRIs)** to serve as a nutrition guide that provides a scientific basis for food guidelines in the United States and Canada. Age, gender, and life stage influence the nutrient reference values of more than 40 nutrient substances (The Institute of Medicine of The National Academies, 2014). In the United States, the **Dietary Guidelines for Americans** are revised by the U.S. Department of Agriculture (USDA) and the U.S. Department of Health and Human Services (DHHS) every 5 years. The 2010 guidelines emphasize the need to include preferences of specific racial/ethnic groups, vegetarians, and other populations when selecting foods to maintain a healthful diet that is balanced with moderation and variety. If alcohol is consumed, it should be limited to one drink per day for women and two drinks for men (U.S. Department of Agriculture [USDA], 2010). Examples of other guidelines are listed in Table 60-1.

TABLE 60-1

Examples of *2010 Dietary Guidelines for Americans*

• Control total calorie intake to manage body weight. • Consume less than 300 mg per day of dietary cholesterol. • Increase intake of fat-free or low-fat milk and milk products, such as milk, yogurt, cheese, or fortified soy products. • Choose a variety of protein foods, which include seafood, lean meat and poultry, eggs, beans and peas, soy products, and unsalted nuts and seeds. • Reduce the intake of calories from solid fats and added sugars. • Reduce daily sodium intake to less than 2300 mg and further reduce intake to 1500 mg among persons who are 51 years of age or older and those of any age who are African American or have hypertension, diabetes, or chronic kidney disease. • Limit the consumption of foods that contain refined grains, especially refined grains that contain solid fats, added sugars, and sodium. • Increase vegetable and fruit intake.

Source: *Dietary Guidelines for Americans Council.* (2014). Retrieved September 2014, from http://www.fns.usda.gov/dietary-guidelines-americans-2010

To remind people about healthy eating habits, the USDA designed "MyPlate," a picture to demonstrate that half of each meal should consist of fruits and vegetables (Fig. 60-1). When grains are consumed, half of them should be whole grains rather than refined grain products.

FIG. 60-1 The U.S. Department of Agriculture MyPlate.

Some people follow vegetarian diet patterns for health, environmental, or moral reasons. In general, vegetarians are leaner than those who consume meat. The **lacto-vegetarian** eats milk, cheese, and dairy foods but avoids meat, fish, poultry, and eggs. The **lacto-ovo-vegetarian** includes eggs in his or her diet. The **vegan** eats only foods of plant origin. Some people among these groups eat fish as well. Vegans can develop anemia as a result of vitamin B_{12} deficiency. Therefore they should include a daily source of vitamin B_{12} in their diets, such as a fortified breakfast cereal, fortified soy beverage, or meat substitute. All vegetarians should ensure that they get adequate amounts of calcium, iron, zinc, and vitamins D and B_{12}. Well-planned vegetarian diets can provide adequate nutrition. The Academy of Nutrition and Dietetics (2013) publishes a number of credible resources regarding vegetarian health at www.eatright.org.

Cultural Considerations

Patient-Centered Care QSEN

Many people have specific food preferences based on their ethnicity or race. For example, for people of Hispanic descent, tortillas, beans, and rice *may* be desired over pasta, risotto, and potatoes. *Never assume that a person's racial or ethnic background means that he or she eats only foods associated with his or her primary ethnicity.* Health teaching about nutrition should incorporate any cultural preferences.

Some people have food allergies or intolerances. For instance, lactose

intolerance (lactose is found in milk and milk products) is a common problem that occurs in a number of ethnic groups. It is found more often in Mexican Americans and black people as well as in some American Indian groups, Asian Americans, and Ashkenazi Jews. A small percentage of white people, particularly those of Mediterranean descent (e.g., Greek, Italian), are also lactose intolerant. The cause of **lactose intolerance** is an inadequate amount of the lactase enzyme, which converts lactose into absorbable glucose. Patients may benefit from learning more about the management of lactose intolerance from resources provided by organizations such as the American Dietetic Association or the Dieticians of Canada.

Considerations for Older Adults

Patient-Centered Care QSEN

The USDA recommends that older adults drink eight glasses of water a day and eat plenty of fiber to prevent or manage constipation. It also suggests daily calcium and vitamins D and B_{12} supplements and a reduction in sodium and cholesterol-containing foods.

One of the most recent publications from Health Canada on Nutrition is the Canada Food Guide. Compared with previous documents, it includes more culturally diverse foods, information on *trans* fats, customized individual recommendations, and exercise guidelines. Several booklets can be purchased to help people select the best foods and nutrients from the new guide, such as *Eating Well with Canada's Food Guide* (Minister of Health Canada, 2011). In addition, Canada has published a separate booklet to address the special needs of some of its indigenous people. The *Eating Well with Canada's Food Guide—First Nations, Inuit, and Métis* includes berries, wild plants, and wild game to reflect the values and traditions for aboriginal people living in Canada (Health Canada, 2011).

Nutrition Assessment

Nutrition status reflects the balance between nutrient requirements and intake. Common factors that affect these requirements include age, gender, disease, infection, and psychological stress. Eating behavior, economic implications, emotional stability, disease, drug therapy, and cultural factors influence nutrient intake. Malnutrition (also called *undernutrition*) and obesity, discussed later in this chapter, are common nutrition health problems that may lead to many comorbidities and complications, including death.

Evaluation of nutrition status is an important part of total patient assessment and includes:

- Review of the nutrition history
- Food and fluid intake record
- Laboratory data
- Food-drug interactions
- Health history and physical assessment
- Anthropometric measurements
- Psychosocial assessment

Monitor the nutrition status of a patient during hospitalization as an important part of your initial assessment. Collaborate with the interdisciplinary health care team to identify patients at risk for nutrition problems.

Initial Nutrition Screening

An initial screening provides an inexpensive, quick way of determining which patients need more extensive nutrition assessment by the health care team. The Joint Commission Patient Care Standards require that a nutrition screening occur within 24 hours of the patient's hospital admission. If indicated, an in-depth nutrition assessment should be performed. When patients are in the hospital for more than a week, nutrition assessment should be part of the daily plan of care.

The initial **nutrition screening** includes inspection, measured height and weight, weight history, usual eating habits, ability to chew and swallow, and any recent changes in appetite or food intake. Examples of questions that help identify patients at risk for nutrition problems are part of the history and physical assessment (Chart 60-1).

Chart 60-1

Best Practice for Patient Safety & Quality Care QSEN

Nutrition Screening Assessment

General

- Does the patient have any conditions that cause nutrient loss, such as malabsorption syndromes, draining abscesses, wounds, fistulas, or prolonged diarrhea?
- Does the patient have any conditions that increase the need for nutrients, such as fever, burns, injury, sepsis, or antineoplastic therapies?
- Has the patient been NPO for 3 days or more?
- Is the patient receiving a modified diet or a diet restricted in one or more nutrients?
- Is the patient being enterally or parenterally fed?
- Does the patient describe food allergies, lactose intolerance, or limited food preferences?
- Has the patient experienced a recent unexplained weight loss?
- Is the patient on drug therapy—either prescription, over-the-counter, or herbal/natural products?

Gastrointestinal

- Does the patient report nausea, indigestion, vomiting, diarrhea, or constipation?
- Does the patient exhibit glossitis (tongue inflammation), stomatitis (oral inflammation), or esophagitis?
- Does the patient have difficulty chewing or swallowing?
- Does the patient have a partial or total GI obstruction?
- What is the patient's state of dentition?

Cardiovascular

- Does the patient have ascites or edema?
- Is the patient able to perform ADLs?
- Does the patient have heart failure?

Genitourinary

- Is fluid intake about equal to fluid output?
- Does the patient have an ostomy?
- Is the patient hemodialyzed or peritoneally dialyzed?

Respiratory

- Is the patient receiving mechanical ventilatory support?
- Is the patient receiving oxygen via nasal prongs?

- Does the patient have chronic obstructive pulmonary disease (COPD) or asthma?

Integumentary

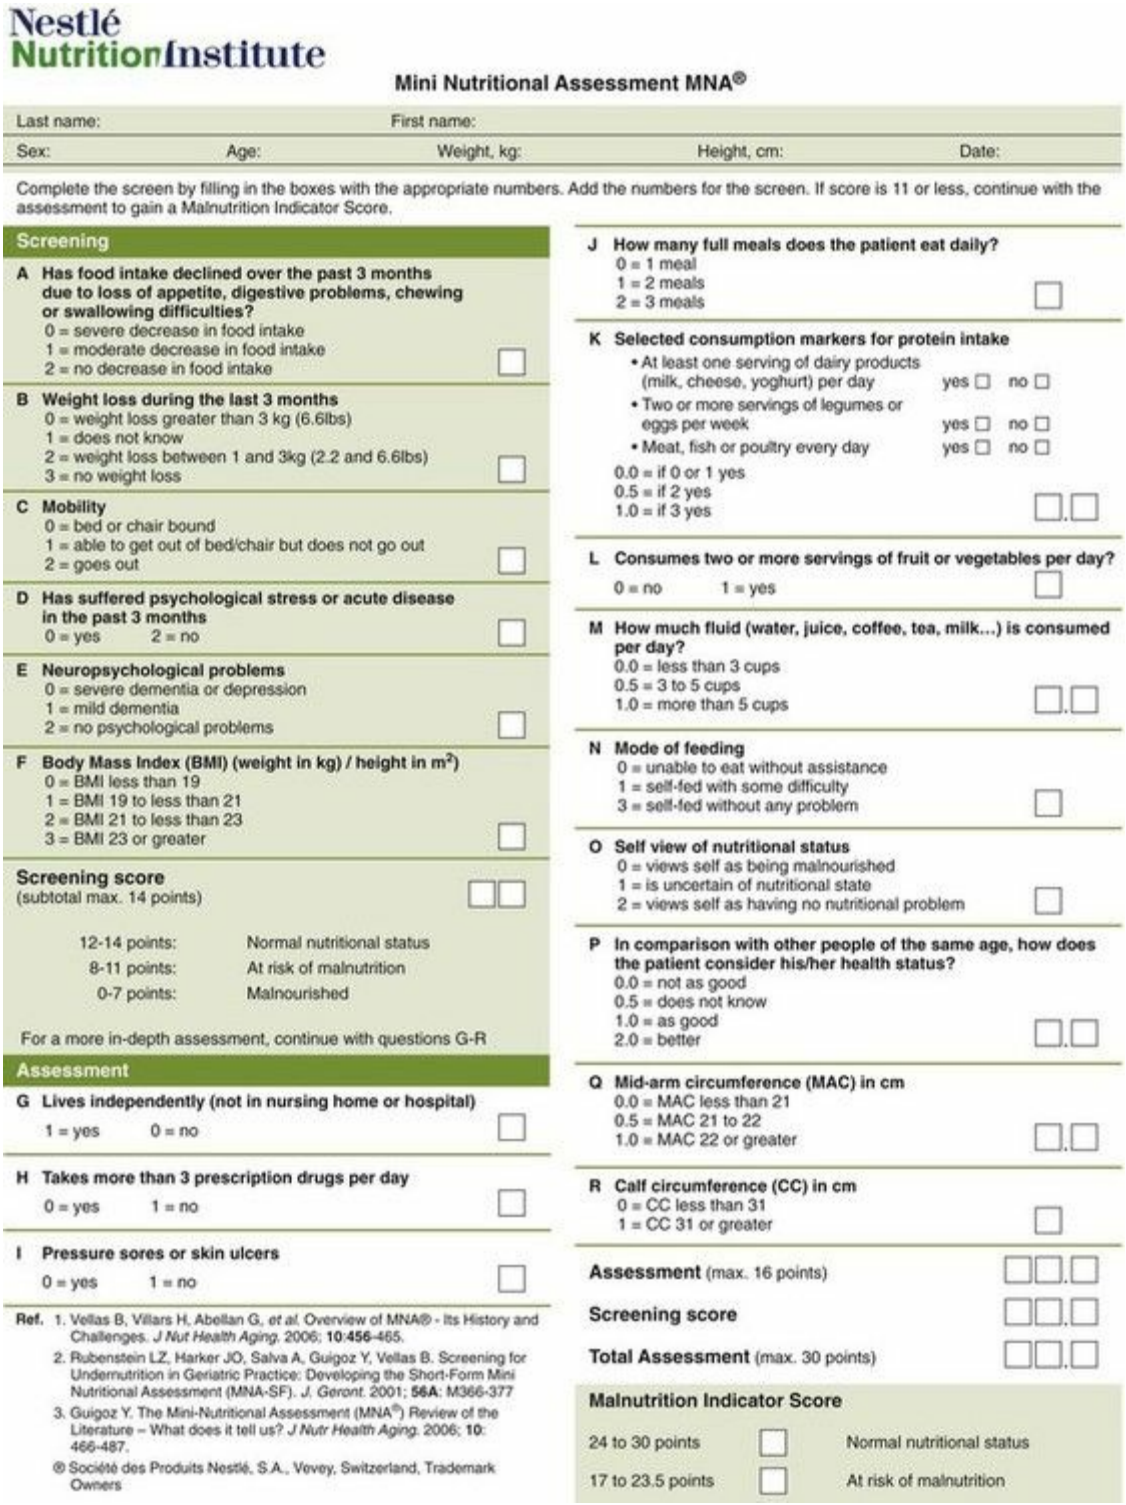
- Does the patient have abnormal nail or hair changes?
- Does the patient have rashes or dermatitis?
- Does the patient have dry or pale mucous membranes or decreased skin turgor?
- Does the patient have pressure areas on the sacrum, hips, heels, or ankles?

Extremities

- Does the patient have pedal edema?
- Does the patient have cachexia?

Modified with courtesy of Ross Products Division, Abbott Laboratories, Columbus, OH.

The Mini Nutritional Assessment (MNA), a two-part tool that has been tested worldwide, provides a reliable, rapid assessment for patients in the community and in any health care setting. The *first* part (A-F) is a screening section that takes 3 minutes to complete and asks about food intake, mobility, and body mass index (BMI) (described on p. 1235). It also screens for weight loss, acute illness, and psychological health problems. If the patient scores 11 points or less, the *second* part (G-R) of the MNA is completed, for an additional 12 questions. The entire assessment takes only minutes to complete (Fig. 60-2). The MNA Short Form can be used as a stand-alone tool to evaluate whether the older patient is well nourished, at risk for malnutrition, or malnourished. The alternative is to take the patient's calf circumference, which can be a reliable alternative if BMI is unavailable.



Nestlé NutritionInstitute

Mini Nutritional Assessment MNA®

Last name: First name:

Sex: Age: Weight, kg: Height, cm: Date:

Complete the screen by filling in the boxes with the appropriate numbers. Add the numbers for the screen. If score is 11 or less, continue with the assessment to gain a Malnutrition Indicator Score.

Screening

A Has food intake declined over the past 3 months due to loss of appetite, digestive problems, chewing or swallowing difficulties?
0 = severe decrease in food intake
1 = moderate decrease in food intake
2 = no decrease in food intake

B Weight loss during the last 3 months
0 = weight loss greater than 3 kg (6.6lbs)
1 = does not know
2 = weight loss between 1 and 3kg (2.2 and 6.6lbs)
3 = no weight loss

C Mobility
0 = bed or chair bound
1 = able to get out of bed/chair but does not go out
2 = goes out

D Has suffered psychological stress or acute disease in the past 3 months
0 = yes 2 = no

E Neuropsychological problems
0 = severe dementia or depression
1 = mild dementia
2 = no psychological problems

F Body Mass Index (BMI) (weight in kg) / height in m²)
0 = BMI less than 19
1 = BMI 19 to less than 21
2 = BMI 21 to less than 23
3 = BMI 23 or greater

Screening score
(subtotal max. 14 points)

12-14 points: Normal nutritional status
8-11 points: At risk of malnutrition
0-7 points: Malnourished

For a more in-depth assessment, continue with questions G-R

Assessment

G Lives independently (not in nursing home or hospital)
1 = yes 0 = no

H Takes more than 3 prescription drugs per day
0 = yes 1 = no

I Pressure sores or skin ulcers
0 = yes 1 = no

J How many full meals does the patient eat daily?
0 = 1 meal
1 = 2 meals
2 = 3 meals

K Selected consumption markers for protein intake
- At least one serving of dairy products (milk, cheese, yoghurt) per day yes no
- Two or more servings of legumes or eggs per week yes no
- Meat, fish or poultry every day yes no

0.0 = if 0 or 1 yes
0.5 = if 2 yes
1.0 = if 3 yes

L Consumes two or more servings of fruit or vegetables per day?
0 = no 1 = yes

M How much fluid (water, juice, coffee, tea, milk...) is consumed per day?
0.0 = less than 3 cups
0.5 = 3 to 5 cups
1.0 = more than 5 cups

N Mode of feeding
0 = unable to eat without assistance
1 = self-fed with some difficulty
2 = self-fed without any problem

O Self view of nutritional status
0 = views self as being malnourished
1 = is uncertain of nutritional state
2 = views self as having no nutritional problem

P In comparison with other people of the same age, how does the patient consider his/her health status?
0.0 = not as good
0.5 = does not know
1.0 = as good
2.0 = better

Q Mid-arm circumference (MAC) in cm
0.0 = MAC less than 21
0.5 = MAC 21 to 22
1.0 = MAC 22 or greater

R Calf circumference (CC) in cm
0 = CC less than 31
1 = CC 31 or greater

Assessment (max. 16 points)

Screening score

Total Assessment (max. 30 points)

Malnutrition Indicator Score

24 to 30 points Normal nutritional status
17 to 23.5 points At risk of malnutrition

FIG. 60-2 The Mini Nutritional Assessment (MNA).

Anthropometric Measurements

Anthropometric measurements are noninvasive methods of evaluating nutrition status. These measurements include height and weight and assessment of body mass index (BMI).

Obtain a current *height and weight* to provide a baseline. Be sure to obtain accurate measurements because patients tend to overestimate

height and underestimate weight. Measurements taken days or weeks later may indicate an early change in nutrition status. *You may delegate this activity to unlicensed assistive personnel (UAP) under your supervision.*

Patients should be measured and weighed while wearing minimal clothing and no shoes. Determine the height in inches or centimeters using the measuring stick of a weight scale if the patient can stand. He or she should stand erect and look straight ahead, with the heels together and the arms at the sides. For patients who cannot stand or those who cannot stand erect (e.g., some older adults), use a sliding-blade **knee height caliper,** if available. This device uses the distance between the patient's patella and heel to estimate height. It is especially useful for patients who have knee or hip contractures.

Remind UAP to weigh ambulatory patients with an upright balance-beam or digital scale. Non-ambulatory patients can be weighed with a digital wheelchair or bed scale.

Nursing Safety Priority QSEN

Action Alert

For daily or sequential weights, obtain the weight at the same time each day, if possible, preferably before breakfast. Conditions such as congestive heart failure and renal disease cause weight gain; dehydration and conditions such as cancer cause weight loss. *Weight is the most reliable indicator of fluid gain or loss, so accurate weights are essential!*

Normal weights for adult men and women are available from several reference standards, such as the Metropolitan Life tables. Some health care professionals prefer these tables because they consider body-build differences by gender and body frame size.

Changes in body weight can be expressed by three different formulas:

Weight as a percentage of ideal body weight (IBW):

$$\%\text{IBW} = \frac{\text{Current weight}}{\text{Ideal body weight}} \times 100$$

Current weight as a percentage of usual body weight (UBW):

$$\%\text{UBW} = \frac{\text{Current weight}}{\text{Usual body weight}} \times 100$$

Change in weight:

$$\text{Weight change} = \frac{\text{Usual weight} - \text{Current weight}}{\text{Usual weight}} \times 100$$

An unintentional weight loss of 10% over a 6-month period at any time significantly affects nutrition status and should be evaluated. Depending on the patient's needs, weights may need to be taken daily, several times a week, or weekly for monitoring status and the effectiveness of nutrition support.

In the health care setting, *assessment of body fat* is usually calculated by the dietitian. For people who participate in a structured exercise program in the community, this assessment is typically performed by a fitness trainer or physical therapist.

The **body mass index (BMI)** is a measure of nutrition status that does not depend on frame size (Centers for Disease Control and Prevention [CDC], 2012). It indirectly estimates total fat stores within the body by the relationship of weight to height. *Therefore an accurate height is as important as an accurate weight.*

A simple calculation for estimating BMI can be programmed into handheld computers or calculators using one of these two formulas:

$$\text{BMI} = \frac{\text{Weight (lb)}}{\text{Height (in inches)}^2} \times 703$$

$$\text{BMI} = \frac{\text{Weight (kg)}}{\text{Height (in meters)}^2}$$

BMI can also be determined using a table that is linked with height

and weight. The least risk for malnutrition is associated with scores between 18.5 and 25. BMIs above and below these values are associated with increased health risks (CDC, 2012a).

Considerations for Older Adults

Patient-Centered Care QSEN

Body weight and BMI usually increase throughout adulthood until about 60 years of age. As people get older, they often become less hungry and eat less, even if they are healthy. Ideally, older adults should have a BMI between 23 and 27.

The average daily energy intake expended by this group tends to be more than the average energy intake. This physiologic change has been called the "anorexia of aging" (Champion, 2011). Many older adults are underweight, leading to undernutrition and increased risk for illness.

NCLEX Examination Challenge

Health Promotion and Maintenance

An older adult is admitted to the hospital with pressure ulcers and septicemia. His height is 5 feet, 8 inches (1.72 meters), and he weighs 302 pounds (137 kg). His current body mass index (BMI) is _____. (Round your answer to the nearest tenth.)

Skinfold measurements estimate body fat and can be measured by either the nurse or the dietitian. The *triceps and subscapular* skinfolds are most commonly measured using a special caliper. Both are compared with standard measurements and recorded as percentiles.

The *midarm circumference (MAC) and calf circumference (CC)* can be obtained to measure muscle mass and subcutaneous fat. These measurements are needed if the Mini Nutritional Assessment tool is used. To measure MAC, place a flexible tape around the upper arm at the midpoint, taking care to hold the tape firmly but gently to avoid compressing the tissue. This measurement is usually recorded in centimeters. The midarm muscle mass (MAMM) measures the amount of muscle in the body and is a sensitive indicator of protein reserves. It can be computed from the MAC and the triceps skinfold measure. The CC is obtained using a similar procedure on the calf.

Malnutrition

Pathophysiology

Protein-energy malnutrition (PEM), also known as **protein-calorie malnutrition (PCM),** may present in three forms: marasmus, kwashiorkor, and marasmic-kwashiorkor. **Marasmus** is generally a calorie malnutrition in which body fat and protein are wasted. Serum proteins are often preserved. **Kwashiorkor** is a lack of protein quantity and quality in the presence of adequate calories. Body weight is more normal, and serum proteins are low. **Marasmic-kwashiorkor** is a combined protein and energy malnutrition. This problem often presents clinically when metabolic stress is imposed on a chronically starved patient. The outcome of unrecognized or untreated PEM is often dysfunction or disability and increased morbidity and mortality.

Malnutrition (also called *undernutrition)* is a multinutrient problem because foods that are good sources of calories and protein are also good sources of other nutrients. In the malnourished patient, protein catabolism exceeds protein intake and synthesis, resulting in negative nitrogen balance, weight loss, decreased muscle mass, and weakness.

The functions of the liver, heart, lungs, GI tract, and immune system decrease in the patient with malnutrition. A decrease in serum proteins **(hypoproteinemia)** occurs as protein synthesis in the liver decreases. Vital capacity is also reduced as a result of respiratory muscle atrophy. Cardiac output diminishes. Malabsorption occurs because of atrophy of GI mucosa and the loss of intestinal villi.

Common complications of *severe* malnutrition in adults include:

- Leanness and **cachexia** (muscle wasting with prolonged malnutrition)
- Decreased activity tolerance
- Lethargy
- Intolerance to cold
- Edema
- Dry, flaking skin and various types of dermatitis
- Poor wound healing
- Infection, particularly postoperative infection and sepsis
- Possible death

Malnutrition results from inadequate nutrient intake, increased nutrient losses, and increased nutrient requirements. Inadequate nutrient intake can be linked to poverty, lack of education, substance abuse, decreased appetite, and a decline in functional ability to eat independently, particularly in older adults. Infectious diseases, such as tuberculosis and human immune deficiency virus (HIV) infection, can

also cause PEM. Diseases that produce diarrhea and infections leading to anorexia result in negative calorie and protein balance. Anorexia then leads to poor food intake. Vomiting causes decreased intestinal absorption with increased nutrient losses. Medical treatments such as chemotherapy can also cause malnutrition. In addition, catabolic processes, such as that caused by prolonged immobility, increase nutrient requirements and metabolic losses.

Inadequate nutrient intake can result also when a person is admitted to the hospital or long-term care facility. For example, decreased staffing may not allow time for patients who need to be fed, especially older adults, who may eat slowly. Many diagnostic tests, surgery, trauma, and unexpected medical complications require a period of NPO or cause **anorexia** (loss of appetite). In a systematic integrative review, Tappenden et al. (2013) reviewed strategies needed to address the needs of hospitalized patients to prevent or treat malnutrition (see the Evidence-Based Practice box).

Evidence-Based Practice QSEN

The Critical Role of Nutrition in Improving Quality of Care

Tappenden, K.A., Quatrara, B., Parkhurst, M.L., Malone, A.M., Fanjiang, G., & Ziegler, T.R. (2013). Critical role of nutrition in improving quality of care: An interdisciplinary call to action to address adult hospital malnutrition. *MEDSURG Nursing, 22*(3), 147-165.

Health care costs have increased tremendously in the United States over the past decades. With substantial changes coming in health care policy that affect the way that health care is delivered, health care facilities will need to continue searching for ways to deliver the best care at the most reasonable cost. At least one third of patients come to the hospital in a state of malnourishment, and others become malnourished after admission. Therefore ways for addressing adult hospital malnutrition are very important for both quality of care and cost containment.

The Alliance to Advance Patient Nutrition (Alliance) reflects combined efforts of the Academy of Medical-Surgical Nurses (AMSN), the Academy of Nutrition and Dietetics (AND), the American Society for Parenteral and Enteral Nutrition (ASPEN), the Society of Hospital Medicine (SHM), and Abbott Nutrition to help achieve positive patient outcomes and support improving patient nutrition. The Alliance recommends a number of strategies for meeting these outcomes, such as:

- Include nutrition as a component of all health care team member conversations and in conversation with patients and family members.
- Provide thorough explanations about the patient's nutrition status, nutrition recommendations, nutrition interventions, and post-discharge nutrition care; document these interventions in the electronic health record.
- Ensure that the patient and/or family member is given comprehensive follow-up nutrition assessment, education, and follow-up appointment recommendations at the time of discharge.
- Provide comprehensive, clear, standardized written instructions for nutrition care at home.
- Prioritize nutrition as part of self-management education, taking into consideration dietary intake, weight change, access to food, and other concerns that may affect nutrition status.

Level of Evidence: 1

The clinical evidence presented was collected and presented as a result of a systematic integrative review conducted by numerous professional health care organizations.

Commentary: Implications for Practice and Research

Quality of care, cost implications, and recovery are of primary concern for all patients who are malnourished. Collaborative efforts among the health care team members can (1) provide a more consistent and reliable approach to addressing nutrition needs for hospitalized patients, (2) avoid overlapping charges that may arise from a lack of communication, and (3) create a best practice approach for teaching the patient and family about meeting nutrition needs at the time of discharge. Nurses who work directly with patients are in a key position to provide consistent, comprehensive nutrition education; this can result in better meeting the nutrition needs of patients who are hospitalized, as well as prepare them better for self-management upon discharge.

Cultural Considerations

Patient-Centered Care QSEN

In some cases, malnutrition results when the provided meals are different from what the patient usually eats. Be sure to identify specific food preferences that the patient can eat and enjoy that are in keeping with his or her cultural practices.

Considerations for Older Adults

Patient-Centered Care QSEN

Older adults in the community or in any health care setting are most at risk for poor nutrition, especially PEM. Risk factors include physiologic changes of aging, environmental factors, and health problems. Chart 60-2 lists some of these major factors. Chapter 2 discusses nutrition for older adults in more detail.

Chart 60-2 Nursing Focus on the Older Adult

Risk Assessment for Malnutrition

Assess for:

- Decreased appetite
- Weight loss
- Poor-fitting or no dentures/poor dental health
- Poor eyesight
- Dry mouth
- Limited income
- Lack of transportation
- Inability to prepare meals because of functional decline or fatigue
- Loneliness and/or depression
- Chronic constipation (e.g., in patients with Alzheimer's disease)
- Decreased meal enjoyment
- Chronic physical illness
- "Failure to thrive" (a combination of three of five symptoms, including weakness, slow walking speed, low physical activity, unintentional weight loss, exhaustion)
- Prescription and over-the-counter (OTC) drugs (including herbs, vitamins, and minerals)
- Acute or chronic pain

Acute PEM may develop in patients who were adequately nourished before hospitalization but experience starvation while in a catabolic state from infection, stress, or injury. *Chronic* PEM can occur in those who have cancer, end-stage kidney or liver disease, or chronic neurologic disease.

Eating disorders such as anorexia nervosa and bulimia nervosa, which are seen most often in teens and young adults, also lead to malnutrition. **Anorexia nervosa** is a self-induced starvation resulting from a fear of fatness, even though the patient is underweight. **Bulimia nervosa** is

characterized by episodes of binge eating in which the patient ingests a large amount of food in a short time. The binge eating is followed by some form of purging behavior, such as self-induced vomiting or excessive use of laxatives and diuretics. If not treated, death can result from starvation, infection, or suicide. Information about eating disorders can be found in textbooks on mental/behavioral health nursing.

Patient-Centered Collaborative Care

Assessment

History.

Review the medical history to determine the possibility of increased metabolic needs or nutrition losses, chronic disease, trauma, recent surgery of the GI tract, drug and alcohol use, and recent significant weight loss. Each of these conditions can contribute to malnutrition. For older adults, explore mental status changes and note poor eyesight, diseases affecting major organs, constipation or incontinence, and slowed reactions. Review prescription and over-the-counter (OTC) drugs, including vitamin, mineral, herbal, and other nutrition supplements.

For patients who live independently in the community, the nurse may assess their performance of instrumental activities of daily living (IADLs). Functional status can best be evaluated for institutionalized patients by assessing their ADL performance. Poor nutrition is a major contributing factor to decreased functional ability.

In collaboration with the dietitian, obtain information about the patient's usual daily food intake, eating behaviors, change in appetite, and recent weight changes. If the patient is able to communicate, ask him or her to describe the usual foods eaten daily, cultural food preferences, and the times of meals and snacks. If available, ask the family these questions if the patient cannot communicate. If the patient cannot understand the questions due to language differences, locate an interpreter to assist with communication. The dietitian can more thoroughly analyze the diet, if necessary, based on your initial nutrition screening.

Ask about changes in eating habits as a result of illness, and document any change in appetite, taste, and weight loss. *A weight loss of 5% or more in 30 days, a weight loss of 10% in 6 months, or a weight that is below ideal may indicate malnutrition.*

Nursing Safety Priority QSEN

Action Alert

When assessing for malnutrition, assess for difficulty or pain in chewing or swallowing. *Unrecognized dysphagia is a common problem among nursing home residents and can cause malnutrition, dehydration, and aspiration pneumonia.* Ask the patient whether any foods are avoided and why. Ask UAP to report any choking while the patient eats. Record the occurrence of nausea, vomiting, heartburn, or any other symptoms of discomfort with eating.

Ask the patient about dental health problems, including the presence of dentures. Dentures or partial plates that do not fit well interfere with food intake. Dental caries (decay) or missing teeth may also cause discomfort while eating.

Physical Assessment/Clinical Manifestations.

Assess for manifestations of various nutrient deficiencies (Table 60-2). Inspect the patient's hair, eyes, oral cavity, nails, and musculoskeletal and neurologic systems. Examine the condition of the skin, including any reddened or open areas. Anthropometric measurements may also be obtained as described on p. 1234. The nurse or UAP monitors all food and fluid intake and notes any mouth pain or difficulty in chewing or swallowing. A 3-day caloric intake may be collected and then calculated by the dietitian.

TABLE 60-2

Manifestations of Nutrient Deficiencies

SIGN/SYMPTOM	POTENTIAL NUTRIENT DEFICIENCY
Hair	
Alopecia	Zinc
Easy to remove	Protein
Lackluster hair	Protein
"Corkscrew" hair	Vitamin C
Decreased pigmentation	Protein
Eyes	
Xerosis of conjunctiva	Vitamin A
Corneal vascularization	Riboflavin
Keratomalacia	Vitamin A
Bitot's spots	Vitamin A
Gastrointestinal Tract	
Nausea, vomiting	Pyridoxine
Diarrhea	Zinc, niacin
Stomatitis	Pyridoxine, riboflavin, iron
Cheilosis	Pyridoxine, iron
Glossitis	Pyridoxine, zinc, niacin, folic acid, vitamin B_{12}
Magenta tongue	Vitamin A, riboflavin
Swollen, bleeding gums	Vitamin C
Fissured tongue	Niacin
Hepatomegaly	Protein
Skin	
Dry and scaling	Vitamin A
Petechiae/ecchymoses	Vitamin C
Follicular hyperkeratosis	Vitamin A
Nasolabial seborrhea	Niacin
Bilateral dermatitis	Niacin
Extremities	
Subcutaneous fat loss	Calories
Muscle wastage	Calories, protein
Edema	Protein
Osteomalacia, bone pain, rickets	Vitamin D
Hematologic	
Anemia	Vitamin B_{12}, iron, folic acid, copper, vitamin E
Leukopenia, neutropenia	Copper
Low prothrombin time, prolonged clotting time	Vitamin K, manganese
Neurologic	
Disorientation	Niacin, thiamine
Confabulation	Thiamine
Neuropathy	Thiamine, pyridoxine, chromium
Paresthesia	Thiamine, pyridoxine, vitamin B_{12}
Cardiovascular	
Congestive heart failure, cardiomegaly, tachycardia	Thiamine
Cardiomyopathy	Selenium
Cardiac dysrhythmias	Magnesium

Psychosocial Assessment.

The psychosocial history provides information about the patient's economic status, occupation, educational level, gender orientation, ethnicity/race, living and cooking arrangements, and mental status. Determine whether financial resources are adequate for providing the necessary food. If resources are inadequate, the social worker or case manager may refer the patient and family to available community services. Chapter 2 discusses nutrition in older adults in more detail.

Laboratory Assessment.

Laboratory tests supply objective data that can support subjective data and identify deficiencies. Interpret laboratory data carefully with regard to the total patient; focusing on an isolated value may yield an inaccurate conclusion.

A low *hemoglobin* level may indicate anemia, recent hemorrhage, or hemodilution caused by fluid retention. Hemoglobin may also be decreased secondary to conditions such as low serum albumin, infection, catabolism, or chronic disease. High levels may indicate hemoconcentration or dehydration or may be found secondary to liver disease.

Low *hematocrit* levels may reflect anemia, hemorrhage, excessive fluid, renal disease, or cirrhosis. High hematocrit levels may indicate dehydration or hemoconcentration.

Serum albumin, thyroxine-binding prealbumin, and transferrin are measures of **visceral proteins.** Serum *albumin* is a plasma protein that reflects the nutrition status of the patient a few weeks before testing; therefore it is not considered to be a sensitive test. Patients who are dehydrated often have high levels of albumin, and those with fluid excess have a lowered value. The normal serum albumin level for men and women is 3.5 to 5.0 g/dL or 35 to 50 g/L (SI units) (Pagana & Pagana, 2014).

Thyroxine-binding **prealbumin (PAB)** is a plasma protein that provides a more sensitive indicator of nutrition deficiency because of its short half-life of 2 days. Depending on the laboratory test used, the normal PAB range is 15 to 36 mg/dL or 150 to 360 mg/L (SI units) (Pagana & Pagana, 2014). Although not used as commonly, serum **transferrin,** an iron-transport protein, can be measured directly or calculated as an indirect measurement of total iron-binding capacity (TIBC). It has a short half-life of 8 to 10 days and therefore is also a more sensitive indicator of

protein status than albumin.

Cholesterol levels normally range between 160 and 200 mg/dL in adult men and women. Values are typically low with malabsorption, liver disease, pernicious anemia, end-stage cancer, or sepsis. A cholesterol level below 160 mg/dL has been identified as a possible indicator of malnutrition. Cholesterol testing is discussed in more detail in Chapter 36.

Total lymphocyte count (TLC) can be used to assess immune function. Malnutrition suppresses the immune system and leaves the patient more likely to get an infection. When a patient is malnourished, the TLC is usually decreased to below 1500/mm^3.

Analysis

The priority problem for the patient with malnutrition is Imbalanced Nutrition: Less Than Body Requirements related to inability to ingest or digest food or absorb nutrients (NANDA-I).

Planning and Implementation

Improving Nutrition

Planning: Expected Outcomes.

The patient with malnutrition is expected to have nutrients available to meet his or her metabolic needs as evidenced by normal serum proteins and adequate hydration.

Interventions.

The preferred route for food intake is through the GI tract because it enhances the immune system and is safer, easier, less expensive, and more enjoyable.

Meal Management.

The dietitian calculates the nutrients required daily and plans the patient's diet. In collaboration with the health care provider and dietitian, provide high-calorie, nutrient-rich foods (e.g., milkshakes, cheese, supplement drinks like Boost or Ensure). Assess the patient's food likes and dislikes. A feeding schedule of six small meals may be tolerated better than three large ones. A pureed or dental soft diet may be easier for those who have problems chewing or are **edentulous** (toothless).

Nursing Safety Priority QSEN

Action Alert

Malnourished ill patients often need to be encouraged to eat. Instruct UAP who are feeding patients to keep food at the appropriate temperature and to provide mouth care before feeding. Assess for other needs, such as pain management, and provide interventions to make the patient comfortable. Pain can prevent patients from enjoying their meals. Remove bedpans, urinals, and emesis basins from sight. Provide a quiet environment, which is conducive to eating. Soft music may calm those with advanced dementia or delirium. Appropriate time should be taken so that the patient does not feel rushed through a meal.

Considerations for Older Adults

Patient-Centered Care QSEN

Some patients, especially older adults, may take a long time to eat even small quantities of food because they tend to be less hungry than younger adults. If available, suggest that family members bring in favorite or ethnic foods that the patient might be more likely to eat. Teach them about ways to encourage the patient to increase food intake. Chart 60-3 describes additional interventions to promote food intake in older adults.

Chart 60-3 Nursing Focus on the Older Adult

Promoting Nutrition Intake

- Be sure that patient is toileted and receives mouth care before mealtime.
- Be sure that patient has glasses and hearing aids in place, if appropriate, during meals.
- Be sure that bedpans, urinals, and emesis basins are removed from sight.
- Give analgesics to control pain and/or antiemetics for nausea at least 1 hour before mealtime.
- Remind unlicensed assistive personnel (UAP) to have patient sit in chair, if possible, at mealtime.
- If needed, open cartons and packages and cut up food at the patient's and/or family's request.
- Observe the patient during meals for food intake.

- Ask the patient about food likes and dislikes and ethnic food preferences.
- Encourage self-feeding, or feed the patient slowly; *delegate* this activity to UAP if desired.
- If feeding patient, sit at eye-level if culturally appropriate.
- Create an environment that is conducive to eating and socialization and relaxation, if possible.
- Decrease distractions, such as environmental noise from television, music, or other people.
- Provide adequate, nonglaring lighting.
- Keep patient away from offensive or medicinal odors.
- Keep eye contact with the patient during the meal if culturally appropriate.
- Serve snacks with activities, especially in long-term care settings; *delegate* this activity to UAP if desired.
- Document the percentage of food eaten at each meal and snack; *delegate* this activity to UAP if appropriate.
- Ensure that meals are visually appealing, appetizing, appropriately warm or cold, and properly prepared.
- Do not interrupt patients during mealtimes for nonurgent procedures or rounds.
- Assess for need for supplements between meals and at bedtime.
- Review the patient's drug profile, and discuss with the health care provider the use of drugs that might be suppressing appetite.
- If the patient is depressed, be sure that the depression is treated by the health care provider.

Restorative feeding programs help nursing home residents who need special assistance. These residents often eat in a separate dining area so that time and attention can be given to them. Some nursing homes have designated food and nutrition nursing assistants and/or trained volunteers who are primarily responsible for promoting and maintaining nutrition and hydration. Delegate appropriate feeding tasks, and supervise these UAPs during resident mealtime.

Nutrition Supplements.

If the patient cannot take in enough nutrients in food, fortified **medical nutrition supplements (MNSs)** (e.g., Ensure, Sustacal, Carnation Instant Breakfast [also available as lactose-free supplement]) may be given, especially to older adults. Many commercial enteral products are available. For patients with medical diagnoses such as liver and renal

disease or diabetes, special products that meet those needs are available (e.g., Glucerna for diabetic patients). Nutrition supplements used in acute care, long-term care, and home care can be costly. In addition, patients may refuse them and the supplements are then wasted. In a classic study, Bender et al. (2000) found that a more successful alternative to having the MNS given by nursing assistant staff in the nursing home was to have the supplements delivered by nurses during their usual medication passes. In this study, the nurses gave 60 mL or more of the MNS at least 4 times a day with the residents' medications. As a result, the patients gained weight and had fewer pressure ulcers, thus making the program very cost-effective and providing positive clinical outcomes.

Nutrition supplements are supplied as liquid formulas, powders, soups, coffee, and puddings in a variety of flavors. They come in different degrees of sweetness and are also available as modular supplements that provide single nutrients. Examples of modular supplements are Polycose glucose polymers for carbohydrates and Resource Beneprotein for protein, both available in liquid and powder form. Carbohydrate modulars are useful only if additional calories are needed. Protein modulars are indicated when metabolic stress causes a need for higher protein intake.

The dietitian may ask the nursing staff to keep a food and fluid intake record for at least 3 consecutive days to help assess the patient's nutrition status. Delegate this activity to UAP under your supervision. UAP also weigh the patient daily, every 3 days, or once a week, depending on the health care setting and severity of malnutrition.

Drug Therapy.

Multivitamins, zinc, and an iron preparation are often prescribed to treat or prevent anemia. Monitor the patient's hemoglobin and hematocrit levels. Drug therapy can affect nutrition and elimination. For example, iron can cause constipation and zinc can cause nausea and vomiting.

If the patient still does not receive enough nutrition by mouth using the interventions just mentioned, request nutrition therapy in the form of **specialized nutrition support (SNS).** SNS consists of either total enteral nutrition (TEN) or total parenteral nutrition (TPN).

Total Enteral Nutrition.

Patients often cannot meet the desired outcomes of adequate nutrition via their usual oral intake because of increased metabolic demands or a decreased ability to eat. Therefore TEN using enteral tube feeding may be necessary to supplement oral intake or to provide total nutrition.

Patients likely to receive TEN can be divided into three groups:

- Those who can eat but cannot maintain adequate nutrition by oral intake of food alone
- Those who have permanent neuromuscular impairment and cannot swallow
- Those who do not have permanent neuromuscular impairment but cannot eat because of their condition

Patients in the first group are often older adults or patients receiving cancer treatment who cannot meet their calorie and protein needs. In some cases, this artificial nutrition and hydration may not be desired. For example, some patients have advance directives stating that they do not want to be kept alive by artificial nutrition and hydration if certain conditions exist. *However, legal and ethical questions arise when patients are not able to make their wishes known!*

For many years it was believed that withholding food and fluids would cause discomfort. Terminally or chronically ill patients who do not eat and drink may not suffer. In fact, they may be more comfortable if food and fluids are withheld. *The decision to feed is complex, and there is no clear right or wrong answer. To compound this legal and ethical dilemma, medical complications (e.g., aspiration, pressure ulcers) are common in older adults who are tube-fed.*

Decisions about these dilemmas are aided by the advice of interdisciplinary ethics committees in health care facilities. When clinicians are making decisions about the desirability of tube feedings in these cases, the focus should be on achieving consensus by:

- Reviewing what is known about tube feedings, especially their risks and benefits
- Reviewing the medical facts about the patient
- Investigating any available evidence that would help understand the patient's wishes
- Obtaining the opinions of all stakeholders in the situation
- Delaying any action until consensus is achieved

Those in the second group of patients likely to receive TEN usually have permanent swallowing problems and require some type of feeding tube for delivery of the enteral product on a long-term basis. Examples of conditions that can cause permanent swallowing problems are strokes, severe head trauma, and advanced multiple sclerosis. Patients in the third group receive enteral nutrition for as long as their illness lasts. The feeding is discontinued when the patient's condition improves and he or she can eat again. TEN is contraindicated for patients in states of significant hemodynamic compromise, such as those with diffuse

peritonitis, severe acute or chronic pancreatitis, intestinal obstruction, intractable vomiting or diarrhea, and paralytic ileus (Bankhead et al., 2009).

Many commercially prepared enteral products are available. A therapeutic combination of carbohydrates, fat, vitamins, minerals, and trace elements is available in liquid form. Differences among products allow the dietitian to select the right formula for each patient. A prescription from the health care provider is required for enteral nutrition, but the dietitian usually makes the recommendation and computes the amount and type of product needed for each patient.

NCLEX Examination Challenge

Health Promotion and Maintenance

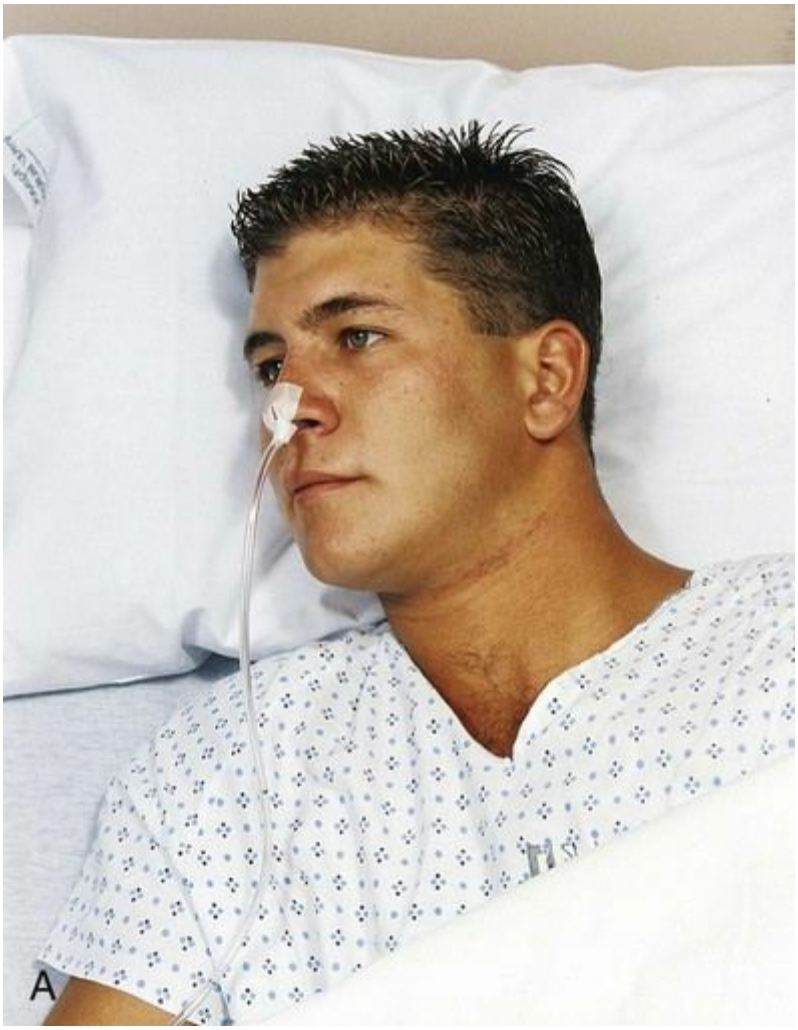
An older client tells the nurse that he does not have an appetite. His wife states that he refuses to eat the food she cooks. What instructions will the nurse provide for the client and wife? **Select all that apply.**

A "Place the fork in his hand and leave the room."
B "As long as you drink fluids, you do not need food."
C "Let him choose what foods he might desire."
D "Eat meals together, to make mealtime feel special."
E "Take your time eating, and do not rush through meals."
F "Use nutrition supplements such as Ensure throughout the day."

Methods of Administering Total Enteral Nutrition.

TEN is administered as "tube feedings" through one of the available GI tubes, either through a nasoenteric or enterostomal tube. It can be used in the patient's home or any health care setting.

A **nasoenteric tube (NET)** is any feeding tube inserted nasally and then advanced into the GI tract, such as a Keofeed, Entriflex, or Dobbhoff tube. Commonly used NETs include the **nasogastric (NG) tube** and the smaller (small-bore) **nasoduodenal tube (NDT)** (Fig. 60-3, *A*). A nasojejunal tube (NJT) is also available but is used less often than the other NETs.



A

B

FIG. 60-3 Feeding tubes used for total enteral nutrition. **A,** Nasoduodenal tube. **B** and **C,** Gastrostomy tubes.

The NDTs are used for delivering *short-term* enteral feedings (usually less than 4 weeks) because they are easy to use and are safer for the patient at risk for aspiration *if the tip of the tube is placed below the pyloric sphincter of the stomach and into the duodenum.* Small-bore polyurethane or silicone tubes from 8 to 12 Fr external diameter are preferred. The smaller tubes are more comfortable and are less likely to cause complications such as nasal irritation, sinusitis, tissue erosion, and pulmonary compromise.

Enterostomal feeding tubes are used for patients who need *long-term* enteral feeding. The most common types are gastrostomies and jejunostomies. The surgeon directly accesses the GI tract using various surgical, endoscopic, and laparoscopic techniques.

A **gastrostomy** is a stoma created from the abdominal wall into the stomach, through which a short feeding tube is inserted by the surgeon. It may require a small abdominal incision or may be placed endoscopically. This tube is called a **percutaneous endoscopic gastrostomy (PEG)** or dual-access gastrostomy-jejunostomy (PEG/J) tube. The PEG requires monitored conscious sedation for placement and is secure and durable. An alternative to either device is the **low-profile gastrostomy device (LPGD)** (Fig. 60-3, *B* and *C*). The LPGD is available with a firm or balloon-style internal bumper or retention disk. An anti-reflux valve keeps GI contents from leaking onto the skin. This device is less irritating to the skin, longer lasting, and more cosmetically pleasing. It also allows greater patient independence. However, skin-level devices do not allow easy access for checking **residuals** (the amount of feeding that remains in the stomach).

Jejunostomies are used less often than gastrostomies. A **jejunostomy** is used for long-term feedings when it is desirable to bypass the stomach,

such as with gastric disease, upper GI obstruction, and abnormal gastric or duodenal emptying.

Tube feedings are administered by bolus feeding, continuous feeding, and cyclic feeding. **Bolus feeding** is an intermittent feeding of a specified amount of enteral product at set intervals during a 24-hour period, typically every 4 hours. This method can be accomplished manually or by infusion through a mechanical pump or controller device. Another method of tube feeding is continuous enteral feeding. **Continuous feeding** is similar to IV therapy in that small amounts are continuously infused (by gravity drip or by a pump or controller device) over a specified time. The most commonly seen method, **cyclic feeding,** is the same as continuous feeding except the infusion is stopped for a specified time in each 24-hour period, usually 6 hours or longer ("down time"). Down time typically occurs in the morning to allow bathing, treatments, and other activities.

Infusion rates for cyclic feedings (and to some extent for intermittent bolus feeding) vary with the total amount of solution to be infused, the specific composition of the product, and the response of the patient to the feeding. The health care provider and dietitian usually decide the type, rate, and method of tube feeding, as well as the amount of additional water ("free water") needed. If the patient can swallow small amounts of food, he or she may also eat orally while the tube is in place.

The nurse is responsible for the care and maintenance of the feeding tube and the enteral feeding. Chart 60-4 lists best practices for the patient receiving TEN.

Chart 60-4 Best Practice for Patient Safety & Quality Care QSEN

Tube Feeding Care and Maintenance

- If nasogastric or nasoduodenal feeding is prescribed, use a soft, flexible, small-bore feeding tube (smaller than 12 Fr). *The initial placement of the tube should be confirmed by x-ray study.* Secure the tube with tape or a commercial attachment device after applying a skin protectant; change the tape regularly.
- Check tube placement by x-ray study when the correct position of the tube is in question; *an x-ray study is the most reliable method.*
- Per The Joint Commission's National Patient Safety Goals, if a gastrostomy or jejunostomy tube is used, assess the insertion site for signs of infection or excoriation (e.g., excessive redness, drainage).

Rotate the tube 360 degrees each day, and check for in-and-out play of about ¼ inch (0.6 cm). If the tube cannot be moved, notify the health care provider immediately because the retention disk may be embedded in the tissue. Cover the site with a dry, sterile dressing, and change the dressing at least once a day.

- Check and record the residual volume every 4 to 6 hours or per facility policy by aspirating stomach contents into a syringe. If residual feeding is obtained, check with the health care provider for the appropriate intervention (usually to slow or stop the feeding for a time) or use the American Society of Parenteral and Enteral Nutrition (ASPEN) best practice recommendations.
- Check the feeding pump to ensure proper mechanical operation.
- Ensure that the enteral product is infused at the prescribed rate (mL/hr).
- Change the feeding bag and tubing every 24 to 48 hours; label the bag with the date and time of the change with your initials. Use an irrigation set for no more than 24 hours.
- For continuous or cyclic feeding, add only 4 hours of product to the bag at a time to prevent bacterial growth. *A closed system is preferred, and each set should be used no longer than 24 hours.*
- Wear clean gloves when changing or opening the feeding system or adding product; wipe the lid of the formula can with clean gauze; wear sterile gloves for critically ill or immunocompromised patients.
- Label open cans with date and time opened; cover, and keep refrigerated. Discard any unused open cans after 24 hours.
- *Do not use blue (or any color) food dye in formula because it does not assess aspiration and can cause serious complications.*
- To prevent aspiration, keep the head of the bed elevated at least 30 degrees during the feeding and for at least 1 hour after the feeding for bolus feeding; continuously maintain semi-Fowler's position for patients receiving cyclic or continuous feeding.
- Monitor laboratory values, especially blood urea nitrogen (BUN), serum electrolytes, hematocrit, prealbumin, and glucose.
- Monitor for complications of tube feeding, especially diarrhea.
- Monitor and carefully record the patient's weight and intake and output as requested by the physician or dietitian.

Complications of Total Enteral Nutrition.

The nursing priority for care is patient safety, including preventing, assessing, and managing complications associated with tube feeding. Some

complications of therapy result from the type of tube used to administer the feeding, and others result from the enteral product itself. The most common problem is the development of an obstructed ("clogged") tube. Use the tips in Chart 60-5 to maintain tube patency.

Chart 60-5 Best Practice for Patient Safety & Quality Care QSEN

Maintaining a Patent Feeding Tube

- Flush the tube with 20 to 30 mL of water (or the amount prescribed by the health care provider or dietitian):
  - At least every 4 hours during a continuous tube feeding
  - Before and after each intermittent tube feeding
  - Before and after drug administration (use warm water)
  - After checking residual volume
- If the tube becomes clogged, use 30 mL of water for flushing, applying gentle pressure with a 50-mL piston syringe.
- Avoid the use of carbonated beverage, except for existing clogs *when water is not effective.* Do not use cranberry juice.
- Whenever possible, use liquid medications instead of crushed tablets unless liquid forms cause diarrhea; make sure that the drug is compatible with the feeding solution.
- Do not mix drugs with the feeding product before giving. Crush tablets as finely as possible, and dissolve in warm water. *(Check to see which tablets are safe to crush. For example, do not crush slow-acting [SA] or slow-release [SR] drugs.)*
- Consider use of automatic flush feeding pump such as Flexiflo or Kangaroo.

Patients receiving TEN are at risk for several other complications, including refeeding syndrome, tube misplacement and dislodgement, abdominal distention and nausea/vomiting, and fluid and electrolyte imbalance, often associated with diarrhea. These problems can be prevented if the patient is carefully monitored and complications are detected early.

Refeeding Syndrome.

Refeeding syndrome is a potentially life-threatening metabolic complication that can occur when nutrition is restarted for a patient who is in a *starvation* state. When a patient is starved for nutrition, the body

breaks down fat and protein, rather than carbohydrates, for energy. Protein catabolism leads to muscle and cell loss, often in major organs like the heart, liver, and lungs. The body's cells lose valuable electrolytes, including potassium and phosphate, into the plasma. Insulin secretion decreases in response to these changes. When *refeeding* begins, insulin production resumes and the cells take up glucose and electrolytes from the bloodstream, thus depleting serum levels.

Nursing Safety Priority QSEN

Critical Rescue

The electrolyte shift of refeeding syndrome can cause cardiovascular, respiratory, and neurologic problems, primarily as a result of hypophosphatemia, according to a classic study by Mehanna et al. (2008). Observe for clinical manifestations of this electrolyte imbalance, including shallow respirations, weakness, acute confusion, seizures, and increased bleeding tendency. Report and document your findings immediately. More information on fluid and electrolyte imbalance can be found in Chapter 11.

Refeeding syndrome can be prevented if patients are carefully assessed and managed for nutrition needs. Interventions to supplement or replace nutrition should be implemented early before the patient is in a starvation state. Patients receiving parenteral nutrition (described on pp. 1244-1245 later in this chapter) also may experience refeeding syndrome.

Tube Misplacement and Dislodgement.

A serious complication is misplacement or dislodgement of the tube, *which can cause aspiration and possible death. Immediately remove any tube that you suspect is dislodged!* The Joint Commission's National Patient Safety Goals and the Centers for Medicare and Medicaid Services require all health care facilities to establish and implement procedures and systems to prevent patient harm from medical complications.

Several techniques should be used to confirm proper placement to prevent harm and to keep the patient safe. *An x-ray is the most accurate confirmation method and should always be done upon initial tube insertion.* After the initial placement is confirmed, check the placement before each intermittent feeding or at least every 4 to 8 hours during feeding. Also check placement before each drug administration.

The traditional auscultatory method for checking tube placement may not be

reliable, especially for patients with small-bore tubes. In this method, the nurse instills 20 to 30 mL of air into the tube ("insufflation") while listening over the epigastric area (stomach) with a stethoscope. *The resulting "whooshing" sound does not guarantee correct tube placement!*

Although some patients have respiratory distress if the tube is misplaced into the lungs, others do not. Therefore better methods for ensuring patient safety are being researched. Several safer procedures have been recommended for checking tube placement *after the initial placement has been confirmed by x-ray.* These methods include:

- Testing aspirated contents for pH, bilirubin, trypsin, or pepsin
- Assessing for carbon dioxide using capnometry

Some hospitals and nursing homes support testing the *pH of GI contents* at the bedside. To perform this procedure, aspirate a sample of the GI content, observe its color, and test its pH. When aspirating fluid, wait at least 1 hour after drug administration and then flush the tube with 20 mL of air to clear it. Collect the aspirate, and test it with pH paper. The pH of gastric fluid ranges from 0 to 4.0. If the tube has moved down into the intestines, the pH will be between 7.0 and 8.0. If the tube is in the lungs, the pH will be greater than 6.0. The pH may also be as high as 6 if the patient takes certain drugs, such as H_2 blockers (e.g., ranitidine [Zantac] and famotidine [Pepcid]). Because these drugs affect pH, bilirubin testing or capnometry may be more reliable and valid methods for predicting tube location.

Capnometry can determine if carbon dioxide is emitted from the tube (Grmec et al., 2011). A device to measure the presence of the gas is attached to the end of the tube after placement. The test is positive for carbon dioxide if the tube is placed into the lungs, rather than the stomach. *The tube should be immediately removed if the gas is detected.*

Nursing Safety Priority QSEN

Action Alert

If enteral tubes are misplaced or become dislodged, the patient is likely to aspirate. Aspiration pneumonia is a life-threatening complication associated with TEN, especially for older adults. Observe for increasing temperature and pulse, as well as for other signs of dehydration such as dry mucous membranes and decreased urinary output. Auscultate lungs every 4 to 8 hours to check for diminishing breath sounds, especially in lower lobes. Patients may become short of breath and report chest discomfort. A chest x-ray confirms this

diagnosis, and treatment with antibiotics is started.

Abdominal Distention and Nausea/Vomiting.

Abdominal distention, nausea, and vomiting during tube feeding are often caused by overfeeding. To *prevent* overfeeding, check gastric residual volumes every 4 to 6 hours, depending on facility policy and the needs of the patient. The American Society of Parenteral and Enteral Nutrition (ASPEN) (2011) recommends holding a feeding if the gastric residual volumes are more than 200 mL on two consecutive assessments. In some facilities, feedings are temporarily held if the gastric residual is 100 mL or more, depending on the patient. After a period of rest, the feeding can be restarted at a lower flow rate.

A problem with frequent residual assessments is that the formula may clog the tube during aspiration, even if flushed with water. If the patient's residual volumes have been low or zero and he or she has no abdominal distention, nausea, or vomiting, consider discontinuing these assessments, depending on facility policy.

Fluid and Electrolyte Imbalances.

Patients receiving enteral nutrition therapy are at an increased risk for fluid imbalances. They are often older or debilitated and may also have cardiac or renal problems. Fluid imbalances associated with enteral nutrition are usually related to the body's response to increased serum osmolarity, but *fluid overload* from too much tube feeding can also occur.

Osmolarity is the amount or concentration of particles dissolved in solution. This concentration exerts a specific osmotic pressure within the solution. Normal osmolarity of extracellular fluid (ECF) ranges between 270 and 300 mOsm. Enteral feeding products range in osmolarity from isotonic (about 300 mOsm) to extremely hypertonic (600 mOsm). Electrolytes (including sodium) contribute to this hypertonicity, but more of the osmolarity is determined by the concentration of proteins and sugar molecules in the enteral product. Even when the product is isotonic, the ECF can become hyperosmolar unless some hypotonic fluids are also administered to the patient. This situation is most likely to develop in patients who are unconscious, unable to respond to the thirst reflex, on fluid restrictions, or receiving hyperosmotic enteral preparations.

Because increased plasma osmolarity is largely a result of extra glucose and proteins (which tend to remain in the plasma rather than move to interstitial spaces), the plasma osmotic pressure (water-pulling pressure)

is increased. In this situation, intracellular and interstitial water move into and expand the plasma volume. This volume expansion results in an increased renal excretion of water (in patients with normal renal function) and leads to osmotic *dehydration.*

Considerations for Older Adults

Patient-Centered Care QSEN

If patients do *not* have normal renal and cardiac function, expansion of the plasma volume can lead to circulatory overload and pulmonary edema, especially in older adults. Therefore early identification of patients at risk for impairment of renal and/or cardiac function is important. Assess for signs and symptoms of circulatory overload, such as peripheral edema, sudden weight gain, crackles, dyspnea, increased blood pressure, and bounding pulse. Collaborate with the dietitian and health care provider to plan the correct amount of fluid to be provided.

Excessive *diarrhea* may develop when hyperosmolar enteral preparations are delivered quickly. This situation can also lead to *dehydration* through excessive water loss. Collaborate with the health care provider and dietitian for recommendations to prevent diarrhea. The dietitian usually changes the feeding to a more iso-osmolar formula. Most of these formulas can be started full strength but slowly at 15 to 20 mL/hr. The rate is gradually increased as the patient tolerates and as the expected nutrition outcome is achieved.

If diarrhea continues, especially if it has a very foul odor, evaluate the patient for *Clostridium difficile* or other infectious organisms. Contamination can occur because of repeated and often faulty handling of the feeding solution and system. *Per The Joint Commission's National Patient Safety Goals, wear clean gloves when changing systems and adding product. Sterile gloves may help prevent infection in critically ill or immunocompromised patients. A closed feeding system is preferred over an open one because the chance of contamination is lessened* (see Chart 60-4). Tubes with ports also minimize contamination by eliminating the need to open the feeding system to administer drugs.

In some cases, diarrhea may be the result of multiple liquid medications, such as elixirs and suspensions that have a very high osmolarity. Examples include acetaminophen (Tylenol), furosemide (Lasix), and phenytoin (Dilantin). Patients receiving multiple liquid drugs should be evaluated by the health care provider to determine whether their drug regimen can be changed to prevent diarrhea. Diluting

these liquids may also be an option.

Depending on the patient's state of health, some electrolyte imbalances can be avoided. This is achieved by the use of enteral preparations containing lower concentrations of the electrolytes that the patient cannot handle well. For example, renal patients with high potassium levels receive a special formula that is used for this imbalance.

The two most common electrolyte imbalances associated with enteral nutrition therapy are hyperkalemia and hyponatremia. Both of these conditions may be related to hyperglycemia-induced hyperosmolarity of the plasma and the resultant osmotic diuresis. Risk for disturbances in fluid and electrolyte balance are discussed in detail in Chapter 11.

Parenteral Nutrition.

When a patient cannot effectively use the GI tract for nutrition, either partial or total parenteral nutrition therapy may be needed. This form of IV therapy differs from standard IV therapy in that any or all nutrients (carbohydrates, proteins, fats, vitamins, minerals, and trace elements) can be given. One liter of IV fluid containing 5% dextrose, which is often used as standard therapy, provides only 170 kcal. A hospitalized patient typically receives 3 to 4 L a day, for a total number of calories ranging between 500 and 700 a day. This calorie intake is not sufficient when the patient requires IV therapy for a prolonged period and cannot eat an adequate diet or has increased calorie needs for tissue repair and building.

Partial Parenteral Nutrition.

Partial, or peripheral, parenteral nutrition (PPN) is usually given through a cannula or catheter in a large distal vein of the arm or through a peripherally inserted central catheter (PICC line). (See Chapter 13 for care of patients with PICC lines.) The alternative is used for some patients who can eat but are not able to take in enough nutrients to meet their needs. The patient must have adequate peripheral vein access and be able to tolerate large volumes of fluid to have PPN. Two types of solutions are commonly used in various combinations for PPN: IV fat (lipid) emulsions (IVFEs) and amino acid–dextrose solutions. IVFEs are usually given using a piggyback method.

Nursing Safety Priority QSEN

Critical Rescue

For patients receiving fat emulsions, monitor for manifestations of fat overload syndrome, especially in those who are critically ill. These manifestations include fever, increased triglycerides, clotting problems, and multi-system organ failure. Discontinue the IVFE infusion and report any of these changes to the health care provider immediately if this complication is suspected.

Most IVFEs (20% fat emulsion) are isotonic, but the tonicity of commercially prepared amino acid–dextrose solutions ranges from 300 mOsm to nearly 900 mOsm for PPN. Amino acid–dextrose solutions are considered more stable than IVFEs, and therefore additives (e.g., vitamins, minerals, electrolytes, trace elements) tend to be mixed with them. These solutions must be delivered through an in-line filter and are administered by an infusion pump for an accurate and constant delivery rate.

Some PPN products are a *mixture* of lipids (10% or 20% fat emulsion) and an amino acid–dextrose (usually 10%) solution. This mixture of three types of nutrients is referred to as a *3 : 1, total nutrient admixture (TNA),* or *triple-mix solution.*

Total Parenteral Nutrition.

When the patient requires intensive nutrition support for an extended time, the health care provider prescribes centrally administered **total parenteral nutrition (TPN).** TPN is delivered through access to central veins, usually through a PICC line or the subclavian or internal jugular veins. Central venous catheters and associated nursing care are described in detail in Chapter 13.

Total parenteral nutrition solutions contain higher concentrations of dextrose and proteins, usually in the form of synthetic amino acids or protein hydrolysates (3% to 5%). These solutions are hyperosmotic (3 to 6 times the osmolarity of normal blood). The base solutions are available as commercially prepared solutions. The hospital or community pharmacist adds components (specific electrolytes, minerals, trace elements, and insulin) according to the patient's nutrition needs. This therapy provides needed calories and spares body proteins from catabolism for energy requirements.

The TPN solutions are administered with an infusion pump. The osmolarity of the fluid and the concentrations of the specific components make controlled delivery essential.

Patients receiving parenteral nutrition fluids are at risk for a wide variety of serious and potentially life-threatening complications.

Complications may result from the solutions or from the peripheral or central venous catheter. The following discussion is limited to the complications that involve fluid and electrolyte balance. Complications of IV cannulas and central venous catheters are discussed in Chapter 13, including infection and sepsis.

Patients receiving parenteral nutrition therapy are at high risk for fluid imbalance. Not only is fluid delivered directly into the venous system but also the extreme hyperosmolarity of the solutions stimulates fluid shifts between body fluid compartments. The hyperosmolarity is caused by their amino acid and dextrose concentrations. Increased dextrose causes hyperglycemia (increased blood glucose). As a result, some of the dextrose moves into the interstitial and intracellular spaces, where it is metabolized. However, dextrose remains in the plasma volume when the solutions are administered too rapidly, without enough insulin coverage, or in the presence of hyponatremia and hypokalemia. The result is a shift of water from the interstitial and intracellular spaces into the plasma. Expansion of the plasma volume together with hyperglycemia can cause osmotic diuresis and lead to serious dehydration and hypovolemic shock. If the patient also has cardiac or renal dysfunction, he or she may develop fluid overload, congestive heart failure, and pulmonary edema. Monitor the infusion rate of the parenteral fluid, and give insulin as prescribed.

Monitor for these complications by taking daily weights and by documenting accurate intake and output while the patient is receiving parenteral nutrition. Serum glucose and electrolyte values are also monitored (Chart 60-6). Report any major changes or abnormalities to the health care provider, and document all assessments and interventions.

Chart 60-6 Best Practice for Patient Safety & Quality Care QSEN

Care and Maintenance of Total Parenteral Nutrition

- Check each bag of total parenteral nutrition (TPN) solution for accuracy by comparing it with the physician's or pharmacist's prescription.
- Monitor the IV pump for accuracy in delivering the prescribed hourly rate.
- If the TPN solution is temporarily unavailable, give 10% dextrose/water ($D_{10}W$) or 20% dextrose/water ($D_{20}W$) until the TPN solution can be

obtained.
- If the TPN administration is not on time ("behind"), do not attempt to "catch up" by increasing the rate.
- Monitor the patient's weight daily or according to facility protocol.
- Monitor serum electrolytes and glucose daily or per facility protocol. (Many facilities require finger-stick blood sugars [FSBSs] every 4 hours, especially if the patient is receiving insulin. Urine testing for ketones may also be requested.)
- Monitor for, report, and document complications, including fluid and electrolyte imbalances.
- Monitor and carefully record the patient's intake and output.
- Assess the patient's IV site for signs of infection or infiltration (see Chapter 13).
- Change the IV tubing every 24 hours or per facility protocol.
- Change the dressing around the IV site every 48 to 72 hours or per facility protocol.
- Before administering TPN, have a second nurse check the prescription and solution to prevent patient harm.

Patients receiving TPN are at an increased risk for many different disturbances of fluid and electrolyte balance, depending on the composition of the solution and whether a fluid imbalance occurs. The health care provider usually requests frequent determinations of serum electrolyte levels to detect these imbalances. The risk for metabolic and electrolyte complications is reduced when the rate of administration is carefully controlled and patients are closely monitored for response to treatment. Potassium and sodium imbalances are common, especially when insulin is also administered as part of the therapy. Calcium imbalances, particularly hypercalcemia, are associated with TPN, although immobility may play more of a role than the actual therapy in developing this imbalance (National Institutes of Health [NIH], 2013a).

Community-Based Care

Malnourished patients can be cared for in a variety of settings, including the acute care hospital, transitional care unit, nursing home, or their own home. Malnutrition is often diagnosed when the patient is admitted to the acute care hospital or shortly after hospitalization if complications such as poor wound healing or sepsis occur. If the patient is severely compromised, he or she may require admission to a traditional nursing home for either transitional or long-term care. If adequate home support

is available, he or she may be discharged to home in the care of a family member or other caregiver. Home care nurses may be needed to monitor and direct the care.

Home Care Management.

The malnourished patient needs a variety of resources at home to continue aggressive nutrition support. If he or she can consume food by the oral route, the case manager or other discharge planner determines whether financial resources are available for the necessary nutrition supplements. If the hospital provides ambulatory nutrition counseling services, the patient is scheduled for follow-up after discharge for assessment of weight gain.

Self-Management Education.

The dietitian teaches the malnourished patient and family about high-calorie, high-protein diet and nutrition supplements. In collaboration with the pharmacist, review specific parenteral solutions with the patient and family or significant others.

Reinforce the importance of adhering to the prescribed diet, and review any drugs the patient may be taking. If using an iron preparation, teach the importance of taking the drug immediately before or during meals. Caution the patient that iron tends to cause constipation. For the older adult already susceptible to constipation, emphasize the importance of measures for prevention, including adequate fiber intake, adequate fluids, and exercise.

Some patients are discharged to home with enteral or parenteral nutrition. Teach the family or other caregiver how to continue these therapies. Remind caregivers to consider the psychosocial aspects of these alternative methods for nutrition. For example, the caregiver can bring the enteral product and napkin to the patient on a decorative tray to make the feeding experience more elegant and "normal." Moving the feeding equipment out of view of the patient when it is not in use is also helpful.

Health Care Resources.

The malnourished patient discharged to home on enteral or parenteral nutrition support needs the specialized services of a home nutrition therapy team. This team generally consists of the physician, nurse, dietitian, pharmacist, and case manager or social worker. Several commercial companies supply these services to patients at home in addition to the feeding supplies and formulas and health teaching.

Evaluation: Outcomes

Evaluate the care of the malnourished patient based on the identified priority patient problem. The primary expected outcome is that he or she has available nutrients to meet the metabolic demands for maintaining weight and total protein and has adequate hydration.

Obesity

Pathophysiology

Obesity is not just one disease; it includes many conditions with varying causes. The terms *obesity* and *overweight* are often used interchangeably, but they refer to different health problems. For both problems, the patient often does not consume enough healthy nutrients and may not receive adequate nutrition. **Overweight** is an increase in body weight for height compared with a reference standard, or up to 10% greater than ideal body weight (IBW) and a body mass index (BMI) of 25 to 29. This weight may not reflect excess body fat. For example, well-developed athletes may appear overweight because of increased muscle (lean) mass, in which the proportion of muscle to fat is greater than average (NIH, 2013b).

Obesity refers to an excess amount of body fat when compared with lean body mass. The normal amount of body fat in *men* is between 15% and 20% of body weight. For *women,* the normal amount is 18% to 32%. An obese person weighs at least 20% above the upper limit of the normal range for ideal body weight and has a BMI of 30 or more. **Morbid obesity,** also called *extreme obesity,* refers to a weight that has a severely negative effect on health—usually more than 100% above IBW and a BMI over 40.

More than one third of Americans are obese (CDC, 2012b). About 10% or more of adults are morbidly obese. *This problem is the second leading cause of preventable deaths in the United States, second only to smoking, and has become a national crisis.* Obesity across the life span is considered an epidemic in the United States and Canada. Worldwide, it is recognized as a major global health problem, costing billions of dollars for health care and lost productivity.

The pathophysiology of obesity is very complex. A number of chemicals in the body, including hormones known as *adipokines,* work together to affect appetite and fat metabolism:

- **Leptin:** a hormone released by fat cells and possibly by gastric cells; it also acts on the hypothalamus to control appetite
- **Adiponectin:** an anti-inflammatory and insulin-sensitizing hormone
- **Resistin:** a hormone produced by fat cells that creates resistance to insulin activity
- **Inflammatory cytokines:** such as inflammatory interleukins and tumor necrosis factor–alpha
- **Apolipoprotein E:** one of several regulators of lipoprotein metabolism
- **Cholecystokinin:** a hormone that stimulates digestive juices and may work with leptin to increase or decrease appetite

- **Ghrelin:** the "hunger hormone" that is secreted in the stomach; increases in a fasting state and decreases after a meal

Some adipokines are neuropeptides, including orexins and anorexins, which play a role in body weight. **Orexins** are appetite stimulants; examples are ghrelin secreted by the stomach and peptide YY from the intestines. **Anorexins** decrease appetite and include leptin and insulin (McCance et al., 2014). Increased circulating plasma levels of orexins are associated with the development of obesity. However, in some people, high levels of leptin may not be effective in suppressing appetite—a condition known as *leptin resistance.* In this case, overeating and excessive weight gain can result. Hyperleptinemia also stimulates the autonomic nervous system and contributes to blood vessel inflammation and ventricular hypertrophy. These actions may help explain why obese patients are most at risk for hypertension, atherosclerosis, and heart disease (Kulie et al., 2011). Obesity is also associated with insulin resistance, which predisposes obese patients to type 2 diabetes mellitus (see Chapter 64) (NIH, 2013b).

The distribution of excess body fat rather than the degree of obesity has been used to predict increased health risks. For example, the waist circumference (WC) is a stronger predictor of coronary artery disease (CAD) than is the BMI. A WC greater than 35 inches (89 cm) in women and a WC greater than 40 inches (102 cm) in men indicate central obesity (National Institute of Diabetes and Digestive and Kidney Diseases, 2012). Central obesity is a major risk factor for CAD, stroke, type 2 diabetes, some cancers (e.g., colon, breast), sleep apnea, and early death (NIH, 2013b).

The waist-to-hip ratio (WHR) is also a predictor of CAD. This measure differentiates peripheral lower body obesity from central obesity. A WHR of 0.95 or greater in men (0.8 or greater in women) indicates android obesity with excess fat at the waist and abdomen.

Complications of Obesity

The major complications of obesity affect primarily the cardiovascular and respiratory systems. However, excess weight can also cause degeneration of the musculoskeletal system, especially the weight-bearing joints like hips and knees (osteoarthritis). Obese people are also more susceptible to infections and infectious diseases than are thinner people and tend to heal more slowly. Table 60-3 lists some of the most common complications of obesity.

TABLE 60-3

Common Complications of Obesity

• Type 2 diabetes mellitus • Hypertension • **Hyperlipidemia** (increased serum lipids) • Coronary artery disease (CAD) • Stroke • Peripheral artery disease (PAD) • Metabolic syndrome • Obstructive sleep apnea
• Obesity hypoventilation syndrome • Depression and other mental health/behavioral health problems • Urinary incontinence • **Cholelithiasis** (gallstones) • Gout • Chronic back pain • Early osteoarthritis • Decreased wound healing

Etiology and Genetic Risk

The causes of obesity involve complex interrelationships of many environmental, genetic, and behavioral factors. One of the most common causes of being overweight or obese is eating *high-fat and high-cholesterol diets.* Obesity is associated with diet when it contains a significant amount of *saturated* fat, which increases low-density lipoproteins (LDL, or LDL-C for low-density lipoproteins cholesterol). *Trans* fatty acids (TFAs), saturated fats, and cholesterol are linked to obesity and CAD (American Heart Association, 2013). By contrast, monounsaturated and polyunsaturated fats are healthy fats.

Physical inactivity has been identified as another cause of overweight and obesity. The major barriers to increasing physical activity include a lack of time, learned behaviors regarding a sedentary lifestyle, or decreased mobility associated with prolonged illness. Regular exercise is associated with lower death rates for adults of any age. It also increases lean muscle, decreases body fat, aids in weight control, and enhances psychological well-being. Although some people think that regular exercise has to include joining a fitness program or exercising for long periods, simple forms of exercise like walking 20 minutes provide the same type of benefit. Older adults can engage in this type of exercise. It does not cost money (like joining a program) and provides health benefits such as strengthening joints and improving cardiovascular health.

Another cause of obesity is *drug therapy.* Some prescribed drugs contribute to weight gain when they are taken on a long-term basis. Examples include:

- Corticosteroids
- Estrogens and certain progestins
- Nonsteroidal anti-inflammatory drugs (NSAIDs)
- Antihypertensives
- Antidepressants and other psychoactive drugs
- Antiepileptic drugs
- Certain oral antidiabetic agents

Genetic/Genomic Considerations

Patient-Centered Care QSEN

Familial and genetic factors seem to play a very important role in obesity. When both parents are overweight, about 80% of their children will be overweight. If neither parent is overweight, fewer than 10% of the children will be overweight. In studies of identical twins, nonidentical twins, and parent-sibling relationships, about 50% of the difference in body fatness is transmitted to children and about 50% of this amount is genetically controlled (McCance et al., 2014).

Genetic composition may predispose some people but not others to obesity. Leptin, the hormone encoded by the *ob* gene, appears to send a message to the brain that the body has stored enough fat. This message serves as a signal to stop eating. In some obese people, other gene mutations have been identified, including an abnormality of the melanocortin-4 receptor that inhibits appetite in families with a history of obesity.

People who have **Prader-Willi syndrome (PWS),** a complex neurodevelopmental genetic disorder, are typically morbidly obese. This disorder results from a hypothalamic-pituitary dysfunction that prevents appetite control (Yearwood et al., 2011).

Health Promotion and Maintenance

Obesity is a major public health problem and is associated with many complications, including death. As a result of this increasing problem, the *Healthy People 2020* agenda addresses the need to reduce the proportion of children, adolescents, and adults who are obese. *Healthy People 2020 objectives for Nutrition and Weight Status* include specific population targets related to obesity and healthy nutrition habits (Table 60-4). In collaboration with the dietitian, teach the importance of weight management and exercise to improve health. Even a 5% weight loss can drastically decrease the risk for coronary artery disease (CAD) and

diabetes mellitus (NIH, 2013b). Nurses who practice healthful behaviors and value a healthy lifestyle are more likely to be seen by patients as credible teachers of this information (Marchiondo, 2014).

TABLE 60-4

Meeting *Healthy People 2020* Sample Objectives and Targets: Nutrition and Weight Status

• Reduce the proportion of adults who are obese (by 10%). • Increase the proportion of adults who are at a healthy weight (by 10%). • Increase the proportion of physician visits made by adult patients that include counseling about nutrition or diet (by 15.2%). • Increase the proportion of primary care physicians who regularly assess body mass index (BMI) in their adult patients (by 10%). • Increase the contribution of total vegetables to the diets of the population aged 2 years and older (to 1.1 cups per 1000 calories). • Increase the contribution of fruits to the diets of the population aged 2 years and older (to 0.9 cups per 1000 calories). • Reduce consumption of saturated fat in the population aged 2 years and older (by 9.5%).

Patient-Centered Collaborative Care

Assessment

History.

In addition to taking a complete history regarding present and past health problems, collect this information about the patient in collaboration with the dietitian:

- Economic status
- Usual food intake
- Eating behavior
- Cultural background
- Attitude toward food
- Appetite
- Chronic diseases
- Drugs (prescribed and OTC, including herbal preparations)
- Physical activity/functional ability
- Family history of obesity
- Developmental level

A nutrition history usually includes a 24-hour recall of food intake and the frequency with which foods are consumed. The adequacy of the diet can be evaluated by comparing the amount and types of foods consumed daily with the established standards. The dietitian then provides a more detailed analysis of nutrition intake.

Physical Assessment/Clinical Manifestations.

Obtain an accurate height and weight. The dietitian calculates the

percentage of ideal body weight (% IBW) and the body mass index (BMI). He or she may also:

- Measure the waist circumference
- Calculate the waist-to-hip ratio
- Determine arm and calf circumferences

Examine the skin of the obese patient for reddened or open areas. Lift skinfold areas, such as pendulous breasts and abdominal aprons **(panniculus),** to observe for *Candida* (yeast) (a condition called *intertrigo*) or other infections or lesions. Infection of the panniculus is referred to as **panniculitis.**

Psychosocial Assessment.

Obtain a psychosocial history to determine the patient's circumstances and emotional factors that might prevent successful therapy or that might be worsened by therapy. Interview the patient to determine his or her perception of current weight and weight reduction. Some patients do not view weight as a problem, which affects planning, treatment, and outcome. Ask the patient questions about his or her health beliefs related to being overweight, such as:

- What does food mean to you?
- Do you want to lose weight?
- What prevents you from losing weight?
- What do you think will motivate you to lose weight?
- How do you think you might benefit from losing weight?

Many patients report that they have tried multiple diets to lose weight but either the diets have not worked or they regained the weight they had initially lost. People who attempt restrictive diets become easy targets for the billion-dollar weight-loss industry, yet most dieters regain lost weight. This problem can be even more concerning for the older adult who loses weight and then regains it. Studies have shown that this cycle may contribute to loss of lean muscle mass, especially in older men (Lee et al., 2010).

The results of dieting and other efforts can lead to a sense of failure and lowered self-esteem, which often stimulates more overeating. Many overweight and obese people eat in response to environmental and emotional stressors rather than because they are hungry. Ask patients to identify their perceived stressors and what triggers their need for food.

Lifestyle changes are difficult without adequate family and community support. Assess useful coping strategies and support systems that the patient can employ during treatment for obesity.

Explore the patient's history to assess:

- Attempts at weight-reduction diets and outcomes
- Effects of obesity on lifestyle
- Effects of obesity on social interactions
- Mental health/behavioral health problems, such as depression
- Effects of obesity on intimate relationships, especially sexuality

Obese men often experience erectile dysfunction (ED), which can cause or worsen depression. Women often experience changes in their menstrual cycles and may have problems getting pregnant.

Interventions

Weight is lost when energy used is greater than intake. Weight loss may be accomplished by nutrition modification with or without the aid of drugs and in combination with a regular exercise program. Patients who may be candidates for surgical treatment include those who have:

- Repeated failure of nonsurgical interventions
- A BMI equal to or greater than 40
- Weight more than 100% above IBW (i.e., morbidly obese)

Nonsurgical Management.

Various nutrition approaches and drug therapy have been attempted to help obese patients achieve permanent weight loss.

Diet Programs.

Diets for helping people lose weight include fasting, very-low-calorie diets, balanced and unbalanced low-energy diets, and novelty diets.

Short-term fasting programs have not been successful in treating morbidly obese patients, and prolonged fasting does not produce permanent benefits. Most patients regain the weight that was lost by this method. In addition, the risks associated with fasting (e.g., severe ketosis) require close medical supervision.

Very-low-calorie diets generally provide 200 to 800 calories/day. Two types of these diets are the *protein-sparing modified fast* and the *liquid formula diet.* The protein-sparing modified fast provides protein of high biologic value (1.5 g/kg of desirable body weight daily) within a limited number of calories. The diet produces rapid weight loss while preserving lean body mass. The liquid formula diet provides between 33 and 70 g of protein daily.

Both diets require an initial cardiac evaluation, supervision by an interdisciplinary health care team with monitoring by a physician, nutrition counseling by a dietitian, and supplementation with vitamins

and minerals. These diets are only one part of a weight-reduction program. Patients who are on these diets should receive nutrition education, psychological counseling, exercise, and behavior therapy. Comparable weight losses have been achieved with both diets, but again, most patients regain the weight they lost.

Nutritionally balanced diets generally provide about 1200 calories/day with a conventional distribution of carbohydrate, protein, and fat. Vitamin and mineral supplements may be necessary if energy intakes fall below 1200 calories for women and 1800 calories for men. This diet provides conventional foods that are economical and easy to obtain. Thus the outcome of weight loss is facilitated, and it is hoped that loss is maintained. For example, Weight Watchers is an organization that provides education about nutritionally balanced diets based on a point system. They offer on-site weekly group support meetings or the option of an online community.

Unbalanced low-energy diets, such as the low-carbohydrate diet (e.g., Atkins or South Beach diet), restrict one or more nutrients. Protein and vegetables are encouraged, but certain carbohydrates and high-fat foods are not. Although they remain controversial in the medical community, these diets are extremely popular. Scientific outcome data have been conflicting.

Novelty diets, such as the grapefruit diet, the Cookie diet, and the Hollywood diet, are often nutritionally *inadequate.* This type of diet implies that a certain food or liquid increases metabolic rate or accelerates the oxidation of body fat. Weight loss is achieved because energy is restricted by food choice, but patients do not sustain weight loss after stopping the diet.

Nutrition Therapy.

Nutrition recommendations for each patient are developed through close interaction among the patient, family, physician, nurse, and dietitian. The diet must meet the patient's needs, habits, and lifestyle and should be realistic.

The dietitian develops a diet plan and instructs the patient. At a minimum, the diet should:

- Have a scientific rationale
- Be nutritionally adequate for all nutrients
- Have a low risk-benefit ratio
- Be practical and conducive to long-term success

Calorie estimates are easily calculated. Resting metabolic rate is determined using a gender-specific formula that incorporates the

appropriate activity factor. This figure reflects the total calories needed daily for maintaining current weight. To encourage a weight loss of 1 pound (0.45 kg) a week, the dietitian subtracts 500 calories each day. To encourage a weight loss of 2 pounds (0.9 kg) a week, 1000 calories each day are subtracted. The amount of weight lost varies with the patient's food intake, level of physical activity, and water losses. A reasonable expected outcome of 5% to 10% loss of body weight has been shown to improve glycemic control and reduce cholesterol and blood pressure. These benefits continue if the weight loss is sustained.

Exercise Program.

Along with change in eating habits, a major intervention to manage obesity is to increase the type and amount of daily exercise to burn calories. For most people, adding exercise to a nutrition intervention produces more weight loss than just dieting alone. More of the weight lost is fat, which preserves lean body mass. An increase in exercise can reduce the waist circumference and the waist-to-hip ratio.

Teach patients that increasing and maintaining physical activity levels are important in maintaining weight loss. Many overweight or obese patients are so unfit that it may take several months of conditioning before they can exercise sufficiently to lose weight.

A minimum-level workout should be developed so that consistency can be achieved. The expected outcome is to maintain a lifetime of increased physical activity. The patient is likely to be less fatigued and discouraged with a low-intensity, short-duration program. Encourage sedentary (physically inactive) patients to increase their activity by walking 30 to 40 minutes at least 5 days each week. The activity may be performed all at once or divided over the course of the day. Remind the patient to exercise only under the supervision of the physician. All members of the interdisciplinary team should encourage and support any increase in physical activity. Structured national programs with support staff may be helpful for some patients. The staff typically offers diet counseling as well as cardiovascular and muscle-toning activities.

Drug Therapy.

A BMI of 30 or a BMI of 27 with comorbidities is one indicator for the use of drug therapy. **Anorectic drugs** suppress appetite, which reduces food intake and, over time, may result in weight loss. The Food and Drug Administration (FDA) in the United States has pulled several drugs off the market and not approved other drugs due to concerns about cardiovascular complications associated with long-term use. Prescription

drugs still available for the *long-term* treatment of obesity include orlistat (Xenical), lorcaserin (Belviq), and phentermine-topiramate (Qsymia).

Orlistat inhibits lipase and leads to partial hydrolysis of triglycerides. Because fats are only partially digested and absorbed, calorie intake is decreased. Most patients taking this drug have GI symptoms that include loose stools, abdominal cramps, and nausea unless they reduce their fat intake to less than 30% of their food intake each day. Therefore the drug should be used with caution and limited to adults between 18 and 75 years of age. Treatment is usually not extended beyond 12 months. A lower-dose 60-mg orlistat tablet (Alli) is the only *over-the-counter* weight-loss aid product that has received FDA approval for long-term use.

Lorcaserin (Belviq) works by activating the serotonin 2C receptor in the brain to help decrease appetite and create a sense of feeling full after eating small amounts of food (Mayo Clinic, 2014). Side effects may include headaches, dizziness, dry mouth, and constipation. Teach patients to report the signs of the rare but serious side effect of serotonin syndrome, including suicidal thoughts, psychiatric concerns, and problems with memory or comprehension (Mayo Clinic, 2014).

Phentermine-topiramate (Qsymia) combines a short-term weight-loss drug (phentermine) with a drug that is used to control seizures (topiramate) (Mayo Clinic, 2014). Side effects may include an increased heart rate, hand and feet tingling, insomnia, dizziness, dry mouth, and constipation. Teach patients that a rare but serious side effect that is associated with this drug is suicidal thoughts, which should immediately be reported to the prescribing health care provider (Mayo Clinic, 2014).

Other sympathomimetic drugs suppress appetite for *short-term* use along with a structured weight-management and exercise program. These drugs act on the central nervous system, including suppressing the appetite center in the hypothalamus. Examples include phentermine (Adipex-P), diethylpropion (Tenuate, Tenuate Dospan), and phendimetrazine (Bontril).

Nursing Safety Priority QSEN

Drug Alert

Patients with hypertension, heart disease, and hyperthyroidism should not take anorectic drugs because they may worsen their symptoms. These drugs are not prescribed for any patient taking psychoactive agents because they cause similar side effects. Teach patients who are candidates for sympathomimetic drugs about side

effects, which include:
- Palpitations
- Diarrhea or constipation
- Restlessness
- Insomnia
- Dry mouth
- Blurred vision (especially with Bontril)
- Change in sex drive or activity
- Anxiety

Behavioral Management.

Behavioral management of obesity helps the patient change daily eating habits to lose weight. Self-monitoring techniques include keeping a record of foods eaten (food diary), exercise patterns, and emotional and situational factors. Stimulus control involves controlling the external cues that promote overeating. Reinforcement techniques are used to self-reward the behavior change. Cognitive restructuring involves modifying negative beliefs by learning positive coping self-statements. Counseling by health care professionals must continue before, during, and after treatment. The 12-step program offered by Overeaters Anonymous (www.oa.org) has helped many people lose weight, especially those who are compulsive eaters.

Complementary and Alternative Therapies.

Many complementary and alternative therapies have been tested and used for obesity. These modalities aim to suppress appetite and therefore limit food intake to lose weight:
- Acupuncture
- Acupressure
- Ayurveda (a combination of holistic approaches)
- Hypnosis

Surgical Management.

At any weight, some patients seek to improve their appearance by having a variety of cosmetic procedures to reduce the amount of adipose tissue in selected areas of the body. A typical example of this type of surgery is **liposuction,** which can be done in a physician's office or ambulatory surgery center. Although the patient's appearance improves, if weight gain continues, the fatty tissue will return. This procedure is not a solution for people who are morbidly obese.

Morbidly obese people who do not respond to traditional interventions may be considered for a major surgical procedure aimed at producing permanent weight loss. Patients with a body mass index (BMI) of 40 or greater or a BMI of 35 or greater along with additional risk factors are considered for surgery. Surgery has been perceived as a last resort to address weight issues, but it *is the only method that has a long-term impact on morbid obesity.*

Bariatrics.

Bariatrics is a branch of medicine that manages patients with obesity and its related diseases. Surgical procedures include these three types: gastric restrictive, malabsorption, or both. *Restrictive* surgeries decrease the volume capacity of the stomach to limit the amount of food that can be eaten at one time. As the name implies, *malabsorption* procedures interfere with the absorption of food and nutrients from the GI tract.

Every year more than 200,000 people in the United States have bariatric surgical procedures (American Society for Bariatric Surgery, 2013), and that number continues to increase. The surgeon may use a conventional open approach or minimally invasive surgery (MIS). Most patients have MIS by having either the laparoscopic adjustable gastric band (LAGB) procedure or the laparoscopic sleeve gastrectomy (LSG). Both procedures are classified as restrictive surgeries (Virji, 2011). The decision of whether the patient is a candidate for the MIS is based on weight, body build, history of abdominal surgery, and co-existing medical complications. With any surgical approach, patients must agree to modify their lifestyle and follow stringent protocols to lose weight and keep the weight off. After bariatric surgery, many patients no longer have complications of obesity, such as diabetes mellitus, hypertension, depression, or sleep apnea.

Preoperative Care.

Preoperative care is similar to that for any patient undergoing abdominal surgery or laparoscopy (see Chapter 14). However, obese patients are at increased surgical risks of pulmonary and thromboembolitic complications, as well as death. Some surgeons require limited weight loss before bariatric surgery to decrease these complications. Patients also have a thorough psychological assessment and testing to detect depression, substance abuse, or other mental health/behavioral health problem that could interfere with their success after surgery. Cognitive ability, coping skills, development, motivation, expectations, and support systems are also assessed. Patients who are not alert and oriented or do

not have sufficient strength and mobility are not considered for bariatric surgery. *The primary role of the nurse is to reinforce health teaching in preparation for surgery.* Most bariatric surgical centers provide education sessions for groups of patients who plan to have the procedure.

Operative Procedures.

Gastric restriction surgeries allow for normal digestion without the risk for nutrition deficiencies. In the LAGB procedure, the surgeon places an adjustable band to create a small proximal stomach pouch through a laparoscope (Fig. 60-4, *A*). The band may or may not be inflatable. For example, the REALIZE band requires that saline be injected into a balloon to control the tightness of the band. This type of procedure is considered to be restrictive; malabsorption complications usually do not occur (Virji, 2011). For the LSG, the surgeon removes the portion of the stomach where ghrelin, the "hunger hormone," is secreted. Restrictive surgeries are the easiest to perform. However, weight lost is often regained after a period of time. By contrast, patients having the malabsorption procedures maintain 60% to 70% of their weight loss even after 20 years.

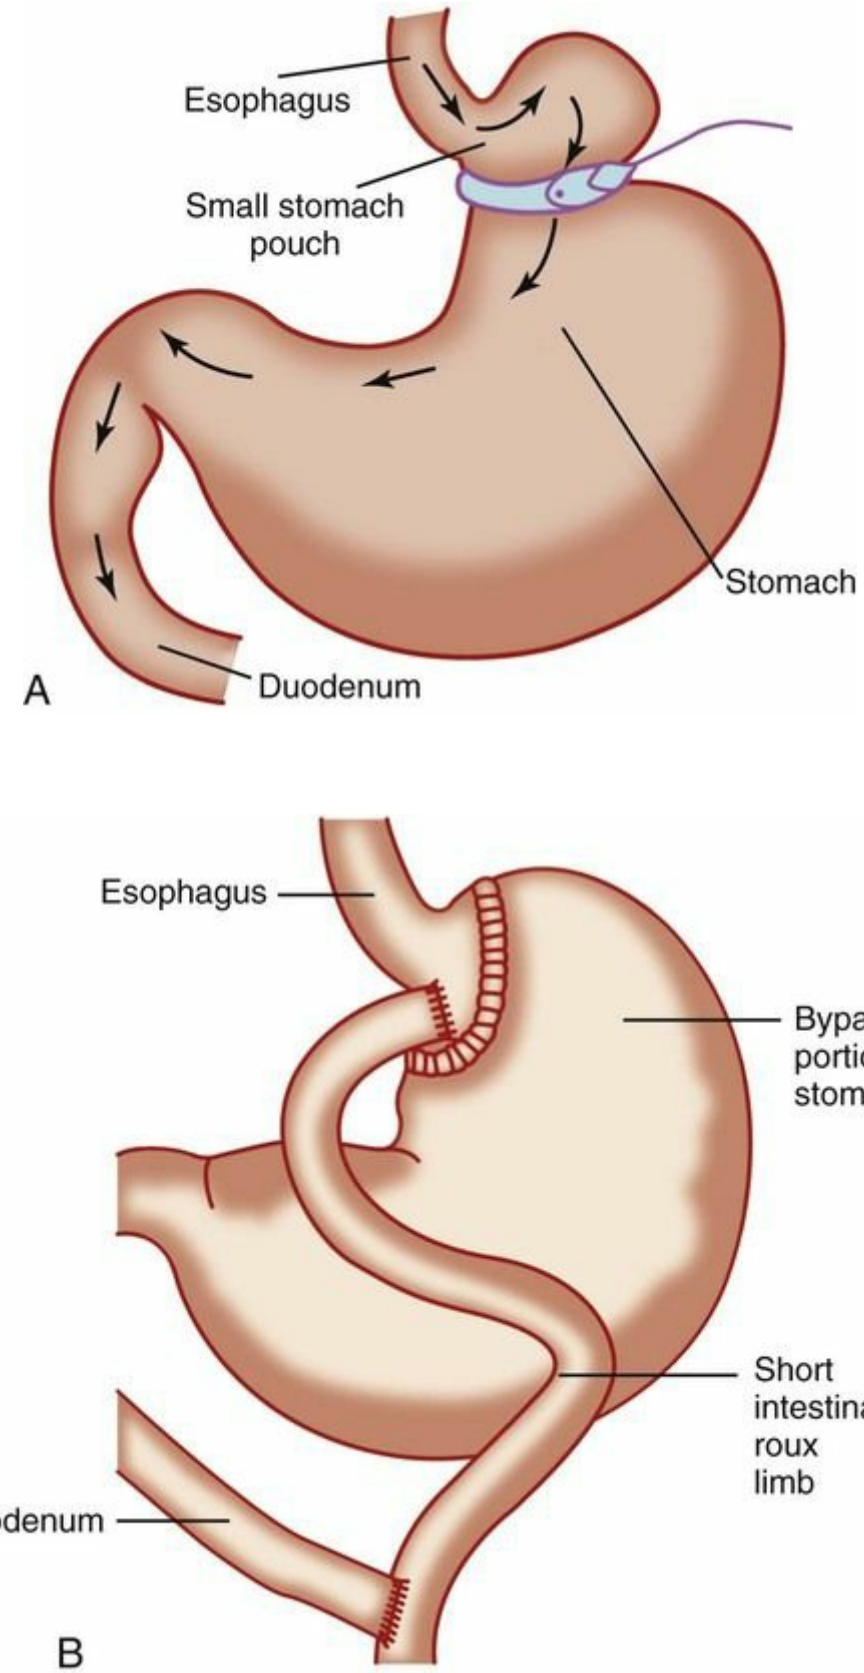


FIG. 60-4 Bariatric surgical procedures. **A,** Adjustable banded gastroplasty. **B,** Roux-en-Y gastric bypass (RNYGB).

The most common *malabsorption surgery* performed in the United States is the *Roux-en-Y gastric bypass (RNYGB),* which is often done as a robotic-assistive surgical procedure. This procedure results in quick

weight loss, but it is more invasive with a higher risk for postoperative complications. In RNYGB, most commonly just called a **gastric bypass,** gastric resection is combined with malabsorption surgery (Virji, 2011). The patient's stomach, duodenum, and part of the jejunum are bypassed so that fewer calories can be absorbed (see Fig. 60-4, *B*).

Postoperative Care.

Postoperative care depends on the type of surgery—the conventional open approach or the minimally invasive technique. Although many patients have MIS, they are considered as having major abdominal surgery along with all its risks and are cared for accordingly. These patients may require less than 24 hours in the hospital; some may need 1 to 2 days. Patients with open procedures may need several days to recover.

Patients having one of the MIS procedures have less pain, scarring, and blood loss. They typically have a faster recovery time and a faster return to daily activities.

The priority for immediate care of postoperative bariatric surgery patients is airway management. Patients with short and thick necks often have compromised airways and need aggressive respiratory support—possibly mechanical ventilation in the critical care unit.

All patients experience some degree of pain, but it is usually less severe when MIS is done. Patients may use patient-controlled analgesia (PCA) with morphine for up to the first 24 hours. All patients receive oral opioid analgesic agents as prescribed after the PCA is discontinued. Liquid forms of drug therapy are preferred. Acute pain management is discussed in detail in Chapter 3.

Care of the bariatric surgical patient is similar to that of any patient having abdominal or laparoscopic surgery. *A major focus is patient and staff safety*. Special bariatric equipment and accommodations, including an extra-wide bed and additional personnel for moving the patient, are needed for both the surgical suite and postoperative care units. Weight-rated beds must be wide enough to allow the patient to turn. Bed rails should not be touching the body because they can cause pressure areas. Pressure between skinfolds, as well as tubes and catheters, can also cause skin breakdown. Monitor the skin in these areas, and keep it clean and dry.

 **Nursing Safety Priority** QSEN

Action Alert

Some patients who have bariatric surgery have a nasogastric (NG) tube put in place, especially after open surgical procedures. In gastroplasty procedures, the NG tube drains both the proximal pouch and the distal stomach. Closely monitor the tube for patency. *Never reposition the tube because its movement can disrupt the suture line!* The NG tube is removed on the second day if the patient is passing flatus.

Clear liquids are introduced slowly if the patient can tolerate water, and 1-ounce cups are used for each serving. Pureed foods, juice, and soups thinned with broth, water, or milk are added to the diet 24 to 48 hours after clear liquids are tolerated. Typically, the patient can increase the volume to 1 ounce over 5 minutes or until satisfied, but the diet is limited to liquids or pureed foods for 6 weeks. The patient then progresses to regular food, with an emphasis on nutrient-dense foods. Nausea, vomiting, or discomfort occurs if too much liquid is ingested.

Nursing Safety Priority QSEN

Critical Rescue

Anastomotic leaks are the most common serious complication and cause of death after gastric bypass surgery. Monitor for manifestations of this life-threatening problem, including increasing back, shoulder, or abdominal pain; restlessness; and unexplained tachycardia and oliguria (scant urine). Report any of these findings to the surgeon immediately!

In addition to the postoperative complications typically associated with abdominal and laparoscopic surgeries, bariatric patients have special needs and risks, such as the risk for anastomotic leaks (a leak of digestive juices and partially digested food through an anastomosis).

Implement these measures to prevent complications:

- Apply an abdominal binder to prevent wound dehiscence for open surgical procedures.
- Place the patient in semi-Fowler's position or use bi-level or continuous positive airway pressure (BiPAP or CPAP) ventilation at night to improve breathing and decrease risk for sleep apnea or other pulmonary complications, such as pneumonia and atelectasis.
- Monitor oxygen saturation; provide oxygen at 2 L/min as prescribed.
- Apply sequential compression stockings and administer prophylactic anticoagulant (usually heparin) therapy as prescribed to help prevent

thromboembolitic complications, including pulmonary embolism (PE), a Joint Commission Core Measure intervention to prevent venous thromboembolism (VTE).
- Observe skin areas and folds for redness, excoriation, or breakdown to treat these problems early.
- Use absorbent padding between folds to prevent pressure areas and skin breakdown; make sure that tubes and catheters are not causing pressure as well.
- Remove urinary catheter within 24 hours after surgery to prevent urinary tract infection per the National Patient Safety Goals.
- Assist the patient out of bed on the day of surgery; encourage and assist with turning every 2 hours using an appropriate weight-bearing overhead trapeze. Collaborate with the physical or occupational therapist if needed for transfers or ambulation assistive devices, such as walkers.
- Ambulate patient as soon as possible to prevent postoperative complications, such as deep vein thrombosis and pulmonary embolus.
- Measure and record abdominal girth daily, as requested.
- In collaboration with the dietitian, provide six small feedings and plenty of fluids to prevent dehydration.
- Observe for signs and symptoms of **dumping syndrome** (caused by food entering the small intestine instead of the stomach) after *gastric bypass,* such as tachycardia, nausea, diarrhea, and abdominal cramping.

Clinical Judgment Challenge

Patient-Centered Care; Evidence-Based Practice; Teamwork and Collaboration; Informatics QSEN

A 32-year-old morbidly obese woman had a laparoscopic sleeve gastrectomy procedure yesterday afternoon as part of a long-term plan for weight loss. She tells you that despite having had surgery, she is afraid she will not live long enough to see her children grow up. She is diaphoretic, with respirations of 32 per minute. You notice that she is wringing her hands as she talks.

1. What patient problems do you think she is having at this time? What data support your answer?
2. What priority health assessments will you perform at this time, and why?
3. How will you respond to her problems at this time, and why?
4. With which members of the health care team will you collaborate to

address the patient's immediate concerns?
5. When she is ready for discharge, what health teaching will you provide related to the *Healthy People 2020 and 2010 Dietary Guidelines for Americans?* Find the complete evidence-based documents online, and develop a teaching plan for this patient.
6. To which community resources would you refer this patient, and why?

Community-Based Care

Obese patients are cared for in a variety of settings, including the acute care hospital and transitional care unit (particularly after surgery) or in their own home. Obesity is a chronic, lifelong problem. Diets, drug therapy, exercise, and behavior modification can produce short-term weight losses with reasonable safety. However, most patients who do lose weight often regain the weight. Treatment of obesity should focus on the long-term reduction of health risks and medical problems associated with obesity, improving quality of life, and promoting a health-oriented lifestyle. Interdisciplinary team members need to provide a nonjudgmental, supportive atmosphere that encourages the patient to:

- Increase physical activity
- Decrease fat intake and reliance on appetite-reducing drugs
- Establish a normal eating pattern in response to physiologic hunger
- Address psychological problems and concerns

Frequent long-term ambulatory care follow-up coordinated by a case manager is essential for successful treatment.

Teach patients that bowel changes are common after surgery, including constipation. Vitamin and mineral supplements are often needed after surgery, especially vitamin D, B-complex vitamins, iron, and calcium.

The most important features of health teaching for any obese patient and family focus on health-related behavior patterns. In collaboration with the dietitian, counsel the patient on a healthful eating pattern. The physical therapist or exercise physiologist recommends an appropriate exercise program. A psychologist may recommend cognitive restructuring approaches that help alter dysfunctional eating patterns. For patients who have surgery, additional discharge teaching is needed. Chart 60-7 lists the important areas that should be reviewed.

Chart 60-7 Patient and Family Education: Preparing for Self-Management

Discharge Teaching for the Patient After Bariatric Surgery

Nutrition: Diet progression, nutrient (including vitamin and mineral) supplements, hydration guidelines
Drug therapy: Analgesics and antiemetic drugs, if needed; drugs for other health problems
Wound care: Clean procedure for open or laparoscopic wounds; cover during shower or bath
Activity level: Restrictions, such as avoiding lifting; activity progression; return to driving and work
Signs and symptoms to report: Fever; excessive nausea or vomiting; epigastric, back, or shoulder pain; red, hot, and/or draining wound(s); pain, redness, or swelling in legs; chest pain; difficulty breathing
Follow-up care: Health care provider office or clinic visits, support groups and other community resources, counseling for patient and family
Continuing education: Nutrition and exercise classes; follow-up visits with dietitian

Bariatric surgery results in a major lifestyle change and a variety of emotions. During weight loss, the patient may become depressed or anxious. Some experience a "hibernation phase" for about a month after surgery because of physical and emotional adjustments. Patients are usually followed closely by the surgeon and dietitian for several years. Encourage them to keep all appointments and to adhere to the community-based treatment plan to ensure success. Plastic surgery, such as **panniculectomy** (removal of the abdominal apron, or **panniculus**), may be performed after weight is stabilized, usually in about 18 to 24 months.

Provide the patient with a list of available community resources, such as Overeaters Anonymous (www.oa.org) and the American Obesity Association (www.obesity.org). For surgical patients, the American Society for Metabolic and Bariatric Surgery (www.asmbs.org) may be helpful.

Nursing Concepts and Clinical Judgment Review

What might you NOTICE if the patient is experiencing inadequate nutrition as a result of malnutrition or obesity?

Malnutrition:

- Weight below ideal body weight or report of unexplained weight loss of 10 lbs (4.5 kg) in 6 months

- Dry, flaky skin
- Brittle nails and hair
- Leanness
- Activity intolerance
- Report of lethargy or fatigue
- Weakness
- Complications, such as infections, pressure ulcers, poor healing

Obesity:

- Weight at least 20% above ideal
- Excessive fat
- Shortness of breath during activity or at rest
- Slowed movement
- Change in gait or limping
- Complications, such as type 2 diabetes mellitus, hypertension, depression

What should you INTERPRET and how should you RESPOND to a patient experiencing inadequate nutrition as a result of malnutrition or obesity?

Perform and interpret assessments, including:

- Taking and recording height and weight
- Calculating BMI based on height and weight
- Checking laboratory values for hematocrit and hemoglobin and visceral proteins
- Taking complete medical history to determine associated complications and cause of nutrition problem
- Assessing impact of nutrition status on daily life, including ADLs
- Assessing coping mechanisms, especially for patients who are morbidly obese

Respond by:

- Teaching patients about their need for a healthy nutrition state
- Teaching patients how to either lose or gain weight, depending on their specific problem (e.g., nutrition supplements for malnutrition; restrictive diet and exercise for obesity)
- Teaching patients to weigh frequently
- Monitoring changes in serum visceral proteins (especially prealbumin) as an indicator of improved nutrition for malnourished patients
- Initiating total enteral or total parenteral nutrition as prescribed for

malnutrition
- Informing morbidly obese patients about bariatric surgery options

On what should you REFLECT?

- Monitor patient for indicators of improved nutrition (e.g., increased prealbumin and weight for malnutrition; weight loss and decreased fat for obesity).
- Think about what may have caused these nutrition problems and how they can be prevented.
- Think about what else you can do to improve nutritional health of patients you care for.

Get Ready for the NCLEX® Examination!

Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Collaborate with the interdisciplinary health care team, especially the dietitian, health care provider, and case manager, when caring for patients with malnutrition or obesity. **Teamwork and Collaboration** QSEN
- Be sure that bariatric furniture and equipment are available for the obese patient in the hospital or other health care setting; avoid pressure on skinfold areas. **Safety** QSEN

Health Promotion and Maintenance

- Perform nutrition screening for all patients to determine if they are at risk (see Charts 60-1 and 60-2).
- Recall the recommendations included in the *2010 Dietary Guidelines for Americans* as listed in Table 60-1.
- Older patients are at increased risk for malnutrition (see Chart 60-2).
- Implement interventions to promote nutrition intake in older adults as specified in Chart 60-3. **Patient-Centered Care** QSEN

Psychosocial Integrity

- Be aware that some obese patients may not view their weight as a problem and are therefore unlikely to be part of a weight-reduction plan.
- Recognize that obesity can cause depression or anxiety, low self-esteem, and a disturbed body image.
- Be aware of legal and ethical issues related to tube-feeding older adults with chronic or terminal illness.

Physiological Integrity

- Review serum prealbumin, hemoglobin, and hematocrit levels to identify patients at nutrition risk.
- Assess patients with severe malnutrition for common complications, such as edema, lethargy, and dry, flaking skin.
- Provide evidence-based nursing interventions for managing total enteral nutrition as listed in Chart 60-4. **Evidence-Based Practice** QSEN

- Maintain feeding tube patency for patients receiving total enteral nutrition as described in Chart 60-5. **Safety** QSEN
- Ensure that feeding tube placement is verified by x-ray; check placement every 4 to 8 hours by aspirating gastric contents and assessing pH for nasogastric tubes. **Safety** QSEN
- Place patients receiving tube feeding in a semi-Fowler's position at all times to prevent aspiration; check residual contents every 4 hours or as designated per facility policy. **Safety** QSEN
- Use gloves when changing feeding system tubing or adding product; use sterile gloves when working with critically ill or immunocompromised patients.
- Use a feeding pump when the patient receives continuous or cyclic tube feeding.
- For patients receiving enteral or parenteral nutrition at home, teach family members or other caregivers how to provide nutrition while avoiding complications.
- Teach patients who are undernourished to eat high-protein, high-calorie foods and nutrition supplements.
- Provide care for patients receiving total parenteral nutrition as specified in Chart 60-6. **Evidence-Based Practice** QSEN
- Recall that normal body mass index (BMI) for adults should be between 18.5 and 25; older adults should have a BMI between 23 and 27. A BMI of 27 to 30 indicates overweight, over 30 indicates obesity, and 40 and greater indicates morbid obesity.
- Recall that obesity causes early onset of many chronic illnesses, such as osteoarthritis, diabetes mellitus, hypertension, and coronary artery disease. Pulmonary problems (e.g., obstructive sleep apnea), delayed wound healing, and infections are also common.
- Instruct obese patients about the importance of health care provider–approved exercise for weight reduction.
- Recognize that many people are following low-carbohydrate rather than low-fat diets to lose weight.
- Remember that bariatric surgery includes gastric restriction procedures or gastric bypass; a panniculectomy may be performed to remove skinfolds once weight is stabilized.
- Be alert for signs and symptoms of anastomotic leak after bariatric surgery, including severe pain, restlessness, anxiety, and unexplained tachycardia. **Safety** QSEN
- Provide postoperative care for patients having bariatric surgery to prevent complications such as wound dehiscence, respiratory distress,

skin breakdown, and thromboembolitic complications, such as pulmonary embolism. Establishing and maintaining an airway is the priority for patients having bariatric surgery! **Safety** QSEN

- Observe for complications, such as dumping syndrome in patients who have a gastric bypass. Tachycardia, nausea, diarrhea, and abdominal cramping are common manifestations of dumping syndrome.
- Provide discharge teaching for patients having bariatric surgery as described in Chart 60-7.

UNIT XIV

Problems of Regulation and Metabolism: Management of Patients with Problems of the Endocrine System

OUTLINE

CHAPTER 61

Assessment of the Endocrine System

M. Linda Workman

PRIORITY CONCEPTS

- Nutrition
- Elimination

Learning Outcomes

Health Promotion and Maintenance

1. Teach all people measures to take to protect the endocrine system.

Psychosocial Integrity

2. Reduce the psychological impact for the patient and family regarding the assessment and testing of the endocrine system.

Physiological Integrity

3. Apply the principles of anatomy, physiology, and the aging process to assess the endocrine system and homeostasis.
4. Perform a focused assessment of endocrine function, incorporating information about genetic risk, age-related changes, and nutrition affecting endocrine function.
5. Coordinate appropriate care for patients and proper handling of specimens during testing of nutrition, elimination, and the endocrine system.

http://evolve.elsevier.com/Iggy/

The tissues and organs of the endocrine system are located in many

body areas (Fig. 61-1). Endocrine glands secrete **hormones**, which are natural chemicals that exert their effects on specific tissues known as **target tissues**. Target tissues are usually located some distance from the endocrine gland, with no connecting duct between the endocrine gland and its target tissue. For this reason, endocrine glands are called "ductless" glands and use the blood to transport secreted hormones to the target tissues (McCance et al., 2014). Endocrine glands include:

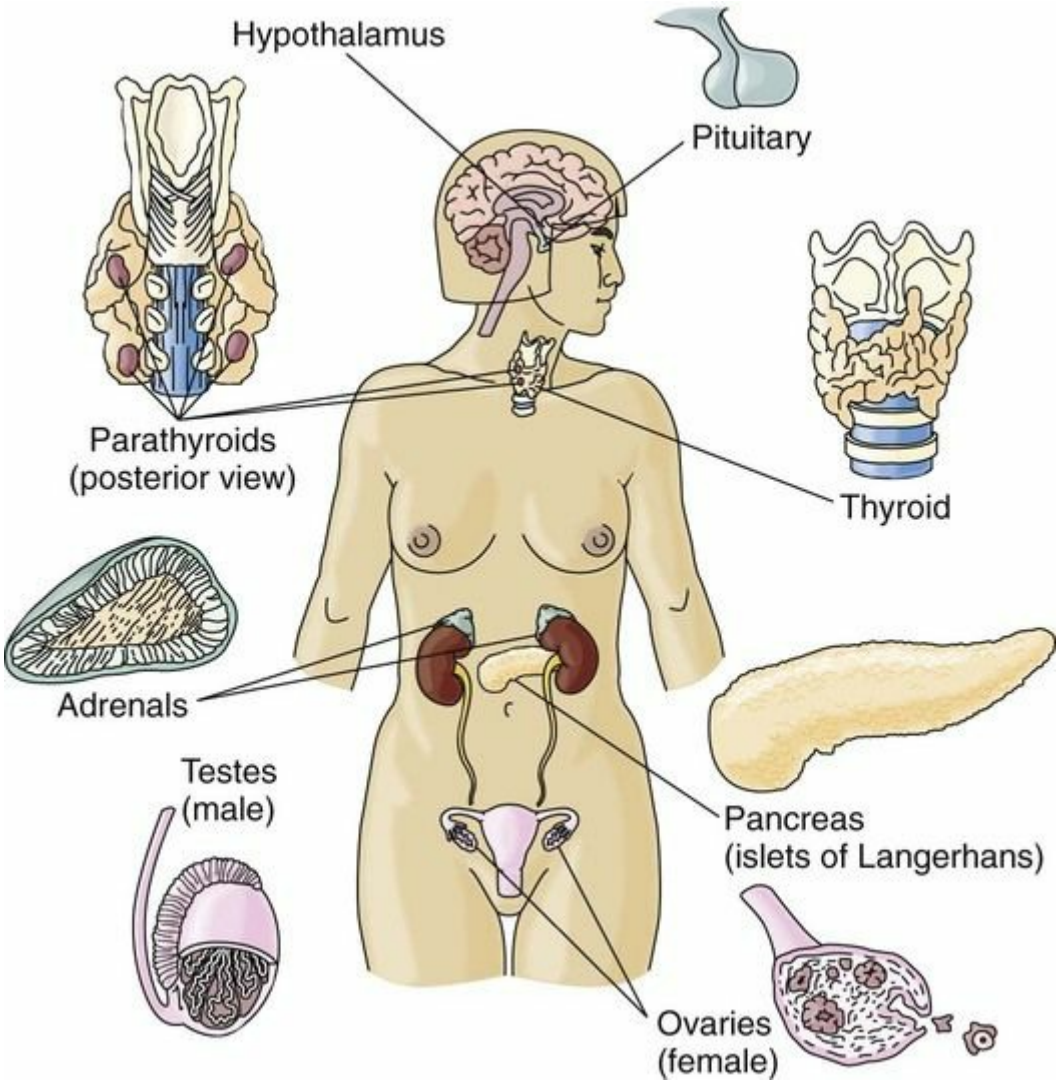

FIG. 61-1 The locations of various glands within the endocrine system.

- Hypothalamus (a neuroendocrine gland)
- Pituitary gland
- Adrenal glands
- Thyroid gland
- Islet cells of the pancreas
- Parathyroid glands

• Gonads

The endocrine system working with the nervous system controls overall body function and regulation, including metabolism, nutrition, elimination, temperature, fluid and electrolyte balance, growth, and reproduction. Many interactions must occur between the endocrine system and all other body systems to ensure that each system maintains a constant normal balance (**homeostasis**) in response to environmental changes. For example, this regulation keeps the internal body temperature at or near 98.6° F (37° C), even when environmental temperatures vary. Other actions keep the serum sodium level between 136 and 145 mEq/L (mmol/L), regardless of whether a healthy person eats 2 g or 12 g of sodium per day.

Table 61-1 lists hormones secreted by various endocrine glands. Hormones travel through the blood to all body areas but exert their actions only on target tissues. They recognize their target tissues and exert their actions by binding to receptors on or within the target tissue cells. In general, each receptor site type is specific for only one hormone. Hormone-receptor actions work in a "lock and key" manner in that only the correct hormone (key) can bind to and activate the receptor site (lock) (Fig. 61-2). Binding a hormone to its receptor causes the target tissue to change its activity, producing specific responses.

TABLE 61-1

Principal Hormones of the Endocrine Glands

GLAND	HORMONES
Hypothalamus	Corticotropin-releasing hormone (CRH) Thyrotropin-releasing hormone (TRH) Gonadotropin-releasing hormone (GnRH) Growth hormone–releasing hormone (GHRH) Growth hormone–inhibiting hormone (somatostatin GHIH) Prolactin-inhibiting hormone (PIH) Melanocyte-inhibiting hormone (MIH)
Anterior pituitary	Thyroid-stimulating hormone (TSH), also known as *thyrotropin* Adrenocorticotropic hormone (ACTH, corticotropin) Luteinizing hormone (LH), also known as *Leydig cell–stimulating hormone (LCSH)* Follicle-stimulating hormone (FSH) Prolactin (PRL) Growth hormone (GH) Melanocyte-stimulating hormone (MSH)
Posterior pituitary	Vasopressin (antidiuretic hormone [ADH]) Oxytocin
Thyroid	Triiodothyronine (T_3) Thyroxine (T_4) Calcitonin
Parathyroid	Parathyroid hormone (PTH)
Adrenal cortex	Glucocorticoids (cortisol) Mineralocorticoids (aldosterone)
Ovary	Estrogen Progesterone
Testes	Testosterone
Pancreas	Insulin Glucagon Somatostatin

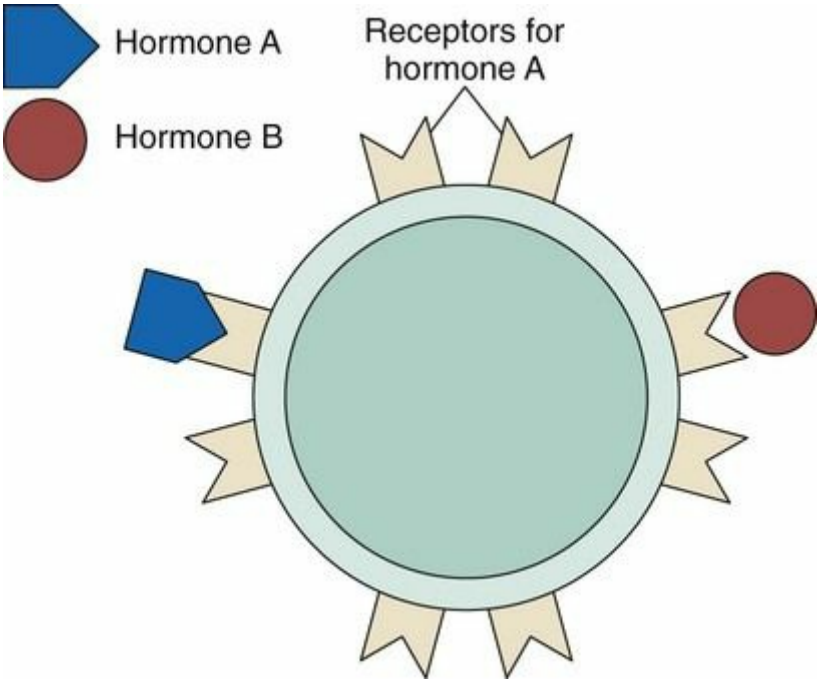

FIG. 61-2 "Lock and Key" hormone-receptor binding. *Hormone A* fits and binds to its receptors, causing a change in cell action. *Hormone B* does not fit or bind to receptors; no change in cell action results.

Disorders of the endocrine system usually are related to:

- An excess of a specific hormone
- A deficiency of a specific hormone
- A receptor defect

Anatomy and Physiology Review

The control of cellular function by any hormone depends on a series of reactions working through negative feedback control mechanisms. Hormone secretion usually depends on the body's need for the final action of that hormone. When a body condition starts to move away from the normal range and a specific response is needed to correct this change, secretion of the hormone capable of starting the correcting action or response is stimulated until the need (demand) is met, and the body condition returns to the normal range. As the correction occurs, hormone secretion decreases (and may halt). This control of hormone synthesis is "**negative feedback**" because the hormone causes the *opposite* action of the initial condition change.

An example of a simple negative feedback hormone response is the control of insulin secretion. When blood glucose levels start to rise above normal, the hormone *insulin* is secreted. Insulin increases glucose uptake by the cells, causing a *decrease* in blood glucose levels. Thus the action of insulin (decreasing blood glucose levels) is the opposite of or negative to the condition that stimulated insulin secretion (elevated blood glucose levels).

Some hormones have more complex interactions for negative feedback. These interactions involve a series of reactions in which more than one endocrine gland, as well as the final target tissues, is stimulated. In this situation, the first hormone in the series may have another endocrine gland or glands as its target tissue. The final result of complex negative feedback for endocrine function is still opposite of the initiating condition.

An example of complex control is the interaction of the hypothalamus and the anterior pituitary with the adrenal cortex (Fig. 61-3). Low blood levels of cortisol from the adrenal cortex stimulate the secretion of corticotropin-releasing hormone (CRH) in the hypothalamus. CRH stimulates the anterior pituitary gland to secrete adrenocorticotropic hormone (ACTH). ACTH then triggers the release of cortisol from the adrenal cortex, the final endocrine gland in this series. The rising blood levels of cortisol inhibit CRH release from the hypothalamus. Without CRH, the anterior pituitary gland stops secretion of ACTH. In response, normal blood cortisol levels are maintained.

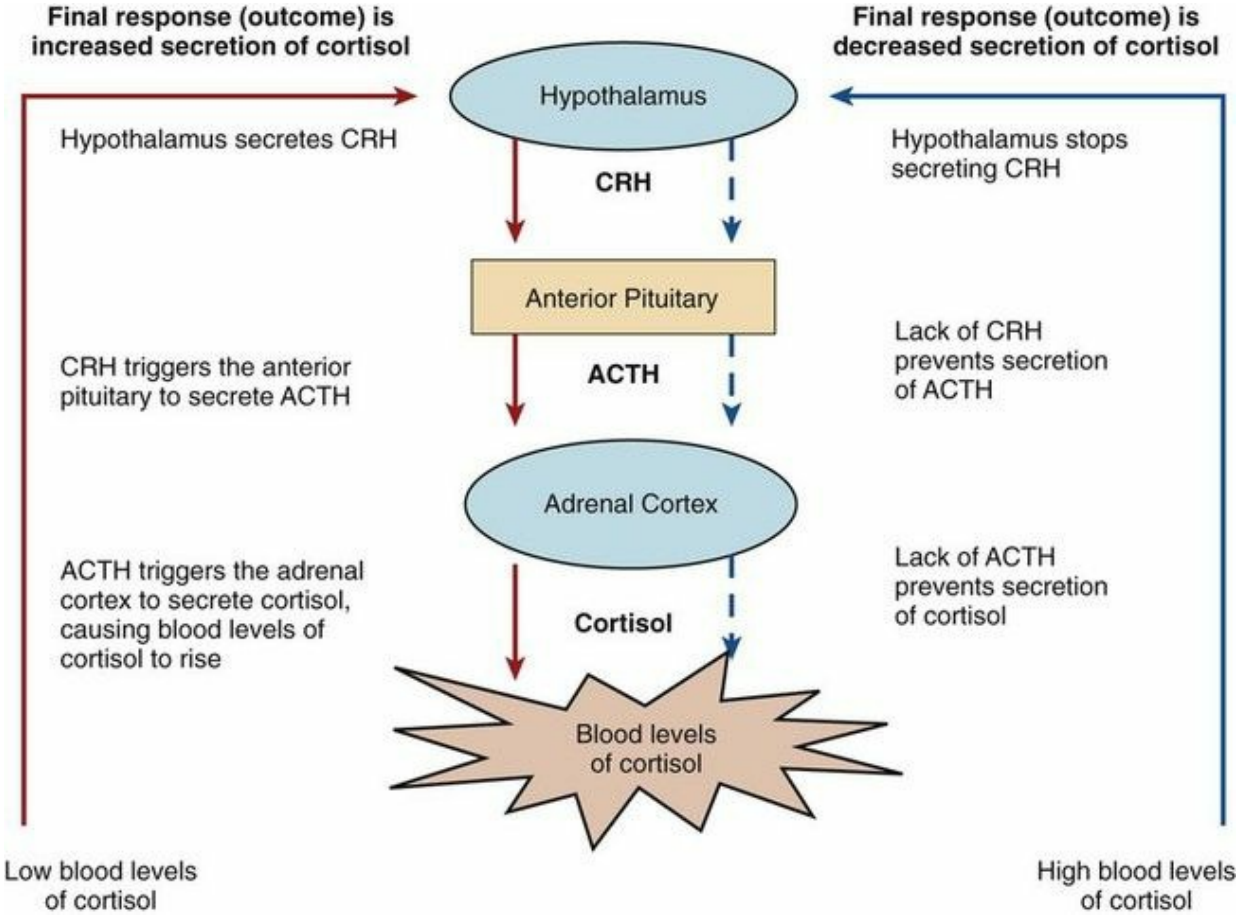

FIG. 61-3 Examples of positive and negative feedback control of hormone secretion. *ACTH,* Adrenocorticotropic hormone; *CRH,* corticotropin-releasing hormone.

The normal blood level range of each hormone is well defined. Excesses or deficiencies of hormone secretion can lead to pathologic conditions.

Hypothalamus and Pituitary Glands

The hypothalamus is a small area of nerve and endocrine tissue located beneath the thalamus in the brain. Nerve fibers connect the hypothalamus to the rest of the central nervous system. The hypothalamus shares a small, closed circulatory system with the anterior pituitary gland, known as the *hypothalamic-hypophysial portal system*. This system allows hormones produced in the hypothalamus to travel directly to the anterior pituitary gland so that only very small amounts are wasted in systemic circulation.

The function of the hypothalamus is to produce regulatory hormones (see Table 61-1). Some of these hormones are released into the blood and travel to the anterior pituitary, where they either stimulate or inhibit the release of anterior pituitary hormones.

The pituitary gland is located at the base of the brain in a protective pocket of the sphenoid bone (see Fig. 61-1). It is divided into the anterior lobe (*adenohypophysis*) and the posterior lobe (*neurohypophysis*). Nerve fibers in the hypophysial stalk connect the hypothalamus to the posterior pituitary (Fig. 61-4).

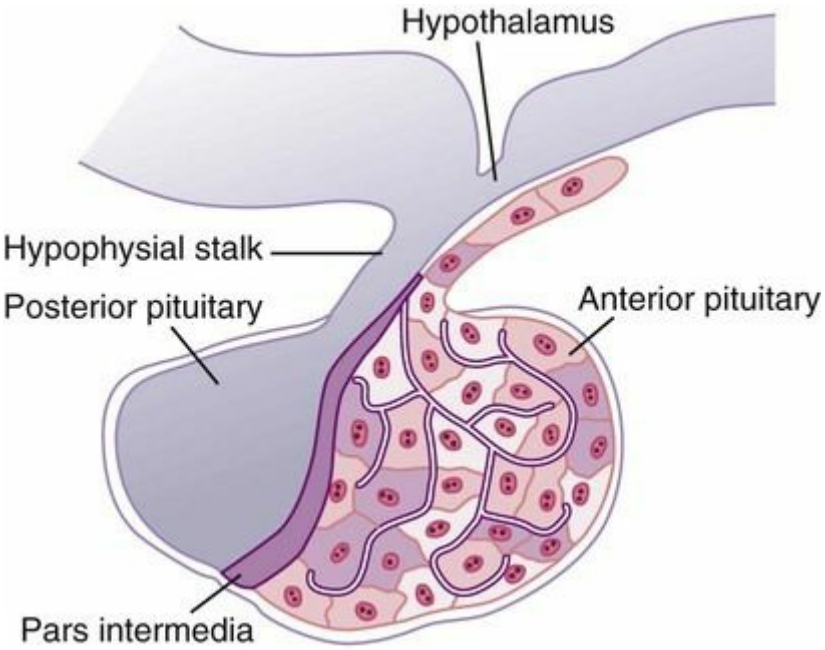

FIG. 61-4 The hypothalamus, hypophysial stalk, anterior pituitary gland, and posterior pituitary gland.

In response to the releasing hormones of the hypothalamus, the anterior pituitary secretes some tropic hormones that stimulate other endocrine glands. Other pituitary hormones, such as prolactin, produce their effect directly on final target tissues (Table 61-2).

TABLE 61-2

Pituitary Hormones: Target Tissues and Subsequent Actions

HORMONE	TARGET TISSUE	ACTIONS
Anterior Pituitary		
TSH (thyroid-stimulating hormone or thyrotropin)	Thyroid	Stimulates synthesis and release of thyroid hormone
ACTH (adrenocorticotropic hormone, corticotropin)	Adrenal cortex	Stimulates synthesis and release of corticosteroids and adrenocortical growth
LH (luteinizing hormone [known as *Leydig cell–stimulating hormone* in males])	Ovary	Stimulates ovulation and progesterone secretion
	Testis	Stimulates testosterone secretion
FSH (follicle-stimulating hormone [known as *interstitial cell–* or *Sertoli cell–stimulating hormone* in males])	Ovary	Stimulates estrogen secretion and follicle maturation
	Testis	Stimulates spermatogenesis
PRL (prolactin)	Mammary glands	Stimulates breast milk production
GH (growth hormone)	Bone and soft tissue	Promotes growth through lipolysis, protein anabolism, and insulin antagonism
MSH (melanocyte-stimulating hormone)	Melanocytes	Promotes pigmentation
Posterior Pituitary*		
Vasopressin (antidiuretic hormone [ADH])	Kidney	Promotes water reabsorption
Oxytocin	Uterus and mammary glands	Stimulates uterine contractions and ejection of breast milk

*These hormones are synthesized in the hypothalamus and are stored in the posterior pituitary gland. They are transported from the hypothalamus down the hypothalamic stalk to the posterior pituitary while bound to proteins known as *neurophysins*.

The hormones of the posterior pituitary—vasopressin (antidiuretic hormone [ADH]) and oxytocin—are produced in the hypothalamus and delivered to the posterior pituitary where they are stored. These hormones are released into the blood when needed.

Other factors can affect the release of hormones from the pituitary gland. Drugs, diet, lifestyle, and pathologic conditions can increase or decrease pituitary hormone secretion.

Gonads

The **gonads** are the male and female reproductive endocrine glands. Male gonads are the testes, and female gonads are the ovaries. Function of these glands begins at puberty when, under the influence of gonadotropic hormones secreted by the anterior pituitary, maturation of the glands and the external genitalia occurs. The testes are stimulated to produce testosterone, and the ovaries are stimulated to produce estrogen. The function of the gonads is detailed in Chapter 69.

Adrenal Glands

The adrenal glands are vascular, tent-shaped organs on the top of each kidney that have an outer cortex and an inner medulla (see Fig. 61-1). The adrenal hormones have effects throughout the body.

Adrenal Cortex

The adrenal cortex makes up about 90% of the adrenal gland and has cells divided into three layers. The main hormone types secreted by the cortex are the mineralocorticoids and the glucocorticoids. In addition, the cortex also secretes small amounts of sex hormones.

Mineralocorticoids are produced and secreted by the adrenal cortex to help control body fluids and electrolytes. **Aldosterone** is the major mineralocorticoid and maintains extracellular fluid volume. It promotes sodium and water reabsorption and potassium excretion in the kidney tubules. Aldosterone secretion is regulated by the renin-angiotensin system, serum potassium ion concentration, and adrenocorticotropic hormone (ACTH).

Renin is produced by specialized cells of the kidney arterioles. Its release is triggered by a decrease in extracellular fluid volume from blood loss, sodium loss, or posture changes. Renin converts renin substrate (angiotensinogen), a plasma protein, to angiotensin I. Angiotensin I is converted by a converting enzyme to form angiotensin II, the active form of angiotensin. In turn, angiotensin II stimulates the secretion of aldosterone. Chapter 11 (Fig. 11-6) further explains the renin-angiotensin system. Aldosterone causes the kidney to reabsorb sodium and water to bring the plasma volume and osmolarity back to normal.

Serum potassium level also controls aldosterone secretion. It is secreted whenever the serum potassium level increases above normal by as little as 0.1 mEq/L. Aldosterone then enhances kidney excretion of potassium to reduce the blood potassium level back to normal.

Glucocorticoids are produced by the adrenal cortex and are essential for life. The main glucocorticoid produced by the adrenal cortex is **cortisol**. Cortisol affects:

- The body's response to stress
- Carbohydrate, protein, and fat metabolism
- Emotional stability
- Immune function
- Sodium and water balance

Cortisol also influences other important body processes. For example, it must be present for catecholamine action and maintaining the normal excitability of the heart muscle cells. Glucocorticoid functions are listed in Table 61-3.

TABLE 61-3

Functions of Glucocorticoid Hormones

• Prevent hypoglycemia by increasing liver gluconeogenesis and inhibiting peripheral glucose use
• Maintain excitability and responsiveness of cardiac muscle
• Increase lipolysis, releasing glycerol and free fatty acids
• Increase protein catabolism
• Degrade collagen and connective tissue
• Increase the number of mature neutrophils released from bone marrow
• Exert anti-inflammatory effects that decrease the migration of inflammatory cells to sites of injury
• Maintain behavior and cognitive functions

Glucocorticoid release is regulated directly by the anterior pituitary hormone *ACTH* and indirectly by the hypothalamic corticotropin-releasing hormone *(CRH).* The release of CRH and ACTH is affected by the serum level of free cortisol, the normal sleep-wake cycle, and stress.

As described earlier and shown in Fig. 61-3, when blood cortisol levels are low, the hypothalamus secretes CRH, which triggers the pituitary to release ACTH. Then ACTH triggers the adrenal cortex to secrete cortisol. Adequate or elevated blood levels of cortisol *inhibit* the release of CRH and ACTH. This inhibitory effect is an example of a negative feedback system.

Glucocorticoid release peaks in the morning and reaches its lowest level 12 hours after each peak. Emotional, chemical, or physical stress increases the release of glucocorticoids.

Sex hormones (androgens and estrogens) are secreted in low levels by the adrenal cortex in both genders. Adrenal secretion of these hormones is usually not significant because the gonads (ovaries and testes) secrete much larger amounts of estrogens and androgens. In women, however, the adrenal gland is the major source of androgens.

NCLEX Examination Challenge

Physiological Integrity

What effect on circulating levels of sodium and glucose does the nurse expect in a client who has been taking an oral cortisol preparation for 2 years because of a respiratory problem?

A Decreased sodium; decreased glucose
B Decreased sodium; increased glucose
C Increased sodium; decreased glucose
D Increased sodium; increased glucose

Adrenal Medulla

The adrenal medulla is a sympathetic nerve ganglion that has secretory cells. Stimulation of the sympathetic nervous system causes the release of adrenal medullary hormones, the **catecholamines** (which include epinephrine and norepinephrine). These hormones travel to all areas of the body through the blood and exert their effects on target cells. The adrenal medullary hormones are not essential for life because they also are secreted by other body tissues, but they do play a role in the stress response.

The adrenal medulla secretes about 15% norepinephrine (NE) and 85% epinephrine. Hormone effects vary with the specific receptor in the cell membranes of the target tissue.

These receptors are of two types: alpha adrenergic and beta adrenergic, which are further classified as $alpha_1$ and $alpha_2$ receptors and $beta_1$, $beta_2$, and $beta_3$ receptors. NE acts mainly on alpha-adrenergic receptors, and epinephrine acts mainly on beta-adrenergic receptors.

Catecholamines exert their actions on many target organs (Table 61-4). Activation of the sympathetic nervous system, which then releases adrenal medullary catecholamines, is an important part of the stress response. Catecholamines are secreted in small amounts at all times to maintain homeostasis. Stress triggers increased secretion of these hormones, resulting in the "fight-or-flight" response, a state of heightened physical and emotional awareness.

TABLE 61-4

Catecholamine Receptors and Effects of Adrenal Medullary Hormone Stimulation on Selected Organs and Tissues

ORGAN OR TISSUE	RECEPTORS	EFFECTS
Heart	$Beta_1$	Increased heart rate
		Increased contractility
Blood vessels	Alpha	Vasoconstriction
	$Beta_2$	Vasodilation
Gastrointestinal tract	Alpha	Increased sphincter tone
	Beta	Decreased motility
Kidneys	$Beta_2$	Increased renin release
Bronchioles	$Beta_2$	Relaxation; dilation
Bladder	Alpha	Sphincter contractions
	$Beta_2$	Relaxation of detrusor muscle
Skin	Alpha	Increased sweating
Fat cells	Beta	Increased lipolysis
Liver	Alpha	Increased gluconeogenesis and glycogenolysis
Pancreas	Alpha	Decreased glucagon and insulin release
	Beta	Increased glucagon and insulin release
Eyes	Alpha	Dilation of pupils

Thyroid Gland

The thyroid gland is in the anterior neck, directly below the cricoid cartilage (Fig. 61-5). It has two lobes joined by a thin strip of tissue *(isthmus)* in front of the trachea.

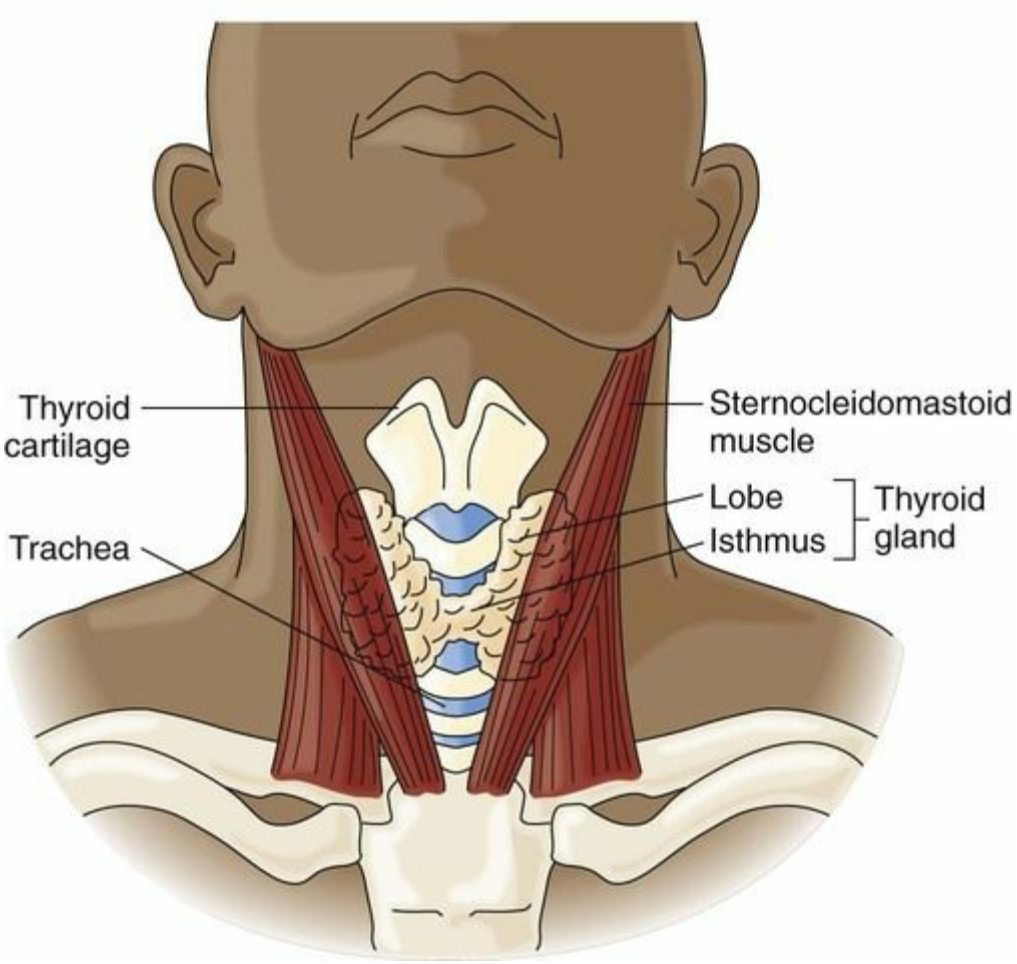

FIG. 61-5 Anatomic location of the thyroid gland.

The thyroid gland is composed of follicular and parafollicular cells. Follicular cells produce the thyroid hormones **thyroxine (T_4)** and **triiodothyronine (T_3)**. Parafollicular cells produce **thyrocalcitonin** (TCT or calcitonin), which helps regulate serum calcium levels.

Control of metabolism occurs through T_3 and T_4. Both hormones increase metabolism, which causes an increase in oxygen use and heat production in all tissues. Most circulating T_4 and T_3 is bound to plasma proteins. The free hormone moves into the cell, where it binds to its receptor in the cell nucleus. Once in the cell, T_4 is converted to T_3, the most active thyroid hormone. The conversion of T_4 to T_3 is impaired by stress, starvation, dyes, and some drugs. Cold temperatures increase the conversion. Table 61-5 lists thyroid hormone functions.

TABLE 61-5

Functions of Thyroid Hormones in Adults

- Control metabolic rate of all cells
- Promote sufficient pituitary secretion of growth hormone and gonadotropins
- Regulate protein, carbohydrate, and fat metabolism
- Exert effects on heart rate and contractility
- Increase red blood cell production
- Affect respiratory rate and drive
- Increase bone formation and decrease bone resorption of calcium
- Act as insulin antagonists

Secretion of T_3 and T_4 is controlled by the hypothalamic-pituitary-thyroid gland axis negative feedback mechanism. The hypothalamus secretes thyrotropin-releasing hormone (TRH). TRH triggers the anterior pituitary gland to secrete thyroid-stimulating hormone (TSH), which then stimulates the thyroid gland to make and release thyroid hormones. If thyroid hormone levels are high, TRH and TSH release is inhibited. If thyroid hormone levels are low, release of TRH and TSH is increased. Cold and stress are two factors that cause the hypothalamus to secrete TRH, which then stimulates the anterior pituitary to secrete TSH.

Dietary intake of protein and iodine is needed to produce thyroid hormones. Iodine is absorbed from the intestinal tract as iodide. The thyroid gland withdraws iodide from the blood and concentrates it. After iodide is in the thyroid, it combines with the amino acid *tyrosine* to form T_4 and T_3. These hormones bind to thyroglobulin and are stored in the follicular cells of the thyroid gland. With stimulation, T_4 and T_3 are released into the blood. They enter many cells, where they bind to DNA receptors and turn on genes important in metabolism to regulate basal metabolic rate (BMR).

Calcium and phosphorus balance occurs partly through the actions of calcitonin (thyrocalcitonin [TCT]), which also is produced in the thyroid gland. Calcitonin lowers serum calcium and serum phosphorus levels by reducing bone resorption (breakdown). Its actions are opposite of parathyroid hormone.

The serum calcium level determines calcitonin secretion. Low serum calcium levels suppress the release of calcitonin. Elevated serum calcium levels increase its secretion.

Parathyroid Glands

The parathyroid glands consist of four small glands located close to or within the back surface of the thyroid gland (see Fig. 61-1). These cells secrete parathyroid hormone (PTH).

Parathyroid hormone regulates calcium and phosphorus metabolism by acting on bones, the kidneys, and the GI tract (Fig. 61-6). Bone is the main storage site of calcium. PTH increases **bone resorption** (bone release of calcium into the blood from bone storage sites), thus increasing serum calcium. In the kidneys, PTH activates vitamin D, which then increases the absorption of calcium and phosphorus from the intestines. In the kidney tubules, PTH allows calcium to be reabsorbed and put back into the blood.

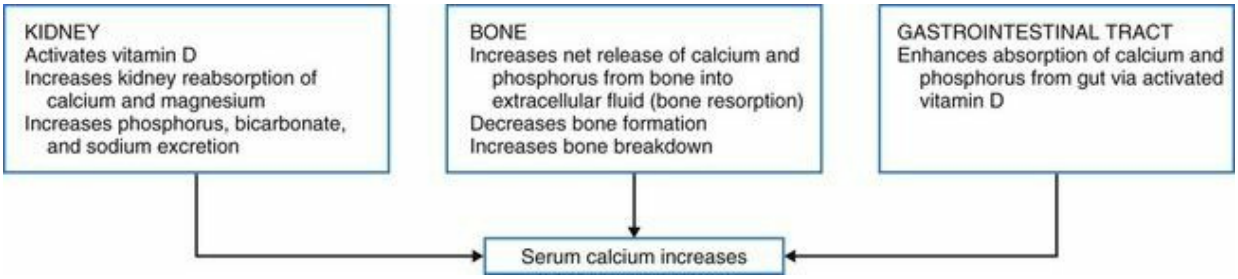

FIG. 61-6 Effects of parathyroid hormone on target tissues to maintain calcium balance.

Serum calcium levels determine PTH secretion. Secretion decreases when serum calcium levels are high, and it increases when serum calcium levels are low. PTH and calcitonin work together to maintain normal calcium levels in the blood and extracellular fluid.

Pancreas

The pancreas has exocrine and endocrine functions. The exocrine function of the pancreas involves the secretion of digestive enzymes through ducts that empty into the duodenum. The cells in the islets of Langerhans perform the pancreatic endocrine functions (Fig. 61-7). About one million islet cells are found throughout the pancreas.

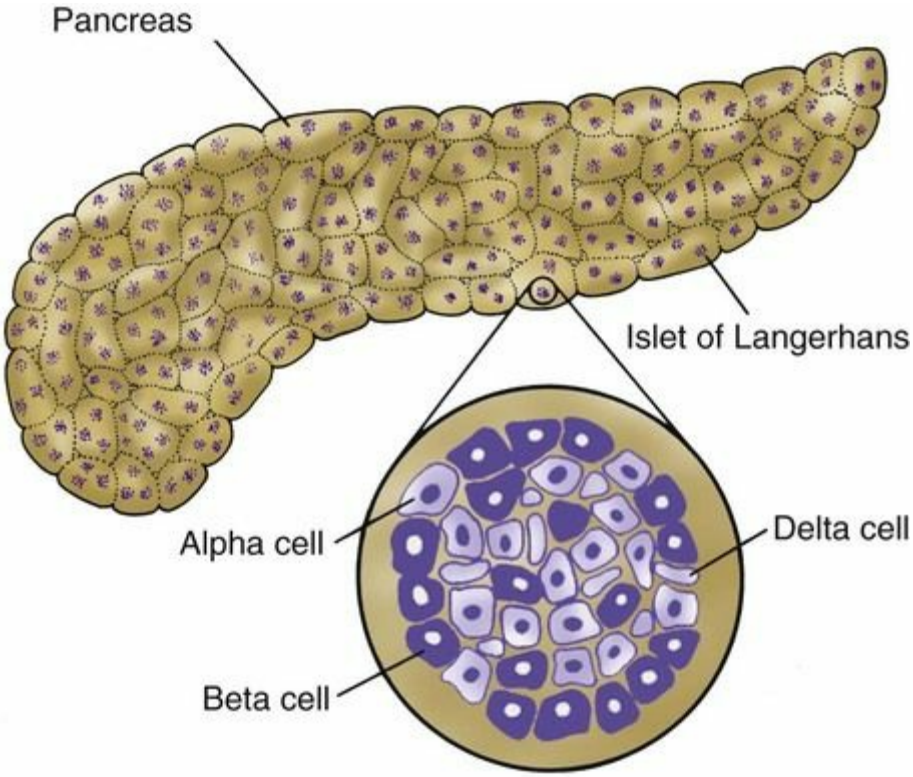

FIG. 61-7 The cells of the islets of Langerhans of the pancreas.

The islets have three distinct cell types: alpha cells, which secrete glucagon; beta cells, which secrete insulin; and delta cells, which secrete somatostatin. Glucagon and insulin affect carbohydrate, protein, and fat metabolism. Somatostatin, which is secreted not only in the pancreas but also in the intestinal tract and the brain, inhibits the release of glucagon and insulin from the pancreas. It also inhibits the release of gastrin, secretin, and other GI peptides.

Glucagon is a hormone that increases blood glucose levels. It is triggered by decreased blood glucose levels and increased blood amino acid levels. This hormone helps prevent hypoglycemia. Chapter 64 discusses glucagon function in more detail.

Insulin promotes the movement and storage of carbohydrate (CHO), protein, and fat. It lowers blood glucose levels by enhancing glucose movement across cell membranes and into the cells of many tissues. Basal levels of insulin are secreted continuously to control metabolism. Insulin secretion rises in response to an increase in blood glucose levels. More information on insulin is presented in Chapter 64.

Endocrine Changes Associated with Aging

The effects of aging on the endocrine system vary. The three endocrine tissues that usually have reduced function with aging are the gonads, the

thyroid gland, and the endocrine pancreas (Touhy & Jett, 2014). It is difficult to distinguish normal from abnormal endocrine activity in older adults because of chronic illness, changes in diet and activity, sleep disturbances, decreased metabolism, and the use of drugs that may affect hormone function. Consider these factors when assessing the older adult with endocrine dysfunction.

Encourage the older adult to participate in regular screening examinations, including fasting and random blood glucose checks, calcium level determinations, and thyroid function testing. Chart 61-1 lists the endocrine changes that occur in the older adult.

Chart 61-1 Nursing Focus on the Older Adult

Changes in the Endocrine System Related to Aging

CHANGES	CLINICAL FINDINGS	NURSING ACTIONS/ADAPTATIONS
Decreased antidiuretic hormone (ADH) production	Urine is more dilute and may not concentrate when fluid intake is low.	The patient is at greater risk for dehydration. Assess the older patient more frequently for dehydration. If fluids are not restricted because of another health problem, teach unlicensed assistive personnel (UAP) to offer fluids at least every 2 hours while awake.
Decreased ovarian production of estrogen	Bone density decreases.	Teach the patient to engage in regular exercise and weight-bearing activity to maintain bone density. Handle the patient carefully to avoid injury from pathologic fractures.
	Skin is thinner, drier, and at greater risk for injury.	Avoid pulling or dragging the patient. Use minimal tape on the skin. Assist patients confined to bed or chairs to change positions at least every 2 hours. Teach patients to use skin moisturizers.
	Perineal and vaginal tissues become drier, and the risk for cystitis increases.	Perform or assist the patient to perform perineal care at least twice daily. Unless another health problem requires fluid restriction, encourage all women to drink at least 2 liters of fluids daily. Teach sexually active women to urinate immediately after sexual intercourse. Teach sexually active women that using vaginal lubricants with sexual activity can reduce discomfort and the risk for tissue damage.
Decreased glucose tolerance	Weight becomes greater than ideal along with: ■ Elevated fasting blood glucose level ■ Elevated random blood glucose level ■ Slow wound healing ■ Frequent yeast infections ■ Polydipsia ■ Polyuria	Obtain a family history of obesity and type 2 diabetes. Encourage the patient to engage in regular exercise and to keep body weight within 10 lbs of ideal. Teach patients the clinical manifestations of diabetes, and instruct them to report any of these manifestations to the health care provider. Suggest diabetes testing for any patient with: ■ Persistent vaginal candidiasis ■ Failure of a foot or leg skin wound to heal in 2 weeks or less ■ Increased hunger and thirst ■ Noticeable decrease in energy level
Decreased general metabolism	Less tolerant of cold. Decreased appetite. Decreased heart rate and blood pressure (BP).	Can be difficult to distinguish from hypothyroidism. Check for additional manifestations of: ■ Lethargy ■ Constipation (as a change from usual bowel habits) ■ Decreased cognition ■ Slowed speech ■ Body temperature consistently below 97° F (36° C) ■ Heart rate below 60 beats/min Teach patients to dress warmly in cool or cold weather.

Assessment Methods

Patient History

Use a systems approach to obtain the history of patients with a possible endocrine problem. This approach can be difficult because of the variety and combination of clinical manifestations. Physical, psychosocial, and laboratory findings are needed for a complete assessment of endocrine function.

The age and gender of the patient provide baseline assessment data. Certain disorders are more common in older than in younger patients, such as diabetes mellitus, loss of ovarian function, and decreased thyroid function.

Manifestations of endocrine disorders can be gender related, such as the sexual effects of hyperpituitarism and hypopituitarism (see Chapter 62). Thyroid problems are more common in women (McCance et al., 2014). Assess for a history of endocrine dysfunction, manifestations that could indicate an endocrine disorder, and hospitalizations. Ask about past and current drugs, such as hydrocortisone, levothyroxine, oral contraceptives, and antihypertensive agents. The use of exogenous hormone drugs, when not needed for hormone replacement, can cause serious dysfunction in many endocrine glands. Use the opportunity to warn patients about the dangers of misusing hormone-based drugs such as androgens and thyroid hormones.

Nutrition History

Nutrition changes or GI tract disturbances may reflect many different endocrine problems. Ask about a history of nausea, vomiting, and abdominal pain. An increase or decrease in food or fluid intake may also indicate specific disorders. For example, diabetes insipidus triggers excessive thirst and adrenal hypofunction triggers salt craving. Hunger and thirst also are associated with diabetes mellitus. Rapid changes in weight without diet changes are often associated with several endocrine disorders, including diabetes mellitus and thyroid problems.

Nutrition deficiencies from an inadequate diet, especially of protein and iodide-containing foods (salt-water fish and seafood, iodized table salt), may be a cause of an endocrine disorder. Teach the patient about a well-balanced diet that includes at least 60 g of protein daily, less animal fat, and fewer concentrated simple sugars. Teach patients who do not eat salt-water fish on a regular basis to use iodized salt in food preparation.

Family History and Genetic Risk

Ask the patient about any family history of obesity, growth or development difficulties, diabetes mellitus, infertility, or thyroid disorders. These problems may have an autosomal dominant, recessive, or cluster pattern of inheritance.

Current Health Problems

Focus on the patient's reason for seeking health care, asking questions such as:

- Did manifestations occur gradually, or was the onset sudden?
- Have you been treated for this problem in the past?
- How have the current problems affected your activities of daily living?

These questions can provide clues to specific endocrine disorders. Also explore changes in energy levels, elimination patterns, sexual and reproductive functions, and physical features.

Energy level changes occur with many endocrine problems, especially thyroid problems (see Chapter 63) and adrenal problems (see Chapter 62). Ask the patient about any change in ability to perform ADLs, and assess his or her current energy level. For instance, has he or she been sleeping longer or are fatigue and generalized weakness present?

Elimination is affected by the endocrine system. Identify the patient's past pattern of elimination to determine deviations from the normal routine. Ask about the amount and frequency of urination. Does he or she urinate frequently in large amounts? Does the patient wake during the night to urinate (**nocturia**), or is pain present with urination (**dysuria**)? Information about the frequency of bowel movements and their consistency and color may provide clues to problems in fluid balance or metabolic rate (i.e., thyroid function).

Sexual and reproductive functions are greatly affected by endocrine disturbances. Ask women about any changes in the menstrual cycle, such as increased flow, duration, and frequency of menses; pain or excessive cramping; or a change in the regularity of menses. Ask men whether they have experienced impotence. Ask men and women about a change in libido (sexual desire) or any fertility problems.

Physical appearance changes can reflect an endocrine problem. Discuss any changes that the patient perceives in physical features. Ask about changes in:

- Hair texture and distribution
- Facial contours and eye protrusion
- Voice quality

• Body proportions
• Secondary sexual characteristics

For example, ask a man whether he is shaving less often or a woman if she has noticed an increase in facial hair. These changes may be associated with pituitary, thyroid, parathyroid, or adrenal dysfunction.

Physical Assessment

Inspection

An endocrine problem can change physical features because of its effect on growth and development, sex hormone levels, fluid and electrolyte balance, and metabolism. Different clinical findings can occur with many endocrine disorders or with nonendocrine problems.

Use a head-to-toe approach for inspection. Observe the patient's general appearance, and assess height, weight, fat distribution, and muscle mass in relation to age. Heredity and age rather than a health problem may be responsible for some physical features (e.g., short stature).

When examining the head, focus on abnormalities of facial structure, features, and expression, such as:

• Prominent forehead or jaw
• Round or puffy face
• Dull or flat expression
• Exophthalmos (protruding eyeballs and retracted upper lids)

Check the lower neck for a visible enlargement of the thyroid gland. Normally the thyroid tissue cannot be observed. The isthmus may be noticeable when the patient swallows. Jugular vein distention may be seen on inspection of the neck and can indicate fluid overload.

Observe skin color, and look for areas of pigment loss (hypopigmentation) or excess (hyperpigmentation). Fungal skin infections, slow wound healing, bruising, and petechiae are often seen in patients with adrenal hyperfunction. Skin infections, foot ulcers, and slow wound healing often occur with diabetes mellitus. With some types of adrenal gland dysfunction, the skin over joints, as well as any scar tissue, may show increased pigmentation due to increased levels of adrenocorticotropic hormone (ACTH) and melanocyte-stimulating hormone.

Vitiligo (patchy areas of pigment loss) is seen with primary hypofunction of the adrenal glands and is caused by autoimmune destruction of melanocytes in the skin. This is seen most often on the face, neck, arms, and legs. Mucous membranes may have large areas of

uneven pigmentation. Document the location, color, distribution, and size of skin color changes.

Inspect the fingernails for malformation, thickness, or brittleness, all of which may suggest thyroid gland problems. Examine the extremities and the base of the spine for edema, which suggests a fluid and electrolyte imbalance.

Check the trunk for any abnormalities in chest size and symmetry. Truncal obesity and the presence of a "buffalo hump" between the shoulders on the back may indicate adrenocortical excess. Hormonal imbalance may also change secondary sexual characteristics. Inspect the breasts of both men and women for size, symmetry, pigmentation, and discharge. **Striae** (reddish purple "stretch marks") on the breasts or abdomen are often seen with adrenocortical excess.

Assess the patient's hair distribution for indications of endocrine gland dysfunction. Changes can include **hirsutism** (excessive growth of body hair, especially on the face, chest, and the center abdominal line of women), excessive scalp hair loss, or changes in hair texture.

Examination of the genitalia may reveal a dysfunction in hormone secretion. Observe the size of the scrotum and penis or of the labia and clitoris in relation to standards for the patient's age. The distribution and quantity of pubic hair are often affected in hypogonadism.

Palpation

The thyroid gland and the testes can be examined by palpation. Chapters 69 and 72 discuss examination of the testes. The thyroid gland is palpated for size, symmetry, general shape, and the presence of nodules or other irregularities.

Palpate the thyroid gland by standing either behind or in front of the patient. The posterior approach may be easier (Jarvis, 2016). Having the patient swallow sips of water during the examination helps you palpate the thyroid gland, which is not easily felt when normal.

Ask the patient to sit and to lower the chin. Using the posterior approach, place both your thumbs on the back of the patient's neck, with the fingers curved around to the front of the neck on either side of the trachea. Ask the patient to swallow, and locate the thyroid as you feel it rising. To examine the right lobe, turn the patient's head to the right and gently displace the trachea to the right with your left fingers. Placing your fingers between the trachea and the neck muscles, palpate the right lobe with your right hand. Reverse this procedure to examine the left lobe.

Nursing Safety Priority QSEN

Action Alert

Always palpate the thyroid gently because vigorous palpation can stimulate a thyroid storm in a person who has or is suspected to have hyperthyroidism.

Auscultation

Auscultate the chest to assess cardiac rate and rhythm to use later as a means of assessing treatment effectiveness. Some endocrine problems induce dysrhythmias. Many endocrine problems can cause dehydration and volume depletion. Document any difference in the patient's blood pressure and pulse in the lying, standing, or sitting positions (orthostatic vital signs).

If an enlarged thyroid gland is palpated, auscultate the area of enlargement for bruits. Hypertrophy of the thyroid gland causes an increase in vascular flow, which may result in bruits.

Psychosocial Assessment

Assess the patient's coping skills, support systems, and health-related beliefs. Many endocrine problems can change a patient's behaviors, personality, and psychological responses. Ask whether the patient has noticed a change in how stress is handled, frequency of crying, or degree of patience and anger expression. The patient may not recognize these changes in himself or herself. When possible, ask the family about changes in the patient's behaviors or personality.

A number of endocrine disorders affect the patient's perception of self. For example, body features can change significantly in disorders of the pituitary, adrenal, and thyroid glands. Infertility, impotence, and other changes in sexual function may result from endocrine dysfunction. Encourage the patient to express his or her feelings and concerns about a change in appearance or in sexual function. Ask about any difficulty in coping with such changes.

Patients with endocrine problems may require lifelong drugs and follow-up care. Assess their readiness to learn and ability to carry out specific self-management skills. Patients may also face financial difficulties resulting from a prolonged medical regimen or loss of employment. A referral to social service agencies may be needed.

Diagnostic Assessment

Laboratory Assessment

Laboratory tests are an essential part of the diagnostic process for possible endocrine problems. Fluids commonly used for these tests include blood, urine, and saliva (Klee, 2011). Always check with the agency's laboratory for proper collection and handling of the specimen. The specialized testing for specific disorders is described in Chapters 62 to 64. Best practices for the collection of specimens for general endocrine testing are listed in Chart 61-2.

Chart 61-2 Best Practice for Patient Safety & Quality Care QSEN

Endocrine Testing

For Blood Tests:

- Check your laboratory's method of handling hormone test samples for tube type, timing, drugs to be administered as part of the test, etc. For example, blood samples drawn for catecholamines must be placed on ice and taken to the laboratory immediately.
- Explain the procedure and any restrictions to the patient.
- If you are drawing blood samples from an IV line, clear the line thoroughly. Do not use a double- or triple-lumen line to obtain samples; contamination or dilution from another port is possible.
- Emphasize the importance of taking a drug prescribed for the test on *time*. Tell the patient to set an alarm if the drug is to be taken during the night.

For Urine Tests:

- Instruct the patient to begin the urine collection (whether for 2, 4, 8, 12, or 24 hours) by first emptying his or her bladder.
- Remind the patient to *not* save the urine specimen that begins the collection. The timing for the urine collection begins *after* this specimen.
- Tell the patient to note the time of the discarded specimen and to plan to collect all urine from this time until the end of the urine collection period.
- To end the collection, instruct the patient to empty his or her bladder at the end of the timed period and *add* that urine to the collection.
- Check with the laboratory to determine any special handling of the

urine specimen (e.g., Is a preservative needed? Does the container need to be kept cold?).
- If needed, make sure that the preservative has been added to the collection container at the *beginning* of the collection.
- Tell the patient about any preservative and the need to avoid splashing urine from the container, because some preservatives make the urine caustic.
- If the specimen must be kept cool or cold, instruct the patient to place the container in an inexpensive cooler with ice. The specimen container should not be kept with food or drinks.

Assays.

An assay measures the level of a specific hormone in blood or other body fluid. The most common assays for endocrine testing are antibody-based immunologic assays and chromatographic assays, which include mass spectrometry. These assays are very sensitive and can detect even minute quantities of a given hormone. Many different hormone concentrations can be analyzed at the same time by the mass spectrometry method.

Stimulation/Suppression Tests.

Measurement of specific hormone blood levels does not always distinguish between the normal and the abnormal. The wide normal range for some hormones makes it necessary to trigger responses by stimulation or suppression tests.

For the patient who might have an underactive endocrine gland, a stimulus may be used to determine whether the gland is capable of normal hormone production. This method is called *stimulation testing.* Measured amounts of selected hormones are given to stimulate the target gland to maximum production. Hormone levels are then measured and compared with expected normal values. Failure of the hormone level to rise with stimulation indicates hypofunction.

Suppression tests are used when hormone levels are high or in the upper range of normal. Drugs or other substances known to normally suppress hormone production are administered. Failure of suppression of hormone production during testing indicates hyperfunction.

Venous Sampling.

Blood samples are taken directly from veins that drain a specific endocrine gland, and hormone levels are measured. Unexpected blood hormone levels may indicate the location of a mass, a dysfunctional

gland, or a dysfunctional part of a gland.

Urine Tests.

Hormone levels and their metabolites in the urine can be measured to determine endocrine function. Because many of the endocrine hormones are secreted in a pulsatile fashion, measurement of a specific hormone in a 24-hour urine collection, rather than as a single blood or urine sample, better reflects specific gland function, such as the adrenal gland. Teach the patient how to collect a 24-hour urine sample (see also Chart 61-2).

Certain hormones require additives in the container at the beginning of the collection. Instruct the patient not to discard the preservative from the container and to use caution when handling it because some are caustic. Remind him or her that this collection is timed for *exactly* 24 hours. Instruct the patient to avoid taking any unnecessary drugs during endocrine testing because some drugs can interfere with the assay.

NCLEX Examination Challenge

Health Promotion and Maintenance

Which precaution or action is most important for the nurse to teach the client who is to collect a 24-hour urine specimen for endocrine testing?

A Eat a normal diet during the collection period.
B Wear gloves when you urinate to prevent contamination of the specimen.
C Urinate at the end of 24 hours and add that sample to the collection container.
D Avoid walking, running, dancing, or any vigorous exercise during the collection period.

Tests for Glucose.

Tests for functions of the islet cells of the pancreas measure the *result* of pancreatic islet cell function. Blood glucose values and the oral glucose tolerance test help diagnose diabetes mellitus. The glycosylated hemoglobin (A1C) value reveals the *average* blood glucose level over a period of 2 to 3 months. (See Chapter 64 for diabetes mellitus testing.)

Imaging Assessment

Anterior, posterior, and lateral skull x-rays may be used to view the sella turcica, the bony pocket in the skull where the pituitary gland rests.

Erosion of the sella turcica indicates invasion of the wall from an abnormal growth.

MRI with contrast is the most sensitive method of imaging the pituitary gland, although CT scans can also be used to evaluate it. The thyroid, parathyroid glands, ovaries, and testes are evaluated by ultrasound. CT scans are used to evaluate the adrenal glands, ovaries, and pancreas.

Other Diagnostic Assessment

Needle biopsy is a relatively safe and quick ambulatory surgery procedure used to indicate the composition of thyroid nodules. It is used to determine whether surgical intervention is needed.

Nursing Concepts and Clinical Judgment Review

What might you NOTICE in a patient with adequate nutrition related to endocrine function?

Vital signs:

- Heart rate and rhythm within normal range
- Oxygen saturation of 95% or higher
- Body temperature within normal range

Physical assessment:

- Weight proportionate to height; does not appear underweight or overweight
- Muscle development even with no muscle loss or excess
- Skin color and texture normal (no jaundice, striae, waxiness, edema, excessive dryness, or severe acne)
- Body hair distribution appropriate for gender
- Scalp hair thickness similar to family members with no recent changes
- Menstrual periods regular

Psychological assessment:

- Oriented and appropriate affect
- Not confused and does not have rapid changes of emotions that are out of proportion to existing situation
- Energy level good; can engage in desired work, recreational, and personal activities

- Sleep average 6 to 8 hours, feeling rested on awakening

Laboratory assessment:

- Hormone levels and production within normal limits for age and gender
- Serum electrolyte levels within normal limits
- Blood glucose levels within normal limits

Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

Health Promotion and Maintenance

- Teach all patients that misusing hormones or steroids can have an adverse effect on endocrine function. **Patient-Centered Care** QSEN

Psychosocial Integrity

- Encourage the patient to express concerns about a change in appearance, sexual function, or fertility as a result of a possible endocrine problem. **Patient-Centered Care** QSEN
- Explain all diagnostic procedures, restrictions, and follow-up care to the patient scheduled for endocrine tests. **Patient-Centered Care** QSEN
- Ask family members about changes in the patient's personality or behavior. **Patient-Centered Care** QSEN

Physiological Integrity

- Be aware that the onset of endocrine problems can be slow and insidious or abrupt and life threatening.
- Ask the patient about other family members with endocrine disorders, because some problems have a genetic component. **Evidence-Based Practice** QSEN
- Ask the patient what prescribed and over-the-counter drugs are taken on a regular basis, because some drugs can alter endocrine function. **Patient-Centered Care** QSEN
- Follow the laboratory's procedures for collecting and handling specimens for endocrine function studies. **Evidence-Based Practice** QSEN
- Differentiate normal from abnormal laboratory test findings and clinical manifestations for patients with possible endocrine problems. **Patient-Centered Care** QSEN

CHAPTER 62

Care of Patients with Pituitary and Adrenal Gland Problems

M. Linda Workman

PRIORITY CONCEPTS

- Fluid and Electrolyte Balance
- Glucose Regulation

Learning Outcomes

Safe and Effective Care Environment

1. Protect the patient with pituitary or adrenal gland problems from injury and from problems associated with changes in fluid and electrolyte balance.

Health Promotion and Maintenance

2. Identify the teaching priorities for the patient taking hormone replacement therapy for pituitary or adrenal hypofunction.

Psychosocial Integrity

3. Reduce the psychological impact for the patient and family experiencing pituitary or adrenal gland problems.

Physiological Integrity

4. Interpret clinical changes and laboratory data to determine the effectiveness of therapy for diabetes insipidus and for syndrome of inappropriate antidiuretic hormone (SIADH).
5. Prioritize nursing care for the patient with acute adrenal insufficiency and poor glucose regulation.

6. Coordinate nursing care for the patient with Cushing's disease or syndrome.
7. Coordinate care for the patient with hyperaldosteronism or pheochromocytoma.

 http://evolve.elsevier.com/Iggy/

Pituitary and adrenal gland problems alter hormone levels and change the function of many tissues and organs. When too much or too little of one or more hormones is secreted, the effects may induce physical and psychological changes. The anterior pituitary gland regulates growth, metabolism, and sexual development. The posterior pituitary gland secretes **vasopressin** (antidiuretic hormone [ADH]). Problems in this gland result in changes in fluid and electrolyte balance. The adrenal gland secretes hormones that influence homeostasis and are life sustaining. Nursing care for the patient with pituitary or adrenal gland disorders includes assessment, patient education, evaluation of patient response to therapy, and providing support.

A complete assessment is performed to detect specific clinical findings. The patient also often undergoes many diagnostic tests and relies on the nurse for explanations. Surgical intervention may be indicated. The patient often needs lifelong hormone replacement therapy, and physical and emotional support are critical.

Disorders of the Anterior Pituitary Gland

The anterior pituitary gland (adenohypophysis) controls growth, metabolic activity, and sexual development through the actions of these hormones:

- Growth hormone (GH; somatotropin)
- Thyrotropin (thyroid-stimulating hormone [TSH])
- Corticotropin (adrenocorticotropic hormone [ACTH])
- Follicle-stimulating hormone (FSH)
- Luteinizing hormone (LH)
- Melanocyte-stimulating hormone (MSH)
- Prolactin (PRL)

Disorders of the anterior pituitary gland can result from problems within the anterior pituitary gland itself *(primary pituitary dysfunction)*, from problems in the hypothalamus that change pituitary function *(secondary pituitary dysfunction)*, or from the influence of exogenous drugs. Regardless of the problem, one or more hormones may be undersecreted *(pituitary hypofunction)* or oversecreted *(pituitary hyperfunction)*.

Hypopituitarism

Pathophysiology

A person with hypopituitarism has a deficiency of one or more anterior pituitary hormones. If only one hormone is affected, the condition is known as *selective hypopituitarism*. Decreased production of *all* of the anterior pituitary hormones *(panhypopituitarism)* is rare.

More often, one hormone has greatly decreased secretion and the secretion of other hormones is reduced to a lesser degree. Deficiencies of *adrenocorticotropic hormone (ACTH)* and *thyroid-stimulating hormone (TSH)* are the *most* life threatening because they cause a decrease in the secretion of vital hormones from the adrenal and thyroid glands. Adrenal gland hypofunction is discussed on pp. 1273-1276; hypothyroidism is discussed in Chapter 63.

Deficiency of the **gonadotropins** (luteinizing hormone [LH] and follicle-stimulating hormone [FSH]—hormones that stimulate the gonads to produce sex hormones) changes sexual function in both men and women. In men, gonadotropin deficiency results in testicular failure with decreased testosterone production that may cause sterility. In women, gonadotropin deficiency results in ovarian failure, amenorrhea, and infertility.

Growth hormone (GH) deficiency changes tissue growth patterns indirectly as a result of reduced liver production of somatomedins. These substances, especially somatomedin C, trigger growth and maintenance activities in bone, cartilage, and other tissues throughout life.

GH deficiency results from decreased GH production, failure of the liver to produce somatomedins, or a failure of tissues to respond to the somatomedins. Deficiency in children leads to short stature and general growth retardation. Deficiency in adults does not affect height but increases the rate of bone destructive activity, leading to thinner bones (**osteoporosis**) and an increased risk for fractures.

The cause of hypopituitarism varies. Benign or malignant pituitary tumors can compress and destroy pituitary tissue. Pituitary function can be impaired by malnutrition or rapid loss of body fat. Shock or severe hypotension reduces blood flow to the pituitary gland, leading to hypoxia and infarction. Other causes of hypopituitarism include head trauma, brain tumors or infection, radiation or surgery of the head and brain, and acquired immune deficiency syndrome (AIDS). *Idiopathic hypopituitarism* has an unknown cause.

Postpartum hemorrhage is the most common cause of pituitary infarction, which results in decreased hormone secretion. This clinical problem is known as *Sheehan's syndrome*. The pituitary gland normally enlarges during pregnancy, and when hypotension results from hemorrhage, ischemia and necrosis of the gland occur. Usually this condition develops immediately after delivery, although some cases have occurred up to several years later.

Patient-Centered Collaborative Care

Assessment

Changes in physical appearance and target organ function occur with deficiencies of specific pituitary hormones (Chart 62-1). Gonadotropin (LH and FSH) deficiency results in the loss of or change in secondary sex characteristics in men and women. In male patients, look for facial and body hair loss. Ask about impotence and decreased *libido* (sex drive). Women may report **amenorrhea** (absence of menstrual periods), **dyspareunia** (painful intercourse), infertility, and decreased libido. In female patients, check for dry skin, breast atrophy, and a decrease or absence of axillary and pubic hair.

Chart 62-1 Key Features

Pituitary Hypofunction

DEFICIENT HORMONE	CLINICAL MANIFESTATIONS
Anterior Pituitary Hormones	
Growth hormone (GH)	Decreased bone density Pathologic fractures Decreased muscle strength Increased serum cholesterol levels
Gonadotropins (luteinizing hormone [LH], follicle-stimulating hormone [FSH])	Women: ■ Amenorrhea ■ Anovulation ■ Low estrogen levels ■ Breast atrophy ■ Loss of bone density ■ Decreased axillary and pubic hair ■ Decreased libido Men: ■ Decreased facial hair ■ Decreased ejaculate volume ■ Reduced muscle mass ■ Loss of bone density ■ Decreased body hair ■ Decreased libido ■ Impotence
Thyroid-stimulating hormone (thyrotropin) (TSH)	Decreased thyroid hormone levels Weight gain Intolerance to cold Scalp alopecia Hirsutism Menstrual abnormalities Decreased libido Slowed cognition Lethargy
Adrenocorticotropic hormone (ACTH)	Decreased serum cortisol levels Pale, sallow complexion Malaise and lethargy Anorexia Postural hypotension Headache Hypoglycemia Hyponatremia Decreased axillary and pubic hair (women)
Posterior Pituitary Hormones	
Vasopressin (antidiuretic hormone [ADH])	Diabetes insipidus: ■ Greatly increased urine output ■ Low urine specific gravity (<1.005) ■ Hypotension ■ Dehydration ■ Increased plasma osmolarity ■ Increased thirst ■ Output does not decrease when fluid intake decreases

Neurologic manifestations of hypopituitarism as a result of tumor growth often first occur as changes in vision. Assess the patient's visual acuity, especially peripheral vision, for changes or loss. Headaches, **diplopia** (double vision), and limited eye movement are common.

Laboratory findings vary widely. Some pituitary hormone levels may be measured directly. As described in Chapter 61, laboratory assessment of some pituitary hormones involves measuring the *effects* of the hormones rather than measuring the actual hormone levels. For example, blood

levels of triiodothyronine (T_3) and thyroxine (T_4) from the thyroid, as well as testosterone and estradiol from the gonads, are measured easily. If levels of one or all of these hormones are low or in the low-normal range, further pituitary evaluation is necessary.

Pituitary problems may cause changes in the sella turcica (the bony nest where the pituitary gland rests) that can be seen with skull x-rays (McCance et al., 2014). Changes may include enlargement, erosion, and calcifications as a result of pituitary tumors. CT and MRI can more distinctly define bone or soft-tissue lesions. An angiogram may be used to rule out the presence of an aneurysm or other vascular problems in the area before surgery.

Interventions

Management of the adult with hypopituitarism focuses on replacement of deficient hormones. Men who have gonadotropin deficiency receive sex steroid replacement therapy with androgens (testosterone). The most effective routes of androgen replacement are parenteral and transdermal. Therapy begins with high-dose testosterone and is continued until **virilization** (presence of male secondary sex characteristics) is achieved, with responses that include increases in penis size, libido, muscle mass, bone size, and bone strength. Chest, facial, pubic, and axillary hair growth also increase. Patients usually report improved self-esteem and body image after therapy is initiated. The dose may then be decreased, but therapy continues throughout life. Therapy to increase fertility requires gonadotropin-releasing hormone (GnRH) injections in addition to testosterone therapy (Melmed et al., 2011).

Androgen therapy is avoided in men with prostate cancer. Side effects of therapy include **gynecomastia** (male breast tissue development), acne, baldness, and prostate enlargement.

Women who have gonadotropin deficiency receive hormone replacement with a combination of estrogen and progesterone. The risk for hypertension or *thrombosis* (formation of blood clots in deep veins) is increased with estrogen therapy, especially among smokers. Emphasize measures to reduce risk and the need for regular health visits. For inducing pregnancy, clomiphene (Clomid) may be given to trigger ovulation. Gonadotropin-releasing hormone (GnRH) and human chorionic gonadotropin (hCG) can be used to stimulate ovulation if therapy with clomiphene fails.

Adult patients with GH deficiency may be treated with subcutaneous injections of human GH (hGH). Injections are given at night to mimic normal GH release.

NCLEX Examination Challenge

Safe and Effective Care Environment

For which client does the nurse question the prescription for androgen replacement therapy?
A 35-year-old man who has had a vasectomy
B 48-year-old man who takes prednisone for severe asthma
C 62-year-old man with a history of prostate cancer
D 70-year-old man who has hypertension and type 2 diabetes

Hyperpituitarism

Pathophysiology

Hyperpituitarism is hormone oversecretion that occurs with pituitary tumors or tissue hyperplasia (tissue overgrowth). Tumors occur most often in the anterior pituitary cells that produce growth hormone (GH), prolactin (PRL), and adrenocorticotropic hormone (ACTH). Overproduction of PRL also may occur in response to tumors that overproduce GH and ACTH. Excess ACTH may occur with increased secretion of melanocyte-stimulating hormone (MSH).

Genetic/Genomic Considerations

Patient-Centered Care QSEN

One cause of hyperpituitarism is multiple endocrine neoplasia, type 1 (*MEN1*), in which there is inactivation of the suppressor gene *MEN1* (Manchester, 2013). This problem has an autosomal dominant inheritance pattern and is usually expressed as a benign tumor that affects the pituitary, parathyroid glands, and pancreas. In the pituitary, this problem causes excessive production of growth hormone and acromegaly. Ask a patient with acromegaly whether either parent also has this problem or has had a tumor of the pancreas or parathyroid glands.

The most common cause of hyperpituitarism is a pituitary adenoma—a benign tumor of one or more tissues within the anterior pituitary. Adenomas are classified by size, invasiveness, and the hormone secreted. As an adenoma gets larger and compresses brain tissue, neurologic changes, as well as endocrine problems, may occur. Such manifestations

may include visual disturbances, headache, and increased intracranial pressure.

Prolactin (PRL)-secreting tumors are the most common type of pituitary adenoma. Excessive PRL inhibits the secretion of gonadotropins and sex hormones in men and women, resulting in *galactorrhea* (breast milk production), amenorrhea, and infertility.

Overproduction of GH in adults results in *acromegaly* (Fig. 62-1). The onset may be gradual with slow progression, and changes may remain unnoticed for years before diagnosis of the disorder. Early detection and treatment are essential to prevent irreversible changes in the soft tissues, such as those of the face, hands, feet, and skin. Other changes include increased skeletal thickness, hypertrophy of the skin, and enlargement of many organs, such as the liver and heart. Some changes may be reversible after treatment, but skeletal changes are permanent.

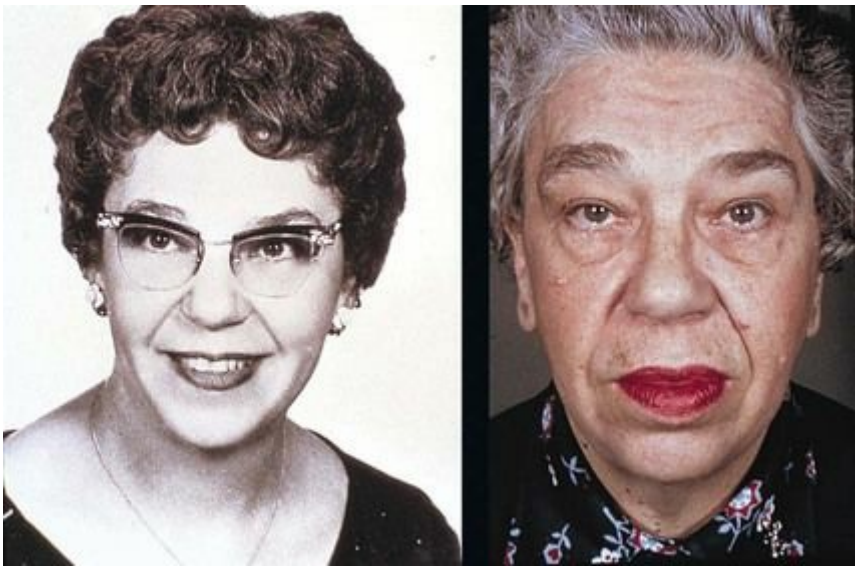

FIG. 62-1 The progression of acromegaly.

Bone thinning and bone cell overgrowth occur slowly. Breakdown of joint cartilage and hypertrophy of ligaments, vocal cords, and eustachian tubes are common. Nerve entrapment and poor glucose regulation with hyperglycemia (elevated blood glucose levels) are common.

Excess ACTH overstimulates the adrenal cortex. The result is excessive production of glucocorticoids, mineralocorticoids, and androgens, which leads to the development of Cushing's disease and problems with fluid and electrolyte balance (see Hypercortisolism [Cushing's Disease], pp. 1276-1281).

Usually, hyperpituitarism is caused by hormone-secreting benign tumors (*adenomas)* arising from one pituitary cell type. It can also be caused by hypothalamic problems that lead to excessive production of

releasing hormones, which overstimulate the normal pituitary gland.

Patient-Centered Collaborative Care

Assessment

The manifestations of hyperpituitarism vary with the hormone produced in excess. Obtain the patient's age, gender, and family history. Ask about any change in hat, glove, ring, or shoe size and the presence of fatigue. The patient with high GH levels may have backache and joint pain from bone changes. Ask specifically about headaches and changes in vision.

The patient with hypersecretion of PRL often reports sexual function difficulty. Ask women about menstrual changes, decreased libido, painful intercourse, and any difficulty in becoming pregnant. Ask men whether they have experienced decreased libido and impotence.

Changes in appearance and target organ function occur with excesses of specific anterior pituitary hormones (Chart 62-2). Manifestations of GH excess are increases in lip and nose sizes, a prominent brow ridge, and increases in head, hand, and foot sizes. The patient with hyperpituitarism often seeks health care because of these dramatic changes in appearance.

Chart 62-2 Key Features

Anterior Pituitary Hyperfunction

Prolactin (PRL)

- Hypogonadism (loss of secondary sexual characteristics)
- Decreased gonadotropin levels
- Galactorrhea
- Increased body fat
- Increased serum prolactin levels

Growth Hormone (GH)

Acromegaly

- Thickened lips
- Coarse facial features
- Increasing head size
- Lower jaw protrusion
- Enlarged hands and feet
- Joint pain

• Barrel-shaped chest
• Hyperglycemia
• Sleep apnea
• Enlarged heart, lungs, and liver

Adrenocorticotropic Hormone (ACTH)

Cushing's Disease (Pituitary)

• Elevated plasma cortisol levels
• Weight gain
• Truncal obesity
• "Moon face"
• Extremity muscle wasting
• Loss of bone density
• Hypertension
• Hyperglycemia
• Striae and acne

Thyrotropin (Thyroid-Stimulating Hormone [TSH])

• Elevated plasma TSH and thyroid hormone levels
• Weight loss
• Tachycardia and dysrhythmias
• Heat intolerance
• Increased GI motility
• Fine tremors

Gonadotropins (Luteinizing Hormone [LH], Follicle-Stimulating Hormone [FSH])

Men:

• Elevated LH and FSH levels
• Hypogonadism or hypergonadism

Women:

• Normal LH and FSH levels

In a person with hyperpituitarism, usually only one hormone is produced in excess because the cell types within the pituitary gland are so individually organized. The most common hormones produced in excess with hyperpituitarism are PRL, ACTH, and GH.

Imaging assessment for hyperpituitarism is the same as for hypopituitarism. Skull x-rays are used to identify abnormalities of the sella turcica. CT scans and MRI can define soft-tissue lesions, and

angiography can rule out an aneurysm or vascular malformations.

Suppression testing can help diagnose hyperpituitarism. For example, high blood glucose levels suppress the release of GH. Giving 100 g of oral glucose or 0.5 g/kg of body weight is followed by serial GH level measurements. GH levels that do not fall below 5 ng/mL indicate a positive (abnormal) result.

◆ Interventions

The expected outcomes of management for the patient who has hyperpituitarism are to return hormone levels to normal or near normal, reduce or eliminate headache and visual disturbances, prevent complications, and reverse as many of the body changes as possible.

Nonsurgical Management.

Encourage the patient to express concerns about his or her altered physical appearance. Help him or her identify personal strengths and positive characteristics. Galactorrhea, gynecomastia, and reduced sexual functioning can disturb self-image and personal identity. Reassure the patient that treatment may reverse some of these problems.

Drug therapy may be used alone or in combination with surgery and radiation. The most common drugs used are the dopamine agonists *bromocriptine mesylate* (Parlodel) and *cabergoline* (Dostinex). These drugs stimulate dopamine receptors in the brain and inhibit the release of GH and PRL. In most cases, small tumors decrease until the pituitary gland is of normal size. Large pituitary tumors usually decrease to some extent.

Side effects of bromocriptine include **orthostatic hypotension** (postural hypotension), gastric irritation, nausea, headaches, abdominal cramps, and constipation. Give and teach patients to take bromocriptine with a meal or a snack to reduce some of these side effects. Treatment starts with a low dose and is gradually increased until the desired level (usually 7.5 mg/day) is reached. *If pregnancy occurs, the drug is stopped immediately.*

Nursing Safety Priority QSEN

Drug Alert

Teach patients taking bromocriptine to seek medical care immediately if chest pain, dizziness, or watery nasal discharge occurs because of the possibility of serious side effects, including cardiac dysrhythmias, coronary artery spasms, and cerebrospinal fluid leakage.

Other agents used for acromegaly are the somatostatin analogs, especially octreotide (Sandostatin) and lanreotide (Somatuline), and a growth hormone receptor blocker, pegvisomant (Somavert). Octreotide inhibits GH release through negative feedback. Pegvisomant blocks growth hormone (GH) receptor activity and blocks production of insulin-like growth factor (IGF). Combination therapy with monthly injections of a somatostatin analog and weekly injections of pegvisomant have provided good control of the disease for some patients.

Radiation therapy does not have immediate effects in reducing pituitary hormone excesses, and several years may pass before a therapeutic effect can be seen. The use of the gamma knife and other more precise methods of delivering radiation to pituitary tumors has reduced the long-term side effects of this therapy. These side effects include hypopituitarism, optic nerve damage, and other eye and vision problems.

Surgical Management.

Surgical removal of the pituitary gland and tumor (**hypophysectomy**) is the most common treatment for hyperpituitarism. Successful surgery decreases hormone levels, relieves headaches, and may reverse changes in sexual functioning.

Preoperative Care.

Explain that because nasal packing is present for 2 to 3 days after surgery, it will be necessary to breathe through the mouth, and a "mustache" dressing ("drip pad") will be placed under the nose. Instruct the patient not to brush teeth, blow the nose, or bend forward after surgery. These activities can increase intracranial pressure (ICP) and delay healing, as can coughing and sneezing.

Operative Procedures.

Usually a minimally invasive endoscopic transnasal approach is used instead of the more traditional transsphenoidal approach. The endoscopic approach uses smaller-diameter instruments and results in less damage to nasal structures. The procedure is performed with the patient under general anesthesia. After the gland is removed, a muscle graft is taken, often from the thigh, to support the area and prevent leakage of cerebrospinal fluid (CSF). Nasal packing is inserted after the incision is closed, and a mustache dressing is applied. If the tumor cannot be reached by either the endoscopic transnasal approach or the transsphenoidal approach, a craniotomy may be indicated (see Chapter 45).

Postoperative Care.

Monitor the patient's neurologic responses, and document any changes in vision or mental status, altered level of consciousness, or decreased strength of the extremities. Observe the patient for complications such as transient diabetes insipidus (discussed on p. 1271), CSF leakage, infection, and increased ICP.

Teach the patient to report any postnasal drip or increased swallowing, which might indicate leakage of CSF. Keep the head of the bed elevated after surgery. Assess nasal drainage for quantity, quality, and the presence of glucose (which indicates that the fluid is CSF). A light yellow color at the edge of the clear drainage on the dressing is called the "halo sign" and indicates CSF. If the patient has persistent, severe headaches, CSF fluid may have leaked into the sinus area. Most CSF leaks resolve with bedrest, and surgical intervention is rarely needed.

Teach the patient to avoid coughing early after surgery because it increases pressure in the incision area and may lead to a CSF leak. Remind the patient to perform deep-breathing exercises hourly while awake to prevent pulmonary problems. Patients may have mouth dryness from mouth breathing. Instruct the patient to rinse the mouth frequently and to apply a lubricating jelly to dry lips.

Assess for manifestations of infection, especially meningitis, such as headache, fever, and nuchal (neck) rigidity. The surgeon may prescribe antibiotics, analgesics, and antipyretics.

If the entire pituitary gland has been removed, replacement of thyroid hormones and glucocorticoids is lifelong. Best practices for care after surgery are listed in Chart 62-3.

Chart 62-3 Best Practice for Patient Safety & Quality Care QSEN

The Patient After Hypophysectomy

- Monitor the patient's neurologic status hourly for the first 24 hours and then every 4 hours.
- Monitor fluid balance, especially for output greater than intake.
- Encourage the patient to perform deep-breathing exercises.
- Instruct the patient to not cough, blow the nose, or sneeze.
- Instruct the patient to use dental floss and oral mouth rinses rather than tooth brushing until the surgeon gives permission.
- Instruct the patient to avoid bending at the waist to prevent increasing intracranial pressure.

- Monitor the nasal drip pad for the type and amount of drainage.
- Teach the patient to avoid constipation and subsequent "straining."
- Teach the patient self-administration of the prescribed hormones.

After surgery the patient needs daily self-management regimens and frequent checkups. Chart 62-4 lists areas for focused assessment for the patient at home after a hypophysectomy. Review drug regimens and manifestations of infection and cerebral edema with the family.

Chart 62-4 Focused Assessment

The Patient Who Has Undergone Nasal Hypophysectomy for Hyperpituitarism

Assess cardiovascular status:
- Vital signs, including apical pulse, pulse pressure, presence or absence of orthostatic hypotension, and the quality/rhythm of peripheral pulses

Assess cognition and mental status

Assess condition of operative site:
- Observe nasal area for drainage:
  If present, note color, clarity, and odor
  Test clear drainage for the presence of glucose

Assess neuromuscular status:
- Reactivity of patellar and biceps reflexes
- Oral temperature
- Handgrip strength
- Steadiness of gait
- Distant and near visual acuity
- Pupillary responses to light

Assess kidney function:
- Observe urine specimen for color, odor, cloudiness, and amount

Ask about:
- Headaches or visual disturbances
- Ease of bowel movements
- 24-hour fluid intake and output
- Over-the-counter and prescribed drugs taken

Assess patient's understanding of illness and adherence with treatment:
- Manifestations to report to health care provider
- Drug plan (correct timing and dose)

After a hypophysectomy, advise the patient to avoid activities that might interfere with healing. Teach him or her to avoid bending over from the waist to pick up objects or tie shoes because this position increases ICP. Teach the patient to bend the knees and then lower the body to pick up fallen objects. ICP also increases when the patient strains to have a bowel movement. Suggest techniques to prevent constipation, such as eating high-fiber foods, drinking plenty of fluids, and using stool softeners or laxatives.

Teach the patient to avoid toothbrushing, which can disturb the operative site, for about 2 weeks after surgery. Frequent mouth care with mouthwash and daily flossing provide adequate oral hygiene. A decreased sense of smell is expected after surgery and usually lasts 3 to 4 months.

Hormone replacement with vasopressin may be needed to maintain fluid balance (see discussion of Interventions starting below in the Diabetes Insipidus section). If the anterior portion of the pituitary gland is removed, instruct the patient in cortisol, thyroid, and gonadal hormone replacement. Teach the patient to report the return of any manifestations of hyperpituitarism immediately to the primary health care provider.

Disorders of the Posterior Pituitary Gland

Disorders of the posterior pituitary gland (**neurohypophysis**) occur with deficiency or excess of the hormone *vasopressin* (antidiuretic hormone [ADH]). ADH deficiency causes diabetes insipidus, and ADH excess causes the syndrome of inappropriate antidiuretic hormone (SIADH). Both types of problems disturb fluid and electrolyte balance.

Diabetes Insipidus

Pathophysiology

Diabetes insipidus (DI) is a water loss problem caused by either an ADH deficiency or an inability of the kidneys to respond to ADH. The result of DI is the excretion of large volumes of dilute urine because the distal kidney tubules and collecting ducts do not reabsorb water; this leads to **polyuria** (excessive water loss through urination), dehydration, and disturbed fluid and electrolyte balance. Electrolyte imbalances most commonly include increased serum sodium levels.

Dehydration from this massive water loss increases plasma osmolarity, which stimulates the sensation of thirst. Thirst promotes increased fluid intake and aids in maintaining water homeostasis. *If the thirst mechanism is poor or absent or if the person is unable to obtain water, dehydration becomes more severe and can lead to death.*

Nursing Safety Priority QSEN

Critical Rescue

Ensure that no patient suspected of having DI is deprived of fluids for more than 4 hours, because he or she cannot reduce urine output. Continued urine output without adequate fluid intake leads to severe dehydration.

ADH deficiency is classified as nephrogenic, drug-related, primary, or secondary, depending on whether the problem is caused by insufficient production of ADH or an inability of the kidney to respond to the presence of ADH (John & Day, 2012).

Genetic/Genomic Considerations

Patient-Centered Care QSEN

Nephrogenic diabetes insipidus is a genetic disorder in which the kidney tubules do not respond to the actions of ADH. The result is poor water reabsorption by the kidney although the actual amount of hormone produced is not deficient. This problem is most commonly inherited as an X-linked recessive disorder in which the *AVPR2* gene coding for the ADH receptor is mutated and only males are affected (Online Mendelian Inheritance in Man [OMIM], 2011). There is also an autosomal form of the disorder in which the *AQP2* gene is mutated and both males and females are affected (OMIM, 2012). When assessing a patient with DI, always ask whether anyone else in the family has ever had this disorder.

Primary diabetes insipidus is caused by a defect in the hypothalamus or posterior pituitary gland, resulting in a lack of ADH production or release. *Secondary diabetes insipidus* most often results from tumors in or near the hypothalamus or pituitary gland, head trauma, infectious processes, brain surgery, or metastatic tumors.

Drug-related diabetes insipidus is usually caused by lithium carbonate (Eskalith, Lithobid, Carbolith) and demeclocycline (Declomycin). These drugs can interfere with the response of the kidneys to ADH.

Patient-Centered Collaborative Care

Assessment

Most manifestations of DI are related to dehydration (Chart 62-5). Key manifestations are an increase in urination and excessive thirst. Ask about a history of recent surgery, head trauma, or drug use (e.g., lithium). Although increased fluid intake prevents serious volume depletion, the patient who is deprived of fluids or who cannot increase oral fluid intake may develop shock from fluid loss. Manifestations of dehydration (e.g., poor skin turgor, dry or cracked mucous membranes) may be present. (See Chapter 11 for discussion of dehydration.)

Chart 62-5 Key Features

Diabetes Insipidus

Cardiovascular Manifestations

- Hypotension
- Tachycardia
- Weak peripheral pulses

• Hemoconcentration

Kidney/Urinary Manifestations

• Increased urine output
• Dilute, low specific gravity

Skin Manifestations

• Poor turgor
• Dry mucous membranes

Neurologic Manifestations

• Decreased cognition*
• Ataxia*
• Increased thirst
• Irritability*

*Occurs when access to water is limited and rapid dehydration results.

Water loss produces changes in blood and urine tests. The first step in diagnosis is to measure a 24-hour fluid intake and output without restricting food or fluid intake. DI is considered if urine output is more than 4 L during this period and is greater than the volume ingested. The amount of urine excreted in 24 hours may vary from 4 to 30 L/day. Urine is dilute with a low specific gravity (less than 1.005) and low osmolarity (50 to 200 mOsm/kg).

Interventions

Management focuses on controlling manifestations with drug therapy. The most preferred drug is desmopressin acetate (DDAVP), a synthetic form of vasopressin given orally or intranasally in a metered spray. The frequency of dosing varies with patient responses. Teach patients that each metered spray delivers 10 mcg and those with mild DI may need only one or two doses in 24 hours. For more severe DI, one or two metered doses 2 or 3 times daily may be needed. During severe dehydration, ADH may be given IV or IM. Ulceration of the mucous membranes, allergy, a sensation of chest tightness, and lung inhalation of the spray may occur with use of the intranasal preparations. If side effects occur or if the patient has an upper respiratory infection, oral or subcutaneous vasopressin is used rather than the intranasal form.

Nursing Safety Priority QSEN

Drug Alert

The parenteral form of desmopressin is 10 times stronger than the oral and intranasal forms, and the dosage must be reduced.

For the hospitalized patient with DI, nursing management focuses on early detection of dehydration and maintaining adequate hydration. Interventions include accurately measuring fluid intake and output, checking urine specific gravity, and recording the patient's weight daily.

Urge the patient to drink fluids in an amount equal to urine output. If fluids are given IV, ensure the patency of the access catheter and accurately monitor the amount infused hourly.

The patient with permanent DI requires lifelong drug therapy. Assess his or her ability to follow instructions and adjust dosages. Teach that polyuria and polydipsia are indications of the need for another dose.

Drugs for DI induce water retention and can cause fluid overload (see Chapter 11). *Teach all patients taking these drugs to weigh themselves daily to identify weight gain.* Stress the importance of using the same scale and weighing at the same time of day while wearing a similar amount of clothing. If a weight gain of more than 2.2 lbs (1 kg) or other signs of water toxicity occur (e.g., persistent headache, acute confusion), instruct the patient or family that the patient must go to the emergency department or call 911. Instruct him or her to wear a medical alert bracelet identifying the disorder and drugs.

Syndrome of Inappropriate Antidiuretic Hormone

Pathophysiology

The **syndrome of inappropriate antidiuretic hormone (SIADH)** or *Schwartz-Bartter syndrome* is a problem in which vasopressin (antidiuretic hormone [ADH]) is secreted even when plasma osmolarity is low or normal. A decrease in plasma osmolarity normally inhibits ADH production and secretion. SIADH occurs with many conditions (e.g., cancer therapy) and with specific drugs, including selective serotonin reuptake inhibitors and fluoroquinolone antibiotics (Yam & Eraly, 2012). Table 62-1 lists common causes of SIADH.

TABLE 62-1

Conditions Causing the Syndrome of Inappropriate Antidiuretic Hormone

Malignancies
• Small cell lung cancer • Pancreatic, duodenal, and GU carcinomas • Thymoma • Hodgkin's lymphoma • Non-Hodgkin's lymphoma
Pulmonary Disorders
• Viral and bacterial pneumonia • Lung abscesses • Active tuberculosis • Pneumothorax • Chronic lung diseases • Mycoses • Positive-pressure ventilation
CNS Disorders
• Trauma • Infection • Tumors (primary or metastatic) • Strokes • Porphyria • Systemic lupus erythematosus
Drugs
• Exogenous ADH • Chlorpropamide • Vincristine • Cyclophosphamide • Carbamazepine • Opioids • Tricyclic antidepressants • General anesthetics • Fluoroquinolone antibiotics

ADH, Antidiuretic hormone; *CNS,* central nervous system; *GU,* genitourinary.

In SIADH, ADH continues to be released even when plasma is hypo-osmolar, leading to disturbances of fluid and electrolyte balance. Water is *retained,* which results in dilutional **hyponatremia** (a decreased serum sodium level) and fluid overload. The increase in blood volume increases the kidney filtration and inhibits the release of renin and aldosterone, which increase urine sodium loss and leads to greater hyponatremia.

Patient-Centered Collaborative Care

Assessment

Ask the patient about his or her medical history, which may reveal conditions that can cause SIADH. Information about these conditions should be obtained:

- Recent head trauma
- Cerebrovascular disease
- Tuberculosis or other pulmonary disease

• Cancer
• All past and current drug use

The early manifestations of SIADH are related to water retention. GI disturbances, such as loss of appetite, nausea, and vomiting, may occur first. Weigh the patient, and document any recent weight gain. Use this information to monitor responses to therapy. In SIADH, free water (not salt) is retained and dependent edema is not usually present, even though water is retained.

Water retention, hyponatremia, and fluid shifts affect central nervous system function, especially when the serum sodium level is below 115 mEq/L. The patient may have lethargy, headaches, hostility, disorientation, and a change in level of consciousness. Lethargy and headaches can progress to decreased responsiveness, seizures, and coma. Assess deep tendon reflexes, which are usually decreased.

Vital sign changes include full and bounding pulse (caused by the increased fluid volume) and hypothermia (caused by central nervous system disturbance). Chapter 11 presents other findings that occur with hyponatremia.

Water retention causes urine volume to decrease and urine osmolarity to increase. At the same time, plasma volume increases and plasma osmolarity decreases. Elevated urine sodium levels and specific gravity reflect increased urine concentration. Serum sodium levels are decreased, often as low as 110 mEq/L, because of fluid retention and sodium loss.

Radioimmunoassay of ADH along with clinical manifestations can help diagnose SIADH, but this test is usually not used for a definitive diagnosis.

◆ Interventions

Medical interventions for SIADH focus on restricting fluid intake, promoting the excretion of water, replacing lost sodium, and interfering with the action of ADH. Nursing interventions focus on monitoring response to therapy, preventing complications, teaching the patient and family about fluid restrictions and drug therapy, and preventing injury.

Fluid restriction is essential because fluid intake further dilutes plasma sodium levels. In some cases, fluid intake may be kept as low as 500 to 1000 mL/24 hr (John & Day, 2012). Dilute tube feedings with saline rather than water, and use saline to irrigate GI tubes. Mix drugs to be given by GI tube with saline.

Measure intake, output, and daily weights to assess the degree of fluid restriction needed. A weight gain of 2.2 lbs (1 kg) or more per day or a

gradual increase over several days is cause for concern. A 2.2-lb (1kg) weight increase is equal to a 1000-mL fluid retention (1 kg = 1 L). Keep the mouth moist by offering frequent oral rinsing (remind the patient not to swallow the rinses).

Drug therapy with tolvaptan (Samsca) or conivaptan (Vaprisol) is used to treat SIADH when hyponatremia is present in hospitalized patients. These drugs are vasopressin antagonists that promote water excretion without causing sodium loss. Tolvaptan is an oral drug, and conivaptan is given IV. Tolvaptan has a black box warning that rapid increases in serum sodium levels (those greater than a 12 mEq/L increase in 24 hours) have been associated with central nervous system demyelination that can lead to serious complications and death. In addition, when this drug is used at higher dosages or for longer than 30 days, there is a significant risk for liver failure and death (Food and Drug Administration [FDA], 2013).

Nursing Safety Priority QSEN

Drug Alert

Administer tolvaptan or conivaptan only in the hospital setting so that serum sodium levels can be monitored closely for the development of hypernatremia.

Diuretics may be used to manage SIADH when sodium levels are near normal and heart failure is present. Be aware of the diuretic effects on sodium loss. Sodium loss can be potentiated, further contributing to the problems caused by SIADH. For milder SIADH, demeclocycline (Declomycin), an oral antibiotic, may help correct the disturbed fluid and electrolyte balance, although it is not approved for this problem (Crawford & Harris, 2012).

Hypertonic saline (i.e., 3% sodium chloride [3% NaCl]) may be used to treat SIADH when the serum sodium level is very low (John & Day, 2012; Robinson & Verbalis, 2011). Give IV saline cautiously because it may add to existing fluid overload and promote heart failure. If the patient needs routine IV fluids, a saline solution rather than a water solution is prescribed.

Monitor the patient's response to therapy to prevent the fluid overload of SIADH from becoming worse, leading to pulmonary edema and heart failure. Any patient with SIADH, regardless of age, is at risk for these complications. The older adult or one who also has cardiac problems, kidney problems, pulmonary problems, or liver problems is at greater

risk.

Monitor for increased fluid overload (bounding pulse, increasing neck vein distention, crackles in lungs, increasing peripheral edema, reduced urine output) at least every 2 hours. *Pulmonary edema can occur very quickly and can lead to death.* Notify the health care provider of any change that indicates the fluid overload is not responding to therapy or is worse.

Providing a safe environment is critical when the serum sodium level falls below 120 mEq/L. Possible neurologic changes and the risk for seizures increase as a result of osmotic fluid shifts into brain tissue. Observe for and document changes in the patient's neurologic status. Assess for subtle changes, such as muscle twitching, before they progress to seizures or coma. Check orientation to time, place, and person every 2 hours because disorientation or confusion may be present. Reduce environmental noise and lighting to prevent overstimulation.

Flow sheets with continuing information about the level of consciousness, neurologic assessments, and laboratory data are helpful in detecting neurologic trends. The frequency of neurologic checks depends on the patient's status. For the patient with SIADH who is hyponatremic but alert, awake, and oriented, checks every 4 hours are sufficient. For the patient who has had a change in level of consciousness, perform neurologic checks at least every hour. Inspect the environment every shift, making sure that basic safety measures, such as siderails being securely in place, are observed.

NCLEX Examination Challenge

Physiological Integrity

Which urine properties indicate to the nurse that the client with syndrome of inappropriate antidiuretic hormone (SIADH) is responding to interventions?

A Urine output volume increased; urine specific gravity increased
B Urine output volume increased; urine specific gravity decreased
C Urine output volume decreased; urine specific gravity increased
D Urine output volume decreased; urine specific gravity decreased

Disorders of the Adrenal Gland

Adrenal Gland Hypofunction

Pathophysiology

Adrenocortical steroid production may decrease as a result of inadequate secretion of adrenocorticotropic hormone (ACTH), dysfunction of the hypothalamic-pituitary control mechanism, or direct dysfunction of adrenal gland tissue. Manifestations may develop gradually or occur quickly with stress. In acute adrenocortical insufficiency (**adrenal crisis**), life-threatening manifestations may appear without warning.

Insufficiency of adrenocortical steroids causes problems through the loss of aldosterone and cortisol action. Decreased cortisol levels result in poor glucose regulation with **hypoglycemia** (low blood glucose levels). Glomerular filtration and gastric acid production decrease, leading to reduced urea nitrogen excretion, which causes anorexia and weight loss.

Reduced aldosterone secretion causes disturbances of fluid and electrolyte balance, especially of potassium, sodium, and water. Potassium excretion is decreased, causing hyperkalemia. Sodium and water excretion are increased, causing hyponatremia and hypovolemia. Potassium retention also promotes reabsorption of hydrogen ions, which can lead to acidosis.

Low adrenal androgen levels decrease the body, axillary, and pubic hair, especially in women, because the adrenals produce most of the androgens in females. The severity of manifestations is related to the degree of hormone deficiency.

Acute adrenal insufficiency, or **Addisonian crisis**, is a life-threatening event in which the need for cortisol and aldosterone is greater than the available supply. It often occurs in response to a stressful event (e.g., surgery, trauma, severe infection), especially when the adrenal hormone output is already reduced. The problems are the same as those of chronic insufficiency but are more severe. *Unless intervention is initiated promptly, however, sodium levels fall and potassium levels rise rapidly. Severe hypotension results from the blood volume depletion that occurs with the loss of aldosterone.* Best practices for emergency care of patients with acute adrenal insufficiency are listed in Chart 62-6.

Chart 62-6 Best Practice for Patient Safety & Quality Care QSEN

Emergency Care of the Patient with Acute Adrenal

Insufficiency

Hormone Replacement

- Start rapid infusion of normal saline or dextrose 5% in normal saline.
- Initial dose of hydrocortisone sodium (Solu-Cortef) is 100 to 300 mg or dexamethasone 4 to 12 mg as an IV bolus.
- Administer additional 100 mg of hydrocortisone sodium by continuous IV infusion over the next 8 hours.
- Give hydrocortisone 50 mg IM concomitantly every 12 hours.
- Initiate an H_2 histamine blocker (e.g., ranitidine) IV for ulcer prevention.

Hyperkalemia Management

- Administer insulin (20 to 50 units) with dextrose (20 to 50 mg) in normal saline to shift potassium into cells.
- Administer potassium binding and excreting resin (e.g., Kayexalate).
- Give loop or thiazide diuretics.
- Avoid potassium-sparing diuretics, as prescribed.
- Initiate potassium restriction.
- Monitor intake and output.
- Monitor heart rate, rhythm, and ECG for manifestations of hyperkalemia (slow heart rate; heart block; tall, peaked T waves; fibrillation; asystole).

Hypoglycemia Management

- Administer IV glucose, as prescribed.
- Administer glucagon, as needed and prescribed.
- Maintain IV access.
- Monitor blood glucose level hourly.

ECG, Electrocardiogram.

Adrenal insufficiency (Addison's disease) is classified as primary or secondary. Causes of primary and secondary adrenal insufficiency are listed in Table 62-2. A common cause of secondary adrenal insufficiency is the sudden cessation of long-term glucocorticoid therapy. This therapy suppresses production of glucocorticoids through negative feedback by causing atrophy of the adrenal cortex. Glucocorticoid drugs must be withdrawn gradually to allow for increasing pituitary production of ACTH and activation of adrenal cells to produce cortisol.

TABLE 62-2

Causes of Primary and Secondary Adrenal Insufficiency

Primary Causes
• Autoimmune disease*
• Tuberculosis
• Metastatic cancer
• AIDS
• Hemorrhage
• Gram-negative sepsis
• Adrenalectomy
• Abdominal radiation therapy
• Drugs (mitotane) and toxins
Secondary Causes
• Pituitary tumors
• Postpartum pituitary necrosis
• Hypophysectomy
• High-dose pituitary or whole-brain radiation

AIDS, Acquired immune deficiency syndrome.

*Most common cause.

Patient-Centered Collaborative Care

Assessment

History.

Ask about manifestations and factors that cause adrenal hypofunction. Ask about any change in activity level, because lethargy, fatigue, and muscle weakness are often present. Include questions about salt intake, because salt craving often occurs with hypofunction.

GI problems, such as anorexia, nausea, vomiting, diarrhea, and abdominal pain, often occur. Ask about weight loss during the past months. Women may have menstrual changes related to weight loss, and men may report impotence.

Ask whether the patient has had radiation to the abdomen or head. Document medical problems (e.g., tuberculosis or previous intracranial surgery) and all past and current drugs, especially steroids, anticoagulants, opioids, and cancer drugs.

Physical Assessment/Clinical Manifestations.

The manifestations of adrenal insufficiency vary, and the severity is related to the degree of hormone deficiency (Chart 62-7). In patients with primary insufficiency, plasma ACTH and melanocyte-stimulating hormone (MSH) levels are elevated in response to the adrenal-hypothalamic-pituitary feedback system. Elevated MSH levels result in

areas of increased pigmentation (Fig. 62-2). In primary autoimmune disease, patchy areas of decreased pigmentation may occur because of destruction of skin melanocytes. Body hair may also be decreased. In secondary disease, skin pigmentation is not changed.

Chart 62-7 Key Features

Adrenal Insufficiency

Neuromuscular Manifestations

- Muscle weakness
- Fatigue
- Joint/muscle pain

Gastrointestinal Manifestations

- Anorexia
- Nausea, vomiting
- Abdominal pain
- Constipation or diarrhea
- Weight loss
- Salt craving

Skin Manifestations

- Vitiligo
- Hyperpigmentation

Cardiovascular Manifestations

- Anemia
- Hypotension
- Hyponatremia
- Hyperkalemia
- Hypercalcemia

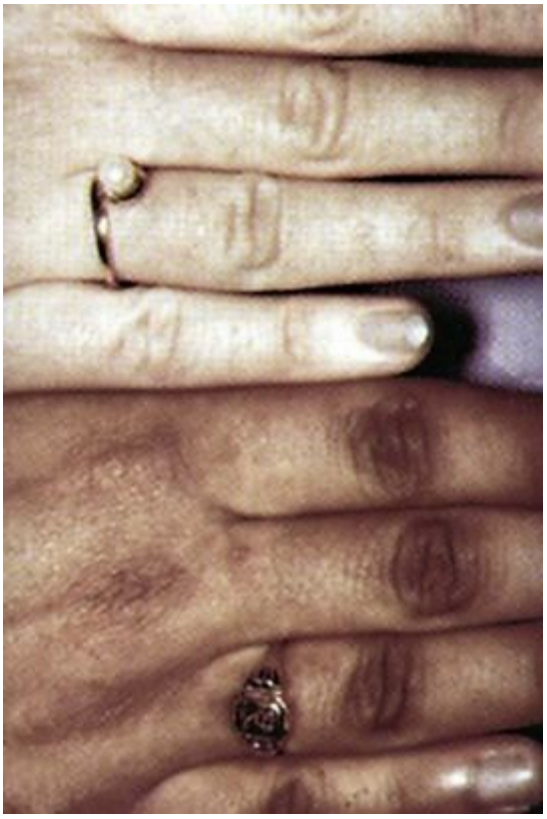

FIG. 62-2 The increased pigmentation seen in primary adrenocortical insufficiency.

Assess for abnormal glucose regulation with hypoglycemia (e.g., sweating, headaches, tachycardia, and tremors) and fluid depletion (postural hypotension and dehydration). **Hyperkalemia** (elevated blood potassium levels) can cause dysrhythmias with an irregular heart rate and can result in cardiac arrest.

Psychosocial Assessment.

Depending on the degree of imbalance, patients may appear lethargic, depressed, confused, and even psychotic. Assess the patient's orientation to person, place, and time. Families may report that the patient has wide mood swings and is forgetful.

Diagnostic Assessment.

Laboratory findings include low serum cortisol, low fasting blood glucose, low sodium, elevated potassium, and increased blood urea nitrogen (BUN) levels (Chart 62-8). In primary disease, the eosinophil count and ACTH level are elevated. Plasma cortisol levels do not rise during provocation tests.

Chart 62-8 Laboratory Profile

Adrenal Gland Assessment

		SIGNIFICANCE OF ABNORMAL FINDINGS	
TEST	NORMAL RANGE FOR ADULTS	HYPOFUNCTION OF THE ADRENAL GLAND	HYPERFUNCTION OF THE ADRENAL GLAND
Sodium	136-145 mEq/L	Decreased	Increased
Potassium	3.5-5.0 mEq/L	Increased	Decreased
Glucose	70-110 mg/dL (fasting) *Older adults:* slightly increased	Normal to decreased	Normal to increased
Calcium	9-10.5 mg/dL (total) 4.5-5.6 mg/dL (ionized) *Older adults:* slightly decreased	Increased	Decreased
Bicarbonate	23-30 mEq/L	Increased	Decreased
BUN	10-20 mg/dL *Older adults:* may be slightly higher	Increased	Normal
Cortisol (serum)	6 am to 8 am: 5-23 mcg/dL or 138-635 SI units (nmol/L) 4 pm to 6 pm: 3-13 mcg/dL or 83-359 SI units (nmol/L)	Decreased	Increased
Cortisol (salivary)	7 am to 9 am: 180-750 ng/dL 3 pm to 5 pm: <401 ng/dL 11 pm to midnight: <100 ng/dL		

BUN, Blood urea nitrogen; *SI,* International System of Units.

Pagana, K., & Pagana, T. (2014). *Mosby's manual of diagnostic and laboratory tests* (5th ed.). St. Louis: Mosby.

Urinary 17-hydroxycorticosteroids are the glucocorticoid metabolites, and 17-ketosteroid levels reflect the adrenal androgen metabolites. Both levels are in the low or low-normal range in adrenal hypofunction.

An ACTH stimulation (provocation) test is the most definitive test for adrenal insufficiency. ACTH 0.25 to 1 mg is given IV, and plasma cortisol levels are obtained at 30-minute and 1-hour intervals. In primary insufficiency, the cortisol response is absent or very decreased. In secondary insufficiency, it is increased. When acute adrenal insufficiency is suspected, treatment is started without stimulation testing (Stewart & Krone, 2011).

Imaging Assessment.

Skull x-rays, CT, MRI, and arteriography may help determine the cause of pituitary problems leading to adrenal insufficiency. CT scans may show adrenal gland atrophy.

Interventions

Nursing interventions focus on promoting fluid balance, monitoring for fluid deficit, and preventing poor glucose regulation with hypoglycemia. *Because hyperkalemia can cause dysrhythmias with an irregular heart rate and result in cardiac arrest, assessing cardiac function is a nursing priority.* Assess vital signs every 1 to 4 hours, depending on the patient's condition and the presence of dysrhythmias or postural hypotension. Weigh the patient daily, and record intake and output. Monitor laboratory values to identify

hemoconcentration (e.g., increased hematocrit or BUN). Chapter 11 discusses fluid volume deficit in detail.

Cortisol and aldosterone deficiencies are corrected by replacement therapy. Hydrocortisone corrects glucocorticoid deficiency (Chart 62-9). Oral cortisol replacement regimens vary. The most common drug used for this purpose is prednisone. Generally, divided doses are given, with two-thirds given in the morning and one-third in the late afternoon to mimic the normal release of this hormone. Although most patients do well on this regimen, some may not tolerate the dosage or may need more.

Chart 62-9 Common Examples of Drug Therapy

Hypofunction of the Adrenal Gland

DRUG AND USUAL DOSAGE	NURSING INTERVENTIONS	RATIONALES
Cortisone 25-50 mg orally daily	Instruct the patient to take the drug with meals or a snack.	GI irritation can occur.
Hydrocortisone (Cortef, Hycort) 20-50 mg orally	Instruct the patient to report these signs or symptoms of excessive drug therapy: ■ Rapid weight gain ■ Round face ■ Fluid retention	Cushing's syndrome, which indicates a need for dosage adjustment, can occur.
Prednisone (Winpred) 5-10 mg orally daily	Instruct the patient to report illness, such as: ■ Severe diarrhea ■ Vomiting ■ Fever	Other conditions may indicate a need for dosage change. The usual daily dosage may not be adequate during periods of illness or severe stress.
Fludrocortisone (Florinef) 0.05-0.2 mg orally daily	Monitor the patient's blood pressure.	Hypertension is a potential side effect.
	Instruct the patient to report weight gain or edema.	Sodium-related fluid retention is possible.

Nursing Safety Priority QSEN

Drug Alert

Prednisone and prednisolone are sound-alike drugs, and care is needed not to confuse them. Although they are both corticosteroids, they are not interchangeable because prednisolone is several times more potent than prednisone and dosages are not the same.

An additional mineralocorticoid hormone, such as fludrocortisone (Florinef), may be needed to maintain or restore fluid and electrolyte balance (especially sodium and potassium). Dosage adjustment may be needed, especially in hot weather when more sodium is lost because of excessive perspiration. *Salt restriction or diuretic therapy should not be started without considering whether it might lead to an adrenal crisis.*

Clinical Judgment Challenge

Patient-Centered Care; Quality Improvement; Safety QSEN

The patient is a 32-year-old woman admitted to your unit after surgery for fractures of the left arm and leg resulting from a car crash. She is awake and able to verify her medical history of rheumatoid arthritis and her usual daily oral medications. These are 10 mg of prednisone, naproxen 800 mg twice daily, oral contraceptives, calcium 600 mg, and one multiple vitamin tablet. All of these are prescribed for her to receive during her hospitalization. She is concerned about pain management and how long the recovery will be for the fractures. She is friendly, somewhat anxious, asks many questions, and wants to do "her part" to ensure good recovery. Over the next 4 days, she has become quieter, mumbles that her head and stomach hurt, and now does not recognize the assistant who has been providing her daily care. When she receives her medications, she has difficulty picking them up. The nursing assistant remarks that taking her pulse is difficult because it is so slow and irregular. When you assess the patient, she is so weak that she is unable to lift her arm for a blood pressure check. Her blood pressure is 92/50, which is down from the 128/84 reading on admission. You also verify that her heart beat is slow and irregular.

1. What other assessment data should you obtain immediately and why?
2. What is the most likely cause of the changes in this patient's physical and mental status?
3. How could this problem have been avoided?
4. What specifically would be the nurse's role in preventing this problem?
5. What could be done to prevent this problem from happening again?

Adrenal Gland Hyperfunction

The adrenal gland may oversecrete just one hormone or all adrenal hormones. Hypersecretion by the adrenal cortex results in hypercortisolism (e.g., **Cushing's disease** or **Cushing's syndrome**), **hyperaldosteronism** (excessive mineralocorticoid production), or excessive androgen production. Hyperstimulation of the adrenal medulla caused by a tumor (**pheochromocytoma**) results in excessive secretion of catecholamines (epinephrine and norepinephrine).

Hypercortisolism (Cushing's Disease)

Pathophysiology

Cushing's disease is the excess secretion of cortisol from the adrenal cortex, causing many problems. It is caused by either a problem in the adrenal cortex itself, a problem in the anterior pituitary gland, or a problem in the hypothalamus. In addition, glucocorticoid therapy can also lead to problems of hypercortisolism.

The presence of excess glucocorticoids, regardless of the cause, affects metabolism and all body systems. An increase in total body fat results from slow turnover of plasma fatty acids. This fat is redistributed, producing truncal obesity, "buffalo hump," and "moon face" (Fig. 62-3). Increases in the breakdown of tissue protein result in decreased muscle mass and muscle strength, thin skin, and fragile capillaries. The effects on minerals lead to bone density loss.

FIG. 62-3 The typical appearance of a patient with Cushing's disease or syndrome. Note truncal obesity, moon face, buffalo hump, thinner arms and legs, and abdominal striae.

High levels of corticosteroids kill lymphocytes and shrink organs containing lymphocytes, such as the spleen and the lymph nodes. White blood cell cytokine production is decreased. These changes reduce the protection of the inflammatory and immune responses.

In most cases, increased androgen production also occurs and causes acne, **hirsutism** (increased body hair growth), and occasionally clitoral hypertrophy in women. Increased androgens disrupt the normal ovarian

hormone feedback mechanism, decreasing the ovary's production of estrogens and progesterone. **Oligomenorrhea** (scant or infrequent menses) results.

Etiology

Cushing's disease or syndrome is a group of clinical problems caused by an excess of cortisol. Table 62-3 lists causes of cortisol excess. When the anterior pituitary gland oversecretes adrenocorticotropic hormone (ACTH), this hormone causes hyperplasia of the adrenal cortex in both adrenal glands and an excess of most hormones secreted by the adrenal cortex. (See Fig. 61-3 in Chapter 61.) This problem is known as **pituitary Cushing's disease** because the tissue causing the problem is the pituitary. When the excess glucocorticoids are caused by a problem in the actual adrenal cortex, usually a benign tumor (adrenal adenoma), the problem is called **adrenal Cushing's disease** and usually occurs in only one adrenal gland. When glucocorticoid excess results from drug therapy for another health problem, it is known as **Cushing's syndrome**.

TABLE 62-3

Conditions Causing Increased Cortisol Secretion

Endogenous Secretion (Cushing's Disease)
• Bilateral adrenal hyperplasia*
• Pituitary adenoma increasing the production of ACTH (pituitary Cushing's disease)
• Malignancies: carcinomas of the lung, GI tract, pancreas
• Adrenal adenomas or carcinomas
Exogenous Administration (Cushing's Syndrome)
• Therapeutic use of ACTH or glucocorticoids—most commonly for treatment of:
• Asthma
• Autoimmune disorders
• Organ transplantation
• Cancer chemotherapy
• Allergic responses
• Chronic fibrosis

ACTH, Adrenocorticotropic hormone.

*Most common cause.

Incidence and Prevalence

The most common cause of Cushing's disease is a pituitary adenoma. Women are more likely than men to develop Cushing's disease. The actual incidence of Cushing's syndrome from chronic use of exogenous corticosteroids is not known. However, because these drugs are commonly used to control serious chronic inflammatory conditions such as asthma, other respiratory problems, and rheumatoid arthritis,

Cushing's syndrome is more common than Cushing's disease and affects both genders equally.

Patient-Centered Collaborative Care

Assessment

History.

Ask about the patient's other health problems and drug therapies, because glucocorticoid therapy is a common cause of hypercortisolism. Regardless of cause, the patient has many changes because of the widespread effect of excessive cortisol. The patient may report weight gain and an increased appetite. Ask about changes in activity or sleep patterns, fatigue, and muscle weakness. Ask about bone pain or a history of fractures, because osteoporosis is common in hypercortisolism. Ask about a history of frequent infections and easy bruising. Women often stop menstruating. GI problems include ulcer formation from increased hydrochloric acid secretion and decreased production of protective gastric mucus.

Physical Assessment/Clinical Manifestations.

The patient with hypercortisolism has specific physical changes, although all body systems are affected (see Fig. 62-3 and Chart 62-10). Changes in fat distribution may result in fat pads on the neck, back, and shoulders ("buffalo hump"); an enlarged trunk with thin arms and legs; and a round face ("moon face"). Other changes include muscle wasting and weakness. Assess and document changes, and use these findings to prioritize patient problems.

Chart 62-10 Key Features

Hypercortisolism (Cushing's Disease/Syndrome)

General Appearance

- Moon face
- Buffalo hump
- Truncal obesity
- Weight gain

Cardiovascular Manifestations

- Hypertension

- Frequent dependent edema
- Bruising
- Petechiae

Musculoskeletal Manifestations

- Muscle atrophy (most apparent in extremities)
- Osteoporosis (bone density loss)
  - Pathologic fractures
  - Decreased height with vertebral collapse
  - Aseptic necrosis of the femur head
  - Slow or poor healing of bone fractures

Skin Manifestations

- Thinning skin
- Striae and increased pigmentation

Immune System Manifestations

- Increased risk for infection
- Decreased immune function
- Decreased inflammatory responses
- Manifestations of infection/inflammation may be masked

ACTH, Adrenocorticotropic hormone.

Skin changes result from increased blood vessel fragility and include bruises, thin or translucent skin, and wounds that have not healed. Reddish purple **striae** ("stretch marks") occur on the abdomen, thighs, and upper arms because of the destructive effect of cortisol on collagen.

Acne and a fine coating of hair may occur over the face and body. In women, look for the presence of hirsutism, clitoral hypertrophy, and male pattern balding related to androgen excess.

Cardiac changes occur as a result of disturbed fluid and electrolyte balance, especially water and mineral metabolism. Both sodium and water are reabsorbed and retained, leading to hypervolemia and edema formation. Blood pressure is elevated, and pulses are full and bounding.

Musculoskeletal changes occur as a result of nitrogen depletion and mineral loss. Muscle mass decreases, especially in arms and legs (see Fig. 62-3). Muscle weakness increases the risk for falls. Bone is thinner as a result of mineral loss, and osteoporosis is common, increasing the risk for pathologic fractures.

Glucose regulation is affected by hypercortisolism. Fasting blood glucose levels are high because the liver releases glucose and the insulin

receptors are less sensitive, so blood glucose does not move as easily into the tissues. Muscle mass loss also reduces glucose uptake.

Immune changes caused by excess cortisol result in immunosuppression and an increased risk for infection. Excess cortisol reduces the number of circulating lymphocytes, inhibits macrophage activity, reduces antibody synthesis, and inhibits production of cytokines and inflammatory chemicals (e.g., histamine) (McCance et al., 2014). The risk for infection is higher, and the patient may not have the expected manifestations (fever, purulent exudate, redness in the affected area) when an infection is present.

Psychosocial Assessment.

Hypercortisolism can result in emotional instability, and patients often say that they do not feel like themselves. Ask about mood swings, irritability, confusion, or depression. Ask the patient whether he or she has been crying or laughing inappropriately or has had difficulty concentrating. Family members often report changes in the patient's mental or emotional status. The excess hormones stimulate the central nervous system, heightening the awareness of and responses to sensory stimulation. The patient often reports sleep difficulties and fatigue.

Laboratory Assessment.

Laboratory tests include blood, salivary, and urine cortisol levels. These are high in patients with any type of hypercortisolism. Plasma ACTH levels vary, depending on the cause of the problem. In pituitary Cushing's disease, ACTH levels are elevated. In adrenal Cushing's disease or when Cushing's syndrome results from chronic steroid use, ACTH levels are low.

Salivary cortisol levels may be used to detect hypercortisolism. Saliva is easily and painlessly collected with the use of a salivary specimen cushion placed in the cheek next to the salivary gland. A normal salivary cortisol level is lower than 2.0 ng/mL. Higher levels indicate hypercortisolism.

Urine is tested to measure levels of free cortisol and the metabolites of cortisol and androgens (17-hydroxycorticosteroids and 17-ketosteroids). In Cushing's disease, levels of urine cortisol and androgens are all elevated in a 24-hour specimen, as are urine calcium, potassium, and glucose levels.

Dexamethasone suppression testing can screen for hypercortisolism and may take place overnight or over a 3-day period. Set doses of dexamethasone are given. A 24-hour urine collection follows drug

administration. When urinary 17-hydroxycorticosteroid excretion and cortisol levels are suppressed by dexamethasone, Cushing's disease is not present.

Additional laboratory findings that accompany hypercortisolism include:

- Increased blood glucose level
- Decreased lymphocyte count
- Increased sodium level
- Decreased serum calcium level

Imaging Assessment.

Imaging for hypercortisolism includes x-rays, CT scans, MRI, and arteriography. These images can identify lesions of the adrenal or pituitary glands, lung, GI tract, or pancreas.

Analysis

The priority NANDA-I nursing diagnoses and collaborative problems for patients with Cushing's disease or Cushing's syndrome include:

1. Fluid overload
2. Risk for Injury related to skin thinning, poor wound healing, and bone density loss (NANDA-I)
3. Risk for Infection (NANDA-I)
4. Potential for acute adrenal insufficiency

Planning and Implementation

Expected outcomes of hypercortisolism management are the reduction of plasma cortisol levels, removal of tumors, and restoration of normal or acceptable body appearance. When the disorder is caused by pituitary or adrenal problems, cure is possible. When caused by drug therapy for another health problem, the focus is to prevent complications from hypercortisolism.

Restoring Fluid Volume Balance

Planning: Expected Outcomes.

The patient with hypercortisolism is expected to achieve and maintain an acceptable fluid and electrolyte balance. Indicators include that these parameters are within or close to the normal range:

- Blood pressure
- Stable body weight
- Serum electrolytes

Interventions.

Interventions for patients with fluid overload from hypercortisolism focus on ensuring patient safety, restoring fluid and electrolyte balance, and providing supportive care. Depending on the cause, surgical management may be used to reduce cortisol production.

Nonsurgical Management.

Patient safety, drug therapy, nutrition therapy, and monitoring are the basis of nonsurgical interventions for hypercortisolism and fluid overload.

Patient safety includes preventing fluid overload from becoming worse, leading to pulmonary edema and heart failure. Any patient with fluid overload, regardless of age, is at risk for these complications. The older adult or one who has coexisting cardiac problems, kidney problems, pulmonary problems, or liver problems is at greater risk.

Monitor for indicators of fluid overload (bounding pulse, increasing neck vein distention, lung crackles, increasing peripheral edema, reduced urine output) at least every 2 hours. *Pulmonary edema can occur very quickly and can lead to death.* Notify the health care provider of any change that indicates fluid overload either is not responding to therapy or is worse.

The patient with fluid overload and dependent edema is at risk for skin breakdown. Use a pressure-reducing or pressure-relieving overlay on the mattress. Assess skin pressure areas, especially the coccyx, elbows, hips, and heels, daily for redness or open areas. For patients receiving oxygen by mask or nasal cannula, check the skin around the mask, nares, and ears and under the elastic band. Assist the patient to change positions every 2 hours, or ensure that others delegated to perform this intervention are diligent in this action.

Drug therapy involves the use of drugs that interfere with adrenocorticotropic hormone (ACTH) production or adrenal hormone synthesis for temporary relief. Metyrapone (Metopirone), aminoglutethimide (Elipten, Cytadren), and ketoconazole use different pathways to decrease cortisol production (Hunt, 2012). For patients with hypercortisolism resulting from increased ACTH production, cyproheptadine (Periactin) may be used because it interferes with ACTH production. Mitotane (Lysodren) is an adrenal cytotoxic agent used for inoperable tumors causing hypercortisolism. For people with increased ACTH production who have type 2 diabetes and who do not respond to other drug therapies, another drug is mifepristone (Korlym), which is a synthetic steroid that blocks glucocorticoid receptors (Aschenbrenner,

2012).

Nursing Safety Priority QSEN

Drug Alert

Mifepristone (Korlym) cannot be used during pregnancy because it also blocks progesterone receptors and would cause termination of the pregnancy.

A new drug to manage hypercortisolism resulting from a pituitary adenoma is pasireotide (Signifor). This drug binds to somatostatin receptors on the adenoma and inhibits tumor production of corticotropin. Lower levels of corticotropin lead to lower levels of cortisol production in the adrenal glands (McKeage, 2013). This subcutaneous drug does not work for people whose tumors do not have somatostatin receptors. In addition, many patients taking this drug have problems with hyperglycemia.

Monitor the patient for response to drug therapy, especially weight loss and increased urine output. Observe for manifestations of problems with fluid and electrolyte balance, especially changes in electrocardiogram (ECG) patterns. Assess laboratory findings, especially sodium and potassium values, whenever they are drawn.

Nutrition therapy for the patient with hypercortisolism may involve restrictions of both fluid and sodium intake to control fluid volume. Review the patient's serum sodium levels whenever fluid overload is present. Often sodium restriction involves only “no added salt” to ordinary table foods when fluid overload is mild. For more pronounced fluid overload, the patient may be restricted to anywhere from 2 g/day to 4 g/day of sodium. When sodium restriction is ongoing, teach the patient and family how to check food labels for sodium content and how to keep a daily record of sodium ingested. Explain to the patient and family the reason for any fluid restriction and the importance of adhering to the prescribed restriction.

Monitoring intake and output and weight can indicate therapy effectiveness. Ensure that unlicensed assistive personnel (UAP) understand that these measurements need to be accurate, not just estimated, because treatment decisions are based on these findings. Schedule fluid offerings throughout the 24 hours. Teach UAP to check urine for color and character and to report these findings. Check the urine specific gravity (a specific gravity below 1.005 may indicate fluid

overload). If IV therapy is used, infuse only the amount prescribed.

Fluid retention may not be visible. Remember that rapid weight gain is the best indicator of fluid retention and overload. Each 1 lb (about 500 g) of weight gained equates to 500 mL of retained water. Weigh the patient at the same time daily (before breakfast), using the same scale. Have the patient wear the same type of clothing for each weigh-in.

Radiation therapy is rarely used to treat hypercortisolism caused by pituitary adenomas because it is not always effective and often destroys normal tissue. Chapter 45 discusses radiation therapy to the head.

Surgical Management.

The surgical treatment of adrenocortical hypersecretion depends on the cause of the disease. When adrenal hyperfunction is due to increased pituitary secretion of ACTH, removal of a pituitary adenoma using minimally invasive techniques may be attempted. Sometimes a total *hypophysectomy* (surgical removal of the pituitary gland) is needed. (See earlier discussion of hypophysectomy on pp. 1270-1271.) If hypercortisolism is caused by an adrenal tumor, an *adrenalectomy* (removal of the adrenal gland) may be needed.

Preoperative Care.

Disturbances of fluid and electrolyte balance are corrected before surgery. Continue to monitor blood potassium, sodium, and chloride levels. Dysrhythmias from potassium imbalance may occur, and cardiac monitoring is needed. Problems with glucose regulation and hyperglycemia are controlled before surgery.

The patient with hypercortisolism is at risk for complications of infections and fractures. Prevent infection with handwashing and aseptic technique. Decrease the risk for falls by raising top siderails and encouraging the patient to ask for assistance when getting out of bed. A high-calorie, high-protein diet is prescribed before surgery.

Glucocorticoid preparations are given before surgery. The patient continues to receive glucocorticoids during surgery to prevent adrenal crisis because the removal of the tumor results in a sudden drop in cortisol levels. Before surgery, discuss the need for long-term drug therapy.

Operative Procedures.

A unilateral adrenalectomy is performed when one gland is involved. A bilateral adrenalectomy is needed when ACTH-producing tumors cannot be treated by other means or when both adrenal glands are diseased.

Surgery is most often performed by laparoscopic adrenalectomy, a minimally invasive surgical approach. If necessary, an open surgery through the abdomen or the lateral flank can be performed.

Postoperative Care.

After an adrenalectomy, the patient is usually sent to a critical care unit. Immediately after surgery, assess the patient every 15 minutes for shock (e.g., hypotension; a rapid, weak pulse; and a decreasing urine output) resulting from insufficient glucocorticoid replacement. Monitor vital signs, central venous pressure, pulmonary wedge pressure, intake and output, daily weights, and serum electrolyte levels.

After a bilateral adrenalectomy, patients require lifelong glucocorticoid and mineralocorticoid replacement, starting immediately after surgery. In unilateral adrenalectomy, hormone replacement continues until the remaining adrenal gland increases hormone production. This therapy may be needed for up to 2 years after surgery.

NCLEX Examination Challenge

Health Promotion and Maintenance

The client who is about to have a unilateral adrenalectomy for an adenoma that is causing hypercortisolism asks the nurse if she will have to continue the severe sodium restriction after surgery. What is the nurse's best response?

A "No, once the tumor has been removed and your cortisol levels have normalized, you will not retain excess sodium anymore."
B "No, after surgery you will have to take oral cortisol, which can be easily controlled so that your sodium levels do not rise."
C "Yes, the fact that you are retaining sodium and have high blood pressure is related to your age and lifestyle, not the tumor."
D "Yes, sodium is very bad for people and everyone needs to eliminate sodium completely from their diets for the rest of their lives."

Preventing Injury.

The patient who has hypercortisolism is at risk for injury from skin breakdown, bone fractures, and GI bleeding. Prevention of these injuries is a major nursing care focus.

Planning: Expected Outcomes.

The patient with hypercortisolism is expected to avoid injury. Indicators

include:
- Skin is intact.
- Minimal or no bruising is present.
- Bones are intact.
- Stools, vomitus, and other GI secretions contain no gross or occult blood.

Interventions.

Priority nursing interventions for prevention of injury focus on skin assessment and protection, coordinating care to ensure gentle handling, and patient teaching regarding drug therapy for prevention of GI ulcers.

Skin injury is a continuing risk even after surgery has corrected the cortisol excess because the changes induced in the skin and blood vessels remain for weeks to months. Assess the skin for reddened areas, excoriation, breakdown, and edema. If mobility is decreased, turn the patient every 2 hours and pad bony prominences.

Instruct the patient to avoid activities that can result in skin trauma. Teach him or her to use a soft toothbrush and an electric shaver. Instruct patients to keep the skin clean and to dry it thoroughly after washing. Excessive dryness can be prevented by using a moisturizing lotion.

Adhesive tape often causes skin breakdown. Use tape sparingly, and remove it carefully. After venipuncture, the patient may have increased bleeding because of blood vessel fragility. Exert pressure over the site for longer than normal to prevent bleeding and bruising.

Pathologic fractures from bone density loss and osteoporosis are possible for months to years after cortisol levels return to normal. Teach the patient about safety issues and dietary needs. When helping the patient move in bed, use a lift sheet instead of grasping him or her. Remind the patient to call for help when ambulating. Review the use of walkers or canes, if needed. Teach UAP to use a gait belt when walking with a patient who has bone density loss.

Coordinate with a dietitian to teach the patient about nutrition therapy. A high-calorie diet is prescribed that includes increased amounts of calcium and vitamin D. Generous amounts of milk, cheese, yogurt, and green leafy and root vegetables add calcium to promote bone density. Advise the patient to avoid caffeine and alcohol, which increase the risk for GI ulcers and may promote bone density loss.

GI bleeding is common with hypercortisolism. Cortisol (1) inhibits production of the thick, gel-like mucus that protects the stomach lining, (2) decreases blood flow to the area, and (3) triggers the release of excess hydrochloric acid. Although surgery reduces the hypercortisolism, the

normal mucus and increased blood flow may take weeks to return. Interventions focus on drug therapy to reduce irritation, protect the GI mucosa, and decrease the secretion of hydrochloric acid.

Antacids buffer stomach acids and protect the GI mucosa. Teach the patient that these drugs should be taken on a regular schedule rather than on an as-needed basis.

When histamine binds to the H_2 receptors in the gastric mucosa, a series of actions release hydrochloric acid. Drugs that block the H_2-receptor site and reduce hydrochloric acid production include cimetidine (Tagamet, Peptol, Novo-Cimetine), ranitidine (Zantac, Apo-Ranitidine), famotidine (Pepcid), and nizatidine (Axid). Omeprazole (Losec, Prilosec) and esomeprazole (Nexium) inhibit the gastric proton pump and prevent the formation of hydrochloric acid.

Instruct the patient to reduce alcohol and caffeine consumption, smoking, and fasting, because these conditions cause gastric irritation. NSAIDs and drugs that contain aspirin or other salicylates can cause gastritis and intensify GI bleeding. These should be avoided or limited.

Preventing Infection.

Glucocorticoids reduce both inflammation and the immune responses, increasing the risk for infection. For the patient who is taking glucocorticoid replacement therapy, the risk is ongoing. For the patient who is recovering from surgery to prevent hypercortisolism, the infection risk continues for weeks after surgery.

Planning: Expected Outcomes.

The patient with hypercortisolism is expected to remain free from infection and avoid situations that increase the risk for infection. Indicators include these manifestations and behaviors:

- Does not have fever and foul-smelling or purulent drainage
- Does not have cough, chest pain, and dyspnea
- Does not have urinary frequency, urgency, or pain and burning
- Avoids crowds and large gatherings
- Obtains appropriate vaccinations
- Washes hands frequently

Interventions.

Protect the patient with hypercortisolism from infection. All personnel must use extreme care during all nursing procedures. Thorough handwashing is important. Anyone with an upper respiratory tract

infection who enters the patient's room must wear a mask. Observe strict aseptic technique when performing dressing changes or any invasive procedure.

Continually assess the patient for possible infection. Manifestations may not be obvious because hypercortisolism suppresses infection manifestations. Fever and the formation of pus depend on the presence of white blood cells (WBCs). The patient who is immunosuppressed may have a severe infection without pus and with only a low-grade fever.

Monitor the patient's daily complete blood count (CBC) with differential WBC count, especially neutrophils. Inspect the mouth during every shift for lesions and mucosa breakdown. Assess the lungs every 8 hours for crackles, wheezes, or reduced breath sounds. Assess all urine for odor and cloudiness. Ask about any urgency, burning, or pain on urination.

Take vital signs at least every 4 hours to assess for fever. A temperature elevation of even 1° F (or 0.5° C) above baseline is significant for a patient who is immunosuppressed and indicates infection until it has been proven otherwise.

Skin care is important for preventing infection because the skin may be the patient's only intact defense. Teach him or her about hygiene, and urge daily bathing. If the patient is immobile, turn him or her every 1 to 2 hours and apply skin lubricants.

Perform pulmonary hygiene every 2 to 4 hours. Listen to the lungs for crackles, wheezes, or reduced breath sounds. Urge the patient to deep breathe or to use an incentive spirometer every hour while awake.

Preventing Acute Adrenal Insufficiency.

The patient most at risk for acute adrenal insufficiency is the one who has Cushing's syndrome as a result of glucocorticoid drug therapy. The exogenous drug inhibits the feedback control pathway (see Fig. 61-3 in Chapter 61), preventing the hypothalamus from secreting corticotropin-releasing hormone (CRH). The lack of CRH inhibits secretion of ACTH from the anterior pituitary gland. Without normal levels of ACTH, the adrenal glands atrophy and completely stop production of the corticosteroids. As a result, the patient completely depends on the exogenous drug. If the drug is stopped, even for a day or two, the atrophied adrenal glands cannot produce the glucocorticoids and the patient develops acute adrenal insufficiency, a life-threatening condition. Management of this problem is described on p. 1274.

Nursing Safety Priority QSEN

Drug Alert

Teach patients who are taking a corticosteroid for more than a week to not stop the drug suddenly. Gradual drug tapering should be done under the care of the health care provider.

Community-Based Care

Home Care Management.

The patient with hypercortisolism usually has muscle weakness and fatigue for some weeks after surgery and remains at risk for falls and other injury. These problems may necessitate one-floor living for a short time, and a home health aide may be needed to assist with hygiene, meal preparation, and maintenance.

Self-Management Education.

The patient taking exogenous glucocorticoids who is discharged to home remains at continuing risk for problems with fluid and electrolyte balance, especially fluid volume excess. Teach him or her and the family to monitor the patient's weight. Suggest that a record of these daily weights be kept to show the health care provider at any checkups. Also, instruct the patient to call the health care provider if more than 3 lbs are gained in a week or more than 1 to 2 lbs are gained in a 24-hour period.

Lifelong hormone replacement is needed after bilateral adrenalectomy. Teach the patient and family about adherence to the drug regimen and its side effects (Chart 62-11).

Chart 62-11 Patient and Family Education: Preparing for Self-Management

Cortisol Replacement Therapy

- Take your medication in divided doses—the first dose in the morning and the second dose between 4 pm and 6 pm.
- Take your medication with meals or snacks.
- Weigh yourself daily, and keep a record to show your health care provider.
- Increase your dosage as directed by your health care provider for increased physical stress or severe emotional stress.
- Never skip a dose of medication. If you have persistent vomiting or

severe diarrhea and cannot take your medication by mouth for 24 to 36 hours, call your physician. If you cannot reach your physician, go to the nearest emergency department. You may need an injection to take the place of your usual oral medication.
- Always wear your medical alert bracelet or necklace.
- Make regular visits for health care follow-up.
- Learn how to give yourself an intramuscular injection of hydrocortisone.

Protecting the patient from infection at home is important. Urge him or her to use proper hygiene and to avoid crowds or others with infections. Encourage the patient and all people living in the same home with him or her to have yearly influenza vaccinations. Stress that the patient should immediately notify the physician if he or she has a fever or any other indication of infection. Chart 40-10 in Chapter 40 lists guidelines for patients for infection prevention.

Health Care Resources.

Immediately after returning home, the patient may need a support person to stay and provide more attention than could be given by a visiting nurse or home care aide. Contact with the health care team is needed for follow-up and identification of potential problems. The patient taking corticosteroid therapy may have manifestations of adrenal insufficiency if the dosage is inadequate. Suggest that the patient obtain and wear a medical alert bracelet listing the condition and the drug replacement therapy.

◆ Evaluation: Outcomes

Evaluate the care of the patient with hypercortisolism based on the identified priority patient problems. The expected outcomes are that the patient should:
- Maintain fluid and electrolyte balance
- Remain free from injury
- Remain free from infection
- Not experience acute adrenal insufficiency

Specific indicators for these outcomes are listed for each priority patient problem under the Planning and Implementation section (see earlier).

Hyperaldosteronism

Pathophysiology

Hyperaldosteronism is an increased secretion of aldosterone with mineralocorticoid excess. Primary hyperaldosteronism *(Conn's syndrome)* in adults results from excessive secretion of aldosterone from one or both adrenal glands, usually caused by an adrenal adenoma. In secondary hyperaldosteronism, excessive secretion of aldosterone is caused by the high levels of angiotensin II that are stimulated by high plasma renin levels. Some causes include kidney hypoxia, diabetic nephropathy, and excessive use of some diuretics. Some forms of hyperaldosterone secretion have a genetic basis and are diagnosed in childhood.

Increased aldosterone levels cause disturbances of fluid and electrolyte balance, which then trigger the kidney tubules to retain sodium and excrete potassium and hydrogen ions. Hypernatremia, hypokalemia, and metabolic alkalosis result. Sodium retention increases blood volume, which raises blood pressure, increasing the risk for strokes, heart attacks, and kidney damage. (See Chapter 11 for discussion of electrolyte imbalances.)

Patient-Centered Collaborative Care

Assessment

Hypokalemia and elevated blood pressure are the most common problems of the patient with hyperaldosteronism. He or she may have headache, fatigue, muscle weakness, dehydration, and loss of stamina. **Polydipsia** (excessive fluid intake) and **polyuria** (excessive urine output) occur less frequently. **Paresthesias** (sensations of numbness and tingling) may occur if potassium depletion is severe (Crawford, & Harris, 2011).

Hyperaldosteronism is diagnosed on the basis of laboratory studies, x-rays, and imaging with CT or MRI. Serum potassium levels are decreased, and sodium levels are elevated. Plasma renin levels are low, and aldosterone levels are high. Hydrogen ion loss leads to metabolic alkalemia (elevated blood pH). Urine has a low specific gravity and high aldosterone levels.

Interventions

Surgery is the most common treatment for hyperaldosteronism. One or both adrenal glands may be removed. Surgery is not performed, however, until the patient's potassium levels are normal. Drugs used to increase potassium levels include spironolactone (Aldactone, Spirono, Sincomen), a potassium-sparing diuretic and aldosterone antagonist. Potassium

supplements may be prescribed to increase potassium levels before surgery. The patient may also benefit from a low-sodium diet before surgery.

The patient who has undergone a unilateral adrenalectomy may need temporary glucocorticoid replacement. Replacement is lifelong if both adrenal glands are removed. Glucocorticoids are given before surgery to prevent adrenal crisis. The patient receiving long-term replacement therapy should wear a medical alert bracelet. (See the discussion of adrenalectomy on pp. 1279-1280 in the Hypercortisolism [Cushing's Disease] section for more discussion of care after surgery and patient education.)

When surgery cannot be performed, spironolactone therapy is continued to control hypokalemia and hypertension. Because spironolactone is a potassium-sparing diuretic, hyperkalemia can occur in patients who have impaired kidney function or excessive potassium intake. Advise the patient to avoid potassium supplements and foods rich in potassium. Hyponatremia can occur with spironolactone therapy, and the patient may need increased dietary sodium. Instruct the patient to report manifestations of hyponatremia, such as dryness of the mouth, thirst, lethargy, or drowsiness. Teach patients to report any additional side effects of spironolactone therapy, including gynecomastia, diarrhea, drowsiness, headache, rash, **urticaria** (hives), confusion, erectile dysfunction, hirsutism, and amenorrhea. Additional drug therapy to control hypertension is often needed.

Pheochromocytoma

Pathophysiology

Pheochromocytoma is a catecholamine-producing tumor that arises in the adrenal medulla. These tumors usually occur as a single lesion in one adrenal gland, although they can be bilateral or in the abdomen. Pheochromocytomas are usually benign, but at least 10% are malignant.

The tumors produce, store, and release epinephrine and norepinephrine (NE). Excessive epinephrine and NE stimulate adrenergic receptors and can have wide-ranging adverse effects mimicking the action of the sympathetic division of the autonomic nervous system.

The cause is unknown, but some pheochromocytomas occur with inherited disorders such as neurofibromatosis (type 1), multiple endocrine neoplasia (MEN-2), Von Hippel-Lindau disease, and

pheochromocytoma-paraganglioma syndrome (OMIM, 2014). These tumors are rare; they occur at any age but appear most commonly in patients between 30 and 50 years of age (Young, 2011).

Patient-Centered Collaborative Care

Assessment

The patient often has intermittent episodes of hypertension or attacks that range from a few minutes to several hours. During these episodes, the patient has severe headaches, palpitations, profuse diaphoresis, flushing, apprehension, or a sense of impending doom. Pain in the chest or abdomen, with nausea and vomiting, can also occur. Increased abdominal pressure, defecation, and vigorous abdominal palpation can provoke a hypertensive crisis. Drugs such as tricyclic antidepressants, droperidol, glucagon, metoclopramide, phenothiazines, and naloxone can induce a hypertensive crisis in the patient with pheochromocytoma. Foods or beverages high in tyramine (e.g., aged cheese, red wine) also induce hypertension. The patient may also report heat intolerance, weight loss, and tremors.

The most common diagnostic test is blood and 24-hour urine collection for fractionated metanephrine and catecholamine levels, all of which are elevated in the presence of a pheochromocytoma. Another test that may be conducted when catecholamine levels are not consistent is the clonidine suppression test (Young, 2011). MRI or CT scans can precisely locate tumors in the adrenal gland, as well as in the chest or abdomen.

Interventions

Surgery is the main treatment for a pheochromocytoma. One or both adrenal glands are removed (depending on whether the tumor is bilateral). After surgery, nursing interventions focus on promoting adequate tissue perfusion, nutritional needs, and comfort measures.

Hypertension is the hallmark of the disease and the most common serious complication after surgery. Monitor the blood pressure regularly, and place the cuff consistently on the same arm, with the patient in lying and standing positions. Identify stressors that may lead to a hypertensive crisis, and attempt to reduce them. Teach the patient to not smoke, drink caffeine-containing beverages, or change position suddenly. Provide a diet rich in calories, vitamins, and minerals.

Nursing Safety Priority QSEN

Action Alert

Do not palpate the abdomen of a patient with a pheochromocytoma, because this action could stimulate a sudden release of catecholamines and trigger severe hypertension.

The patient often benefits from hydration before surgery because decreased blood volume increases the risk for hypotension during and after surgery. Assess the patient's hydration status, and report manifestations of dehydration or fluid overload.

The patient's blood pressure is stabilized with adrenergic blocking agents such as phenoxybenzamine (Dibenzyline) starting 7 to 10 days before surgery because of the increased risk for severe hypertension during surgery. The drug dosages are adjusted until blood pressure is controlled and hypertensive attacks do not occur. The blood volume expands, and blood pressure in the supine position returns to normal.

Anesthetic agents and touching of the tumor during surgery can cause a catecholamine release. Short-acting alpha-adrenergic blockers are given by IV bolus or continuous infusion for a hypertensive crisis.

Nursing care after surgery is similar to that for the patient who has undergone an adrenalectomy (see Hypercortisolism [Cushing's Disease], pp. 1279-1280). Monitor the patient for hypertension and for hypotension (from the sudden decrease in catecholamine levels) and for hypovolemia. Hemorrhage and shock are possible, and plasma expanders or fluids may be needed. Monitor vital signs, as well as fluid intake and output. If opioids are given, check for their effect on blood pressure.

When tumors are inoperable, management is medical, with alpha-adrenergic and beta-adrenergic blocking agents. For these patients, self-measurement of blood pressure with home monitoring equipment is essential. (See Chapter 36 for teaching priorities and community-based care of the patient with chronic hypertension.)

Nursing Concepts and Clinical Judgment Review

What might you NOTICE if the patient is experiencing disturbances of fluid and electrolyte balance and glucose regulation as a result of adrenal gland hypofunction?

Assessment:

- Postural hypotension
- Irregular heart rate

- Sweating
- Headaches
- Tachycardia
- Tremors
- Muscle weakness
- Forgetfulness
- Lethargy and confusion
- Salt craving

What should you INTERPRET and how should you RESPOND to a patient experiencing disturbances of fluid and electrolyte imbalance and glucose regulation as a result of adrenal gland hypofunction?

Interpret by:

- Taking vital signs
- Assessing cognition
- Assessing blood pressure in the sitting and standing positions
- Assessing muscle strength and function

Interpret laboratory values, including:

- Blood glucose levels
- Serum potassium levels
- Serum sodium levels
- Serum cortisol levels
- Blood urea nitrogen levels

Respond by:

- Ensuring fluid intake
- Providing adequate calorie and carbohydrate intake
- Monitoring for fluid deficit
- Obtaining daily weights
- Measuring intake and output
- Administering prescribed hormone replacements
- Assisting the patient with ambulation
- Monitoring electrocardiograph changes

On what should you REFLECT?

- Observe the patient for evidence of improved fluid and electrolyte balance and glucose regulation.
- Think about what patient education focus could help reduce the intensity of disturbances of fluid and electrolyte balance and glucose regulation in the future.

Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Handle all patients with bone density loss carefully, using lift sheets whenever possible. **Safety** QSEN
- Use good handwashing techniques before providing any care to a patient who is immunosuppressed. **Safety** QSEN
- Ensure that hormone replacement drugs are given as close to the prescribed times as possible. **Safety** QSEN

Health Promotion and Maintenance

- Instruct the patient with adrenal insufficiency to wear a medical alert bracelet and to carry simple carbohydrates with him or her at all times. **Patient-Centered Care** QSEN
- Teach the patient and family about the clinical manifestations of infection and when to seek medical advice. **Patient-Centered Care** QSEN
- Teach patients who have permanent endocrine hypofunction the proper techniques and timing of hormone replacement therapy. **Patient-Centered Care** QSEN
- Teach patients taking bromocriptine to seek medical care immediately if chest pain, dizziness, or watery nasal discharge occurs. **Safety** QSEN
- Teach patients with diabetes insipidus the proper way to self-administer desmopressin orally or by nasal spray. **Patient-Centered Care** QSEN
- Teach patients who are taking a corticosteroid for more than a week to not stop the drug suddenly. **Safety** QSEN

Psychosocial Integrity

- Encourage the patient and family to express concerns about a change in health status. **Patient-Centered Care** QSEN
- Explain all treatment procedures, restrictions, and follow-up care to the patient. **Patient-Centered Care** QSEN
- Allow patients who experience a change in physical appearance to mourn this change. **Patient-Centered Care** QSEN

Physiological Integrity

- During the immediate period after a hypophysectomy, teach the patient to avoid activities that increase intracranial pressure (e.g., bending at the waist, straining to have a bowel movement, coughing). **Patient-Centered Care** QSEN
- Measure intake and output accurately on patients who have either diabetes insipidus or syndrome of inappropriate antidiuretic hormone (SIADH). **Evidence-Based Practice** QSEN
- Teach the patient with diabetes insipidus the manifestations of dehydration. **Evidence-Based Practice** QSEN
- Ensure that no patient suspected of having DI is deprived of fluids for more than 4 hours. **Safety** QSEN
- Administer tolvaptan or conivaptan only in the hospital setting. **Safety** QSEN
- Do not confuse prednisone with prednisolone. **Safety** QSEN
- Do not palpate the abdomen of a patient who has a pheochromocytoma. **Safety** QSEN
- Work with physicians, dietitians, and pharmacists to help the patient experiencing problems of the pituitary or adrenal gland to achieve and maintain fluid and electrolyte balance and glucose regulation. **Teamwork and Collaboration** QSEN

CHAPTER 63

Care of Patients with Problems of the Thyroid and Parathyroid Glands

M. Linda Workman

PRIORITY CONCEPTS

- Nutrition
- Thermoregulation

Learning Outcomes

Safe and Effective Care Environment

1. Protect the patient with thyroid or adrenal parathyroid gland problems from injury and complications.

Health Promotion and Maintenance

2. Identify the teaching priorities and nutrition needs for the patient taking hormone replacement therapy for thyroid or parathyroid problems.

Psychosocial Integrity

3. Reduce the psychological impact for the patient and family experiencing thyroid or parathyroid gland problems.

Physiological Integrity

4. Interpret clinical changes and laboratory data to determine the effectiveness of interventions for thyroid problems.
5. Prioritize nursing care for the patient experiencing severe thyrotoxicosis (thyroid storm) and impaired thermoregulation.
6. Coordinate nursing care for the patient during the first 24 hours after

thyroid or parathyroid surgery.
7. Coordinate care for the patient who has hyperparathyroidism.
8. Coordinate care for the patient who has hypoparathyroidism.

 http://evolve.elsevier.com/Iggy/

The hormones secreted from the thyroid and parathyroid glands affect metabolism, thermoregulation, nutrition, electrolyte balance, and excitable membrane activity. Problems of either gland often have many effects and manifestations. Mild disturbances produce subtle problems. More severe disturbances may produce life-threatening problems.

Thyroid Disorders

Hyperthyroidism

Pathophysiology

Hyperthyroidism is excessive thyroid hormone secretion from the thyroid gland. The manifestations of hyperthyroidism are called **thyrotoxicosis**, regardless of the origin of the thyroid hormones. This term is correct even when a person takes a large amount of synthetic thyroid hormones that manifests as thyrotoxicosis although he or she does not have hyperthyroidism. Thyroid hormones increase metabolism in all body organs, producing many different manifestations. Hyperthyroidism can be temporary or permanent, depending on the cause.

The excessive thyroid hormones stimulate most body systems, causing hypermetabolism and increased sympathetic nervous system activity. Manifestations are listed in Chart 63-1.

Chart 63-1 Key Features

Hyperthyroidism

Skin Manifestations

- Diaphoresis (excessive sweating)
- Fine, soft, silky body hair
- Smooth, warm, moist skin
- Thinning of scalp hair

Cardiopulmonary Manifestations

- Palpitations
- Chest pain
- Increased systolic blood pressure
- Tachycardia
- Dysrhythmias
- Rapid, shallow respirations

Gastrointestinal Manifestations

- Weight loss
- Increased appetite
- Increased stools

Neurologic Manifestations

- Blurred or double vision
- Eye fatigue
- Increased tears
- Injected (red) conjunctiva
- Photophobia
- Exophthalmos*
- Eyelid retraction, eyelid lag
- Globe lag
- Hyperactive deep tendon reflexes
- Tremors
- Insomnia

Metabolic Manifestations

- Increased basal metabolic rate
- Heat intolerance
- Low-grade fever
- Fatigue

Psychological/Emotional Manifestations

- Decreased attention span
- Restlessness and irritability
- Emotional lability
- Manic behavior

Reproductive Manifestations

- Amenorrhea
- Increased libido

Other Manifestations

- Goiter
- Wide-eyed or startled appearance (exophthalmos)*
- Enlarged spleen
- Muscle weakness and wasting

*Present in Graves' disease only.

Thyroid hormones stimulate the heart, increasing both heart rate and stroke volume. These responses increase cardiac output, systolic blood pressure, and blood flow (McCance et al., 2014).

Elevated thyroid hormone levels affect protein, fat, and glucose

metabolism. Protein buildup and breakdown are increased, but breakdown exceeds buildup, causing a net loss of body protein known as a **negative nitrogen balance**. Glucose tolerance is decreased, and the patient has **hyperglycemia** (elevated blood glucose levels). Fat metabolism is increased, and body fat decreases. Although the patient has an increased appetite, the increased metabolism causes weight loss and nutrition deficits.

Thyroid hormones are produced in response to the stimulation hormones secreted by the hypothalamus and anterior pituitary glands. Thus oversecretion of thyroid hormones changes the secretion of hormones from the hypothalamus and the anterior pituitary gland through negative feedback (see Chapter 61). Thyroid hormones also have some influence over sex hormone production. Women have menstrual problems and decreased fertility. Both men and women with hyperthyroidism have an increased **libido** (sexual interest).

Etiology and Genetic Risk

Hyperthyroidism has many causes. The most common form of the disease is Graves' disease, also called *toxic diffuse goiter.* **Graves' disease** is an autoimmune disorder resulting from Hashimoto's thyroiditis (HT) (Mandel et al., 2011). HT results in the production of autoantibodies to different substances and structures within the thyroid gland. In Graves' disease, these antibodies (thyroid-stimulating immunoglobulins [TSIs]) attach to the thyroid-stimulating hormone (TSH) receptors on the thyroid tissue. The thyroid gland responds by increasing the glandular cells, which enlarges the gland, forming a **goiter**, and overproduces thyroid hormones (**thyrotoxicosis**). When HT causes production of antibodies to other structures within the thyroid gland, hypothyroidism results. (See the discussion of Etiology on pp. 1291-1292) in the Hypothyroidism section.)

In Graves' disease, all the general manifestations of hyperthyroidism are present. In addition, other manifestations specific to Graves' disease may occur, including **exophthalmos** (abnormal protrusion of the eyes) and **pretibial myxedema** (dry, waxy swelling of the front surfaces of the lower legs that resembles benign tumors or keloids). *Not all patients with a goiter have hyperthyroidism.*

Hyperthyroidism caused by multiple thyroid nodules is termed **toxic multinodular goiter**. The nodules may be enlarged thyroid tissues or benign tumors (adenomas). These patients usually have had a goiter for years. The manifestations are milder than those seen in Graves' disease, and the patient does not have exophthalmos or pretibial myxedema.

Hyperthyroidism also can be caused by excessive use of thyroid replacement hormones. This type of problem is called **exogenous hyperthyroidism**.

Genetic/Genomic Considerations

Patient-Centered Care QSEN

Susceptibility to Graves' disease is associated with mutations in several genes, including *GRD1*, *GRD2*, *GRDX1*, and *GRDX2*. The pattern of inheritance appears to be autosomal recessive with sex limitation to females and reduced penetrance. Graves' disease also has a strong association with other autoimmune disorders, such as diabetes mellitus, vitiligo, and rheumatoid arthritis. It often occurs in both members of identical twins (Online Mendelian Inheritance in Man [OMIM], 2014). Be sure to ask the patient with Graves' disease whether any other family members have the problem.

Incidence and Prevalence

Hyperthyroidism is a common endocrine disorder. Graves' disease can occur at any age but is diagnosed most often in women between 20 and 40 years of age (Mandel et al., 2011). Toxic multinodular goiter usually occurs after the age of 50 years and affects women 4 times more often than men (McCance et al., 2014).

Patient-Centered Collaborative Care

Assessment

History.

Many changes and problems occur because hyperthyroidism affects all body systems, although changes may occur over such a long period that not all patients are aware of them. Record age, gender, and usual weight. The increased metabolic rate affects nutrition. The patient may report a recent unplanned weight loss, an increased appetite, and an increase in the number of bowel movements per day.

A hallmark of hyperthyroidism is poor thermoregulation with heat intolerance. The patient may have increased sweating even when environmental temperatures are comfortable for others. He or she often wears lighter clothing in cold weather. The patient may also report palpitations or chest pain as a result of the cardiovascular effects. Ask

about changes in breathing patterns, because dyspnea (with or without exertion) is common.

Visual changes may be the earliest problem the patient or family notices, especially exophthalmos with Graves' disease (Fig. 63-1). Ask about changes in vision, such as blurring or double vision, and tiring of the eyes.

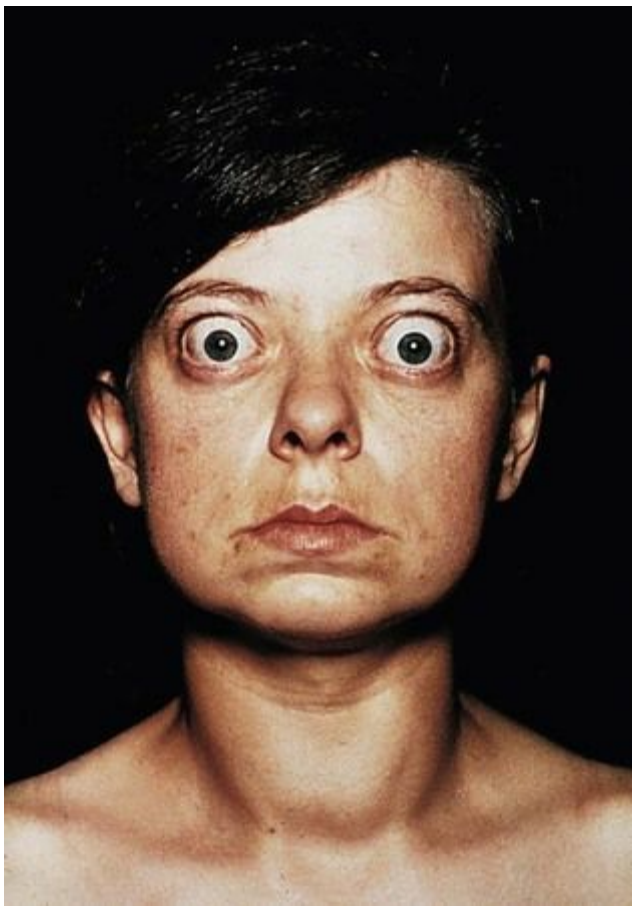

FIG. 63-1 Exophthalmos.

Ask whether there has been a change in energy level or in the ability to perform ADLs. Fatigue and insomnia are common. Family and friends may report that the patient has become irritable or depressed.

Ask women about changes in menses, because amenorrhea or a decreased menstrual flow is common. Initially, both men and women may have an increase in libido, but this changes as the patient becomes more fatigued.

Ask about previous thyroid surgery or radiation therapy to the neck, because some people remain hyperthyroid after surgery or are resistant to radiation therapy. Ask about past and current drugs, especially the use of thyroid hormone replacement or antithyroid drugs.

Physical Assessment/Clinical Manifestations.

Exophthalmos is common in patients with Graves' disease. The wide-eyed or "startled" look is due to edema in the extraocular muscles and increased fatty tissue behind the eye, which pushes the eyeball forward and may cause problems with focusing. Pressure on the optic nerve may impair vision. If the eyelids fail to close completely and the eyes are unprotected, they may become dry and corneal ulcers may develop. Observe the eyes for excessive tearing and a bloodshot appearance. Ask about sensitivity to light (**photophobia**).

Two other eye problems are common in all types of hyperthyroidism: eyelid retraction (eyelid lag) and globe (eyeball) lag. In eyelid lag, the upper eyelid fails to descend when the patient gazes slowly downward. In globe lag, the upper eyelid pulls back faster than the eyeball when the patient gazes upward. During assessment, ask the patient to look down and then up, and document the response.

Observe the size and symmetry of the thyroid gland. Palpate the thyroid gland to assess its size and consistency. In goiter, a generalized thyroid enlargement, the thyroid gland may increase to 4 times its normal size (Fig. 63-2). Goiters are common in Graves' disease and are classified by size (Table 63-1). Bruits (turbulence from increased blood flow) may be heard in the neck with a stethoscope. (See Chapter 61 for thyroid palpation and auscultation.)

TABLE 63-1

Goiter Classification

GOITER GRADE	DESCRIPTION
0	No palpable or visible goiter.
1	Mass is not visible with neck in the normal position.
	Goiter can be palpated and moves up when the patient swallows.
2	Mass is visible as swelling when the neck is in the normal position.
	Goiter is easily palpated and is usually asymmetric.

FIG. 63-2 Goiter.

The cardiovascular problems of hyperthyroidism include increased systolic blood pressure, tachycardia, and dysrhythmias. Usually the diastolic pressure is decreased, causing a widened pulse pressure.

Inspect the hair and skin. Fine, soft, silky hair and smooth, warm, moist skin are common. Many patients notice thinning of scalp hair. Muscle weakness and hyperactive deep tendon reflexes are common. Observe motor movements of the hands for tremors. The patient may appear restless, irritable, and fatigued.

Psychosocial Assessment.

The patient often has wide mood swings, irritability, decreased attention span, and manic behavior. Hyperactivity often leads to fatigue because of the inability to sleep well. Some patients describe their activity as having two modes—either "full speed ahead" or "completely stopped." Ask whether he or she cries or laughs without cause or has difficulty concentrating. Family members often report a change in the patient's mental or emotional status.

Laboratory Assessment.

Testing for hyperthyroidism involves measurement of blood values for triiodothyronine (T_3), thyroxine (T_4), and thyroid-stimulating hormone (TSH). Antibodies to the TSH receptor (thyrotropin receptor [TRAbs]) are measured to diagnose Graves' disease. The most common changes in

laboratory tests for hyperthyroidism are listed in Chart 63-2.

Chart 63-2 Laboratory Profile

Thyroid Function

TEST	NORMAL RANGE FOR ADULTS	SIGNIFICANCE OF ABNORMAL FINDINGS	
		HYPERTHYROIDISM	HYPOTHYROIDISM
Serum T_3	70-205 ng/dL, or 1.2-3.4 SI units	Increased	Decreased
Serum T_4 (total)	4-12 mcg/dL, or 51-154 SI units	Increased	Decreased
Free T_4 index	0.8-2.8 ng/dL, or 10-36 SI units	Increased	Decreased
TSH stimulation test (thyroid stimulation test)	>10% in RAIU or >1.5 mcg/dL	N/A (test differentiates primary from secondary hypothyroidism)	No response in primary hypothyroidism Normal response in secondary hypothyroidism
Thyroid-stimulating immunoglobulins (TSI)	<130% of basal activity	Elevated in Graves' disease Normal in other types of hyperthyroidism	No change
Thyrotropin receptor antibodies (TRAb)	Titer: 0%	80%-95% indicates Graves' disease	No response
TSH	0.3-5.0 μU/mL or 0.3-5.0 SI units	Low in Graves' disease High in secondary or tertiary hyperthyroidism	High in primary disease Low in secondary or tertiary disease

N/A, Nonapplicable; *SI,* International System of Units; *T_3,* triiodothyronine; *T_4,* thyroxine; *TSH,* thyroid-stimulating hormone.

Data from Pagana, K., & Pagana, T. (2014). *Mosby's manual of diagnostic and laboratory tests* (5th ed.). St. Louis: Mosby.

Other Diagnostic Assessment.

Thyroid scan evaluates the position, size, and functioning of the thyroid gland. Radioactive iodine (RAI [^{123}I]) is given by mouth, and the uptake of iodine by the thyroid gland (radioactive iodine uptake [RAIU]) is measured. The half-life of ^{123}I is short, and radiation precautions are not needed. Pregnancy should be ruled out before the scan is performed. The normal thyroid gland has an uptake of 5% to 35% of the given dose at 24 hours. RAIU is increased in hyperthyroidism and can be used to identify active thyroid nodules. It is no longer the most common test for thyroid function (Mandel et al., 2011).

Ultrasonography of the thyroid gland can determine its size and the general composition of any masses or nodules. This procedure takes about 30 minutes to perform and is painless.

Electrocardiography (ECG) usually shows tachycardia. Other ECG changes with hyperthyroidism include atrial fibrillation, dysrhythmias, and changes in P and T waveforms.

NCLEX Examination Challenge

Physiological Integrity

Which manifestations are most often seen in general hyperthyroidism? **Select all that apply.**

A Increased appetite
B Cold intolerance
C Constipation
D Eyelid retraction
E Insomnia
F Palpitations
G Tremors
H Weight gain

Interventions

Because Graves' disease is the most common form of hyperthyroidism, the interventions discussed in the following sections include those specific for the problems that occur with Graves' disease. The purposes of medical management are to decrease the effect of thyroid hormone on cardiac function and to reduce thyroid hormone secretion. The priorities for nursing care focus on monitoring for complications, reducing stimulation, promoting comfort, and teaching the patient and family about therapeutic drugs and procedures.

Nonsurgical Management.

Monitoring includes measuring the patient's apical pulse, blood pressure (BP), and temperature at least every 4 hours. Instruct the patient to report immediately any palpitations, dyspnea, vertigo, or chest pain. Increases in temperature may indicate a rapid worsening of the patient's condition and the onset of *thyroid storm,* a life-threatening event that occurs with uncontrolled hyperthyroidism and is characterized by high fever and severe hypertension. *Immediately report a temperature increase of even one degree Fahrenheit.* If this task is delegated to unlicensed assistive personnel (UAP), instruct them to report the patient's temperature to you as soon as it has been obtained. If temperature is elevated, immediately assess the patient's cardiac status. If the patient has a cardiac monitor, check for dysrhythmias.

Reducing stimulation helps prevent increasing the manifestations of hyperthyroidism and the risk for cardiac complications. Encourage the patient to rest. Keep the environment as quiet as possible by closing the door to his or her room, limiting visitors, and eliminating or postponing nonessential care or treatments.

Promoting comfort includes reducing the room temperature to decrease discomfort caused by heat intolerance. Instruct UAP to ensure the patient always has a fresh pitcher of ice water and to change the bed linen whenever it becomes damp from diaphoresis. Suggest that the patient take a cool shower or sponge bath several times each day. For patients with exophthalmos, prevent eye dryness by encouraging the use of artificial tears.

Drug therapy with antithyroid drugs is the initial treatment for hyperthyroidism. Chart 63-3 lists teaching priorities for the patient receiving drug therapy for hyperthyroidism. The preferred drugs are the thionamides, especially methimazole (Tapazole). Propylthiouracil (PTU) is used less often because of its liver toxic effects (Mandel et al., 2011). These drugs block thyroid hormone production by preventing iodide binding in the thyroid gland. The response to these drugs is delayed because the patient may have large amounts of stored thyroid hormones that continue to be released.

Chart 63-3 Common Examples of Drug Therapy

Hyperthyroidism

DRUG/USUAL DOSAGE	NURSING INTERVENTION	RATIONALE
Thionamides Reduce manifestations of hyperthyroidism by preventing the new formation of thyroid hormones by inhibiting thyroid binding of iodide.		
Propylthiouracil (PTU, Propyl-Thyracil) Initial dose 100-150 mg orally every 8 hr Maintenance dose 50-150 mg orally every 8 hr	Teach patient to avoid crowds and people who are ill.	Drug reduces blood cell counts and the immune response, increasing the risk for infection.
	Teach patient to report darkening of the urine, a yellow appearance to the skin or whites of the eyes.	These manifestations may indicate liver toxicity or failure, a possible side effect of the drug.
	Teach patient to check for weight gain, slow heart rate, and cold intolerance.	These indicate hypothyroidism and may require a lower drug dose.
Methimazole (Northyx, Tapazole) Initial dose 5-20 mg orally every 8 hr Maintenance dose 1-4 mg orally every 8 hr	Remind women to notify their health care providers if they become pregnant.	This drug causes birth defects and should not be used during pregnancy.
	Teach patient to avoid crowds and people who are ill.	Drug reduces blood cell counts and the immune response, increasing the risk for infection.
	Teach patient to check for weight gain, slow heart rate, and cold intolerance.	These indicate hypothyroidism and may require a lower drug dose.
Iodine and Iodine-Containing Agents The sudden excess of iodine rapidly inhibits thyroid hormone release and dramatically (but temporarily) resolves the cardiac and other manifestations of hyperthyroidism. For initial treatment of severe hyperthyroidism or thyroid storm.		
Lugol's solution Saturated solution of potassium iodide (SSKI) Dosages vary depending on the agent, how the drug is administered, and the severity of the manifestations	Administer these drugs orally 1 hour *after* a thionamide has been given.	Initially, the iodine agents can cause an increase in the production of thyroid hormones. Giving a thionamide first prevents this initial increase in thyroid hormone production.
	Check patient for a fever or rash, and ask about a metallic taste, mouth sores, sore throat, or GI distress.	These are manifestations of *iodism*, a toxic effect of the drugs, and may require that the drug be discontinued.

Nursing Safety Priority QSEN

Drug Alert

Although similar in action, methimazole and propylthiouracil are not interchangeable. The dosages for propylthiouracil are much higher than

those for methimazole.

Nursing Safety Priority QSEN

Drug Alert

Methimazole can cause birth defects and should not be used during pregnancy, especially during the first trimester. Instruct women to notify their health care provider if pregnancy occurs.

Iodine preparations may be used for short-term therapy before surgery. They decrease blood flow through the thyroid gland, reducing the production and release of thyroid hormones. Improvement usually occurs within 2 weeks, but it may be weeks before metabolism returns to normal. This treatment can result in hypothyroidism, and the patient is monitored closely for the need to adjust the drug regimen.

Beta-adrenergic blocking drugs such as propranolol (Inderal, Detensol) may be used as supportive therapy. These drugs relieve diaphoresis, anxiety, tachycardia, and palpitations but do not inhibit thyroid hormone production. See Chapters 34 and 36 for a discussion of the actions and nursing implications of these agents.

Radioactive iodine (RAI) therapy is not used in pregnant women because ^{131}I crosses the placenta and can damage the fetal thyroid gland. The patient with hyperthyroidism may receive RAI in the form of oral ^{131}I. The dosage depends on the thyroid gland's size and sensitivity to radiation. The thyroid gland picks up the RAI, and some of the cells that produce thyroid hormone are destroyed by the local radiation. Because the thyroid gland stores thyroid hormones to some degree, the patient may not have complete symptom relief until 6 to 8 weeks after RAI therapy. Additional drug therapy for hyperthyroidism is still needed during the first few weeks after RAI treatment.

RAI therapy is performed on an outpatient basis. One dose may be sufficient, although some patients need a second or third dose. The radiation dose is low and is usually completely eliminated within a month; however, the source is unsealed and some radioactivity is present in the patient's body fluids and stool for a few weeks after therapy. Radiation precautions are needed to prevent exposure to family members and other people. Chart 63-4 lists precautions to teach the patient during the first few weeks after receiving ^{131}I.

Chart 63-4

Patient and Family Education: Preparing for Self-Management

Safety Precautions for the Patient Receiving an Unsealed Radioactive Isotope

- Use a toilet that is not used by others for at least 2 weeks after receiving the radioactive iodine.
- Sit to urinate (males and females) to avoid splashing the seat, walls, and floor.
- Flush the toilet 3 times after each use.
- If urine is spilled on the toilet seat or floor, use paper tissues or towels to clean it up, bag them in sealable plastic bags, and take them to the hospital's radiation therapy department.
- Men with urinary incontinence should use condom catheters and a drainage bag rather than absorbent gel-filled briefs or pads.
- Women with urinary incontinence should use facial tissue layers in their clothing to catch the urine rather than absorbent gel-filled briefs or pads. These tissues should then be flushed down the toilet exclusively used by the patient.
- Using a laxative on the second and third days after receiving the radioactive drug helps you excrete the contaminated stool faster (this also decreases the exposure of your abdominal organs to radiation).
- Wear only machine-washable clothing, and wash these items separately from others in your household.
- After washing your clothing, run the washing machine for a full cycle on empty before it is used to wash the clothing of others.
- Avoid close contact with pregnant women, infants, and young children for the first week after therapy. Remain at least 3 feet (about 1 meter) away from these people, and limit your exposure to them to no more than 1 hour daily.
- Some radioactivity will be in your saliva during the first week after therapy. Precautions to avoid exposing others to this contamination (both household members and trash collectors) include:
  - Not sharing toothbrushes or toothpaste tubes
  - Using disposable tissues rather than cloth handkerchiefs, and either flushing used ones down the toilet or keeping them in a plastic bag and turning them in to the radiation department of the hospital for disposal
  - Using disposable utensils, plates, and cups

- Selecting foods that can be eaten completely and do not result in a saliva-coated remnant (Foods to avoid are fruit with a core that can be contaminated, meat with a bone [e.g., chicken wings or legs, ribs])

Data from Al-Shakhrah, I. (2008). Radioprotection using iodine-131 for thyroid cancer and hyperthyroidism: A review. *Clinical Journal of Oncology Nursing, 12*(6), 905-912.

The degree of thyroid destruction varies. Some patients become hypothyroid as a result of treatment. The patient then needs lifelong thyroid hormone replacement. All patients who have undergone RAI therapy should be monitored regularly for changes in thyroid function.

Surgical Management.

Surgery to remove all or part of the thyroid gland is the preferred management for Graves' disease. It is also used when a large goiter causes tracheal or esophageal compression or when hyperthyroidism does not respond to drug therapy. Removal of all (**total thyroidectomy**) or part (**subtotal thyroidectomy**) of the thyroid tissue decreases the production of thyroid hormones. After a total thyroidectomy, patients must take lifelong thyroid hormone replacement.

Preoperative Care.

The patient is treated with thionamide drug therapy first to have near-normal thyroid function (**euthyroid**) before thyroid surgery. Iodine preparations also are used to decrease thyroid size and vascularity, thereby reducing the risk for hemorrhage and the potential for thyroid storm during surgery.

Hypertension, dysrhythmias, and tachycardia must be controlled before surgery. The patient with hyperthyroidism may need to follow a high-protein, high-carbohydrate diet for days or weeks before surgery.

Teach the patient to perform deep-breathing exercises. Stress the importance of supporting the neck when coughing or moving by placing both hands behind the neck to reduce strain on the incision. Explain that hoarseness may be present for a few days as a result of endotracheal tube placement during surgery.

Reassure the patient by calmly explaining the surgery and the care after surgery. Remind him or her that a drain as well as a dressing may be in place after surgery. Answer any questions the patient and family have.

Operative Procedures.

Many thyroidectomies are now performed as minimally invasive

surgeries or mini-incision surgeries. With these surgeries, as with the traditional open approach, the parathyroid glands and recurrent laryngeal nerves are avoided to reduce the risk for complications and injury. Usually, general anesthesia is used even for the minimally invasive techniques.

With a subtotal thyroidectomy, the remaining thyroid tissues are sutured to the trachea. With a total thyroidectomy, the entire thyroid gland is removed but the parathyroid glands are left with an intact blood supply to prevent causing hypoparathyroidism.

Postoperative Care.

Monitoring the patient for complications is the most important nursing action after thyroid surgery. Monitor vital signs every 15 minutes until the patient is stable and then every 30 minutes. Increase or decrease the monitoring of vital signs based on changes in the patient's condition.

Assess the patient's level of discomfort. Use pillows to support the head and neck. Place the patient, while he or she is awake, in a semi-Fowler's position. Avoid positions that cause neck extension. Give prescribed drugs for pain control as needed.

Assist the patient to deep-breathe every 30 minutes to 1 hour. Suction oral and tracheal secretions when necessary.

Thyroid surgery can cause hemorrhage, respiratory distress, parathyroid gland injury (resulting in **hypocalcemia** [low serum calcium levels] and **tetany** [hyperexcitability of nerves and muscles]), damage to the laryngeal nerves, and thyroid storm. Remain alert to the potential for complications, and identify manifestations early.

Hemorrhage is most likely to occur during the first 24 hours after surgery. Inspect the neck dressing and behind the patient's neck for blood. A drain may be present, and a moderate amount of serosanguineous drainage is normal. Hemorrhage may be seen as bleeding at the incision site or as respiratory distress caused by tracheal compression with swelling of the site.

Respiratory distress can result from swelling, tetany, or damage to the laryngeal nerve resulting in spasms. Laryngeal **stridor** (harsh, high-pitched respiratory sounds) is heard in acute respiratory obstruction. Keep emergency tracheostomy equipment in the patient's room. Check that oxygen and suctioning equipment are nearby and in working order.

 **Nursing Safety Priority** QSEN

Critical Rescue

When stridor, dyspnea, or other symptoms of obstruction appear after thyroid surgery, notify the Rapid Response Team.

Hypocalcemia and tetany may occur if the parathyroid glands are removed or damaged or their blood supply is impaired during thyroid surgery, resulting in decreased parathyroid hormone (PTH) levels. Ask the patient hourly about tingling around the mouth or of the toes and fingers. Assess for muscle twitching as a sign of calcium deficiency. Calcium gluconate or calcium chloride for IV use should be available in an emergency situation. (For information on the later signs of hypocalcemia, see the discussion of postoperative care on p. 1297 in the Hyperparathyroidism section and p. 1298 in the Assessment discussion in the Hypoparathyroidism section. Hypocalcemia is also discussed in Chapter 11.)

Laryngeal nerve damage may occur during surgery. This problem results in hoarseness and a weak voice. Assess the patient's voice at 2-hour intervals, and document any changes. Reassure the patient that hoarseness is usually temporary.

Thyroid storm or **thyroid crisis** is a life-threatening event that occurs in patients with uncontrolled hyperthyroidism and occurs most often with Graves' disease. Manifestations develop quickly. It is often triggered by stressors such as trauma, infection, diabetic ketoacidosis, and pregnancy. Other conditions that can lead to thyroid storm include vigorous palpation of the goiter, exposure to iodine, and radioactive iodine (RAI) therapy. Although thyroid storm after surgery is less common because of drug therapy before thyroid surgery, it can still occur.

The manifestations of thyroid storm are caused by excessive thyroid hormone release, which dramatically increases metabolic rate. *Key manifestations include fever, tachycardia, and systolic hypertension.* The patient may have abdominal pain, nausea, vomiting, and diarrhea. Often he or she is very anxious and has tremors. As the crisis progresses, the patient may become restless, confused, or psychotic and may have seizures, leading to coma. *Even with treatment, thyroid storm may lead to death.*

Nursing Safety Priority QSEN

Critical Rescue

When caring for a patient with hyperthyroidism, even after a

thyroidectomy, immediately report a temperature increase of even 1° F because it may indicate an impending thyroid crisis.

Emergency measures to prevent death vary with the intensity and type of manifestations. Interventions focus on maintaining airway patency, providing adequate ventilation, reducing fever, and stabilizing the hemodynamic status. Chart 63-5 outlines the best practices for emergency management of thyroid storm.

Chart 63-5 Best Practice for Patient Safety & Quality Care QSEN

Emergency Care of the Patient During Thyroid Storm

- Maintain a patent airway and adequate ventilation.
- Give oral antithyroid drugs as prescribed: methimazole (Tapazole), up to 60 mg daily; propylthiouracil (PTU, Propyl-Thyracil), 300 to 900 mg daily.
- Administer sodium iodide solution, 2 g IV daily as prescribed.
- Give propranolol (Inderal, Detensol), 1 to 3 mg IV as prescribed. Give slowly over 3 minutes. The patient should be connected to a cardiac monitor, and a central venous pressure catheter should be in place.
- Give glucocorticoids as prescribed: hydrocortisone, 100 to 500 mg IV daily; prednisone, 4 to 60 mg IV daily; or dexamethasone, 2 mg IM every 6 hours.
- Monitor continually for cardiac dysrhythmias.
- Monitor vital signs every 30 minutes.
- Provide comfort measures, including a cooling blanket.
- Give non-salicylate antipyretics as prescribed.
- Correct dehydration with normal saline infusions.
- Apply cooling blanket or ice packs to reduce fever.

Eye and vision problems of Graves' disease are not corrected by treatment for hyperthyroidism, and management is symptomatic. Teach the patient with mild problems to elevate the head of the bed at night and to use artificial tears. If **photophobia** (sensitivity to light) is present, dark glasses may be helpful. For those who cannot close the eyelids completely, recommend gently taping the lids closed with nonallergenic tape at bedtime. These actions prevent eye irritation and injury. If pressure behind the eye continues and forces the eye forward, the blood

supply to the eye can be compromised, leading to ischemia and blindness.

In severe cases, short-term steroid therapy is prescribed to reduce swelling and halt the infiltrative process. Prednisone (Deltasone, Winpred) is given in high doses (often 120 mg daily) at first and then is tapered down according to the patient's response. Explain the need to reduce the prednisone gradually, and review its side effects with the patient.

Other management strategies include external radiation combined with lower-dose steroid therapy. Surgical intervention (orbital decompression) may be needed if loss of sight or damage to the eyeball is possible. Rituximab injections are an experimental approach for this problem (Mandel et al., 2011).

Health teaching includes reviewing with the patient and family the manifestations of hyperthyroidism and instructing the patient to report any increase or recurrence of these. Also teach about the manifestations of hypothyroidism (discussed in the next section) and the need for thyroid hormone replacement. Reinforce the need for regular follow-up because hypothyroidism can occur several years after radioactive iodine therapy.

The discharged patient may continue to have mood changes as a result of hyperthyroidism. Explain the reason for mood swings to the patient and family, and reassure them that these will decrease with continued treatment.

NCLEX Examination Challenge

Safe and Effective Care Environment

For which assessment finding in a client who has severe hyperthyroidism does the nurse notify the Rapid Response Team?

A An increase in premature ventricular heart contractions from 4 per minute to 5 per minute

B An increase in or widening of pulse pressure from 40 mm Hg to 46 mm Hg

C An increase in temperature from 99.5° F (37.5° C) to 101.3° F (38.5° C)

D An increase of 20 mL of urine output per hour

Hypothyroidism

Pathophysiology

The manifestations of hypothyroidism (Chart 63-6) are the result of decreased metabolism from low levels of thyroid hormones. Thyroid cells may fail to produce sufficient levels of thyroid hormones (THs) for several reasons. Sometimes the cells themselves are damaged and no longer function normally. At other times the thyroid cells are functional but the person does not ingest enough of the substances needed to make thyroid hormones, especially iodide and tyrosine. When the production of thyroid hormones is too low or absent, the blood levels of TH are very low and the patient has a decreased metabolic rate. This lowered metabolism causes the hypothalamus and anterior pituitary gland to make stimulatory hormones, especially thyroid-stimulating hormone (TSH), in an attempt to trigger hormone release from the poorly responsive thyroid gland. The TSH binds to thyroid cells and causes the thyroid gland to enlarge, forming a goiter, although thyroid hormone production does not increase.

Chart 63-6 Key Features

Hypothyroidism

Skin Manifestations

- Cool, pale or yellowish, dry, coarse, scaly skin
- Thick, brittle nails
- Dry, coarse, brittle hair
- Decreased hair growth, with loss of eyebrow hair
- Poor wound healing

Pulmonary Manifestations

- Hypoventilation
- Pleural effusion
- Dyspnea

Cardiovascular Manifestations

- Bradycardia
- Dysrhythmias
- Enlarged heart
- Decreased activity tolerance
- Hypotension

Metabolic Manifestations

- Decreased basal metabolic rate

- Decreased body temperature
- Cold intolerance

Psychological/Emotional Manifestations

- Apathy
- Depression
- Paranoia

Gastrointestinal Manifestations

- Anorexia
- Weight gain
- Constipation
- Abdominal distention

Neuromuscular Manifestations

- Slowing of intellectual functions:
  - Slowness or slurring of speech
  - Impaired memory
  - Inattentiveness
- Lethargy or somnolence
- Confusion
- Hearing loss
- Paresthesia (numbness and tingling) of the extremities
- Decreased tendon reflexes
- Muscle aches and pain

Reproductive Manifestations

Women

- Changes in menses (amenorrhea or prolonged menstrual periods)
- Anovulation
- Decreased libido

Men

- Decreased libido
- Impotence

Other Manifestations

- Periorbital edema
- Facial puffiness
- Nonpitting edema of the hands and feet
- Hoarseness
- Goiter (enlarged thyroid gland)

- Thick tongue
- Increased sensitivity to opioids and tranquilizers
- Weakness, fatigue
- Decreased urine output
- Easy bruising
- Iron deficiency anemia
- Vitamin deficiencies

Most tissues and organs are affected by the low metabolic rate caused by hypothyroidism. Cellular energy is decreased, and metabolites that are compounds of proteins and sugars called *glycosaminoglycans (GAGs)* build up inside cells. This GAG buildup increases the mucus and water, forms cellular edema, and changes organ texture. The edema is mucinous and called **myxedema**, rather than edema caused by water alone. This edema changes the patient's appearance (Fig. 63-3). Nonpitting edema forms everywhere, especially around the eyes, in the hands and feet, and between the shoulder blades. The tongue thickens, and edema forms in the larynx, making the voice husky. All general physiologic function is decreased.

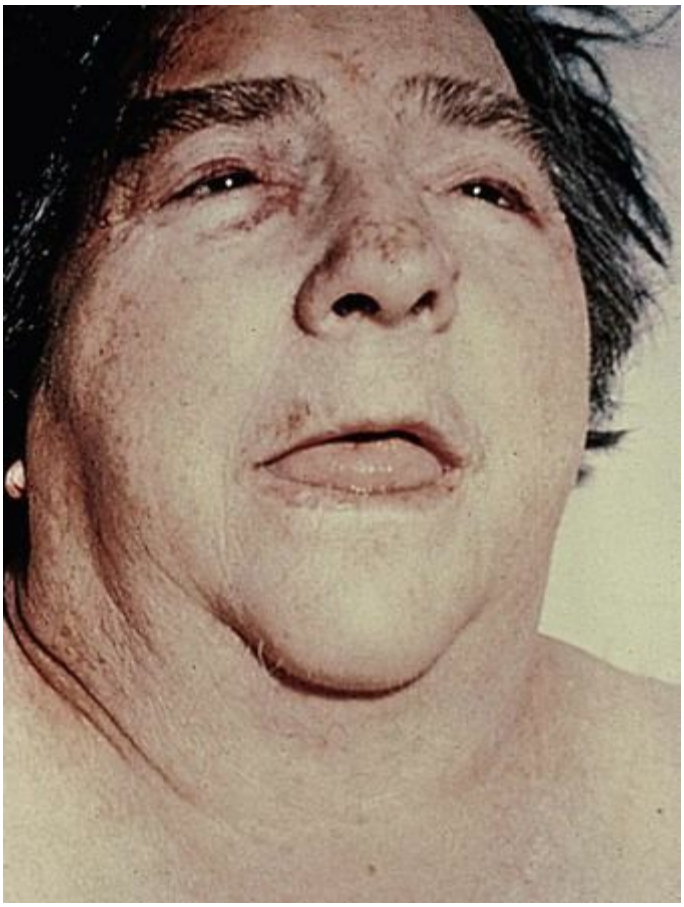

FIG. 63-3 Myxedema.

Myxedema coma is a rare, serious complication of untreated or poorly treated hypothyroidism. The decreased metabolism causes the heart muscle to become flabby and the chamber size to increase. The result is decreased cardiac output and decreased perfusion to the brain and other vital organs, which makes the already slowed cellular metabolism worse, resulting in tissue and organ failure. *The mortality rate for myxedema coma is extremely high, and this condition is a life-threatening emergency.* Myxedema coma can be caused by a variety of events, drugs, or conditions.

Etiology

Most cases of hypothyroidism in the United States occur as a result of thyroid surgery and radioactive iodine (RAI) treatment of hyperthyroidism. Worldwide, hypothyroidism is common in areas where the soil and water have little natural iodide, causing endemic goiter. Hypothyroidism is also caused by a variety of other conditions (Table 63-2).

TABLE 63-2

Causes of Hypothyroidism

Primary Causes
Decreased Thyroid Tissue
• Surgical or radiation-induced thyroid destruction • Autoimmune thyroid destruction • Congenital poor thyroid development • Cancer (thyroidal or metastatic)
Decreased Synthesis of Thyroid Hormone

• Endemic iodine deficiency
• Drugs:
  • Lithium
  • Propylthiouracil
  • Sodium or potassium perchlorate
  • Aminoglutethimide

Secondary Causes
Inadequate Production of Thyroid-Stimulating Hormone
• Pituitary tumors, trauma, infections, or infarcts • Congenital pituitary defects • Hypothalamic tumors, trauma, infections, or infarcts

Incidence and Prevalence

Hypothyroidism occurs most often in women between 30 and 60 years of age. Women are affected 7 to 10 times more often than men (McCance et al., 2014).

❖ Patient-Centered Collaborative Care

◆ Assessment

History.

A decrease in thyroid hormones produces many manifestations related to decreased metabolism. However, changes may have occurred slowly and the patient may not have noticed them. Ask him or her to compare activity now with that of a year ago. The patient often reports an increase in time spent sleeping, sometimes up to 14 to 16 hours daily. Generalized weakness, anorexia, muscle aches, and paresthesias may also be present. Constipation and cold intolerance are common. Ask whether more blankets at night or extra clothing, even in warm weather, has been needed. Some changes may be subtle and are often missed, especially in older adults.

Both men and women may report a decreased libido. Women may have had difficulty becoming pregnant or have changes in menses (heavy, prolonged bleeding or amenorrhea). Men may have problems with

impotence and infertility.

Ask about current or previous use of drugs, such as lithium, thiocyanates, aminoglutethimide, sodium or potassium perchlorate, or cobalt. All these drugs can impair thyroid hormone production. In particular, the cardiac drug *amiodarone* (Cordarone) often has damaging effects on the thyroid gland (Mosher, 2011). Also ask whether the patient has ever been treated for hyperthyroidism and what specific treatment was used.

Physical Assessment/Clinical Manifestations.

Observe the patient's overall appearance. Fig. 63-3 shows the typical appearance of an adult with hypothyroidism. Common changes include coarse features, edema around the eyes and face, a blank expression, and a thick tongue. The patient's overall muscle movement is slow. He or she may not speak clearly and may take a longer time to respond to questions.

Cardiac and respiratory functions are decreased. Heart rate may be below 60 beats per minute, and respiratory rate may be slow. Body temperature is often lower than 97° F.

Weight gain is very common, even when the person is not overeating. Weigh the patient, and ask whether the result is the same or different from his or her weight a year ago.

Depending on the cause of hypothyroidism, the patient may have a goiter. However, some types of hypothyroidism do not induce a goiter and some types of hyperthyroidism do. The presence of a goiter suggests a thyroid problem but does not indicate whether the problem is excessive hormone secretion or too little hormone secretion.

Psychosocial Assessment.

Hypothyroidism causes many problems in psychosocial functioning. Depression is the most common reason for seeking medical attention. Family members often bring the patient for the initial evaluation. The patient may be too lethargic, apathetic, or drowsy to recognize changes in his or her condition. Families may report that the patient is withdrawn and has reduced mental function. Assess his or her attention span and memory, both of which can be impaired by hypothyroidism. The mental slowness can contribute to social isolation.

Laboratory Assessment.

Laboratory findings for hypothyroidism are the opposite of those for

hyperthyroidism. Triiodothyronine (T_3) and thyroxine (T_4) serum levels are decreased. TSH levels are high in primary hypothyroidism but can be decreased or near normal in patients with secondary hypothyroidism (see Chart 63-2). Patients older than 80 years may have lower-than-normal levels of thyroid hormones without manifestations of hypothyroidism, and hormone replacement is not used until other manifestations are present (Touhy & Jett, 2014).

Analysis

The priority NANDA-I nursing diagnoses and collaborative problems for patients with hypothyroidism include:
1. Impaired Gas Exchange related to decreased energy, obesity, muscle weakness, and fatigue (NANDA-I)
2. Hypotension related to altered heart rate and rhythm as a result of decreased myocardial metabolism
3. Altered cognitive functioning related to impaired brain metabolism and edema
4. Potential for myxedema coma

Planning and Implementation

Both cardiac and respiratory problems are serious, and their management is a priority. The most common cause of death among patients with myxedema coma is respiratory failure.

Improving Gas Exchange

Planning: Expected Outcomes.

The patient with hypothyroidism is expected to have improved gas exchange. Indicators include:
- Maintenance of Spo_2 of at least 90%
- Absence of cyanosis
- Maintenance of cognitive orientation

Interventions.

Observe and record the rate and depth of respirations. Measure oxygen saturation by pulse oximetry, and apply oxygen if the patient has hypoxemia. Auscultate the lungs for a decrease in breath sounds. If hypothyroidism is severe, the patient may require ventilatory support. Severe respiratory distress often occurs with myxedema coma.

Sedating a patient with hypothyroidism can make gas exchange worse

and is avoided if possible. When sedation is needed, the dosage is reduced because hypothyroidism increases sensitivity to these drugs. For the patient receiving sedation, assess for adequate gas exchange.

Preventing Hypotension

Planning: Expected Outcomes.

The patient with hypothyroidism is expected to have adequate cardiovascular function and tissue perfusion. Indicators include that the patient:

- Maintains heart rate above 60 beats/min
- Maintains blood pressure within normal limits for his or her age and general health
- Has no dysrhythmias, peripheral edema, or neck vein distention

Interventions.

The patient with hypothyroidism can have decreased blood pressure, bradycardia, and dysrhythmias. Nursing priorities are monitoring for condition changes and preventing complications. Monitor blood pressure and heart rate and rhythm, and observe for manifestations of shock (e.g., hypotension, decreased urine output, changes in mental status).

If hypothyroidism is chronic, the patient may have cardiovascular disease. *Instruct the patient to report episodes of chest pain or chest discomfort immediately.*

The patient with hypothyroidism requires lifelong thyroid hormone replacement. Synthetic hormone preparations are usually prescribed. The most common is levothyroxine sodium (Synthroid, T_4, Eltroxin). Therapy is started with low doses and gradually increased over a period of weeks. *The patient with more severe symptoms of hypothyroidism is started on the lowest dose of thyroid hormone replacement.* This precaution is very important when the patient has known cardiac problems. Starting at too high a dose or increasing the dose too rapidly can cause severe hypertension, heart failure, and myocardial infarction (Brent & Davies, 2011). *Teach patients, as well as their families, who are beginning thyroid replacement hormone therapy to take the drug exactly as prescribed and not to change the dose or schedule without consulting the prescriber. Also teach them not to switch brands because the response to different drug brands can vary.*

Assess the patient for chest pain and dyspnea during initiation of therapy. The final dosage is determined by blood levels of TSH and the patient's physical responses. The dosage and time required for symptom relief vary with each patient. Monitor for and teach the patient and family

about the manifestations of hyperthyroidism (see Chart 63-1), which can occur with replacement therapy.

Supporting Cognition

Planning: Expected Outcomes.

The patient with hypothyroidism is expected to have cognitive function at the same level as before the thyroid problem started. Indicators include that the patient consistently:

- Demonstrates immediate memory
- Communicates clearly and appropriately for age and ability
- Is attentive during conversations

Interventions.

Observe for and record the presence and severity of lethargy, drowsiness, memory deficit, poor attention span, and difficulty communicating. These problems should decrease with thyroid hormone treatment, and mental awareness usually returns to the patient's normal level within 2 weeks. Orient the patient to person, place, and time, and explain all procedures slowly and carefully. Provide a safe environment.

Family members may have difficulty coping with the patient's behavior. Encourage them to accept the mood changes and mental slowness as manifestations of the disease. Remind the family that these problems should improve with therapy.

Preventing Myxedema Coma.

Any patient with hypothyroidism who has any other health problem or who is newly diagnosed is at risk for myxedema coma. Factors leading to myxedema coma include acute illness, surgery, chemotherapy, discontinuing thyroid replacement therapy, and the use of sedatives or opioids. Problems that often occur with this condition include:

- Coma
- Respiratory failure
- Hypotension
- Hyponatremia
- Hypothermia
- Hypoglycemia

 **Nursing Safety Priority** QSEN

Action Alert

Myxedema coma can lead to shock, organ damage, and death. Assess the patient with hypothyroidism at least every 8 hours for changes that indicate increasing severity, especially changes in mental status, and report these promptly to the health care provider.

Treatment is instituted quickly according to the patient's manifestations and without waiting for laboratory confirmation. Best practices for emergency care of the patient with myxedema coma are listed in Chart 63-7.

Chart 63-7 Best Practice for Patient Safety & Quality Care QSEN

Emergency Care of the Patient During Myxedema Coma

- Maintain a patent airway.
- Replace fluids with IV normal or hypertonic saline as prescribed.
- Give levothyroxine sodium IV as prescribed.
- Give glucose IV as prescribed.
- Give corticosteroids as prescribed.
- Check the patient's temperature hourly.
- Monitor blood pressure hourly.
- Cover the patient with warm blankets.
- Monitor for changes in mental status.
- Turn every 2 hours.
- Institute Aspiration Precautions.

Community-Based Care

Hypothyroidism is usually chronic. Patients usually live in the community and are managed on an outpatient basis. Patients in acute care settings, subacute care settings, and rehabilitation centers may have long-standing hypothyroidism in addition to other health problems. Ensure that whoever is responsible for overseeing the patient's daily care is aware of the condition and understands its management.

Home Care Management.

The patient with hypothyroidism does not usually require changes in the home unless cognition has decreased to the point that he or she poses a danger to himself or herself. Activity intolerance and fatigue may necessitate one-floor living for a short time. If manifestations have not

improved before discharge, discuss the need for extra heat or clothing because of cold intolerance. The patient may need help with the drug regimen. Discuss this issue with the family and patient, and develop a plan for drug therapy. One person should be clearly designated as responsible for drug preparation and delivery so that doses are neither missed nor duplicated.

Self-Management Education.

The most important educational need for the patient with hypothyroidism is about hormone replacement therapy and its side effects. Emphasize the need for lifelong drugs, and review the manifestations of both hyperthyroidism and hypothyroidism. Teach the patient to wear a medical alert bracelet. Teach the patient and family when to seek medical interventions for dosage adjustment and the need for periodic blood tests of hormone levels. Instruct the patient to not take any over-the-counter (OTC) drugs without consulting his or her health care provider because thyroid hormone preparations interact with many other drugs. Older patients may need additional information about the effects of aging on the thyroid gland (Chart 63-8).

Chart 63-8 Nursing Focus on the Older Adult

Thyroid Problems

Teach the patient these facts about changes in the thyroid gland related to aging:

- Thyroid hormone secretion decreases with age, but the hormone level remains stable because storage site clearance of the hormone also decreases with age.
- The basal metabolic rate decreases with age, which changes body composition from predominantly muscular to predominantly fatty.
- Older patients require lower doses of replacement thyroid hormone. Too large a dose may adversely affect the heart muscle.

Advise the patient to maintain nutrition by eating a well-balanced diet with adequate fiber and fluid intake to prevent constipation. Caution him or her that use of fiber supplements may interfere with the absorption of thyroid hormone. Thyroid hormones should be taken on an empty stomach. Remind the patient about the importance of adequate rest.

Assist the family in understanding that the time required for resolution of hypothyroidism varies. During this time the patient may

continue to have mental slowness. Teach the family to orient the patient often and to explain everything clearly, simply, and as often as needed.

Teach the patient to monitor himself or herself for therapy effectiveness. The two easiest parameters to check are need for sleep and bowel elimination. When the patient requires more sleep and is constipated, the dose of replacement hormone may need to be increased. When the patient has difficulty getting to sleep and has more bowel movements than normal for him or her, the dose may need to be decreased.

Health Care Resources.

Immediately after returning home, the patient may need a support person to stay and provide day and night attention. Contact with the health care team is needed for follow-up and identification of potential problems. The patient taking thyroid drugs may have manifestations of hypothyroidism if the dosage is inadequate or may have manifestations of hyperthyroidism if the dosage is too high. A home care nurse performs a focused assessment at every home visit to the patient with thyroid dysfunction (Chart 63-9).

Chart 63-9 Focused Assessment

The Patient with Thyroid Dysfunction

Assess cardiovascular status:

- Vital signs, including apical pulse, pulse pressure, presence or absence of orthostatic hypotension, and the quality and rhythm of peripheral pulses
- Presence or absence of peripheral edema
- Weight gain or loss

Assess cognition and mental status:

- Level of consciousness
- Orientation to time, place, and person
- Ability to accurately read a seven-word sentence containing no words greater than three syllables
- Ability to count backward from 100 by 3s

Assess condition of skin and mucous membranes:

- Moistness of skin, most reliable on chest and back
- Skin temperature and color

Assess neuromuscular status:

- Reactivity of patellar and biceps reflexes

- Oral temperature
- Handgrip strength
- Steadiness of gait
- Presence or absence of fine tremors in the hand

Ask about:

- Sleep in the past 24 hours
- Patient warm enough or too warm indoors
- 24-hour diet recall
- 24-hour activity recall
- Over-the-counter and prescribed drugs taken
- Last bowel movement

Assess patient's understanding of illness and adherence with therapy:

- Manifestations to report to health care provider
- Drug therapy plan (correct timing and dose)

Evaluation: Outcomes

Evaluate the care of the patient with hypothyroidism based on the identified priority patient problems. The expected outcomes are that with proper management the patient should:

- Maintain normal cardiovascular function
- Maintain adequate respiratory function
- Experience improvement in thought processes

Specific indicators for these outcomes are listed for each patient problem in the Planning and Implementation section (see earlier).

Clinical Judgment Challenge

Patient-Centered Care; Safety QSEN

The patient, a 45-year-old former school teacher, is residing in a skilled nursing facility to recover from a tibia-fibula fracture that is being managed with an external fixation system. On admission 2 weeks ago, she told you that she felt she was "getting old too fast." She explained that she had gained 54 pounds in the previous 6 months, had no energy, was often constipated, and was always cold. She teared up and said that her ability to concentrate was so bad that not only could she no longer help her high school children with their homework but also that she didn't recognize the step hazard that caused her to fall and break her ankle. Today the nursing assistant assigned to her care reports that the patient's pulse is only 42 beats per minute and that her temperature was 96° F even with two blankets. When you enter her room, she is sleeping

and an untouched breakfast tray is on her table.

1. What are the priority assessment data you should obtain? Provide a rationale for your choices.
2. Should oxygen be applied? Why or why not?
3. What indications do you have that the changes in her health status are not related to complications of her fractured ankle?
4. What manifestations of hypothyroidism are in her history and present during this assessment?

Thyroiditis

❖ Pathophysiology

Thyroiditis is an inflammation of the thyroid gland. There are three types: acute, subacute, and chronic. Chronic thyroiditis (Hashimoto's disease) is the most common type.

Acute thyroiditis is caused by bacterial invasion of the thyroid gland. Manifestations include pain, neck tenderness, malaise, fever, and dysphagia (difficulty swallowing). It usually resolves with antibiotic therapy.

Subacute or granulomatous thyroiditis results from a viral infection of the thyroid gland after a cold or other upper respiratory infection. Manifestations include fever, chills, dysphagia, and muscle and joint pain. Pain can radiate to the ears and the jaw. The thyroid gland feels hard and enlarged on palpation. Thyroid function can remain normal, although hyperthyroidism or hypothyroidism may develop.

Chronic thyroiditis (Hashimoto's disease) is a common type of hypothyroidism that affects women more often than men, usually when patients are in their 30s to 50s (Brent & Davies, 2011). Hashimoto's disease is an autoimmune disorder that is usually triggered by a bacterial or viral infection. The thyroid is invaded by antithyroid antibodies and lymphocytes, causing selective thyroid tissue destruction. When large amounts of the gland are destroyed, serum thyroid hormone levels are low and secretion of thyroid-stimulating hormone (TSH) is increased.

❖ Patient-Centered Collaborative Care

The manifestations of Hashimoto's disease are dysphagia and painless enlargement of the gland. Diagnosis is based on circulating antithyroid antibodies and needle biopsy of the thyroid gland. Serum thyroid hormone levels and TSH levels vary with disease stage.

The patient is given thyroid hormone to prevent hypothyroidism and

to suppress TSH secretion, which decreases the size of the thyroid gland. Surgery (subtotal thyroidectomy) is needed if the goiter does not respond to thyroid hormone, is disfiguring, or compresses other structures. Nursing interventions focus on promoting comfort and teaching the patient about hypothyroidism, drugs, and surgery.

Thyroid Cancer

❖ Pathophysiology

The four distinct types of thyroid cancer are papillary, follicular, medullary, and anaplastic (American Cancer Society, 2014). The initial manifestation of thyroid cancer is a single, painless lump or nodule in the thyroid gland. Additional manifestations depend on the presence and location of **metastasis** (spread of cancer cells).

Papillary carcinoma, the most common type of thyroid cancer, occurs most often in younger women. It is a slow-growing tumor that can be present for years before spreading to nearby lymph nodes. When the tumor is confined to the thyroid gland, the chance for cure is good with a partial or total thyroidectomy.

Follicular carcinoma occurs most often in older patients. The cancer invades blood vessels and spreads to bone and lung tissue. It can adhere to the trachea, neck muscles, great vessels, and skin, resulting in **dyspnea** (difficulty breathing) and **dysphagia** (difficulty swallowing). When the tumor involves the recurrent laryngeal nerves, the patient may have a hoarse voice.

Medullary carcinoma is most common in patients older than 50 years. This tumor often occurs as part of multiple endocrine neoplasia (MEN) type II, a familial endocrine disorder. The tumor usually secretes calcitonin, adrenocorticotropic hormone (ACTH), prostaglandins, and serotonin.

Anaplastic carcinoma is a rapid-growing, aggressive tumor that directly invades nearby structures. Manifestations include stridor (harsh, high-pitched respiratory sounds), hoarseness, and dysphagia.

A hallmark of thyroid cancer is an elevated serum thyroglobulin (Tg) level. The normal range of Tg for men is 0.5 to 53.0 ng/mL and for women is 0.5 to 43.0 ng/mL (Pagana & Pagana, 2014).

❖ Patient-Centered Collaborative Care

Radiation therapy is used most often for anaplastic carcinoma because this cancer has usually metastasized at diagnosis. The patient is treated

with **ablative** (enough to destroy the tissue) amounts of RAI. (See Chart 63-4 for precautions to teach the patient receiving unsealed RAI therapy.) If spread has occurred to the neck or mediastinum, external radiation is also applied. If thyroid cancer does not respond to RAI, chemotherapy is initiated.

Surgery is the treatment of choice for other types of thyroid cancer. A total thyroidectomy is usually performed with dissection of lymph nodes in the neck if regional lymph nodes are involved. (See the postoperative care discussion in the Surgical Management section for Hyperthyroidism on p. 1290.) Suppressive doses of thyroid hormone are usually taken for 3 months after surgery. Thyroglobulin levels are monitored after surgery. A rising level indicates the probable presence of cancer cells.

The patient is hypothyroid after treatment for thyroid cancer. Nursing interventions then focus on teaching the patient about the management of hypothyroidism. (See discussion of Patient-Centered Collaborative Care on pp. 1293-1294 in the Hypothyroidism section.)

Parathyroid Disorders

Hyperparathyroidism

❖ Pathophysiology

The parathyroid glands maintain calcium and phosphate balance (see Fig. 61-6 in Chapter 61). Serum calcium level is normally maintained within a narrow range. Increased levels of parathyroid hormone (PTH) act directly on the kidney, causing increased kidney reabsorption of calcium and increased phosphorus excretion. In hyperparathyroidism, these processes cause **hypercalcemia** (excessive calcium) and **hypophosphatemia** (inadequate blood phosphorus level).

In bone, excessive PTH levels increase bone *resorption* (bone loss of calcium) by decreasing *osteoblastic* (bone production) activity and increasing *osteoclastic* (bone destruction) activity. This process releases calcium and phosphorus into the blood and reduces bone density. With chronic calcium excess and hypercalcemia, calcium is deposited in soft tissues.

Although the exact triggering mechanisms are unknown, primary hyperparathyroidism results when one or more parathyroid glands do not respond to the normal feedback of serum calcium levels. The most common cause is a benign tumor in one parathyroid gland. Table 63-3 lists other causes of hyperparathyroidism.

TABLE 63-3

Causes of Parathyroid Dysfunction

Causes of Hyperparathyroidism
• Parathyroid tumor or cancer • Congenital hyperplasia • Neck trauma or radiation • Vitamin D deficiency • Chronic kidney disease with hypocalcemia • Parathyroid hormone–secreting carcinomas of the lung, kidney, or GI tract
Causes of Hypoparathyroidism
• Surgical or radiation-induced thyroid ablation • Parathyroidectomy • Congenital dysgenesis • Idiopathic (autoimmune) hypoparathyroidism • Hypomagnesemia

❖ Patient-Centered Collaborative Care

◆ Assessment

Manifestations of hyperparathyroidism may be related either to the

effects of excessive PTH or to the effects of the accompanying hypercalcemia.

Ask about any bone fractures, recent weight loss, arthritis, or psychological stress. Ask whether the patient has received radiation treatment to the head or neck. The patient with chronic disease may have a waxy pallor of the skin and bone deformities in the extremities and back.

High levels of PTH cause kidney stones and deposits of calcium in the soft tissue of the kidney. Bone lesions are due to an increased rate of bone destruction and may result in pathologic fractures, bone cysts, and osteoporosis.

GI problems (e.g., anorexia, nausea, vomiting, epigastric pain, constipation, weight loss) are common when serum calcium levels are high. Elevated serum gastrin levels are caused by hypercalcemia and lead to peptic ulcer disease. Fatigue and lethargy may be present and worsen as the serum calcium levels increase. When serum calcium levels are greater than 12 mg/dL, the patient may have psychosis with mental confusion, which leads to coma and death if left untreated. (See Chapter 11 for more information about hypercalcemia.)

Serum PTH, calcium, and phosphorus levels and urine cyclic adenosine monophosphate (cAMP) levels are the laboratory tests used to detect hyperparathyroidism (Chart 63-10). X-rays may show kidney stones, calcium deposits, and bone lesions. Loss of bone density occurs in the patient with chronic hyperparathyroidism. Other diagnostic tests include arteriography, CT scans, venous sampling of the thyroid for blood PTH levels, and ultrasonography. Explain the procedures and care for the patient undergoing diagnostic tests.

Chart 63-10 Laboratory Profile

Parathyroid Function

		SIGNIFICANCE OF ABNORMAL FINDINGS	
TEST	NORMAL RANGE FOR ADULTS	HYPERPARATHYROIDISM	HYPOPARATHYROIDISM
Serum calcium	Total: 9.0-10.5 mg/dL or 2.25-2.75 SI units Ionized (active): 4.64-5.28 mg/dL or 1.16-1.32 SI units	Increased in primary hyperparathyroidism	Decreased
Serum phosphorus	3.0-4.5 mg/dL or 0.97-1.45 SI units *Older adults:* May be slightly lower	Decreased	Increased
Serum magnesium	1.3-2.1 mEq/L	Increased	Decreased
Serum parathyroid hormone	C-terminal 50-330 pg/mL N-terminal 8-25 pg/mL Whole 10-65 pg/mL	Increased	Decreased
Vitamin D (calciferol)	25-80 ng/mL	Variable	Decreased
Urine cAMP	18.3-45.4 nmol/L in a 24-hour urine collection specimen	Increased	Decreased

cAMP, Cyclic adenosine monophosphate; *SI,* International System of Units.

Data from Pagana, K., & Pagana, T. (2014). *Mosby's manual of diagnostic and laboratory tests* (5th ed.). St. Louis: Mosby.

Interventions

Surgical management is the treatment of choice for patients with hyperparathyroidism. For those who are not candidates for surgery, medication can help control the problems. Priority nursing interventions focus on monitoring and preventing injury.

Nonsurgical Management.

Diuretic and hydration therapies are used for reducing serum calcium levels in patients who have milder disease. Usually furosemide (Lasix, Uritol), a diuretic that increases kidney excretion of calcium, is used together with IV saline in large volumes to promote calcium excretion.

Drug therapy for patients who have more severe manifestations of primary or secondary hyperparathyroidism or who have hypercalcemia related to parathyroid cancer involves the use of cinacalcet (Sensipar). This drug is the first in a new class of drugs known as *calcimimetics.* When taken orally, the drug binds to calcium-sensitive receptors on parathyroid tissue. This binding reduces PTH production and release. The result is decreased serum calcium levels, stabilization of other minerals, and decreased progression of PTH-induced bone complications. The initial dose is low (30 mg orally twice daily) and is gradually increased to the maximum maintenance dose of 90 mg three times daily. The patient's serum calcium must be monitored for hypocalcemia on a regular basis for the duration of therapy.

For patients who do not respond to cinacalcet, oral phosphates are used to inhibit bone resorption and interfere with calcium absorption. IV phosphates are used only when serum calcium levels must be lowered rapidly. Calcitonin decreases the release of skeletal calcium and increases the kidney excretion of calcium. It is not effective when used alone

because of its short duration of action. The therapeutic effects are greatly enhanced if calcitonin is given along with glucocorticoids.

Monitor cardiac function and intake and output every 2 hours during hydration therapy. Continuous cardiac monitoring may be needed. Compare recent ECG tracings with the patient's baseline tracings. Especially look for changes in the T waves and the QT interval, as well as changes in rate and rhythm. Monitor serum calcium levels, and immediately report any sudden drop to the health care provider. Sudden drops in calcium levels may cause tingling and numbness in the muscles.

Preventing injury is important because the patient with chronic hyperparathyroidism often has significant bone density loss and is at risk for pathologic fractures. Teach unlicensed assistive personnel (UAP) to handle the patient carefully. Use a lift sheet to reposition the patient rather than pulling him or her.

Surgical Management.

Surgical management of hyperparathyroidism is a parathyroidectomy. Before surgery the patient is stabilized and calcium levels are decreased to near normal.

The operative procedure can be performed as minimally invasive surgery, mini-incision surgery, or with a traditional transverse incision in the lower neck. All four parathyroid glands are examined for enlargement. If a tumor is present on one side but the other side is normal, the surgeon removes the glands containing tumor and leaves the remaining glands on the opposite side intact. If all four glands are diseased, they are all removed.

Nursing care before and after surgical removal of the parathyroid glands is the same as that for thyroidectomy. See the Preoperative Care section on p. 1289 and the Postoperative Care section on p. 1290 for specific nursing interventions.

The remaining glands, which may have atrophied as a result of PTH overproduction, require several days to several weeks to return to normal function. A hypocalcemic crisis can occur during this critical period, and the serum calcium level is assessed frequently after surgery. Check serum calcium levels whenever they are drawn until calcium levels stabilize. Monitor for manifestations of hypocalcemia, such as tingling and twitching in the extremities and face. Check for Trousseau's and Chvostek's signs, either of which indicates potential tetany (see Chapter 11).

The recurrent laryngeal nerve can be damaged. Assess the patient for changes in voice patterns and hoarseness.

When hyperparathyroidism is due to **hyperplasia** (tissue overgrowth), three glands plus half of the fourth gland are usually removed. If all four glands are removed, a small portion of a gland may be implanted in the forearm, where it produces PTH and maintains calcium homeostasis. If all these maneuvers fail, the patient will need lifelong treatment with calcium and vitamin D because the resulting hypoparathyroidism is permanent (see next section).

Hypoparathyroidism

Pathophysiology

Hypoparathyroidism is a rare endocrine disorder in which parathyroid function is decreased. Problems are directly related to a lack of parathyroid hormone (PTH) secretion or to decreased effectiveness of PTH on target tissue. Whether the problem is a lack of PTH secretion or an ineffectiveness of PTH on tissues, the result is the same: *hypocalcemia*.

Iatrogenic hypoparathyroidism, the most common form, is caused by the removal of all parathyroid tissue during total thyroidectomy or by surgical removal of the parathyroid glands.

Idiopathic hypoparathyroidism can occur spontaneously. The exact cause is unknown, but an autoimmune basis is suspected. It may occur with other autoimmune disorders such as adrenal insufficiency, hypothyroidism, diabetes mellitus, pernicious anemia, and vitiligo.

Hypomagnesemia (decreased serum magnesium levels) may also cause hypoparathyroidism. Hypomagnesemia is seen in patients with malabsorption syndromes, chronic kidney disease, and malnutrition. It causes impairment of PTH secretion and may interfere with the effects of PTH on the bones, kidneys, and calcium regulation.

Patient-Centered Collaborative Care

Assessment

Ask about any head or neck surgery or radiation therapy because these treatments may damage the parathyroid glands and cause hypoparathyroidism. Also ask whether the neck has ever sustained a serious injury in a car crash or by strangulation. Assess whether the patient has any manifestations of hypoparathyroidism, which may range from mild tingling and numbness to muscle tetany. Tingling and numbness around the mouth or in the hands and feet reflect mild to moderate hypocalcemia. Severe muscle cramps, spasms of the hands and feet, and seizures (with no loss of consciousness or incontinence) reflect

a more severe hypocalcemia. The patient or family may notice mental changes ranging from irritability to psychosis.

The physical assessment may show excessive or inappropriate muscle contractions that cause finger, hand, and elbow flexion. This can signal an impending attack of tetany. Check for Chvostek's sign and Trousseau's sign; positive responses indicate potential tetany (see Chapter 11). Bands or pits may encircle the crowns of the teeth, which indicate a loss of calcium from the teeth with enamel loss.

Diagnostic tests for hypoparathyroidism include electroencephalography (EEG), blood tests, and CT scans. EEG changes revert to normal with correction of hypocalcemia. Serum calcium, phosphorus, magnesium, vitamin D, and urine cyclic adenosine monophosphate (cAMP) levels may be used in the diagnostic workup for hypoparathyroidism (see Chart 63-10). The CT scan can show brain calcifications, which indicate chronic hypocalcemia.

Interventions

Nonsurgical management of hypoparathyroidism focuses on correcting hypocalcemia, vitamin D deficiency, and hypomagnesemia. For patients with acute and severe hypocalcemia, IV calcium is given as a 10% solution of calcium chloride or calcium gluconate over 10 to 15 minutes. Acute vitamin D deficiency is treated with oral calcitriol (Rocaltrol), 0.5 to 2 mg daily. Acute hypomagnesemia is corrected with 50% magnesium sulfate in 2-mL doses (up to 4 g daily) IV. Long-term oral therapy for hypocalcemia involves the intake of calcium, 0.5 to 2 g daily, in divided doses.

Long-term therapy for vitamin D deficiency is 50,000 to 400,000 units of oral ergocalciferol daily. The dosage is adjusted to keep the patient's calcium level in the low-normal range (slightly hypocalcemic), enough to prevent symptoms of hypocalcemia. It must also be low enough to prevent increased urine calcium levels, which can lead to stone formation.

Nursing management includes teaching about the drug regimen and interventions to reduce anxiety. Teach the patient to eat foods high in calcium but low in phosphorus. Milk, yogurt, and processed cheeses are avoided because of their high phosphorus content. *Stress that therapy for hypocalcemia is lifelong.* Advise the patient to wear a medical alert bracelet. With adherence to the prescribed drug and diet regimen, the calcium level usually remains high enough to prevent a hypocalcemic crisis.

NCLEX Examination Challenge

Safe and Effective Care Environment

When taking the blood pressure of a client receiving treatment for hyperparathyroidism, the nurse observes the client's hand to undergo flexion contractions. What is the nurse's interpretation of this observation?

A Hyperphosphatemia
B Hypophosphatemia
C Hypercalcemia
D Hypocalcemia

Nursing Concepts and Clinical Judgment Review

What might you NOTICE in a patient with hyperthyroidism who demonstrates inadequate thermoregulation?

Vital signs:

- Blood pressure elevated with a widened pulse pressure
- Heart rate rapid and irregular
- Temperature above 100° F

Physical assessment:

- Excessive sweating
- Smooth, warm, moist skin
- Underweight for height
- Fine hand tremors

Psychosocial assessment:

- Decreased attention span
- Restlessness and irritability
- Emotional lability

Laboratory assessment:

- Elevated T_3 and T_4 levels
- Abnormal TSH levels

What should you INTERPRET and how should you RESPOND to a patient experiencing inadequate thermoregulation as a result of hyperthyroidism?

Perform and interpret physical assessment, including:

- Assessing body temperature
- Assessing cardiac effectiveness
- Checking deep tendon reflexes

Respond by:

- Maintaining a calm approach
- Cooling the environment
- Offering a sponge bath or shower
- Avoiding palpation of the neck or thyroid gland
- Maintaining a patent airway
- Administering prescribed drugs appropriately
- Notifying the health care provider of changes in cardiac or neurologic status

On what should you REFLECT?

- Think about how the environment could be made more calming.
- Think about what emergency equipment might be needed.

Get Ready for the NCLEX® Examination!

Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Keep the environment of a patient at risk for thyroid storm cool, dark, and quiet. **Safety** QSEN
- Keep emergency suctioning and tracheotomy equipment in the room of a patient who has had thyroid or parathyroid surgery. **Safety** QSEN
- Use a lift sheet to move or reposition a patient with hypocalcemia. **Safety** QSEN

Health Promotion and Maintenance

- Teach all patients to take antithyroid drugs or thyroid hormone replacement therapy as prescribed. **Patient-Centered Care** QSEN
- Teach patients to use clinical manifestations (e.g., the number of bowel movements per day, the ability to sleep) as indicators of therapy effectiveness and when the dose of thyroid hormone replacement may need to be adjusted. **Patient-Centered Care** QSEN
- Include the person who prepares the patient's meals when teaching about dietary electrolyte restrictions. **Patient-Centered Care** QSEN
- Collaborate with the registered dietitian to teach patients about diets that are restricted in calcium or phosphorus. **Teamwork and Collaboration** QSEN

Psychosocial Integrity

- Be accepting of patient behavior. **Patient-Centered Care** QSEN
- Remind patients and family members that changes in cognition and behavior related to thyroid problems are usually temporary. **Patient-Centered Care** QSEN
- Encourage the patient who has a permanent change in appearance (e.g., exophthalmia) to mourn the change. **Patient-Centered Care** QSEN

Physiological Integrity

- Be aware that:
  - The presence of a goiter indicates a problem with the thyroid gland but can accompany either hyperthyroidism or hypothyroidism.
  - Although similar in action, methimazole and propylthiouracil are not

interchangeable.
    - Methimazole can cause birth defects and should not be used during pregnancy, especially during the first trimester.
- When stridor, dyspnea, or other symptoms of obstruction appear after thyroid surgery, notify the Rapid Response Team. **Safety** QSEN
- When caring for a patient with hyperthyroidism, even after a thyroidectomy, immediately report a temperature increase of even 1° F because it may indicate an impending thyroid crisis. **Evidence-Based Practice** QSEN
- Assess the cardiopulmonary status of any patient with hypothyroidism for decreased perfusion or decreased gas exchange at least every 8 hours. **Patient-Centered Care** QSEN
- Use sedating drugs or opioids sparingly with patients who have hypothyroidism. **Patient-Centered Care** QSEN
- Monitor the hydration status of patients who have hypercalcemia. **Patient-Centered Care** QSEN
- Assess the patient with hypoparathyroidism for manifestations of hypocalcemia, especially numbness or tingling around the mouth and a positive Chvostek's sign or Trousseau's sign. **Patient-Centered Care** QSEN

CHAPTER 64

Care of Patients with Diabetes Mellitus

Margaret Elaine McLeod

PRIORITY CONCEPTS

- Glucose Regulation
- Tissue Integrity
- Sensory Perception
- Perfusion
- Infection
- Pain
- Nutrition

Learning Outcomes

Safe and Effective Care Environment

1. Protect the patient who has diabetes mellitus from injury.
2. Protect the patient who has diabetes mellitus from infection.

Health Promotion and Maintenance

3. Teach all people how to prevent or delay development of type 2 diabetes.
4. Teach people who have diabetes to prevent or delay long-term complications of the disorder.
5. Teach all patients with diabetes and their family members how to self-manage their disease.
6. Teach the patient with diabetes and the family the importance of foot care and good nutrition.
7. Work with other health care professionals to help the patient and family

experiencing diabetes mellitus achieve health goals.

Psychosocial Integrity

8. Reduce the psychological impact of diabetes mellitus for the patient and family.
9. Work with other members of the health care team to ensure that patient values, preferences, and expressed needs related to diabetes mellitus are respected.

Physiological Integrity

10. Compare the risk factors, age of onset, manifestations, and pathologic mechanisms of type 1 and type 2 diabetes mellitus.
11. Apply knowledge of anatomy, physiology, and pathophysiology to assess the adequacy of glucose regulation for the patient with diabetes.
12. Ensure that pain is appropriately managed for the patient with diabetes.
13. Evaluate laboratory data and clinical manifestations to determine effectiveness of the prescribed dietary, drug, and exercise therapies for diabetes.
14. Prioritize care for the patient with diabetes experiencing hypoglycemia, ketoacidosis, or hyperglycemic-hyperosmolar state (HHS).
15. Coordinate care for the patient with diabetes in the community.

http://evolve.elsevier.com/Iggy/

Diabetes mellitus (DM) resulting in poor glucose regulation is a major public health problem, and its complications, especially hypertension and **hyperlipidemia** (high blood lipid levels), cause many serious health problems. In the United States, DM is a leading cause of blindness, end-stage kidney disease, and foot or leg amputations. Many people have undiagnosed diabetes, and among those who are diagnosed, many continue to have high blood glucose levels. The complications of DM can be greatly reduced with **glycemic** (blood glucose) control along with management of hypertension and hyperlipidemia. Thus nursing priorities focus on helping the patient with diabetes achieve and maintain lifestyle changes that prevent long-term complications by keeping blood glucose levels and cholesterol levels as close to normal as possible.

Because DM is a chronic metabolic disease affecting glucose regulation, it

requires lifelong behavioral and lifestyle changes for best management. A collaborative approach helps the patient be successful in achieving desired outcomes. As part of the team, you will plan, organize, and coordinate care with other health care team members to provide care and promote the patient's health and well-being.

❖ Pathophysiology

Classification of Diabetes

For all types of diabetes mellitus (DM), the main feature is chronic **hyperglycemia** (high blood glucose level) resulting from problems with glucose regulation that include reduced insulin secretion or reduced insulin action (McCance et al., 2014). The disease is classified by the underlying problem causing a lack of insulin or its action and the severity of the insulin deficiency. Table 64-1 outlines the types of DM.

TABLE 64-1

Classification of Diabetes Mellitus

Type 1 Diabetes
• Beta-cell destruction leading to absolute insulin deficiency • Autoimmune • Idiopathic
Type 2 Diabetes
• Ranges from insulin resistance with relative insulin deficiency to secretory deficit with insulin resistance
Other Conditions Resulting in Hyperglycemia
• Genetic defects of beta-cell function • Genetic defects in insulin action • Pancreatic diseases (pancreatitis, trauma, cancer, cystic fibrosis, hemochromatosis) • Endocrinopathies: acromegaly, Cushing's disease, glucagonoma, pheochromocytoma, hyperthyroidism, aldosteronism • Drug- or chemical-induced hyperglycemia • Infections: congenital rubella, cytomegalovirus, human immune deficiency virus • Genetic syndromes associated with diabetes: Down syndrome, Klinefelter syndrome, Turner's syndrome, Huntington disease, and others
Gestational Diabetes Mellitus (GDM)
• Glucose intolerance with onset or first recognition during pregnancy

Data from American Diabetes Association (ADA). (2014d). Position statement: Diagnosis and classification of diabetes mellitus. *Diabetes Care, 37*(Suppl. 1), S81-S90.

The Endocrine Pancreas

The pancreas has exocrine functions that are related to digestion and endocrine functions for blood glucose regulation. The endocrine portion of the pancreas has about 1 million small glands, the islets of Langerhans, scattered through the organ. The islet cells are only a small portion of the gland. The two types of islet cells important to glucose regulation are the *alpha* cells, which secrete glucagon, and the *beta* cells, which produce

insulin and amylin. **Glucagon** is a "counterregulatory" hormone that has actions opposite those of insulin. It prevents *hypoglycemia* (low blood glucose levels) by triggering the release of glucose from cell storage sites. Insulin prevents hyperglycemia by allowing body cells to take up, use, and store carbohydrate, fat, and protein.

Active insulin is a protein made up of 51 amino acids. It is initially produced as inactive *proinsulin,* a prohormone that contains an additional amino acid chain (the C-peptide chain). Proinsulin is converted into active insulin by removal of the C-peptide (Fig. 64-1).

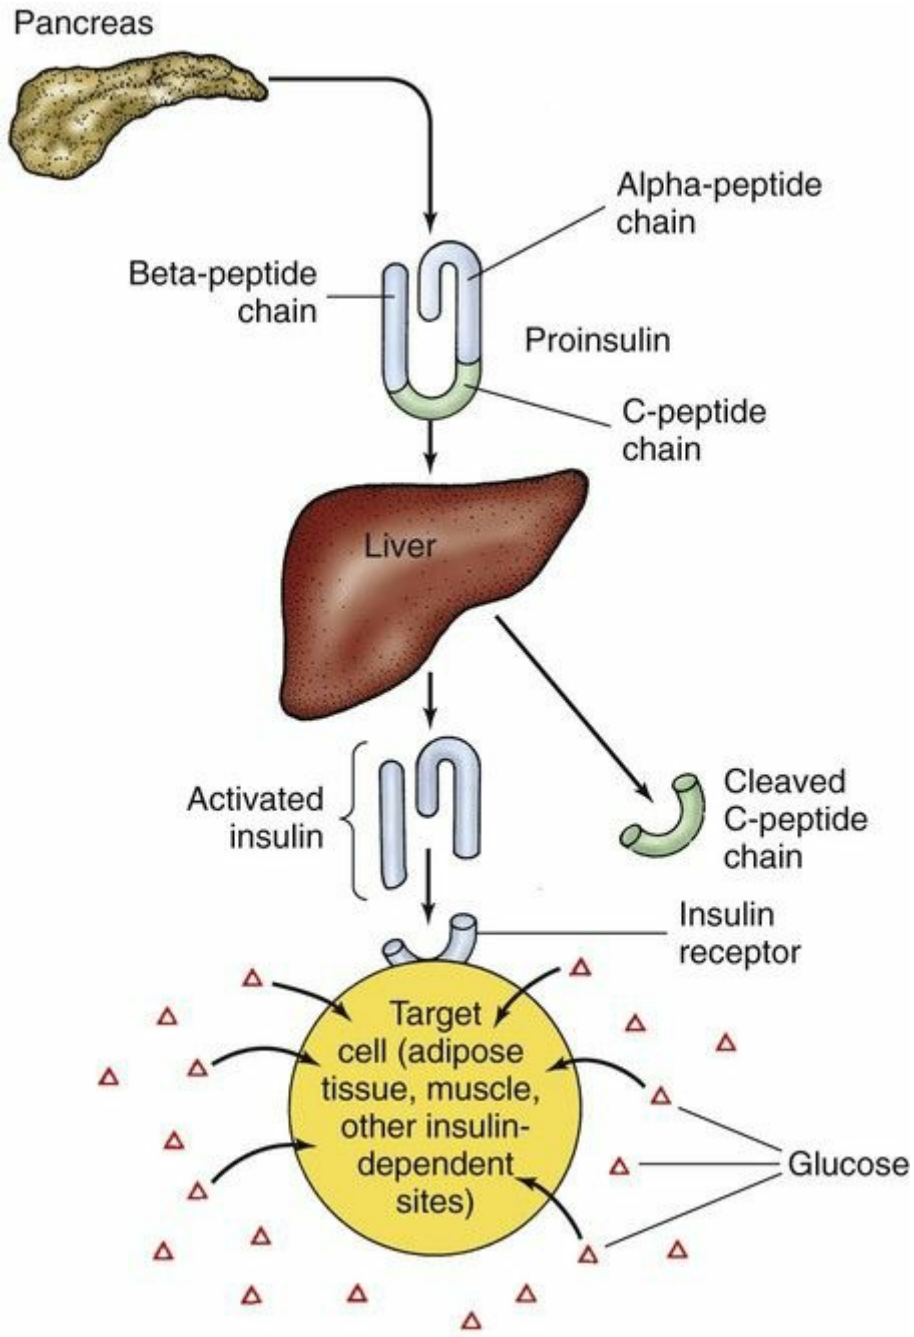

FIG. 64-1 Proinsulin, secreted by and stored in the beta cells of the islets of Langerhans in the pancreas, is transformed by the liver into active insulin. Insulin attaches to receptors on target cells, where it promotes glucose transport into the cells through the cell membranes.

Insulin is secreted daily directly into liver circulation in a two-step manner. It is secreted at low levels during fasting (basal insulin secretion) and at increased levels after eating (**prandial**). An early burst of insulin secretion occurs within 10 minutes of eating. This is followed by an increasing release that lasts until the blood glucose level is normal.

Glucose Regulation and Homeostasis

Glucose is the main fuel for central nervous system (CNS) cells. Because the brain cannot produce or store much glucose, it needs a continuous supply from circulation to prevent neuron dysfunction and cell death. Other organs can use both glucose and fatty acids to generate energy. Glucose is stored inside cells as glycogen in the liver and muscles, and free fatty acids are stored as triglyceride in fat cells. Fat is the most efficient means of storing energy, with 9 calories of stored energy per gram. Protein and carbohydrate have only 4 calories per gram. During a prolonged fast or after illness, proteins are broken down and some of the amino acids are converted into glucose.

Several organs and hormones play a role in maintaining glucose regulation. During fasting, when the stomach is empty, blood glucose is maintained between 60 and 150 mg/dL (3.3 and 8.3 mmol/L) by a balance between glucose uptake by cells and glucose production by the liver. Insulin plays a pivotal role in this process.

Movement of glucose into some cells requires the presence of specific carrier proteins, known as glucose transport (GLUT) proteins, along with insulin. Insulin is like a "key" that opens "locked" membranes to glucose, allowing blood glucose to move into cells to generate energy. Insulin starts this action by binding to insulin receptors on the cell membranes, which changes membrane permeability to glucose.

Insulin exerts many effects on metabolism and cellular processes in all tissues and organs. The main metabolic effects of insulin are to stimulate glucose uptake in skeletal muscle and heart muscle and to suppress liver production of glucose and very-low-density lipoprotein (VLDL). In the liver, insulin promotes the production and storage of glycogen (**glycogenesis**) at the same time that it inhibits glycogen breakdown into glucose (**glycogenolysis**). It increases protein and lipid (fat) synthesis and inhibits **ketogenesis** (conversion of fats to acids) and **gluconeogenesis** (conversion of proteins to glucose). In muscle, insulin promotes protein and glycogen synthesis. In fat cells, it promotes triglyceride storage. Overall, insulin keeps blood glucose levels from becoming too high and helps keep blood lipid levels in the normal range.

In the *fasting state* (not eating for 8 hours), insulin secretion is suppressed, which leads to increased gluconeogenesis in the liver and kidneys, along with increased glucose generation by the breakdown of liver glycogen. In the fed state, insulin released from pancreatic beta cells reverses this process. Instead, glycogen breakdown and gluconeogenesis are inhibited. At the same time, insulin also enhances glucose uptake and use by cells and reduces both fat breakdown (**lipolysis**) and protein breakdown (**proteolysis**). When more glucose is present in liver cells

than can be used for energy or stored as glycogen, insulin causes the excess glucose to be converted to free fatty acids (FFAs). These extra FFAs are deposited in fat cells.

Glucose in the blood after a meal is controlled by the emptying rate of the stomach and delivery of nutrients to the small intestine where they are absorbed into circulation. Incretin hormones (e.g., GLP-1), secreted in response to food in the stomach, have several actions. They increase insulin secretion, inhibit glucagon secretion, and slow the rate of gastric emptying, thereby preventing hyperglycemia after meals.

Counterregulatory hormones increase blood glucose by actions opposite those of insulin when more energy is needed. Glucagon is the main counterregulatory hormone. Other hormones that increase blood glucose levels are epinephrine, norepinephrine, growth hormone, and cortisol. The combined actions of insulin and counterregulatory hormones (discussed in the next section) participate in glucose regulation and keep blood glucose levels in the range of 60 to 100 mg/dL (3.3 to 5.6 mmol/L) to support brain function. When blood glucose levels fall, insulin secretion stops and glucagon is released. Glucagon causes glucose release from the liver. Liver glucose is made through breakdown of glycogen to glucose (glycogenolysis) and conversion of amino acids into glucose. When liver glucose is unavailable, the breakdown of fat (lipolysis) and the breakdown of proteins (proteolysis) provide fuel for energy.

NCLEX Examination Challenge

Physiological Integrity

How is hypoglycemia prevented in the healthy person who does not have diabetes even after fasting for 8 hours?

A Metabolism is so slow when a person sleeps without eating for 8 hours that blood glucose does not enter cells to be used for energy. As a result, hypoglycemia does not occur.

B Fasting for 8 hours triggers conversion of proteins into glycogen (glycogenesis) so that hyperglycemia develops rather than hypoglycemia.

C Lipolysis (fat breakdown) in fat stores occurs, converting fatty acids into glucose to maintain blood glucose levels.

D The secretion of glucagon prevents hypoglycemia by promoting glucose release from liver storage sites.

Absence of Insulin

Insulin for glucose regulation is needed to move glucose into many body tissues. The lack of insulin in diabetes, from either a lack of production or a problem with insulin use at its cell receptor, prevents some cells from using glucose for energy. The body then breaks down fat and protein in an attempt to provide energy and increases levels of counterregulatory hormones to make glucose from other sources. Table 64-2 outlines responses to insufficient insulin.

TABLE 64-2

Physiologic Response to Insufficient Insulin

• Decreased glycogenesis (conversion of glucose to glycogen)
• Increased glycogenolysis (conversion of glycogen to glucose)
• Increased gluconeogenesis (formation of glucose from noncarbohydrate sources such as amino acids and lactate)
• Increased lipolysis (breakdown of triglycerides to glycerol and free fatty acids)
• Increased ketogenesis (formation of ketones from free fatty acids)
• Proteolysis (breakdown of protein with amino acid release in muscles)

Without insulin, glucose builds up in the blood, causing high blood glucose levels (**hyperglycemia**). Hyperglycemia causes fluid and electrolyte imbalances, leading to the classic manifestations of diabetes: polyuria, polydipsia, and polyphagia.

Polyuria is frequent and excessive urination and results from an osmotic diuresis caused by excess glucose in the blood and urine. With diuresis, electrolytes are excreted in the urine and water loss is severe. Dehydration results, and **polydipsia** (excessive thirst) occurs. Because the cells receive no glucose, cell starvation triggers **polyphagia** (excessive eating). Despite eating, the person remains in cellular starvation until insulin is available to move glucose into the cells.

With insulin deficiency, fats break down, releasing free fatty acids. Conversion of fatty acids to **ketone bodies** (small acids) provides a backup energy source. Ketone bodies or "ketones" are abnormal breakdown products that collect in the blood when insulin is not available, leading to a type of metabolic acidosis known as ketoacidosis.

Dehydration with diabetes leads to hemoconcentration (increased blood concentration); hypovolemia (decreased blood volume); thick, concentrated blood; poor tissue perfusion; and hypoxia (poor tissue oxygenation), especially to the brain. Hypoxic cells do not metabolize glucose efficiently, the Krebs' cycle is blocked, and lactic acid increases, causing more acidosis.

The excess acids caused by absence of insulin increase hydrogen ion (H^+) and carbon dioxide (CO_2) levels in the blood, causing anion-gap

metabolic acidosis. These products trigger the brain to increase the rate and depth of respiration in an attempt to "blow off" carbon dioxide and acid. This type of breathing is known as **Kussmaul respiration**. Acetone is exhaled, giving the breath a "rotting fruit" odor. When the lungs can no longer offset acidosis, the blood pH drops. Arterial blood gas studies show a metabolic acidosis (decreased pH with decreased arterial bicarbonate [HCO_3^-] levels) and compensatory respiratory alkalosis (decreased partial pressure of arterial carbon dioxide [$Paco_2$]).

Insulin lack initially causes potassium depletion. With the increased fluid loss from hyperglycemia, excessive potassium is excreted in the urine, leading to low serum potassium levels. High serum potassium levels may occur in acidosis because of the shift of potassium from inside the cells to the blood. Serum potassium levels in DM, then, may be low (**hypokalemia**), high (**hyperkalemia**), or normal, depending on hydration, the severity of acidosis, and the patient's response to treatment. Chapter 12 discusses acid-base balance and acidosis in more detail.

Acute Complications of Diabetes

Three glucose-related emergencies can occur in patients with diabetes:

- Diabetic ketoacidosis (DKA) caused by lack of insulin and ketosis
- Hyperglycemic-hyperosmolar state (HHS) caused by insulin deficiency and profound dehydration
- Hypoglycemia from too much insulin or too little glucose

All three problems require emergency treatment and can be fatal if treatment is delayed or incorrect. These problems and their interventions are described later, starting on p. 1330.

Chronic Complications of Diabetes

Diabetes mellitus (DM) can lead to health problems and early death because of changes in large blood vessels (**macrovascular**) and small blood vessels (**microvascular**) in tissues and organs (McCance et al., 2014). Complications result from poor tissue perfusion and cell death. Macrovascular complications, including coronary heart disease, cerebrovascular disease, and peripheral vascular disease, lead to increased early death. Microvascular complications of blood vessel structure and function lead to **nephropathy** (kidney dysfunction), **neuropathy** (nerve dysfunction), and **retinopathy** (vision problems). Causes of these diabetic vascular complications include:

- Chronic hyperglycemia thickens basement membranes, which causes organ damage.

- Glucose toxicity directly or indirectly affects functional cell integrity.
- Chronic ischemia in small blood vessels causes connective tissue hypoxia and microischemia.

Chronic high blood glucose levels are the main cause of microvascular complications and allow premature development of macrovascular complications. Other risk factors contributing to poor health outcomes for people with DM include smoking, physical inactivity, obesity, hypertension, and high blood fat and cholesterol levels. Many of these factors can be modified to reduce complications related to DM.

Hyperglycemia from poor glucose regulation is a critical factor for long-term complications in patients with type 1 DM. Intensive therapy to maintain blood glucose levels as close to normal as possible delays the onset and progression of retinopathy, nephropathy, neuropathy, and macrovascular disease for patients with type 1 and type 2 DM. For every percentage point decrease in A1C (glycosylated hemoglobin A1C), a risk reduction of at least 25% to 30% for kidney and eye complications has been shown (American Diabetes Association [ADA], 2014b).

Macrovascular Complications

Cardiovascular Disease.

Diabetes mellitus (DM) is associated with a reduced life span, largely as a result of cardiovascular disease (CVD). Most patients with DM die as a result of a thrombotic event, usually myocardial infarction (MI). Systolic and diastolic heart failure are associated with DM. Patients with DM are more likely to develop left ventricular dysfunction with heart failure and fatal cardiac dysrhythmias after MI.

Patients with diabetes, those with prediabetes, and those with metabolic syndrome are at increased risk for CVD (ADA, 2014f). This risk affects women to a greater degree than men and is influenced by the patient's ethnic group. Diabetes is now considered a “coronary heart disease risk equivalent” and a target for aggressive reduction of risk factors.

Patients with diabetes often have the traditional CVD risk factors of obesity, high blood lipid levels, hypertension, and sedentary lifestyle. Cigarette smoking and a positive family history also increase risk for CVD. Kidney disease, indicated by **albuminuria** (presence of albumin in the urine), increases the risk for coronary heart disease and mortality from MI. Patients with DM often have higher levels of C-reactive protein (CRP), an inflammatory marker associated with increased risk for cardiovascular problems and death. In addition, the presence of diabetic

retinopathy is associated with an increased risk for mortality and cardiovascular events in both type 1 and type 2 DM.

Cardiovascular complication rates can be reduced through aggressive management of hyperglycemia, hypertension, and hyperlipidemia. The American Diabetes Association (ADA) recommends that blood pressure be maintained below 140/80 mm Hg and that low-density lipoprotein (LDL) cholesterol remains below 100 mg/dL (2.60 mmol/L) for patients without manifestations of CVD and below 70 mg/dL (1.8 mmol/L) for patients with manifestations of CVD (ADA, 2014f). Lifestyle modifications that focus on reducing saturated fat, *trans* fat, and cholesterol intake; increasing intake of omega-3 fatty acids, fiber, and plant sterols; weight loss (if indicated); and increasing physical activity are recommended to improve the lipid profile for patients with DM (ADA, 2013).

Priority nursing actions focus on interventions to reduce modifiable risk factors associated with CVD, such as smoking cessation, diet, exercise, blood pressure control, maintaining prescribed aspirin use, and maintaining prescribed lipid-lowering drug therapy. Many patients with DM do not have the traditional and more obvious manifestations of myocardial infarction (i.e., crushing chest pain radiating down the left arm or up the jaw). Instead the manifestations are more subtle. These include dyspnea with or without cough, extreme fatigue, and sudden onset of nausea and vomiting. Teach patients to report any of these subtle manifestations of MI to their health care provider for evaluation.

Cerebrovascular Disease.

The risk for stroke is 2 to 4 times higher in people with DM compared with those who do not have the disease. Diabetes also increases the likelihood of severe carotid atherosclerosis. Hypertension, hyperlipidemia, nephropathy, peripheral vascular disease, and alcohol and tobacco use further increase the risk for stroke in people with DM.

DM also affects stroke outcomes. Patients with DM are likely to suffer irreversible brain damage with carotid emboli that produce only transient ischemic attacks in people without DM. Elevated blood glucose levels at the time of the stroke may lead to greater brain injury and higher mortality.

Microvascular Complications

Eye and Vision Complications.

Legal blindness (a corrected visual acuity of 20/200 or less) is 25 times

more common in patients with DM. Diabetic retinopathy (DR) is strongly related to the duration of diabetes. After 20 years of DM, nearly all patients with type 1 disease and most with type 2 disease have some degree of retinopathy. Unfortunately, DR has few manifestations until vision loss occurs.

The cause and progression of DR are related to problems that block retinal blood vessels and cause them to leak, leading to retinal hypoxia. Nonproliferative diabetic retinopathy causes structural problems in retinal vessels, including areas of poor retinal circulation, edema, hard fatty deposits in the eye, and retinal hemorrhages. Fluid and blood leak from the retinal vessels and cause retinal edema and hard exudates.

Other retinal problems include optic nerve atrophy from hypoxia and venous beading. **Venous beading** is the abnormal appearance of retinal veins in which areas of swelling and constriction along a segment of vein resemble links of sausage. It occurs in areas of retinal ischemia. Nonproliferative diabetic retinopathies develop slowly and rarely reduce vision to the point of blindness.

Proliferative diabetic retinopathy is the growth of new retinal blood vessels, also known as "neovascularization." When retinal blood flow is poor and hypoxia develops, retinal cells secrete growth factors that stimulate formation of new blood vessels in the eye. These new vessels are thin, fragile, and bleed easily, leading to eye hemorrhage and vision loss.

Visual sensory perception loss from DR has several mechanisms. Central vision may be impaired by macular edema, characterized by increased blood vessel permeability and deposits of hard exudates at the center of the retina. This problem is the main cause of vision loss in the person with DM. Monthly injections of ranibizumab (Lucentis) into the vitreous can improve vision for some people with macular edema (Aschenbrenner, 2012). Vision loss also occurs from macular degeneration, corneal scarring, and changes in lens shape or clarity.

Hyperglycemia may cause blurred vision, even with eyeglasses. Hypoglycemia may cause double vision. Cataracts occur at a younger age and progress faster among patients with DM. Open-angle glaucoma also is more common in patients with DM. The management of cataracts and glaucoma is the same as for patients who do not have diabetes (see Chapter 47).

Control of blood glucose, blood pressure, and blood lipid levels is important in preventing DR. Thus patients with DM should have routine ophthalmic evaluations to detect vision problems early before vision loss occurs. The ADA recommends eye care examinations with an

ophthalmologist every year after a person has been diagnosed with type 2 diabetes and yearly for a person who has had type 1 diabetes for more than 5 years (Chou et al., 2014). Not all people with DM understand the importance of these annual eye screenings (see the Evidence-Based Practice box).

Evidence-Based Practice QSEN

Why Do Adults with Diabetes Forego Annual Eye Care?

Chou, C., Sherrod, C., Zhang, Z., Barker, L., Bullard, K., Crews, J., et al. (2014). Barriers to eye care among people aged 40 years and older with diagnosed diabetes, 2006-2010. *Diabetes Care, 37*(1), 180-188.

Both type 1 and type 2 diabetes mellitus (DM) are associated with major eye problems and blindness. Extensive research has shown that maintaining tight glucose control and having at least annual ophthalmologic evaluations can reduce or delay eye complications. Previous studies have indicated that vision impairment related to DM has increased by 20% in less than 10 years. The purposes of this large retrospective and descriptive study were to determine (1) about what percentage of people with diabetes mellitus were following the recommended guidelines of annual eye examinations from the time of diagnosis of type 2 DM and starting at 5 years after initial diagnosis of type 1 DM, and (2) what were the barriers to eye care for those who were not following the recommended guidelines. The researchers re-analyzed the existing data previously collected through the Behavior Risk Factor Surveillance System (BRFSS), an annual state-based random-digit-dialed telephone survey, from 22 states between the years 2006 and 2010. The defined categories of barriers to eye care were (1) cost, lack of insurance; (2) no need, have not thought of it, no reason to; (3) no eye doctor, transportation issues, couldn't get an appointment; and (4) other (everything else). More than 27,000 people who were diagnosed with DM responded to the survey.

Of the subjects with DM, 23.5% (more than 6500) reported not having had an eye examination in the previous 12 months. The barrier categories cited among these subjects were: 39.7% category **1,** 32.3% category **2,** 6.4% category **3,** and 20.5% category **4**. The majority of subjects citing barrier category **1** issues were women between the ages of 40 years and 64 years, those who have lower annual incomes, those of Hispanic or African-American ethnicity, and those who had less formal education. The majority of subjects citing barrier category **2** issues were white men, those with higher incomes, those with more formal

education, and those with diagnosed visual problems. The researchers indicated that the cost issue was not surprising because Medicare does cover an annual eye examination for people older than 65 years, and the younger subjects may not have had sufficient funds or insurance to cover this cost. The surprising results were the people, especially those who already had some degree of visual problem, who said they believed there was essentially “no need” for an annual eye examination.

Level of Evidence: 4

Although very large, the study was retrospective and descriptive in nature without randomization of subject selection or assignment. The data collected relied on subject self-report and was subject to social desirability bias in that more subjects may have reported receiving annual eye examinations than actually participated in the health-seeking behavior. Also, subjects did not include people without telephones, those who had only cell phone access, those residing in institutions, and those with undiagnosed diabetes. In addition to the study size and the fact that many ethnic groups were represented, a major strength was the detailed questions asked about the barriers to eye care behaviors. The methods of statistical analysis were appropriate for the research questions posed.

Commentary: Implications for Practice and Research

The results of this study indicate that cost is a significant barrier to annual eye care for people with diabetes. Perhaps this barrier will change with the implementation of the Affordable Care Act. Nurses can help people with diabetes check their insurance policies to determine what types of eye care are covered and encourage them to make use of this benefit. Of equal concern is the subjects' beliefs that there is no compelling need for annual eye care. It is possible that some patients think that all vision issues over age 65 years are related to old age and are unavoidable. Nurses can help patients with DM understand that annual eye care can slow the progression of existing vision problems and may help prevent blindness. Other strategies for increasing adherence to annual eye care include reminders from the health care provider and nurses' asking patient's with DM during any encounter when the last eye care appointment was and reinforcing the importance of this health care behavior. More research is needed to determine specifically why patients with DM believe that annual eye care is not necessary so that more targeted interventions could be developed.

Considerations for Older Adults

Patient-Centered Care QSEN

The older patient with diabetic retinopathy also has visual changes from aging, and his or her ability to perform self-care may be seriously affected. The patient with retinopathy may have blurred vision, distorted central vision, fluctuating vision, loss of color perception, and mobility problems resulting from loss of depth perception. It is especially important to assess the patient's ability to measure and inject insulin and to monitor blood glucose levels to determine if adaptive devices are needed to assist in self-management activities.

Diabetic Peripheral Neuropathy.

Diabetic peripheral neuropathy (DPN) is a progressive deterioration of nerve function that results in loss of sensory perception. It is a common complication of DM and often involves all parts of the body. Damage to sensory nerve fibers results in either pain or loss of sensation. Damage to motor nerve fibers results in muscle weakness. Damage to nerve fibers in the autonomic nervous system can cause dysfunction in every part of the body. The combination of interacting factors leading to the nerve damage in DPN are:

- Hyperglycemia, long duration of DM, hyperlipidemia, low insulin levels
- Damaged blood vessels leading to reduced neuronal oxygen and other nutrients
- Autoimmune neuronal inflammation
- Increased genetic susceptibility to nerve damage
- Smoking and alcohol use

Hyperglycemia leads to DPN through blood vessel changes and reduced tissue perfusion that cause nerve hypoxia. Both the axon and its myelin sheath are damaged by reduced blood flow, resulting in blocked nerve impulse transmission. Excessive glucose is converted to sorbitol, which collects in nerves and impairs motor nerve conduction. Common diabetic neuropathies are listed in Table 64-3. Autonomic nervous system neuropathy leads to problems in cardiovascular, GI, and urinary function. Keeping blood glucose levels in the normal range can slow the development and progression of diabetic neuropathies.

TABLE 64-3

Features of Diabetic Neuropathy

COMPLICATION		MANIFESTATION
Diffuse Neuropathies		
Distal symmetric polyneuropathy	Sensory alterations	Paresthesias: burning/tingling sensations, starting in toes and moving up legs
		Dysesthesias: burning, stinging, or stabbing pain
		Anesthesia: loss of sensation
	Motor alterations in intrinsic muscles of foot	Foot deformities: high arch, claw toes, hammertoes; shift of weight-bearing to metatarsal heads and tips of toes
Autonomic neuropathy	Anhidrosis	Drying, cracking of skin
	Gastrointestinal	Delayed gastric emptying, gastric retention, early satiety, bloating, nausea, vomiting, anorexia, constipation, diarrhea
	Neurogenic bladder	Atonic bladder, urinary retention
	Impotence	Erectile dysfunction
	Cardiovascular autonomic neuropathy	Early fatigue, weakness with exercise, orthostatic hypotension
	Defective counterregulation	Loss of warning signs of hypoglycemia
Focal Neuropathies		
Focal ischemia	Thoracolumbar radiculopathy with sensory and reflex loss	Pain radiating across back, side, and front of chest or abdomen
	Cranial nerve palsies, third and sixth nerves	Sudden diplopia or ptosis; eye pain
	Amyotrophy	Pain; asymmetric weakness; wasting of iliopsoas, quadriceps, and adductor muscles

Diabetic neuropathy can be focal or diffuse, each with different causes and rates of progression. *Diffuse neuropathies* are the most common neuropathies in DM and involve widespread nerve function loss and sensory perception loss. The onset is slow, affects both sides of the body, involves motor and sensory nerves, progresses slowly, is permanent, and includes autonomic nerve dysfunction. Late complications include foot ulcers and deformities.

Focal neuropathies in DM affect a single nerve or nerve group and usually are caused by an acute ischemic event that leads to nerve damage or nerve death. Ischemic neuropathies occur when the blood supply to a nerve or nerve group is disrupted. Manifestations begin suddenly, affect only one side of the body area, and are self-limiting. The most common neuropathies affect the nerves that control the eye muscles. Manifestations begin with pain on one side of the face near the affected eye. The eye muscles become paralyzed, resulting in double vision. The problem usually resolves in 2 to 3 months.

Cardiovascular autonomic neuropathy (CAN) affects sympathetic and parasympathetic nerves to the heart and blood vessels. This problem contributes to left ventricular dysfunction, painless myocardial infarction, and exercise intolerance. Most often, CAN leads to **orthostatic hypotension** (postural hypotension) and **syncope** (brief loss of consciousness on standing). These problems result from failure of the heart and arteries to adjust to position changes by increasing heart rate and vascular tone. As a result, blood flow to the brain is interrupted

briefly. Orthostatic hypotension and syncope increase the risk for falls, especially among older adults.

Autonomic neuropathy can affect the entire GI system. Common GI problems from diabetic neuropathy include gastroesophageal reflex, delayed gastric emptying and gastric retention, early satiety, heartburn, nausea, vomiting, and anorexia. Sluggish movement of the small intestine can lead to bacterial overgrowth, which causes bloating, gas, and diarrhea. Diarrhea caused by diabetes is chronic, may be severe, and often occurs at night. Constipation, the most common GI problem with DM, is intermittent and may alternate with bouts of diarrhea. **Gastroparesis** (delay in gastric emptying) is a cause of hypoglycemia.

Urinary problems from neuropathy result in incomplete bladder emptying and urine retention, which lead to urinary infection and kidney problems. Manifestations include frequency, urgency, and incontinence.

Diabetic Nephropathy.

Nephropathy is a pathologic change in the kidney that reduces kidney function and leads to kidney failure. Diabetes is the leading cause of chronic kidney disease (CKD) and end-stage kidney disease (ESKD) in the United States. Risk factors include a 10- to 15-year history of DM, poor blood glucose control, uncontrolled hypertension, and genetic predisposition. Patients who have a genetic predisposition appear to have higher serum uric acid levels and higher levels of tumor necrosis factor receptors. When a person has these genetic differences, the risk for progression of kidney problems to ESKD is greater even when blood glucose levels are controlled (Krolewski et al., 2014). The onset of diabetic kidney disease may be prevented and the progression to ESKD can be delayed by maintaining optimum blood glucose regulation, keeping blood pressure within the normal ranges, and using drug therapy to protect the kidneys (ADA, 2014b; Krolewski et al., 2014; Zitkus, 2012). Drugs that protect the kidneys are the angiotensin-converting enzyme (ACE) inhibitors and the angiotensin receptor blockers (ABRs).

Kidney disease causes progressive albumin excretion and declining glomerular filtration rate (GFR). Early manifestations of nephropathy are **microalbuminuria** (small amounts of albumin in the urine) and elevated serum uric acid levels. Annual testing for microalbuminuria is recommended for patients who have had type 1 DM for at least 5 years and in everyone with type 2 DM (ADA, 2014b).

Chronic high blood glucose levels cause hypertension in kidney blood vessels and excess kidney tissue perfusion. The increased pressure damages the kidney in many ways. The blood vessels become leakier, especially in

the glomerulus. This leakiness allows filtration of albumin and other proteins, which then form deposits in the kidney tissue and blood vessels. Blood vessels narrow, decreasing kidney oxygenation and leading to kidney cell hypoxia and cell death. These processes worsen over time, with scarring of glomerular blood vessels and loss of urine filtration ability, leading to kidney failure.

Kidney damage is also related to hypertension for patients with DM and cardiovascular disease. Both systolic and diastolic hypertension speed the progression of diabetic nephropathy.

Male Erectile Dysfunction.

Erectile dysfunction (ED) is the inability to achieve or maintain a sufficient penile erection for satisfactory sexual performance. ED occurs at a higher rate and 10 to 15 years earlier among men with DM as compared with the general population. It is related to poor blood glucose regulation, obesity, hypertension, heavy cigarette smoking, and the presence of other chronic vascular complications. Chapter 72 discusses erectile function problems in depth.

Cognitive Dysfunction.

People age 65 years or older with diabetes are at a significantly higher risk for developing all types of dementia as compared with people who do not have the disease. Chronic hyperglycemia with microvascular disease contributes to neuron damage, brain atrophy, and cognitive impairment (Acee, 2012). These problems occur more frequently and are more severe in patients with longer-duration DM and increase the complications of neuropathy and retinopathy. Depression is highly prevalent in people with diabetes and is associated with worse outcomes.

NCLEX Examination Challenge

Physiological Integrity

Which health problems are considered results of microvascular complications from long-term or poorly controlled diabetes mellitus?
A Obesity and hyperglycemia
B Systolic hypertension and heart failure
C Retinal hemorrhage and male erectile dysfunction
D Diabetic ketoacidosis and hyperglycemic-hyperosmolar state

Etiology and Genetic Risk

Type 1 Diabetes.

Type 1 diabetes mellitus (DM) is an autoimmune disorder in which beta cells are destroyed in a genetically susceptible person (Table 64-4). The immune system fails to recognize normal body cells as "self," and immune system cells and antibodies take destructive actions against the insulin-secreting cells in the islets. People with certain tissue types are more likely to develop autoimmune diseases, including type 1 DM. Viral infections, such as mumps and coxsackievirus infection, may trigger autoimmune destructive actions (McCance et al., 2014).

TABLE 64-4

Differentiation of Type 1 and Type 2 Diabetes

FEATURES	TYPE 1	TYPE 2
Former names	Juvenile-onset diabetes	Adult-onset diabetes
	Ketosis-prone diabetes	Ketosis-resistant diabetes
	Insulin-dependent diabetes mellitus (IDDM)	Non–insulin-dependent diabetes mellitus (NIDDM)
Age at onset	Usually younger than 30 yr, occurs at any age	Peaks in 50s; may occur earlier
Symptoms	Abrupt onset, thirst, hunger, increased urine output, weight loss	Frequently none; thirst, fatigue, blurred vision, vascular or neural complications
Etiology	Viral infection	Not known
Pathology	Pancreatic beta-cell destruction	Insulin resistance
		Dysfunctional pancreatic beta cell
Antigen patterns	*HLA-DR, HLA-DQ*	None
Antibodies	ICAs present at diagnosis	None
Endogenous insulin and C-peptide	None	Low, normal, or high
Inheritance	Complex	Dominant, multifactorial
Nutritional status	Usually nonobese	60% to 80% obese
Insulin	All dependent on insulin	Required for 20% to 30%
Medical nutrition therapy	Mandatory	Mandatory

ICAs, Islet cell antibodies.

Genetic/Genomic Considerations

Patient-Centered Care QSEN

Risk for type 1 diabetes is determined by inheritance of genes coding for the *HLA-DR* and *HLA-DQA* and *DQB* tissues types (ADA, 2014d). However, inheritance of these genes only increases the risk and most people with these genes do not develop type 1 DM. Development of DM is an interactive effect of genetic predisposition and exposure to certain environmental factors. It is unclear why some genetically susceptible people develop diabetes and others do not. Ask patients newly diagnosed with type 1 diabetes whether any other relatives have diabetes or other autoimmune disease.

Type 2 Diabetes and Metabolic Syndrome.

Type 2 DM is a progressive disorder in which the person has a combination of insulin resistance and decreased beta-cell secretion of insulin. Insulin resistance (a reduced cell response to insulin) develops from obesity and physical inactivity in a genetically susceptible person. It occurs before the onset of type 2 DM and often is accompanied by the cardiovascular risk factors of hyperlipidemia, hypertension, and increased clot formation. Most patients with type 2 DM are obese (ADA, 2014d). The specific causes of type 2 DM are not known, although insulin resistance and beta-cell failure have many genetic and nongenetic causes. Heredity plays a major role in the development of type 2 DM, although not all gene variations that increase the risk for type 2 DM are known.

Metabolic syndrome is the simultaneous presence of metabolic factors known to increase risk for developing type 2 DM and cardiovascular disease. Features of the syndrome include:

- Abdominal obesity: waist circumference of 40 inches (100 cm) or more for men and 35 inches (88 cm) or more for women
- Hyperglycemia: fasting blood glucose level of 100 mg/dL or more or on drug treatment for elevated glucose
- Abnormal A1C: between 5.5% and 6.0%
- Hypertension: systolic BP of 130 mm Hg or more or diastolic BP of 85 mm Hg or more or on drug treatment for hypertension
- Hyperlipidemia: triglyceride level of 150 mg/dL or more or on drug treatment for elevated triglycerides; high-density lipoprotein (HDL) cholesterol less than 40 mg/dL for men or less than 50 mg/dL for women

Any one of these health problems increases the rate of atherosclerosis and the risk for stroke, coronary heart disease, and early death. Teach patients about the lifestyle changes that can improve health (Bosak, 2012a). (See the Health Promotion and Maintenance section below.)

Incidence and Prevalence

More than 57 million American adults have **prediabetes**, defined as impaired fasting glucose (IFG) or impaired glucose tolerance (IGT) or an A1C level between 5.5% and 6.0%. IFG (fasting blood glucose levels of 100 mg/dL [5.6 mmol/L] to 125 mg/dL [6.9 mmol/L] and IGT (2-hr oral glucose tolerance values of 140 mg/dL [7.8 mmol/L] to 199 mg/dL [11.0 mmol/L]) are considered risk factors for diabetes and for cardiovascular disease. Over a 3- to 5-year period, people with prediabetes have a fivefold to fifteenfold higher risk for developing type

2 DM than do those with normal blood glucose levels. IFG and IGT are associated with obesity (especially abdominal or central obesity), dyslipidemia with high triglycerides and/or low HDL cholesterol, and hypertension (ADA, 2014d).

In the United States, nearly 26 million people are living with DM and another 79 million have prediabetes. This means almost one third of the total U.S. population are affected by diabetes (CDC, 2011).

About 90% of people with diabetes have type 2 DM (ADA, 2014d). It is diagnosed most often among middle-aged and older adults, affecting about 9.6% of patients ages 20 to 59 years and 20.9% of patients ages 60 years and older. It is more common among men than women (National Institute of Diabetes and Digestive and Kidney Diseases [NIDDK], 2011). With the prevalence of obesity rising in North America, diabetes will become even more common.

Cultural Considerations

Patient-Centered Care QSEN

Racial and ethnic minorities have a higher prevalence and greater burden of diabetes compared with whites, and some minority groups also have higher rates of complications. The risk for diabetes is 77% higher among African Americans than non-Hispanic white Americans. At nearly 16.1%, American Indians and Alaska Indians have the highest age-adjusted prevalence of diabetes among U.S. racial and ethnic groups (Chow et al., 2012). The increase in obesity and sedentary lifestyles in the U. S. population intensifies this growing problem. The ADA has identified patients who should be tested for diabetes in Table 64-5.

TABLE 64-5

Indications for Testing People for Type 2 Diabetes

- Testing for diabetes should be considered in people 45 years of age and older, particularly in those with a BMI greater than 25 kg/m². If normal, it should be repeated at 3-year intervals.
- Testing should be considered at a younger age or be carried out more frequently in people who are overweight (BMI >25 kg/m²) and have these additional associated factors:
  - Have a first-degree relative with diabetes
  - Are physically inactive
  - Are members of a high-risk ethnic population (e.g., African American, Hispanic American, American Indian, Asian American, or Pacific Islander)
  - Deliver a baby weighing more than 9 pounds or have been diagnosed with GDM
  - Are hypertensive (>140/90 mm Hg)
  - Have a high-density lipoprotein (HDL) cholesterol level less than 35 mg/dL (0.90 mmol/L) and/or a triglyceride level greater than 250 mg/dL (2.82 mmol/L)
  - Have polycystic ovary syndrome
  - Have IFG or IGT on previous testing
  - Have a history of vascular disease

BMI, Body mass index; *GDM*, gestational diabetes mellitus; *IFG*, impaired fasting glucose, *IGT*, impaired glucose tolerance.

Data from American Diabetes Association (ADA). (2014d). Position statement: Diagnosis and classification of diabetes mellitus. *Diabetes Care, 37*(Suppl. 1), S81-S90.

The overall clinical outcomes for minority patients with diabetes are worse than for non-Hispanic whites with DM. Possible factors for these outcome differences include lack of access to health care, lifestyle issues, mistrust of the health care system, reduced financial resources, and lack of knowledge about the relationship between glucose control and complications. Be alert to the risk for diabetes whenever you are interviewing or assessing people who belong to these higher risk racial or ethnic groups.

Health Promotion and Maintenance

Diabetes causes many preventable but devastating complications and is a major public health problem. Control of diabetes and its complications is a major focus for health promotion activities. No interventions are successful in preventing type 1 DM, but health promotion activities focus on controlling hyperglycemia to reduce its long-term complications.

Adopting a low calorie diet that results in weight loss and increasing physical activity improve metabolic and cardiac risk factors. These improvements include reducing hypertension, increasing heart rate variability between resting rate and exercise rate, lowering triglyceride levels, increasing high-density lipoprotein cholesterol (the "good" cholesterol) levels, and reducing low-density lipoprotein cholesterol (the "bad" cholesterol) levels.

Teach all patients with DM that tight control of blood glucose levels can prevent many complications. Urge all patients with DM to regularly follow up with their health care provider or endocrinologist, to have their eyes and vision tested yearly by an ophthalmologist, and to have urine microalbumin levels assessed yearly. Early detection of changes in the eye or kidney permits adjustments in treatment regimens that can slow or halt progression of retinopathy and nephropathy. Encourage all people to maintain weight within an appropriate range for height and body build and to engage in physical activity at least 3 times per week (Bosak, 2012b).

❖ Patient-Centered Collaborative Care

◆ Assessment

History.

Ask about risk factors and manifestations related to diabetes. Age is important because type 2 diabetes mellitus (DM) is more common in

older patients, especially among African Americans and Mexican Americans. Ask women how large their children were at birth, because many women who develop type 2 DM had gestational diabetes mellitus (GDM) or glucose intolerance during pregnancy (ADA, 2014d). These women often have given birth to infants weighing 9 pounds or more.

Assessing weight and weight change is important, because excess weight and obesity are risk factors for type 2 DM. The patient with type 1 DM often has weight loss with increased appetite during the weeks before diagnosis. For both types of DM, patients usually have fatigue, polyuria, and polydipsia. Ask about recent major or minor infections. In particular, ask women about frequent vaginal yeast infections. Ask all patients whether they have noticed that small skin injuries become infected more easily or take longer to heal. Also ask whether they have noticed any changes in vision or in the sense of touch.

Laboratory Assessment

Diagnosis of Diabetes.

Diabetes can be diagnosed by assessing blood glucose levels. The ADA defines normal blood glucose values in Chart 64-1. A test result indicating DM should be repeated to rule out laboratory error unless manifestations of hyperglycemia or hyperglycemic crisis are also present. Table 64-6 lists criteria for the diagnosis of diabetes.

Chart 64-1 Laboratory Profile

Blood Glucose Values

TEST	NORMAL RANGE FOR ADULTS	SIGNIFICANCE OF ABNORMAL RESULTS
Fasting blood glucose test	<100 mg/dL (5.6 mmol/L) Older adults: Levels rise 1 mg/dL per decade of age	Levels >100 mg/dL (5.6 mmol/L) but <126 mg/dL (7.0 mmol/L) indicate impaired fasting glucose (IFG).
		Levels >126 mg/dL (7.0 mmol/L) obtained on at least two occasions are diagnostic of diabetes, even in older adults.
Glucose tolerance test (2-hr post-load result)	<140 mg/dL (7.8 mmol/L)	Levels >140 mg/dL (7.8 mmol/L) and <200 mg/dL (11.1 mmol/L) indicate impaired glucose tolerance (IGT).
		Levels >200 mg/dL (11.1 mmol/L) indicate provisional diagnosis of diabetes.
Glycosylated hemoglobin (A1C) test	4%-6%	Levels of 5.7 to 6.4% indicate increased risk for development of diabetes. Levels >8% indicate poor diabetes control and need for adherence to regimen or changes in therapy.

Data from American Diabetes Association (ADA). (2014d). Position statement: Diagnosis and classification of diabetes mellitus. *Diabetes Care, 37*(Suppl. 1), S81-S90.

TABLE 64-6
Criteria for the Diagnosis of Diabetes

A1C >6.5%. The test should be performed in a laboratory using

a method that is NGSP certified and standardized to the DCCT assay.
Or
Fasting blood glucose greater than 126 mg/dL (7.0 mmol/L). *Fasting* is defined as no caloric intake for at least 8 hours.
Or
Two-hour blood glucose equal to or greater than 200 mg/dL (11.1 mmol/L) during oral glucose tolerance test. The test should be performed using a glucose load containing the equivalent of 75 g anhydrous glucose dissolved in water.
Or
In a patient with classic manifestations of hyperglycemia or hyperglycemic crisis, a random blood glucose concentration greater than 200 mg/dL (11.1 mmol/L). *Casual* is defined as any time of the day without regard to time since last meal. The classic symptoms of diabetes include polyuria, polydipsia, and unexplained weight loss. **Note:** In the absence of unequivocal hyperglycemia, the first three criteria should be confirmed by repeat testing.
DCCT, Diabetes Control and Complications Trial; *NGSP,* National Glycohemoglobin Standardization Program.

Data from American Diabetes Association (ADA). (2014d). Position statement: Diagnosis and classification of diabetes mellitus. *Diabetes Care, 37*(Suppl. 1), S81-S90.

The diagnosis of diabetes mellitus includes elevated glycosylated hemoglobin levels. **Glycosylated hemoglobin (A1C)** is a standardized test that measures how much glucose permanently attaches to the hemoglobin molecule. Because glucose binds to many proteins, including hemoglobin, through a process called *glycosylation,* the higher the blood glucose level is over time, the more glycosylated hemoglobin becomes. The ADA defines A1C levels greater than 6.5% as diagnostic of DM (ADA, 2014d; Funnell, 2014).

Fasting plasma glucose (FPG) (fasting blood glucose [FBG]) is used to diagnose diabetes in nonpregnant adults. The patient should have no caloric intake for at least 8 hours (water is permitted). The blood sample needs to be obtained before insulin or oral antidiabetic agents have been taken. A diagnosis of diabetes is made with two separate test results greater than 126 mg/dL (7 mmol/L) (ADA, 2014d). *Random* or *casual*

plasma (blood) glucose greater than 200 mg/dL (7.0 mmol/L) is used to diagnose diabetes in patients with severe classic hyperglycemia or hyperglycemic crisis.

Oral glucose tolerance testing (OGTT) is the most sensitive test for the diagnosis of DM. It is often used to diagnose gestational diabetes mellitus (GDM) during pregnancy and is not routinely used for general diagnosis.

Other blood tests for diabetes can help determine whether a patient has type 1 or type 2 DM. Type 1 DM results from autoimmune destruction of the beta cells of the pancreas. Markers of this destruction include islet cell autoantibodies (ICAs), autoantibodies to insulin, and autoantibodies to glutamic acid decarboxylase (GAD65). ICAs are present in 85% to 90% of people with new-onset type 1 DM.

Measurement of C-peptide levels indicates beta secretory function of the pancreas. Low to absent C-peptide levels diagnose type 1 DM, as well as late-stage type 2 DM when the ability of the pancreas to secrete insulin is severely impaired.

Screening for Diabetes.

Measurement of islet cell antibodies may identify people who are at risk for developing type 1 DM. Testing to detect prediabetes and type 2 DM should be considered in patients older than 45 years and those defined as overweight (body mass index [BMI] greater than 25 kg/m^2). Testing is considered for patients who are younger than 45 years and are overweight if they have additional risk factors for diabetes or have other health problems associated with diabetes. Screening for diabetes usually is done with either hemoglobin A1C levels or fasting plasma glucose levels (ADA, 2014d). The use of portable glucose meters for the diagnosis of diabetes is not recommended because of imprecise results and variance in results among the different glucose monitors (Sacks, 2011).

Ongoing Assessment.

Glycosylated hemoglobin assays are useful because blood glucose permanently attaches to hemoglobin. The higher the blood glucose level is over time, the more glycosylated hemoglobin becomes. Thus glycosylated hemoglobin A1C (A1C) is a good indicator of the average blood glucose levels because it shows the average blood glucose level during the previous 120 days—the life span of red blood cells. A1C testing can help assess long-term glycemic control and predict the risk for complications. *Unlike the fasting blood glucose test, A1C test results are*

not altered by eating habits the day before the test. This testing is performed at diagnosis and at specific intervals to evaluate the treatment plan. A1C testing is recommended at least twice yearly in patients who are meeting expected treatment outcomes and have stable blood glucose control. Quarterly assessment is recommended for patients whose therapy has changed or who are not meeting prescribed glycemic levels (ADA, 2014d). Table 64-7 shows the correlation between A1C and mean blood glucose levels.

TABLE 64-7

Correlation Between A1C Level and Mean Blood Glucose Levels

	MEAN BLOOD GLUCOSE	
A1C (%)	Mg/dL	mmol/L
6	126	7.0
7	154	8.6
8	183	10.2
9	212	11.8
10	240	13.4
11	269	14.9
12	298	16.5

Data from American Diabetes Association (ADA). (2013). Standards of medical care in diabetes—2013. *Diabetes Care, 36*(Suppl. 1), S19.

When glucose binds to amino groups on serum proteins, especially albumin, the glycosylated protein product is called *fructosamine.* This product increases with elevated blood glucose levels in the same way as hemoglobin does but can indicate blood glucose control over a shorter period. These measures are useful for short-term follow-up of treatment changes or in patients with hemoglobin abnormalities in which A1C is not an accurate reflection of glucose control. Available tests are called *glycosylated serum albumin (GSA), glycosylated serum protein (GSP),* and *fructosamine*.

Urine Tests.

Ketone bodies are a product of fat metabolism, and the presence of moderate to high urine ketones (hyperketonuria) indicates a severe lack of insulin. Hyperketonuria in the presence of hyperglycemia is a medical emergency that, when detected early, can be managed with insulin and careful monitoring. Urine testing for ketones should be performed during acute illness or stress, when blood glucose levels consistently

exceed 300 mg/dL (16.7 mmol/L), during pregnancy, or when any manifestations of ketoacidosis are present. Ketone testing is recommended for patients with diabetes participating in a weight-loss program. Hyperketonuria without hyperglycemia suggests that weight loss is occurring without disrupting blood glucose control.

Ketone bodies appear in urine in the same proportion as they do in blood but are affected by urine volume and concentration. Thus urine ketone bodies are not used to evaluate the effectiveness of treatment for ketoacidosis.

Tests for kidney function are important in detecting kidney disease in diabetes. Persistent albuminuria in the range of 30 to 299 mg/24 hr is an indicator of early-stage diabetic nephropathy in type 1 diabetes and a marker for development of nephropathy in type 2 diabetes. Persistent albuminuria is also a marker for increased cardiovascular risk (ADA, 2014f). Screening for increased urinary albumin excretion can be performed by measurement of albumin-to-creatinine ratio in a random spot collection.

Serum creatinine is used to estimate kidney function (e.g., glomerular filtration rate) and to stage the level of chronic kidney disease. In patients with nephropathy, a rise in serum creatinine level is related to both poor blood glucose control and hypertension.

Urine glucose testing is an indirect measurement of blood glucose and is not accurate. This test is not used for monitoring DM management.

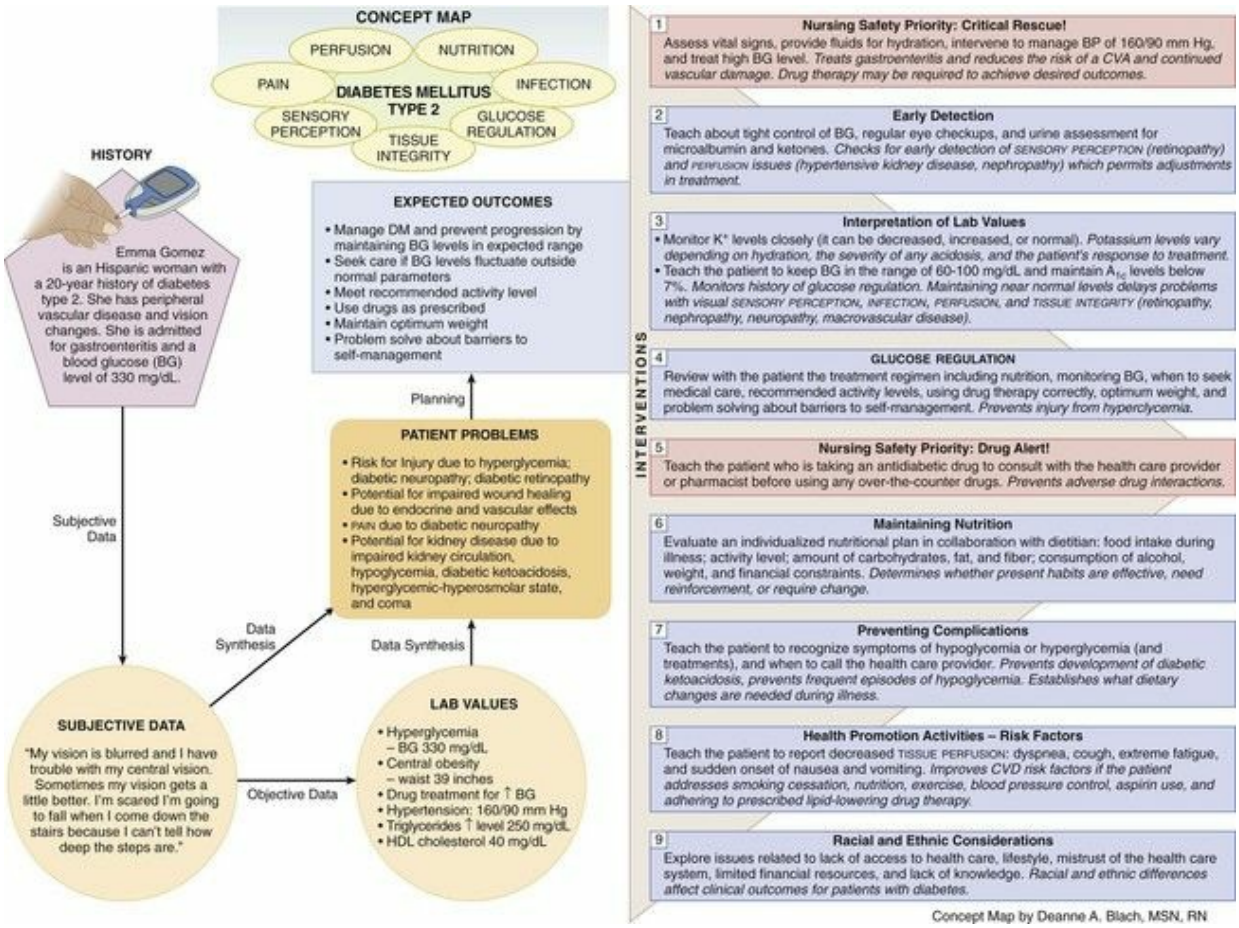
Analysis

The priority NANDA-I nursing diagnoses and collaborative problems for patients with diabetes include:

1. Risk for Injury related to hyperglycemia (NANDA-I)
2. Potential for impaired wound healing related to endocrine and vascular effects of diabetes
3. Risk for Injury related to diabetic neuropathy (NANDA-I)
4. Acute Pain and Chronic Pain related to diabetic neuropathy (NANDA-I)
5. Risk for Injury related to diabetic retinopathy–induced reduced vision (NANDA-I)
6. Potential for kidney disease related to impaired kidney circulation
7. Potential for hypoglycemia
8. Potential for diabetic ketoacidosis
9. Potential for hyperglycemic-hyperosmolar state and coma

Planning and Implementation

The management of diabetes mellitus (DM) is complex and involves extensive patient education. The Concept Map on p. 1311 highlights care issues for the patient with type 2 DM.



Preventing Injury from Hyperglycemia

Planning: Expected Outcomes.

The patient with diabetes is expected to manage DM and prevent disease progression by maintaining blood glucose levels in his or her target range. Indicators are that the patient consistently demonstrates these behaviors:

- Performs treatment regimen as prescribed
- Follows recommended diet
- Monitors blood glucose using correct testing procedures
- Seeks health care if blood glucose levels fluctuate outside of recommended parameters
- Meets recommended activity levels

- Uses drugs as prescribed
- Maintains optimum weight
- Problem solves about barriers to self-management

Interventions

Nonsurgical Management.

Nonsurgical management of diabetes mellitus (DM) involves nutrition interventions, blood glucose monitoring, a planned exercise program, and often, drugs to lower blood glucose levels. The nurse, together with the patient, physician, dietitian, pharmacist, case manager, and other health care professionals, plans, coordinates, and delivers care.

The American Diabetes Association (ADA) has proposed these treatment outcomes for glycosylated hemoglobin (A1C) and blood glucose levels (ADA, 2014d):

- A1C levels are maintained at 6.5% or below.
- The majority of premeal blood glucose levels are 70 to 130 mg/dL (3.9 to 7.2 mmol/L).
- Peak after-meal blood glucose levels are less than 180 mg/dL (<10.0 mmol/L).

Drug Therapy.

Drug therapy is indicated when a patient with type 2 DM does not achieve blood glucose control with diet changes, regular exercise, and stress management. Several categories of drugs are available to lower blood glucose levels. Patients with type 1 DM require insulin therapy for blood glucose control.

Drugs are started at the lowest effective dose and increased every 1 to 2 weeks until the patient reaches desired blood glucose control or the maximum dosage. If the maximum dosage of one agent does not control blood glucose levels, a second agent with a different mechanism of action may be added. Insulin therapy is indicated for the patient with type 2 DM when blood glucose cannot be controlled with the use of two or three different antidiabetic agents.

Antidiabetic drugs are not a substitute for dietary modification and exercise. Teach the patient about the need for continuing dietary restrictions and regular exercise while taking antidiabetic drugs.

 **Nursing Safety Priority** QSEN

Drug Alert

To avoid adverse drug interactions, teach the patient who is taking an antidiabetic drug to consult with his or her primary care provider or pharmacist before using *any* over-the-counter drugs.

Drug Selection.

The choice of antidiabetic drug is based on cost, the patient's ability to manage multiple drug dosages, age, and response to the drugs. Shorter-acting agents (e.g., glipizide) are preferable in older patients, those with irregular eating schedules, or those with liver, kidney, or cardiac dysfunction. Longer-acting agents (e.g., glyburide, glimepiride) with once-a-day dosing are better for adherence. Beta-cell function in type 2 DM often declines over time, reducing the effectiveness of some drugs. The treatment regimen for a patient with type 2 DM may eventually require insulin therapy either alone or with other antidiabetic drugs.

Antidiabetic Drugs.

Some antidiabetic drugs are oral agents, and others require subcutaneous injection. Chart 64-2 lists common antidiabetic drugs in each category.

Chart 64-2 Common Examples of Drug Therapy

Diabetes Mellitus

DRUG/CLASS	ROUTE OF ADMINISTRATION	SIDE EFFECTS
Secretagogues—Lower fasting plasma (blood) glucose levels by triggering the release of insulin from beta cells.		
Second-Generation Sulfonylurea Agents		
Glipizide (Glucotrol)	Oral	Hypoglycemia Weight gain Interacts with many drugs
Glimepiride (Amaryl)	Oral	Hypoglycemia
Meglitinide Analogs—Lower fasting plasma (blood) glucose levels by triggering the release of insulin from beta cells.		
Repaglinide (Prandin)	Oral	Hypoglycemia
Nateglinide (Starlix)	Oral	Hypoglycemia
Biguanides		
Metformin (Glucophage)	Oral	Abdominal discomfort (diarrhea, nausea, vomiting, flatulence, indigestion) Lactic acidosis Interacts with contrast material and can induce acute kidney injury
Insulin Sensitizers—Do not increase insulin secretion. Decrease liver glucose production, reducing fasting plasma (blood) glucose release, and improve insulin receptor sensitivity. TDZs also increase cellular utilization of glucose.		
Thiazolidinediones (TZDs)		
Pioglitazone (Actos)	Oral	Increased risk for heart-related deaths; not to be used by patients with symptomatic heart failure Increased risk for bone fracture and macular edema Increased risk for liver impairment Increased risk for bladder cancer
Rosiglitazone (Avandia)	Oral	Increased risk for heart-related deaths; not to be used by patients with symptomatic heart failure Increased risk for bone fracture and macular edema Increased risk for liver impairment
Alpha-Glucosidase Inhibitors—Prevent after-meal hyperglycemia by inhibiting enzymes in the intestinal tract, reducing the rate of digestion of starches, and delaying absorption of carbohydrate from the small intestine.		
Acarbose (Precose)	Oral	Abdominal discomfort (diarrhea, nausea, vomiting, flatulence, bloating, indigestion) Elevates serum transaminase levels and reduces liver function Drug accumulates in patients with kidney impairment
Miglitol (Glyset)	Oral	Abdominal discomfort (diarrhea, nausea, vomiting, flatulence, bloating, indigestion) Elevates serum transaminase levels and reduces liver function Drug accumulates in patients with kidney impairment
Incretin Mimetics (GLP-1 agonists)—Act like natural "gut" hormones that work with insulin to lower plasma (blood) glucose levels. They lower glucagon secretion from the pancreas, leading to reduced liver glucose production. Also reduce blood glucose levels by delaying gastric emptying, slowing the rate of nutrient absorption into the blood, and reducing food intake.		
Albiglutide (Tanzeum)	Subcutaneous injection (once weekly)	Increased risk for pancreatitis Increased risk for thyroid cancer
Exenatide (Byetta)	Subcutaneous injection	Increased risk for pancreatitis Increased risk for hypersensitivity reactions, including Stevens-Johnson syndrome
Exenatide extended release (Bydureon)	Subcutaneous injection	Increased risk for pancreatitis Increased risk for thyroid cancer
Liraglutide (Victoza)	Subcutaneous injection	Increased risk for pancreatitis Increased risk for thyroid cancer
DPP-4 Inhibitors—DPP-4 is an enzyme that breaks down the natural gut hormones (GLP-1 and GIP). DPP-4 inhibitors increase the amount of natural substances that work with insulin to lower glucagon secretion from the pancreas, leading to reduced liver glucose production. Also reduce blood glucose levels by delaying gastric emptying, slowing the rate of nutrient absorption into the blood, and reducing food intake.		
Sitagliptin (Januvia)	Oral	Increased risk for acute pancreatitis
Saxagliptin (Onglyza)	Oral	Increased risk for acute pancreatitis
Linagliptin (Tradjenta)	Oral	Increased risk for acute pancreatitis
Alogliptin (Nesina)	Oral	Increased risk for acute pancreatitis Kazano (alogliptin/metformin combination) carries black box warning for lactic acidosis
Amylin Analogs—Similar to amylin, a naturally occurring hormone produced by beta cells in the pancreas that is co-secreted with insulin and lowers blood glucose levels by delaying gastric emptying and triggering satiety.		
Pramlintide (Symlin)	Subcutaneous injection	Severe hypoglycemia Nausea and vomiting
Fixed Combinations—There are many fixed combinations of oral drugs available. The side effects of these combination drugs are the same as for each component of the combination. When a drug that has the side effect of hypoglycemia is combined with a drug that does not alone produce hypoglycemia, the development of hypoglycemia is still very much a risk for the combination agent.		

Insulin Secretogogues.

Insulin secretagogues stimulate insulin release from pancreatic beta cells and are used for patients who are still able to produce insulin.

Sulfonylurea Agents.

Sulfonylurea agents lower fasting blood glucose levels by triggering the release of insulin from beta cells. Many drugs interact with sulfonylureas. Be sure to consult a drug reference book or pharmacologist when instructing patients who are prescribed a drug from this class.

Meglitinide Analogs.

Meglitinide analogs are classified as insulin secretagogues and have actions and adverse effects similar to those of sulfonylureas. They tend to increase meal-related insulin secretion.

Biguanides.

Metformin (Glucophage) does not increase insulin secretion. It decreases liver glucose production and decreases intestinal absorption of glucose. It also improves insulin sensitivity by increasing peripheral glucose uptake and utilization.

Nursing Safety Priority QSEN

Drug Alert

Metformin can cause lactic acidosis in patients with renal insufficiency and should not be used by anyone with kidney disease. To prevent kidney damage, the drug should be withheld after using contrast material or any surgical procedure requiring anesthesia until adequate kidney function is established.

Insulin Sensitizers.

Thiazolidinediones (TZDs) increase cellular utilization of glucose, which lowers blood glucose levels. Both of the TZDs—rosiglitazone (Avandia) and pioglitazone (Actos)—are associated with an increased risk for heart-related deaths, bone fracture, and macular edema. The Food and Drug Administration (FDA) has issued a black box warning indicating that these drugs are not to be used by patients who have symptomatic heart failure or other specific types of cardiovascular disease (Sisson et al., 2012). (A **Black Box Warning** is a government designation indicating that a drug has at least one serious side effect and must be used with caution.)

Alpha-Glucosidase Inhibitors.

Alpha-glucosidase inhibitors prevent after-meal hyperglycemia by delaying absorption of carbohydrate from the small intestine. These

drugs inhibit enzymes in the intestinal tract, reducing the rate of digestion of starches and the absorption of glucose. This action prevents a sudden blood glucose surge after meals. These drugs do not cause hypoglycemia unless given with sulfonylureas or insulin.

Incretin Mimetics.

Incretin mimetics work like the natural "gut" hormones—glucagon-like peptide-1 (GLP-1) and glucose-dependent insulinotropic polypeptide (GIP)—that are released by the intestine in response to food intake and act with insulin to perform glucose regulation. Drugs in this class include the GLP-1 agonists *exenatide* (Byetta), *exenatide extended-release* (Bydureon), and the glucagon-like peptide-1 (GLP-1) agonists *liraglutide* (Victoza) and *albiglutide* (Tanzeum). These drugs are used in addition to diet and exercise to improve glycemic control in adults with type 2 DM. Liraglutide carries a black box warning for thyroid tumors and is not to be used by patients with a history of medullary thyroid carcinoma.

 **Nursing Safety Priority** QSEN

Drug Alert

Albiglutide (Tanzeum) is only administered once per week, not daily like other incretin mimetics.

DPP-4 Inhibitors.

The natural incretins *GLP* and *GIP* are rapidly metabolized and inactivated by the enzyme *DPP-4 (dipeptidyl peptidase 4).* DPP-4 inhibitors work by reducing the inactivation of the incretin hormones so that they remain available for blood glucose regulation. The four DPP-4 inhibitors approved for use in patients with type 2 DM are sitagliptin (Januvia), saxagliptin (Onglyza), linagliptin (Tradjenta), and alogliptin (Nesina) (Sisson et al., 2012).

 **Nursing Safety Priority** QSEN

Drug Alert

All four DPP-4 inhibitors and the incretin mimetic *liraglutide* are associated with an increased risk for pancreatitis. Warn patients taking these drugs to immediately report these manifestations to the health care provider: jaundice; sudden onset of intense abdominal pain that

radiates to the back, left flank, or left shoulder; or gray-blue discoloration of the abdomen or periumbilical area.

Amylin Analogs.

Amylin analogs are drugs similar to amylin, a naturally occurring hormone produced by pancreatic beta cells that works with and is co-secreted with insulin in response to blood glucose elevation. Amylin levels are deficient in patients with type 1 DM who are also deficient in insulin. Pramlintide (Symlin), an analog of amylin, is approved for patients with either type 1 or type 2 DM treated with insulin. It works by three mechanisms: delaying gastric emptying; reducing after-meal blood glucose levels; and triggering satiety (in the brain). (Satiety leads to decreased caloric intake and eventual weight loss.)

Nursing Safety Priority QSEN

Drug Alert

Do not mix pramlintide and insulin in the same syringe because the pH of the two drugs is not compatible.

Sodium-Glucose Co-transport Inhibitors.

Sodium-glucose co-transport inhibitors are the newest class of antidiabetic drugs. They lower blood glucose levels by preventing kidney reabsorption of the glucose that was filtered from the blood into the urine. Thus the filtered glucose is excreted in the urine rather than moved back into the blood. These oral drugs include *canagliflozin* (Invokana) and *dapagliflozin* (Farxiga).

Combination Agents.

Combination agents combine drugs with different mechanisms of action. Glucovance, for example, combines glyburide with metformin. Combining drugs with different mechanisms of action may be highly effective in maintaining desired blood glucose control. Some patients may need a combination of oral agents and insulin to control blood glucose levels.

Insulin Therapy.

Insulin therapy is needed for type 1 DM and also may be used for type 2 DM. The safety of insulin therapy in older patients may be affected by reduced vision, mobility and coordination problems, and decreased

memory. There are many types of insulin and regimens to achieve normal blood glucose levels. Because insulin is a small protein that is quickly digested and inactivated in the GI tract, it must be administered as an injection.

Types of Insulin.

Insulin is manufactured using DNA technology to produce pure human insulin. Insulin analogs are synthetic human insulins in which the structure of the insulin molecule is altered to change the rate of absorption and duration of action within the body (Dokken, 2013). An example is Lispro insulin, a rapid-acting insulin analog that is created by switching the positions of lysine and proline in one area of the insulin molecule.

Rapid-, short-, intermediate-, and long-acting forms of insulin can be injected separately, and some can be mixed in the same syringe. Insulin is available in concentrations of 100 units/mL (U-100) or 500 units/mL (U-500). U-500 is indicated only for patients with severe insulin resistance whose total daily insulin dose exceeds 200 units.

Teach the patient that the insulin types, the injection technique, the site of injection, and the patient response can all affect the absorption, onset, degree, and duration of insulin activity. Reinforce that changing insulins may affect blood glucose control and should be done only under supervision of the health care provider. Table 64-8 outlines the time activity of human insulin.

TABLE 64-8

Time Activity of Pharmaceutical Insulin

PREPARATION	BRAND	ONSET (Hr)	PEAK (Hr)	DURATION (Hr)
Rapid-Acting Insulin				
Insulin aspart	Novo Log	0.25	1-3	3-5
Insulin glulisine	Apidra	0.3	0.5-1.5	3-4
Human lispro injection	Humalog	0.25	0.5-1.5	5
Short-Acting Insulin				
Regular human insulin injection	Humulin R	0.5	2-4	5-7
	Novolin R	0.5	2.5-5	8
	ReliOn R	0.5	2.5-5	8-12

75% insulin lispro protamine suspension/25% insulin lispro injection	Humalog Mix 75/25	0.25	1-2	24
Long-Acting Insulin				
Insulin glargine injection	Lantus	2-4	None	24
Insulin detemir injection	Levemir	1	6-8	5.7-24

Insulin Regimens.

Insulin regimens try to duplicate the normal insulin release pattern from the pancreas. The pancreas produces a constant *(basal)* amount of insulin that balances liver glucose production with glucose use and maintains normal blood glucose levels between meals. The pancreas also produces additional *(prandial)* insulin to prevent blood glucose elevation after meals. The insulin dose required for blood glucose control varies among patients. A usual starting dose is between 0.5 and 1 unit/kg of body weight per day. For multiple-dose regimens or continuous subcutaneous insulin infusion (CSII), basal insulin makes up about 40% to 50% of the total daily dosage, with the remainder divided into premeal doses of rapid-acting insulin analogs or regular insulin. Basal insulin coverage is provided by intermediate-acting insulin such as NPH insulin or by long-acting insulin analogs, such as insulin glargine (Lantus) or insulin detemir (Levemir). Dosages are adjusted based on the results of blood

glucose monitoring.

Single daily injection protocols require insulin injection only once daily. This protocol may include one injection of intermediate- or long-acting insulin or a combination of short- and intermediate-acting insulin. Many patients with type 2 diabetes combine once-daily insulin injection with oral agent therapy.

Multiple-component insulin therapy combines short- and intermediate-acting insulin injected twice daily. Two thirds of the daily dose is given before breakfast and one third before the evening meal. Ratios of intermediate-acting and regular insulin are based on results of blood glucose monitoring.

Intensified regimens include a basal dose of intermediate- or long-acting insulin and a bolus dose of short- or rapid-acting insulin designed to bring the *next* blood glucose value into the target range. Blood glucose elevations above the target range are treated with "correction" doses of short- or rapid-acting insulin. The patient's blood glucose patterns determine insulin dosage. Frequency of blood glucose monitoring is based on the timed action of insulin and may occur as often as 8 times daily. Blood glucose testing 1 to 2 hours after meals and within 10 minutes before the next meal helps determine the adequacy of the bolus dose. The patient determines the effects of basal insulin by monitoring blood glucose levels before breakfast (fasting) and before the evening meal.

Patients on intensified insulin regimens need extensive education to achieve target blood glucose values. They need to know how to adjust insulin doses and understand nutrition therapy for dietary flexibility and target blood glucose values. Patients must also be able to accurately monitor blood glucose levels so that therapy decisions can be based on accurate data.

Regardless of the specific insulin regimen, adherence to insulin injection schedules is critical in achieving glycemic control and maintaining A1C levels below the 6.5% needed to reduce long-term complications. At times, skipping an occasional insulin dose may be related to an unusual meal pattern for a day or a change in exercise.

Factors Influencing Insulin Absorption.

Many factors affect insulin absorption and availability, including injection site; timing, type, or dose of insulin used; and physical activity.

Injection site area affects the speed of insulin absorption. Fig. 64-2 shows common insulin injection areas. Absorption is fastest in the abdomen, and except for a 2-inch radius around the navel, it is the

preferred injection site area. Rotating injection site areas prevents lipohypertrophy (increased fat deposits in the skin) and lipoatrophy (loss of fatty tissue, leaving an uneven appearance). Rotation *within* one anatomic site is preferred to rotation from one area to another to prevent day-to-day changes in absorption.

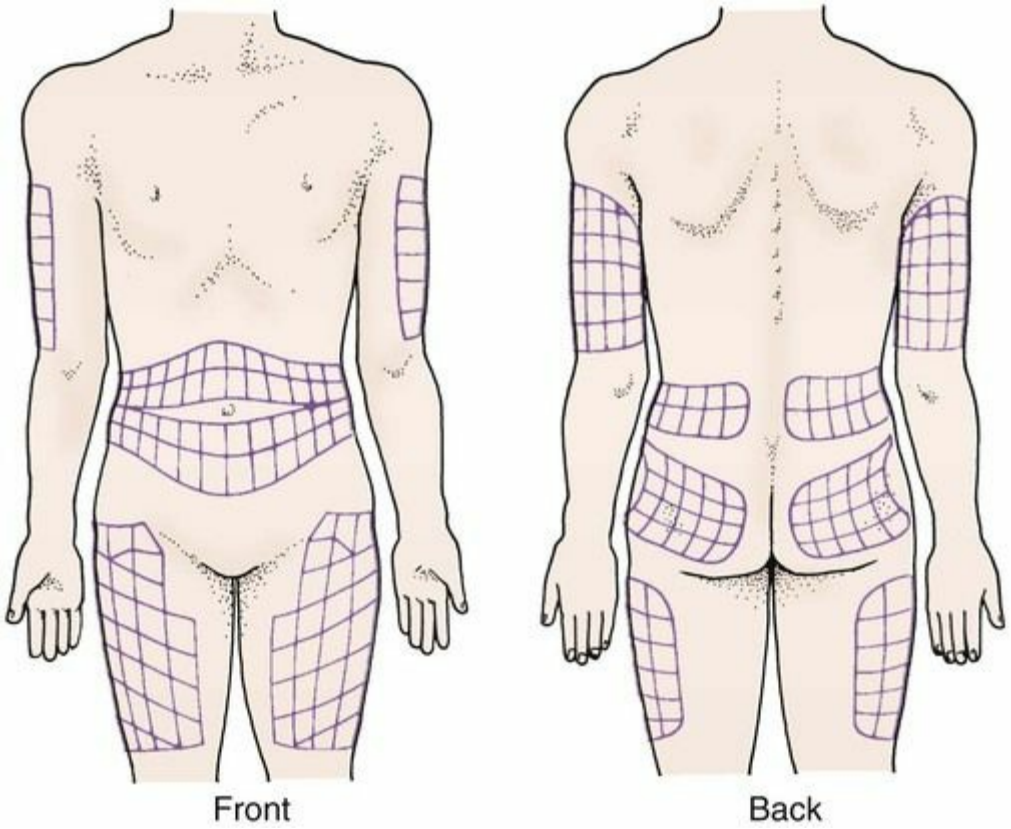

FIG. 64-2 Common insulin injection areas and sites.

Absorption rate is determined by insulin properties. The longer the duration of action, the more unpredictable is absorption. Larger doses of insulin also prolong the absorption. Factors that increase blood flow from the injection site, such as local application of heat, massage of the area, and exercise of the injected area, increase insulin absorption. Scarred sites often become favorite injection sites because they are less sensitive to pain, but these areas usually slow the rate of insulin absorption.

Injection depth changes insulin absorption. Usually, injections are made into the subcutaneous tissue. IM injection has a faster absorption and is not used for routine insulin use. Most patients lightly grasp a fold of skin and inject at a 90-degree angle; however, a 45-degree angle is advised for frail older adults and those who are cachexic. Aspiration for blood is not needed. Patients with high body mass index (BMI) levels can use 4 mm or 5 mm needles to inject insulin at a 90-degree angle without pinching a

skinfold before injection. Assess the older patient's ability to inject insulin, and arrange for assistance when self-care is no longer possible.

Timing of injection affects blood glucose levels. The interval between premeal injections and eating, known as "lag time," affects blood glucose levels after meals. Insulin lispro, insulin aspart, and insulin glulisine have rapid onsets of action and should be given within 10 minutes before mealtime when blood glucose is in the target range. If hyperglycemia or hypoglycemia is not present, these insulins can be given at any time from 10 minutes before mealtime to just before eating or even immediately after eating. Regular insulin should be given at least 20 to 30 minutes before eating when glucose levels are within the target range. When blood glucose levels are above the target range, the lag time should be increased to permit insulin to begin to have an effect sooner. Rapid-acting insulin analogs can be given 15 minutes before and regular insulin 30 to 60 minutes before eating a meal. When blood glucose levels are below the target range, injection of regular insulin should be delayed until immediately before eating and injection of rapid-acting insulin should be delayed until sometime after eating the meal.

Mixing insulins can change the time of peak action. Mixtures of short- and intermediate-acting insulins produce a more normal blood glucose response in some patients than does a single dose. The patient's response to mixed insulin may differ from the response to the same insulins given separately.

Nursing Safety Priority QSEN

Drug Alert

Do not mix any other insulin type with insulin glargine, with insulin detemir, or with any of the premixed insulin formulations, such as Humalog Mix 75/25.

Complications of Insulin Therapy.

Hypoglycemia from insulin excess has many causes. Its effects and treatment are discussed on p. 1330 in the Preventing Hypoglycemia section.

Lipoatrophy is a loss of fat tissue in areas of repeated injection that results from an immune reaction to impurities in insulin. Treatment consists of injection of insulin at the edge of the atrophied area. *Lipohypertrophy* is an increased swelling of fat that occurs at the site of repeated insulin injections. The overlying skin has decreased sensitivity,

and the area can become large and unsightly. Treatment consists of rotating the injection site among different body areas.

Two conditions of fasting hyperglycemia can occur (Fig. 64-3). *Dawn phenomenon* results from a nighttime release of growth hormone that causes release of liver glucose resulting in blood glucose elevations at about 5 to 6 am. It is managed by providing more insulin for the overnight period (e.g., giving the evening dose of intermediate-acting insulin at 10 pm). *Somogyi phenomenon* is morning hyperglycemia from the counterregulatory response to nighttime hypoglycemia resulting in release of liver glucose. It is managed by ensuring adequate dietary intake at bedtime and evaluating the insulin dose and exercise programs to prevent conditions that lead to hypoglycemia. Both problems are diagnosed by blood glucose monitoring during the night. Help identify these problems, and teach the patient and family about management.

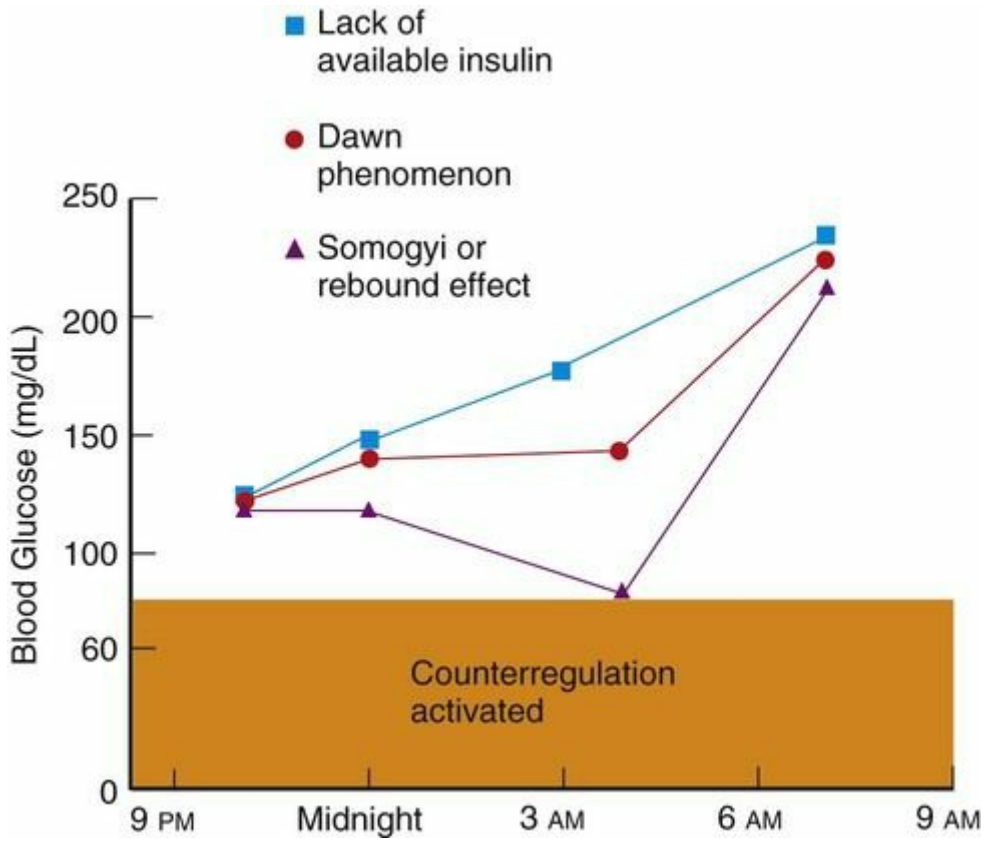

FIG. 64-3 Three blood glucose phenomena in patients with diabetes.

Alternative Methods of Insulin Administration.

Many methods of insulin delivery are available in addition to traditional subcutaneous injections.

Continuous subcutaneous infusion of a basal dose of insulin (CSII) with

increases in insulin at mealtimes is more effective in controlling blood glucose levels than other schedules. It allows flexibility in meal timing, because if a meal is skipped, the additional mealtime dose of insulin is not given. CSII is given by an externally worn pump containing a syringe and reservoir with rapid-acting insulin and is connected to the patient by an infusion set. Teach him or her to adjust the amount of insulin based on data from blood glucose monitoring. Rapid-acting insulin analogs are used with insulin infusion pumps (Hughes, 2012a) (Fig. 64-4).

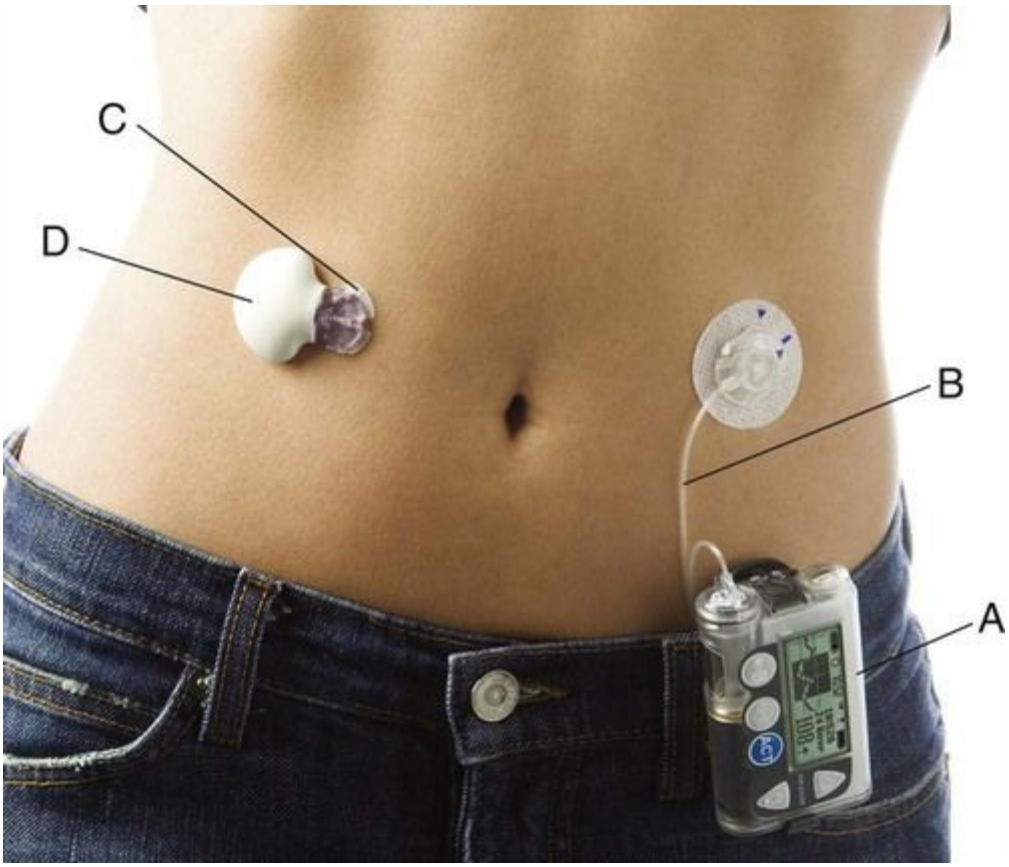

FIG. 64-4 The MiniMed Paradigm REAL-Time Insulin Pump and Continuous Glucose Monitoring System. **A,** Pump. **B,** Injection cannula. **C,** Glucose sensor. **D,** Data transmitter.

Problems with CSII include skin infections that can occur when the infusion site is not cleaned or the needle is not changed every 2 to 3 days. CSII may lead to more episodes of ketoacidosis than other methods of insulin delivery because of inexperience in pump use, infection, accidental cessation or obstruction of the infusion, or mechanical pump problems (Hughes, 2012a). Stress the importance of testing for ketones when blood glucose levels are greater than 300 mg/dL (16.7 mmol/L).

Patients using CSII need intensive education. Because of the risk for hypoglycemia or hyperglycemia, he or she must be able to operate the

pump, adjust the settings, and respond appropriately to alarms. Removing the pump for any length of time can result in hyperglycemia. Provide supplemental insulin schedules for times when the pump is not operational. CSII is more costly than traditional insulin injections, and not all costs are covered by insurance.

Injection devices include a needleless system and a pen-type injector in addition to traditional insulin syringes. With a needleless device, the needle is replaced by an ultrathin liquid stream of insulin forced through the skin under high pressure known as "jet injection." Insulin given by jet injection is absorbed at a faster rate and has a shorter duration of action. Cost is a drawback to this system.

Patient Education: Drugs.

Provide specific instructions about insulin therapy, new drug therapies, and self-monitoring of blood glucose levels.

Insulin storage varies by use. Teach patients to refrigerate insulin that is not in use to maintain potency, prevent exposure to sunlight, and inhibit bacterial growth. Insulin in use may be kept at room temperature for up to 28 days to reduce irritation at the injection site caused by cold insulin.

To prevent loss of drug potency, teach the patient to avoid exposing insulin to temperatures below 36° F (2.2° C) or above 86° F (30° C), to avoid excessive shaking, and to protect insulin from direct heat and light. Insulin should not be allowed to freeze. Insulin glargine (Lantus) should be stored in a refrigerator (36° to 46° F [2.2° to 7.8° C]) even when in use. Teach patients to discard any unused insulin after 28 days.

Teach patients to always have a spare bottle of each type of insulin used. A slight loss in potency may occur for bottles in use for more than 30 days, even when the expiration date has not passed. Prefilled syringes are stable up to 30 days when refrigerated. Store prefilled syringes in the upright position, with the needle pointing upward, so that insulin particles do not clog it. Teach patients to roll, not shake, prefilled syringes between the hands before using.

Dose preparation is critical for insulin effectiveness and patient safety. Teach patients that the person giving the insulin needs to inspect the insulin before each use for changes (e.g., clumping, frosting, precipitation, or change in clarity or color) that may indicate loss in potency. Rapid-acting, short-acting, and glargine insulins should be clear. Preparations containing NPH insulin should be uniformly cloudy after gently rolling the vial between the hands. If potency is questionable, another vial of the same type of insulin should be used.

Syringes are the most commonly used method to administer insulin.

The standard insulin syringes are marked in insulin units. They are available in 1-mL (100-U), ½-mL (50-U), and 3/10-mL (30-U) sizes. The unit scale on the barrel of the syringe differs with the syringe size and manufacturer. Insulin syringe needles are measured in 28-, 29-, 30-, and 31-gauge and in lengths of 6 mm, 8 mm, and 12.7 mm. To ensure accurate insulin measurement, instruct the patient to always buy the same type of syringe. Chart 64-3 reviews instructions for drawing up a single insulin injection.

Chart 64-3 Patient and Family Education: Preparing for Self-Management

Subcutaneous Insulin Administration

- Wash your hands.
- Inspect the bottle for the type of insulin and the expiration date.
- Gently roll the bottle of intermediate-acting insulin in the palms of your hands to mix the insulin.
- Clean the rubber stopper with an alcohol swab.
- Remove the needle cover, and pull back the plunger to draw air into the syringe. The amount of air should be equal to the insulin dose. Push the needle through the rubber stopper, and inject the air into the insulin bottle.
- Turn the bottle upside down, and draw the insulin dose into the syringe.
- Remove air bubbles in the syringe by tapping on the syringe or injecting air back into the bottle. Redraw the correct amount.
- Make certain the tip of the plunger is on the line for your dose of insulin. Magnifiers are available to assist in measuring accurate doses of insulin.
- Remove the needle from the bottle. Recap the needle if the insulin is not to be given immediately.
- Select a site within your injection area that has not been used in the past month.
- Clean your skin with an alcohol swab. Lightly grasp an area of skin, and insert the needle at a 90-degree angle.
- Push the plunger all the way down. This will push the insulin into your body. Release the pinched skin.
- Pull the needle straight out quickly. Do not rub the place where you gave the shot.
- Dispose of the syringe and needle without recapping in a puncture-

proof container.

Disposable needles should be used only once. Reuse of an insulin syringe and needle can compromise insulin sterility. A reason not to reuse smaller (30- and 31-gauge) needles is that even with one injection, the needle tip can become bent to form a hook, which can lacerate tissue or break off to leave needle fragments in the skin (Fig. 64-5). Teach the patient to discard the syringe and needle after one use. Information on needle disposal can be obtained at www.safeneedledisposal.org.

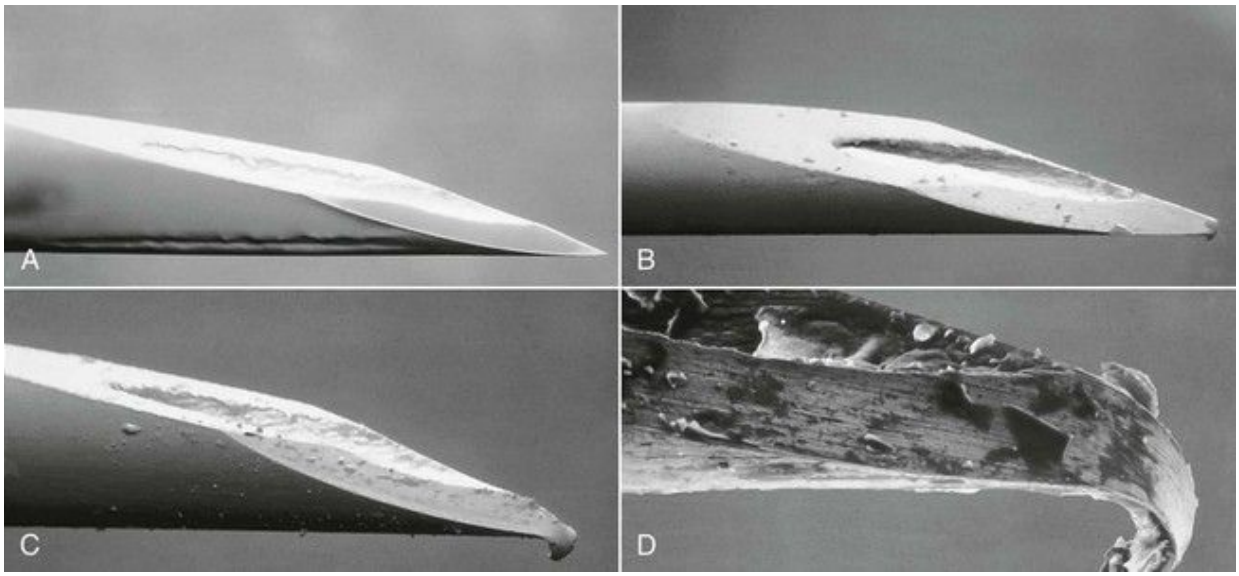

FIG. 64-5 Reuse of an insulin needle. **A,** A new needle. **B,** A needle that has been used once. **C,** A needle that has been used twice. **D,** A needle that has been used 6 times.

Pen-type injectors hold small, lightweight, prefilled insulin cartridges. The injectors are easy to carry and make intensive therapy with multiple injections easier. These devices allow greater accuracy than traditional insulin syringes, especially when measuring small doses. Discuss proper storage for prefilled insulin pens or cartridges. Ensure that the product is appropriate to the patient's unique needs. *Pen-type injectors are not designed for independent use by visually impaired patients or by those with cognitive impairment.* Ensure that the patient has received education on its use. Each syringe or cartridge has specific requirements. Patients using the FlexPen (Novo Nordisk) must be able to attach a needle and to perform an air shot of 2 units to ensure that a dose of insulin is administered. The Institute for Safe Medication Practices (ISMP) and The Joint Commission's National Patient Safety Goals identify insulin as a *High-Alert* drug. (**High-Alert drugs** are those that have an increased risk

for causing patient harm if given in error.) The ISMP cautions that digital displays on some of the newer insulin pens can be misread. If the pen is held upside down, as a left-handed person might do, a dose of 52 units actually appears to be a dose of 25 units and a dose of 12 units looks like a dose of 21 units.

NCLEX Examination Challenge

Health Promotion and Maintenance

Which statement made by a client who is learning about self-injection of insulin indicates to the nurse that clarification is needed about injection site selection and rotation?

A "The abdominal site is best because it is closest to the pancreas."
B "I can reach my thigh best, so I will use different areas of the same thigh."
C "By rotating sites within one area, my chance of having skin changes is less."
D "If I change my injection site from the thigh to an arm, the insulin absorption may be different."

Patient Education: Blood Glucose Monitoring.

Self-monitoring of blood glucose (SMBG) levels provides information to assess effectiveness of the management plan. SMBG allows patients and providers to evaluate patient response to therapy and assess whether glycemic targets are being reached. Results of SMBG are useful in preventing hypoglycemia and adjusting drug therapy, diet therapy, and physical activity. Assessment of blood glucose levels is very important for these situations:

- Manifestations of hypoglycemia/hyperglycemia
- Hypoglycemic unawareness
- Periods of illness
- Before and after exercise
- Gastroparesis
- Adjustment of diabetes drugs
- Evaluation of other drug therapies (e.g., steroids)
- Preconception planning
- Pregnancy

Technique for SMBG follows principles that are the same for most self-monitoring systems. The finger is pricked, a drop of blood flows over or is drawn into a testing strip or disc impregnated with chemicals, and the

glucose value is displayed in mg/dL or mmol/L. Most meters display blood glucose results on a screen. For vision-impaired patients, "talking-meters" are available to allow independence in blood glucose monitoring.

Data obtained from SMBG are evaluated along with other measures of blood glucose (e.g., A1C values) or periodic laboratory blood glucose tests. Even when SMBG is performed correctly, the results are affected by hematocrit values (anemia falsely elevates glucose values; polycythemia falsely depresses them) and may be unreliable in the hypoglycemic or severe hyperglycemic ranges.

The performance of SMBG systems depends on accuracy of the specific blood glucose meter, operator proficiency, and test strip quality. Results are influenced by the size and quality of the blood sample; the meter's calibration to the strip in use; and environmental conditions of altitude, temperature, and moisture. Patient-specific conditions influencing results include hematocrit level, triglyceride level, high levels of substances such as ascorbic acid in blood, and the presence of hypotension or hypoxia.

Accuracy of the blood glucose monitor is ensured when the manufacturer's directions are followed. The most common source of error is related to the skill of the user rather than to errors of the instrument. Common errors involve failure to obtain a sufficient blood drop, poor storage of test strips, using expired strips, and not changing the code number on the meter to match the strip bottle code. Help the patient select a meter based on cost, ease of use, and availability of repair and servicing. Provide training, explain and demonstrate procedures, assess visual acuity, and check the patient's ability to perform the procedure using "teach-back" strategies. Glucose meters are designed to reduce user error as much as possible. Newer meters have fewer steps, include error signals for inadequate sample size, "lock out" if control solutions are not tested, and store hundreds of SMBG results. (See the *Consumer Guide* published yearly in the January edition of *Diabetes Forecast* [forecast.diabetes.org] for information to help patients determine which blood glucose meter best meets their needs.)

Accuracy and precision vary widely among capillary blood glucose monitoring devices. Teach patients to properly calibrate ("code") the machine. Instruct them to re-check the calibration and re-test if they obtain a test result that is unusual for them and whenever they are in doubt about test accuracy. Continued retraining of patients performing SMBG helps ensure accurate results because performance accuracy deteriorates over time. Laboratory glucose determinations are more

accurate than SMBG.

Frequency of testing varies with the drug schedules and the patient's prescribed therapy target outcomes. The ADA recommends that patients taking multiple insulin injections or using insulin pump therapy monitor glucose levels 3 or more times daily. For patients taking less-frequent injections of insulin, non-insulin therapy, or diet therapy alone, SMBG is useful for evaluation of therapy.

Blood glucose therapy target goals are set individually for each patient. The health care team works with him or her to reach target blood glucose levels. The ADA recommends that patients with type 1 diabetes aim for A1C values less than 6.5%, premeal glucose levels of 70 to 130 mg/dL (3.9 to 7.2 mmol/L), and postmeal glucose levels less than 180 mg/dL (10.0 mmol/L) (ADA, 2013).

Infection control measures are needed for SMBG. The chance of becoming infected from blood glucose monitoring processes is reduced by handwashing before monitoring and by not reusing lancets. *Instruct patients to not share their blood glucose monitoring equipment.* Hepatitis B virus can survive in a dried state for at least 1 week. Infection can be spread by the lancet holder even when the lancet itself has been changed. Small particles of blood can stick to the device and infect multiple users. Regular cleaning of the meter is critical for infection control. Remind health care staff who perform blood glucose testing and family members who help with testing to wear gloves.

Many meters allow data to be downloaded by a cable or by infrared technology to a computer that has diabetes management software (Hunt et al., 2014). Some meters allow entry of additional data such as insulin dose, amounts of carbohydrate eaten, or exercise. A radio link to an insulin pump allows automatic transfer of glucose readings to a calculator that assists the patient in deciding on an appropriate insulin dose. Some patients use smart phone applications to record and trend or graph serial blood glucose levels, insulin dosages, food intake, and other data. This information can be sent to the health care provider electronically or downloaded and printed.

Once the patient learns the technical aspects of meter use, help him or her use the results of SMBG to achieve glycemic control. Post-meal glucose monitoring provides information about the effects of the size and content of their meals. SMBG allows the patient to assess effects of exercise on glucose control and provides critical information to help patients who take insulin to exercise safely. Teach patients how to use SMBG results to adjust the treatment plan. Patients should make agreed upon adjustments in the treatment plan when results are consistently

out of range for a 3-day period when no change in meal plan, medications, or activity has occurred.

The U.S. Food and Drug Administration issued an Important Safety Information Notice about blood glucose measurement following use of parenteral maltose, parenteral galactose, oral xylose-containing products, and the peritoneal dialysis solution *icodextrin* (EXTRANEAL). Galactose and xylose are found in some foods, herbs, and dietary supplements; they are also used in diagnostic tests. Some meters and test strips read these substances as glucose and falsely report the blood glucose as elevated. There have been insulin overdoses with severe hypoglycemia, coma, and death when patients have used this falsely elevated glucose reading in calculating an insulin dose. The Core Measures of The Joint Commission and other agencies recommend meters and test strips that use a technology in which *only glucose* in the blood is recognized for accurate blood glucose monitoring.

Nursing Safety Priority QSEN

Action Alert

Prevent hypoglycemia by ensuring that appropriate blood glucose testing products are used for patients receiving parenteral maltose, parenteral galactose, and oral xylose products.

It is important that staff understand the potential for hypoglycemia when patients are admitted to the hospital. In that instance, it is safest to monitor blood glucose patterns by laboratory methods. Blood glucose monitoring needs to be performed with a system in which the test strips use a different enzyme technology. The best resource for guidance in selecting a glucose monitoring system that is not reactive to maltose interference is the manufacturer of the test strip. Some manufacturers produce test strips that use more than one type of enzyme technology.

Alternate site testing allows patients to obtain blood from sites other than the fingertip and is available on many meters. However, use caution when interpreting results obtained from alternate sites. Comparison studies have shown wide variation between fingertip and alternate sites and the variation is most evident during times when blood glucose levels are rapidly changing. Teach patients that there is a lag time for blood glucose levels between the fingertip and other sites when blood glucose levels are changing rapidly and that the fingertip reading is the only safe choice at those times.

Nursing Safety Priority QSEN

Critical Rescue

Teach patients with a history of hypoglycemic unawareness ***not*** to test at alternative sites.

Continuous glucose monitoring (CGM) systems monitor glucose levels in interstitial fluid to provide real-time glucose information to the user. The system consists of three parts: a disposable sensor that measures glucose levels, a transmitter that is attached to the sensor, and a receiver that displays and stores glucose information. After an initiation or warm-up period, the sensor gives glucose values every 1 to 5 minutes. Sensors may be used for 3 to 7 days, depending on the manufacturer. CGM provides information about the current blood glucose level, provides short-term feedback about results of treatment, and provides warnings when glucose readings become dangerously high or low. Most available sensors require at least two capillary glucose readings per day for calibration of the sensor. Sensor accuracy depends on these calibrations. There may be a lag time between the capillary glucose measurement and the glucose sensor value. If the blood glucose value is changing rapidly, the time between capillary and interstitial glucose values may be as long as 30 minutes. For this reason, capillary glucose readings need to be checked on all extreme values and before any corrective treatment is given.

The costs for CGM systems are substantial, starting with the cost of the device. There are additional monthly charges for disposable sensors and for the glucose test strips used to calibrate the sensors and perform FDA-required capillary glucose testing before treatment decisions are made. *Continuous glucose monitoring is meant to supplement, not replace, finger stick tests. Insulin should be given only after confirming the results of any of the continuous glucose monitoring systems.*

Nutrition Therapy.

Effective self-management of diabetes requires that nutrition, including the meal plan, education, and counseling programs be "patientized" for each patient. A registered dietitian (RD) should be a member of the treatment team. The nurse, RD, patient, and family work together on all aspects of the meal plan, which must be realistic and as flexible as possible. Plans that consider the patient's cultural background, financial status, and lifestyle are more likely to be successful. The desired outcomes of nutrition and diet therapy are listed in Table 64-9.

TABLE 64-9

Desired Outcomes of Nutrition Therapy for the Patient With Diabetes

- Achieving and maintaining blood glucose levels in the normal range or as close to normal as is safely possible
- Achieving and maintaining a blood lipid profile that reduces the risk for vascular disease
- Achieving blood pressure levels in the normal range or as close to normal as is safely possible
- Preventing or slowing the rate of development of the chronic complications of diabetes by modifying nutrient intake and lifestyle
- Addressing patient nutrition needs taking into account personal and cultural preferences and willingness to change
- Maintaining the pleasure of eating by limiting food choices only when indicated by scientific evidence
- Meeting the nutrition needs of unique times of the life cycle, particularly for pregnant and lactating women and for older adults with diabetes
- Providing self-management training for patients treated with insulin or insulin secretagogues for exercising safely, including the prevention and treatment of hypoglycemia, and managing diabetes during acute illness

Principles of Nutrition in Diabetes.

No one meal plan is right for all patients with diabetes. Each patient's nutrition recommendations are based on blood glucose monitoring results, total blood lipid levels, and A1C levels. These tests help determine whether current meal and exercise patterns need adjustment or whether present habits need reinforcement. The RD individually develops a meal plan based on the patient's usual food intake, weight-management expectations, and lipid and blood glucose patterns (ADA, 2014e). Day-to-day consistency in the timing and amount of food eaten helps control blood glucose. Patients receiving insulin therapy need to eat at times that are coordinated with the timed action of insulin. Teach patients using intense insulin therapy to adjust premeal insulin to allow for timing and quantity changes in their meal plan.

Carbohydrate intake and available insulin are responsible for postmeal glucose levels, and managing carbohydrate intake is the main strategy for achieving glucose regulation and glycemic control. The recommendation for the patient with diabetes is a diet containing 45% of calories from carbohydrate, with a minimum intake of 130 g carbohydrate/day. However, the upper limit on daily carbohydrate intake is now considered somewhat flexible so that individual patient nutrition needs can be met with some variation in the carbohydrate-protein mix distribution (ADA, 2014e). The diet should include carbohydrate from fruit, vegetables, whole grains, legumes, and low-fat milk products.

The percentage of calories from carbohydrates is determined for each patient. Various starches have different blood glucose responses. The *total amount* of carbohydrate consumed each day rather than the source of the carbohydrate is still important.

Dietary fat and cholesterol intake for people with diabetes is the same as the Institute of Medicine's (IOM) recommendations for the general population to reduce the risk for cardiovascular disease. These recommendations are based on the issue that fat *quality* is more important in lipid control than is fat *quantity* (ADA, 2014e). Current

recommendations are:

- Limiting total fat intake to 20% to 35% of daily calorie intake
- Choosing monounsaturated and polyunsaturated fats over saturated fats and *trans* fats
- Limiting dietary cholesterol to less than 200 mg/day
- Having two or more servings of fatty fish per week (with the exception of commercially fried fish) to provide n-3 polyunsaturated fatty acids

Trans fatty acids increase the risk for cardiovascular disease and are found in hard margarine and in foods prepared with or fried in hydrogenated and partly hydrogenated oils. Teach the patient to limit the amount of commercially fried foods and bakery goods eaten.

Further dietary fat restrictions for diabetes are determined by the RD based on specific lipid levels. Adults with diabetes should be tested annually for abnormalities of fasting serum cholesterol, triglyceride, HDL cholesterol, and calculated LDL cholesterol levels.

Protein intake of 15% to 20% of total daily calories is appropriate for patients with diabetes and normal kidney function. Some patients may need a higher percentage of calories from protein, substituted from carbohydrates, to maintain satiety and control blood glucose levels. Diets higher in protein have demonstrated improvement in insulin response but do not prevent hypoglycemia (ADA, 2014e). In patients with progressive kidney disease, reducing protein intake is needed and the level of protein reduction must be individualized.

Fiber improves carbohydrate metabolism and lowers cholesterol levels. Recommendations for the person with diabetes are the same as for the general population, which include foods containing a minimum of 25 g of fiber daily for women and 38 g daily for men (ADA, 2014e). Teach the patient to select a variety of fiber-containing foods such as legumes, fiber-rich cereals (more than 5 g fiber/serving), fruits, vegetables, and whole-grain products because they provide vitamins, minerals, and other substances important for good health.

Teach the patient that adding high-fiber foods to the diet gradually can reduce abdominal cramping, loose stools, and flatulence. An increase in fluid intake should accompany increased fiber intake. Teach the patient to pay careful attention to blood glucose levels because hypoglycemia can result when dietary fiber intake increases significantly.

Sucrose, fructose, and nonnutritive sweeteners (NNSs) are present in a variety of foods. Dietary sucrose does not increase blood glucose more than equal amounts of other starches. Intake of sucrose and sucrose-containing foods by patients with diabetes does not need to be restricted out of a concern for causing hyperglycemia. Sucrose can be included in

the meal plan as long as it is adequately covered with insulin or other glucose-lowering agents; however, all people with diabetes are encouraged to avoid sugar sweetened beverages (SSBs) (ADA, 2014e). The use of nonnutritive sweeteners to enhance the taste of food while not disturbing blood glucose control is desirable. Foods sweetened with high-fructose corn syrup should be avoided by people with diabetes because this substance has been found to increase the levels of triglycerides and other lipids. Free fructose, such as that found in fruit, does not appear to alter lipid metabolism in the way that foods containing high-fructose corn syrup do (ADA, 2014e).

Alcohol consumption can affect blood glucose levels. Levels are not affected by *moderate* use of alcohol when diabetes is well controlled. Teach patients with diabetes that two alcoholic beverages for men and one for women daily can be ingested with, and in addition to, the usual meal plan. (One alcoholic beverage equals 12 ounces of beer, 5 ounces of wine, or 1.5 ounces of distilled spirits.) Because alcohol raises blood triglycerides, reducing or abstaining from alcohol is important for patients with high blood lipid levels.

Nursing Safety Priority QSEN

Action Alert

Because of the potential for alcohol-induced hypoglycemia, instruct the patient with diabetes to ingest alcohol only with or shortly after meals.

Patient Education: Prescribed Nutrition Plan.

Reinforce nutrition information provided by the RD. The patient with DM must understand how to adjust food intake during illness, planned exercise, and social occasions (e.g., restaurant meals) when the usual time of eating may be delayed. He or she may be unable to follow the prescribed plan because of an inability to read or understand printed materials. Share dietary information with the person who prepares the meals. The RD sees each patient at least yearly to identify changes in lifestyle and make appropriate diet therapy changes. Some patients, such as those with weight-control problems or low incomes, may need more frequent evaluation and counseling.

Meal Planning Strategies.

Many meal planning approaches for good nutrition are available. Each

approach emphasizes different aspects of nutrition.

Carbohydrate (CHO) counting is a simple approach to nutrition and meal planning that uses label information of the nutrition content of packaged food items. Because fat and protein have little effect on after-meal blood glucose levels, CHO counting focuses on the nutrient that has the greatest impact on these levels. It uses total grams of carbohydrate, regardless of the food source. The RD determines the number of grams of carbohydrate to be eaten at each meal and snack and helps the patient make appropriate food choices. This method is effective in achieving overall blood glucose control when carbohydrate intake is consistent from day to day.

Patients using intensive insulin or pump therapies can use CHO counting to determine insulin coverage. After the amount of insulin needed to cover the usual meal is determined, insulin may be added or subtracted for changes in carbohydrate intake. An initial formula of 1 unit of rapid-acting insulin for each 15 g of carbohydrate provides flexibility to meal plans. The patient determines the grams of carbohydrate in a specific meal or snack by reading labels or weighing and measuring each item. The total grams of carbohydrate are used to calculate the bolus dose of insulin based on his or her prescribed insulin-to-carbohydrate ratio.

People at high risk for type 2 diabetes are encouraged to achieve moderate weight loss (7% total body weight), participate in regular physical activity (150 minutes per week), and reduce caloric and dietary fat intake. These at-risk people are also encouraged to increase fiber intake to at least 14 g per 1000 calories consumed and to eat foods containing whole grains.

Special considerations for type 1 diabetes include developing insulin regimens that conform to the patient's preferred meal routines, food preferences, and exercise patterns. Patients using rapid-acting insulin by injection or an insulin pump should adjust insulin doses based on the carbohydrate content of the meals and snacks. Insulin-to-carbohydrate ratios are developed and are used to provide mealtime insulin doses. Blood glucose monitoring before and 2 hours after meals determines whether the insulin-to-carbohydrate ratio is correct. For patients who are on fixed insulin regimens and do not adjust premeal insulin dosages, consistency of timing of meals and the amount of CHO eaten at each meal is important to prevent hypoglycemia.

Exercise can cause hypoglycemia if insulin is not decreased before activity. For planned exercise, reduction in insulin dosage is used for hypoglycemia prevention. For unplanned exercise, intake of additional

CHO is usually needed. Moderate exercise increases glucose utilization by 2 to 3 mg/kg/min. A 70-kg (154-lb) person would need about 10 to 15 g additional CHO per hour of moderate-intensity activity. More CHO is needed for intense activity.

It is important for patients with type 1 diabetes to avoid gaining weight. Chronic high insulin levels (**hyperinsulinemia**) can occur with intensive management schedules and may result in weight gain. These patients may need to manage hyperglycemia by restricting calories rather than increasing insulin. Weight gain can be minimized by following the prescribed meal plan, getting regular exercise, and avoiding overtreatment of hypoglycemia.

Special considerations for type 2 diabetes focus on lifestyle changes. Many patients with type 2 diabetes are overweight and insulin resistant. Nutrition therapy stresses lifestyle changes that reduce calories eaten and increase calories expended through physical activity. Many patients also have abnormal blood fat levels and hypertension (metabolic syndrome), making reductions of saturated fat, cholesterol, and sodium desirable. A moderate caloric restriction (250 to 500 calories less than average daily intake) and an increase in physical activity improve diabetes control and weight control. Decreases of more than 10% of body weight can result in significant improvement in A1C. Decreasing intake of cholesterol-raising fatty acids helps reduce the risk for cardiovascular disease.

When patients with type 2 diabetes need insulin, consistency in timing and carbohydrate content of meals is important. Division of the total daily calories into three meals or into smaller meals and snacks is based on patient preference.

Considerations for Older Adults

Patient-Centered Care QSEN

Older patients are at increased risk for poor nutrition, hypoglycemia, and especially dehydration, a factor in the development of hyperglycemic-hyperosmolar state (HHS). Many factors contribute to malnutrition. Nutrition needs of the older adult change as the person's taste, smell, and appetite diminish and his or her ability to obtain and prepare food decreases. Older patients who prepare their own food or have tooth loss or poorly fitting dentures may not eat enough food. Neuropathy with gastric retention or diarrhea compounds poor food intake. Impaired cognition and depression may disrupt self-care. Older patients may have a marginal food supply because of inadequate income, may have poor understanding of meal-planning needs, or may

live alone and have reduced incentive to prepare or eat proper meals. They may eat in restaurants or live in situations in which they have little control over meal preparation. Regular visits by home health nurses can assist older patients in following a diabetic meal plan.

A realistic approach to nutrition therapy is essential for the older patient with diabetes. Changing the eating habits of 60 to 70 years is very difficult. The nurse, dietitian, and patient assess the patient's usual eating patterns. Teach the older patient taking antidiabetic drugs about the importance of eating meals and snacks at the same time every day, eating the same amount of food from day to day, and eating all food allowed on the diet.

Exercise Therapy.

Regular exercise is an essential part of diabetic management. It has beneficial effects on carbohydrate metabolism and insulin sensitivity. Programs of increased physical activity and weight loss reduce the incidence of type 2 diabetes in patients with impaired glucose tolerance (American Association of Diabetes Educators [AADE], 2011).

Blood glucose levels remain stable in physically active patients without diabetes because of the balance between glucose use by exercising muscles and glucose production by the liver. The patient with type 1 DM cannot make the hormonal changes needed to maintain stable blood glucose levels during exercise. Without an adequate insulin supply, cells cannot use glucose. Low insulin levels trigger release of glucagon and epinephrine (counterregulatory hormones) to increase liver glucose production, further raising blood glucose levels. In the absence of insulin, free fatty acids become the source of energy. Exercise in the patient with uncontrolled diabetes results in further hyperglycemia and the formation of ketone bodies. He or she may have prolonged elevated blood glucose levels after vigorous exercise.

Exercise in the person with diabetes also can cause hypoglycemia because of increased muscle glucose uptake and inhibited glucose release from the liver. It can occur during exercise and for up to 24 hours after exercise. Replacement of muscle and liver glycogen stores, along with increased insulin sensitivity after exercise, causes insulin requirements to drop.

Benefits of Exercise.

Appropriate exercise results in better blood glucose regulation and reduced insulin requirements for patients with type 1 DM. Exercise also increases

insulin sensitivity, which enhances cell uptake of glucose and promotes weight loss.

Regular exercise decreases risk for cardiovascular disease. It decreases most blood lipid levels and increases high-density lipoproteins (HDLs). Exercise decreases blood pressure and improves cardiovascular function. Regular vigorous physical activity prevents or delays type 2 DM by reducing body weight, insulin resistance, and glucose intolerance.

Adjustments for Diabetes Complications.

Exercise in the presence of long-term complications of diabetes often requires some adjustment. Vigorous aerobic or resistance exercise should be avoided in the presence of proliferative diabetic retinopathy or severe nonproliferative diabetic retinopathy. Teach the patient with retinopathy to avoid the *Valsalva maneuver* (breath holding while bearing down) and activities that increase blood pressure. Heavy lifting, rapid head motion, or jarring activities can cause vitreous hemorrhage or retinal detachment. Decreased pain sensation in the extremities increases the risk for skin breakdown and infection and for joint destruction. Teach patients with diabetic peripheral neuropathy (DPN) to wear proper footwear and to examine their feet daily for lesions. Teach anyone with a foot injury or open sore to engage in non-weight-bearing activities such as swimming, bicycling, seated yoga, or arm exercises. Those with autonomic neuropathy are at increased risk for exercise-induced injury from impaired temperature control, postural hypotension, and impaired thirst with risk for dehydration. Physical activity also can increase urine protein excretion. Encourage high-risk patients to start with short periods of low-intensity exercise and to increase the intensity and duration slowly (ADA, 2013).

Safety Assessment.

Assessment before initiating an exercise program is necessary to ensure patient safety. Although current ADA guidelines do not recommend routine screening for patients with diabetes who have no manifestations of cardiovascular disease, be alert to conditions that might predispose the patient to injury or that contraindicate certain types of exercise. Regular physical activity increases the risk for both musculoskeletal injury and life-threatening cardiovascular events. Patients with diabetes often take drugs to reduce blood pressure, to normalize blood lipid concentrations, and to inhibit platelet activity. These drugs may increase fall risk, change physiologic response to exercise and physical activity, alter muscle performance, and increase bleeding risk (Sisson et al., 2012).

The ADA recommends screening when any of these conditions exist:

- Chest pain or discomfort
- Abnormal electrocardiogram (ECG) suggestive of ischemia or infarction
- Peripheral or carotid occlusive disease
- Age older than 35 years with sedentary lifestyle in a patient who plans a vigorous exercise program
- Two or more risk factors in addition to diabetes, such as dyslipidemia, hypertension, tobacco use
- Family history for premature coronary artery disease, or microalbuminuria or macroalbuminuria of more than 10 years' duration
- Age older than 25 years and type 1 diabetes of more than 15 years' duration
- Severe autonomic neuropathy, severe diabetic peripheral neuropathy, history of foot lesions, and unstable proliferative retinopathy

Screening for coronary artery disease before an exercise program is started is recommended for patients with cardiovascular risk factors. Exercise treadmill testing (ETT) is used to determine if a person can exercise to 85% of his or her predicted heart rate without having ischemic changes. It also provides information about exercise capacity and functional status. Failure to achieve 85% of the predicted heart rate is associated with increased incidence of death.

Other studies to determine the risk for exercise-induced problems include medical stress tests with vasodilator therapy and stress echocardiography. Additional tests may be performed to determine the presence of obstructive lesions in coronary arteries.

Advise people with DM to perform at least 150 min/wk of moderate-intensive aerobic physical activity or 75 min/wk of vigorous aerobic physical activity or an equivalent combination of the two. In the absence of contraindications, patients with type 2 diabetes are urged to perform resistance exercise 3 times a week, targeting all major muscle groups (ADA 2013). The ADA recommends that there be no more than 2 consecutive days without aerobic physical activity.

A 5- to 10-minute warm-up period with stretching and low-intensity exercise before exercise prepares the skeletal muscles, heart, and lungs for a progressive increase in exercise intensity. After the activity session, a cool-down should be performed similarly to the warm-up. The cool-down should last 5 to 10 minutes and gradually bring the heart rate down to pre-exercise level.

Guidelines for exercise are based on blood glucose levels and urine

ketone levels. Recommend that the patient test blood glucose before exercise, at intervals during exercise, and after exercise to determine if it is safe to exercise and to evaluate the effects of exercise. The absence of urine ketones indicates that enough insulin is available for glucose transport and that exercise should be effective in lowering blood glucose levels. *When urine ketones are present, the patient should* ***NOT*** *exercise.* Ketones indicate that current insulin levels are not adequate and that exercise would elevate blood glucose levels. Carbohydrate foods should be ingested to raise blood glucose levels above 100 mg/dL (5.6 mmol/L) before engaging in exercise. Chart 64-4 lists tips to teach the patient and family about self-management and exercise.

Chart 64-4 Patient and Family Education: Preparing for Self-Management

Exercise

- Teach the patient about the relationship between regularly scheduled exercise and blood glucose levels, blood lipid levels, and complications of diabetes.
- Reinforce the level of exercise recommended for the patient based on his or her physical health.
- Instruct the patient to wear appropriate footwear designed for exercise.
- Remind the patient to examine his or her feet daily and after exercising.
- Remind the patient to stay hydrated and not to exercise in extreme heat or cold.
- Warn the patient not to exercise within 1 hour of insulin injection or near the time of peak insulin action.
- Teach patients how to prevent hypoglycemia during exercise:
  - Do not exercise unless blood glucose level is at least 80 and less than 250 mg/dL.
  - Have a carbohydrate snack before exercising if 1 hour has passed since the last meal or if the planned exercise is high intensity.
  - Carry a simple sugar to eat during exercise if symptoms of hypoglycemia occur.
  - Ensure that identification information about diabetes is carried during exercise.
- Remind the patient to check blood glucose levels more frequently on days in which exercise is performed and that extra carbohydrate and less insulin may be needed during the 24-hour period after extensive exercise.

Nursing Safety Priority QSEN

Critical Rescue

Teach patients with type 1 diabetes to perform vigorous exercise only when blood glucose levels are 100 to 250 mg/dL (5.6 to 13.8 mmol/L) and no ketones are present in the urine.

Considerations for Older Adults

Patient-Centered Care QSEN

With age, the ability of the heart and lungs to deliver oxygen to tissues and organs declines. Muscle strength and power decline gradually. Connective tissue becomes less elastic, affecting range of motion and flexibility. Limited range of motion can alter gait, increasing risk for falls. Older adults who remain active can limit losses in muscle mass and function.

The emphasis for any activity program is on changing sedentary behavior to active behavior at any level. Encourage sedentary older adults to begin with low-intensity physical activity. Start low-intensity activities in short sessions (less than 10 minutes); include warm-up and cool-down components with active stretching. Changes in activity levels should be gradual. Formal evaluation by a physical therapist or occupational therapist may be needed. Examples of specific exercise can be found at www.geri.com.

Blood Glucose Control in Hospitalized Patients.

Hyperglycemia in hospitalized patients occurs for many reasons and is associated with poor outcomes (Kubacka, 2014). In patients without a previous diagnosis of diabetes, elevated blood glucose is often "stress hyperglycemia." Hyperglycemia may result from decline in basic level of glucose regulation caused by illness, decreased physical activity, withholding of antidiabetic drugs, use of drugs that cause hyperglycemia such as corticosteroids, and initiation of tube feedings or parenteral nutrition (Freeland & Funnell, 2012).

Hyperglycemia among medical-surgical patients is linked with higher infection rates, longer hospital stays, increased need for intensive care, and greater mortality. Admission glucose levels greater than 198 mg/dL (10.9 mmol/L) are associated with greater risk for mortality and complications. Hypoglycemia, defined as blood glucose values lower than 40 mg/dL (2.2 mmol/L), is an independent risk factor for mortality.

Current American Association of Clinical Endocrinologists (AACE) and ADA Core Measures recommend treatment protocols that maintain blood glucose levels between 140 and 180 mg/dL (7.8 and 10.0 mmol/L) for critically ill patients. For the majority of non–critically ill patients, premeal glucose targets should be lower than 140 mg/dL (7.8 mmol/L) with random blood glucose values less than 180 mg/dL (10.0 mmol/L). To prevent hypoglycemia, insulin regimens should be reviewed if blood glucose levels fall below 100 mg/dL (5.6 mmol/L) and should be modified when blood glucose levels are less than 70 mg/dL (3.9 mmol/L) (ADA, 2013).

Continuous IV insulin solutions are the most effective method for achieving glycemic targets in the intensive care setting. Scheduled subcutaneous injection with basal, meal, and correction elements is the preferred method for achieving and maintaining glucose control in non–critically ill patients. Using correction dose or "supplemental insulin" to correct premeal hyperglycemia in addition to scheduled prandial and basal insulin is recommended. The correction dose is determined by the patient's insulin sensitivity and current blood glucose level.

Prevention of hypoglycemia is also part of managing blood glucose levels. Causes of inpatient hypoglycemia include an inappropriate insulin type, mismatch between insulin type and/or timing of food intake, and altered eating plan without insulin dosage adjustment. The Joint Commission (TJC), together with the ADA, has established Core Measures for preventing hypoglycemia in the inpatient care of people with diabetes (The Joint Commission [TJC], 2014). These involve protocols for hypoglycemia treatment that direct staff to provide carbohydrate replacement if the patient is alert and able to swallow or to administer 50% dextrose intravenously or glucagon by subcutaneous injection if the patient cannot swallow.

There is confusion about whether to give or to hold insulin from a patient who is NPO. Administration of rapid-acting or short-acting insulin, as well as amylin and incretin mimetics, will cause hypoglycemia if a patient is not eating. Basal insulin should be administered when the patient is NPO because it controls baseline glucose levels. Insulin mixtures are not administered because they contain some short-acting or rapid-acting insulin and will cause hypoglycemia.

Surgical Management.

Surgical interventions for diabetes include a pancreas transplantation. When successful, this procedure eliminates the need for insulin injections, blood glucose monitoring, and many dietary restrictions. It

can eliminate the acute complications related to blood glucose control but is only partially successful in reversing long-term diabetes complications. Pancreatic transplant is successful when the patient no longer needs insulin therapy and all blood measures of glucose are normal.

Transplantation requires lifelong drug therapy to prevent graft rejection. These drug regimens have toxic side effects that restrict their use to patients who have serious progressive complications of diabetes. In addition, some anti-rejection drugs have the effect of increasing blood glucose levels. Pancreas-alone transplants are most often considered for patients with severe metabolic complications and for those with consistent failure of insulin-based therapy to prevent acute complications.

Pancreas transplantation is considered in patients with diabetes and end-stage kidney disease who have had or plan to have a kidney transplant. Normal blood glucose levels after pancreas transplantation improve kidney graft survival. Pancreas graft survival is better when performed at the time of the kidney transplant.

Whole-Pancreas Transplantation.

Improved surgical techniques and newer anti-rejection drugs have improved transplantation outcomes. The 1-year survival rate for patients is above 95%, with more than 83% of patients remaining free of insulin injection and diet restrictions after 1 year. The degree of tissue-type matching affects the results.

Pancreatic transplantation is performed in one of three ways: pancreas transplant alone (PTA), pancreas after kidney (PAK) transplant, and simultaneous pancreas and kidney (SPK) transplant. SPK transplant is the ideal procedure for patients with DM and uremia.

Operative Procedure.

Most pancreatic transplants are from cadaver donors using a total pancreas still attached to the exit of the pancreatic duct. The recipient's pancreas is left in place, and the donated pancreas is placed in the pelvis. The insulin released by the pancreas graft is secreted into the bloodstream. The new pancreas also produces about 800 to 1000 mL of fluid daily, which is diverted to either the bladder or the bowel.

Excretion of pancreatic fluids can cause dehydration and electrolyte imbalance, and drainage of these fluids into the urinary bladder causes irritation. When the pancreas is attached to the bladder, the loss of fluid rich in bicarbonate may cause acidosis.

Rejection Management.

A combination of drugs and antibodies is used to reverse rejection. (See Chapter 17 for a listing of agents used to prevent or manage transplant rejection.) Patients undergoing anti-rejection therapy first receive drugs to prevent viral, bacterial, and fungal infection because of the risk for opportunistic infections. Most patients receiving high-dose steroids, as well as those on chronic long-term steroid therapy, will require dosage adjustments in insulin to achieve desired levels of glucose control.

In most episodes of rejections, kidney problems occur before pancreatic problems. An increase in serum creatinine indicates rejection of both the transplanted kidney and the pancreas. In patients with bladder drainage of pancreatic hormones, a decrease in the urine amylase level by 25% is an indication to treat rejection. High blood glucose levels are a later marker of rejection and usually indicate irreversible graft failure.

Long-Term Effects.

Long-term anti-rejection therapy increases the risk for infection, cancer, and atherosclerosis. When insulin drains into systemic rather than portal (liver) circulation, blood insulin levels rise (hyperinsulinemia) and increase the risk for hypertension and macrovascular disease.

Complications.

Complications are common in patients taking long-term anti-rejection therapy. Monitor laboratory values, fluid and electrolyte status, physical changes, and changes in vital signs to identify possible complications. Early removal of IV and intra-arterial lines, use of sterile technique with dressing changes and catheter irrigations, strict handwashing by all health care personnel, and good pulmonary hygiene help prevent infection.

Complications immediately after surgery include thrombosis, pancreatitis, anastomosis leak with infection, and rejection of the transplanted pancreas. Pancreatic blood vessel thrombosis occurs in about 30% of patients after transplantation. Observe for and report any sudden drop in urine amylase levels, rapid increases in blood glucose, gross **hematuria** (bloody urine), and tenderness or pain in the graft area (iliac fossa). Pancreatitis in the transplanted organ occurs to some degree in all patients after surgery. Report elevations in serum amylase that persist after 48 to 96 hours.

The most serious complication of enteric-drained pancreas transplantation is leaking and infection with intra-abdominal abscess

formation. Observe for and report elevation in temperature, abdominal discomfort, and elevation in white blood cell (WBC) count. Bladder-drained pancreas transplantation has a lower rate of intra-abdominal abscess formation. However, drainage of bicarbonate-rich fluid with pancreatic enzymes into the urinary bladder can cause urinary tract infections, cystitis, urethritis, and balanitis. Metabolic acidosis occurs from the loss of large amounts of alkaline pancreatic secretions.

Assess for and document manifestations of rejection. In acute rejection, decreased kidney function is indicated by increased serum creatinine, decreased urine output, hypertension, increased weight, graft tenderness, and fever. Proteinuria is often the first indicator of chronic graft rejection. Check for increased blood amylase, lipase, or glucose; decreased urine amylase; graft tenderness; hyperglycemia; and fever. *It is especially important to assess for infection and start appropriate therapy. Fever can indicate both infection and rejection.*

Monitor for side effects of the anti-rejection drugs. Cyclosporine (Neoral) is toxic to the kidney. Indications of toxicity are elevated creatinine and decreased urine output. Monitor WBC counts daily, because azathioprine (Imuran) can suppress bone marrow function. Common side effects of tacrolimus (Prograf) are hypertension, kidney toxicity, neurotoxicity, GI toxicity, and glucose intolerance. Prednisone has many side effects, including elevated blood glucose levels.

Islet Cell Transplantation.

Islet cell transplantation eliminates the need for insulin and protects against the complications of diabetes. Wider use of this procedure is hindered by the limited supply of beta cells available for transplantation and by issues related to rejection. Islet cells from tissue-typed (HLA-matched) cadaver pancreas glands are injected into the portal vein. The new cells lodge in the liver and begin to function, secreting insulin and maintaining near-perfect blood glucose control.

Islet cell transplantation may successfully restore long-term endogenous insulin production and glycemic control in patients with type 1 diabetes and unstable baseline control. Most patients undergoing this procedure eventually have a progressive loss of islet cell function. Very few islet cell transplant recipients have remained insulin-free for more than 4 years. The reasons for this gradual loss of function are not known and make this procedure a long-term but temporary intervention. It is considered an experimental procedure.

Enhancing Surgical Recovery

Planning: Expected Outcomes.

The patient with diabetes undergoing a surgical procedure is expected to recover completely without complications. Indicators include:

- Wound healing
- Absence of infection
- Maintenance of blood glucose levels within expected range

Interventions.

Surgery is a physical and emotional stressor, and the patient with diabetes has a higher risk for complications. Anesthesia and surgery cause a stress response with release of counterregulatory hormones that elevate blood glucose. Stress hormones suppress insulin action, increasing the risk for ketoacidosis. Hyperglycemic-hyperosmolar state (HHS) is a common complication after major surgery and is associated with increased mortality. Diuresis from hyperglycemia can cause dehydration and increases the risk for kidney failure.

Complications of diabetes increase the risk for surgical complications. Patients with DM are at higher risk for hypertension, ischemic heart disease, cerebrovascular disease, MI, and cardiomyopathy. Heart failure is a serious risk factor and must be improved before surgery. Autonomic neuropathy may result in sudden tachycardia, bradycardia, or postural hypotension. The patient with DM is at risk for acute kidney injury and urinary retention after surgery, especially if he or she has albumin in the urine (indicator of kidney damage). Nerves to the intestinal wall and sphincters can be impaired, leading to delayed gastric emptying and reflux of gastric acid, which increases the risk for aspiration with anesthesia. Autonomic neuropathy may cause paralytic ileus after surgery.

Preoperative Care.

Patients undergoing major surgery are admitted to the hospital 2 to 3 days before surgery to optimize blood glucose control. Sulfonylureas are discontinued 1 day before surgery. Metformin (Glucophage) is stopped at least 24 hours before surgery and restarted only after kidney function is normal. All other oral drugs are stopped the day of surgery. Patients taking long-acting insulin may need to be switched to intermediate-acting insulin forms 1 to 2 days before surgery.

Preoperative blood glucose levels should be less than 200 mg/dL (11.1 mmol/L). Higher levels are associated with increased infection rates and impaired wound healing.

Plan ahead for pain control after surgery. Pain, a stressor, triggers the release of counterregulatory hormones, increasing blood glucose levels and insulin needs. Opioid analgesics slow GI motility and alter blood glucose levels. The older patient who receives opioids is more at risk for confusion, paralytic ileus, hypoventilation, hypotension, and urinary retention. Patient-controlled analgesia (PCA) systems reduce respiratory complications and confusion. (See Chapter 3 for pain interventions and Chapter 14 for general preoperative care.)

Intraoperative Care.

IV infusion of insulin, glucose, and potassium is standard therapy for perioperative management of diabetes. In accordance with The Joint Commission's NPSGs, the objective is to keep the blood glucose level between 140 and 180 mg/dL (7.8 and 10.0 mmol/L) during surgery to prevent hypoglycemia and reduce risks from hyperglycemia (TJC, 2014). Insulin/glucose infusion rates are based on hourly capillary glucose tests. Higher insulin doses may be needed because stress releases glucagon and epinephrine. Patients with DM usually receive about 5 g of glucose per hour during surgery to prevent hypoglycemia, ketosis, and protein breakdown.

Monitor the patient's temperature—it may be lowered deliberately in some surgical procedures and inadvertently in others. Low operating room temperatures and large incisions also lower body temperature. Hypothermia decreases metabolic needs, depresses heart rate and contractility, causes vasoconstriction, and impairs insulin release, resulting in high blood glucose levels. Monitor arterial blood gas values for acidosis.

Postoperative Care.

Hyperglycemia is associated with increased mortality after surgical procedures. Current AACE and ADA Core Measures recommend insulin protocols that maintain blood glucose between 140 and 180 mg/dL (7.8 and 10.0 mmol/L) for critically ill patients (ADA, 2013).

Protocols and computer-based programs can be used to determine the insulin infusion rate required to maintain blood glucose levels within a defined target range. Many insulin infusion algorithms are implemented by nursing staff. Continue glucose and insulin infusions as prescribed until the patient is stable and can tolerate oral feedings. Short-term insulin therapy may be needed after surgery for the patient who usually uses oral agents. For those receiving insulin therapy, dosage adjustments may be required until the stress of surgery subsides.

Monitoring.

Patients with autonomic neuropathy or vascular disease need close monitoring to avoid hypotension or respiratory arrest. Those who take beta blockers for hypertension need close monitoring for hypoglycemia because these drugs mask manifestations of hypoglycemia. Patients with increased protein or nitrogen waste products in the blood may have problems with fluid management. Check central venous pressure or pulmonary artery pressure as needed.

Glucose levels are a sensitive marker of counterregulatory hormones, which are often activated before patients become febrile. Hyperglycemia often occurs before a fever.

Nursing Safety Priority QSEN

Critical Rescue

When a patient who has had reasonably controlled blood glucose levels in the hospital develops an unexpected rise in blood glucose values, check for wound infection.

Hyperkalemia (high blood potassium level) is common in patients with mild to moderate kidney failure and can lead to cardiac dysrhythmia. In other patients, **hypokalemia** (low blood potassium level) may occur and be made worse by insulin and glucose given during surgery. Monitor the cardiac rhythm and serum potassium values.

Cardiovascular monitoring by continuous electrocardiograms (ECGs) is recommended for older patients with diabetes, those with long-standing type 1 DM, and those with heart disease. Patients with diabetes are at higher risk for MI after surgery with a higher mortality rate. Changes in ECG or in potassium level may indicate a silent MI.

Kidney monitoring, especially observing fluid balance, helps detect acute kidney injury (AKI). Diagnosis of kidney impairment may require the use of x-ray studies using dyes, which may be nephrotoxic. Management of infection may require the use of nephrotoxic antibiotics. Ensure adequate hydration when these drugs are used. Check for impending kidney failure by assessing fluid and electrolyte status.

Nutrition.

Patients requiring clear or full liquid diets should receive about 200 g of carbohydrate daily in equally divided amounts at meals and snack times. Initial liquids should not be sugar-free. Most patients require 25 to 35

calories per kg of body weight every 24 hours. After surgery, food intake is initiated as quickly as possible with progression from clear liquids to solid foods occurring as rapidly as tolerated. Returning to a normal meal plan as soon as possible after surgery promotes healing and metabolic balance. When oral foods are tolerated, make sure the patient takes at least 150 to 200 g of carbohydrate daily to prevent hypoglycemia.

If total parenteral nutrition (TPN) is used after surgery, severe hyperglycemia may occur. Monitor blood glucose often to determine the need for supplemental insulin.

Preventing Injury from Peripheral Neuropathy

Planning: Expected Outcomes.

The patient with diabetes is expected to identify factors that increase the risk for injury, practice proper foot care, and maintain skin tissue integrity on the feet. Indicators include that the patient consistently demonstrates these behaviors:

- Cleanses and inspects the feet daily
- Wears properly fitting shoes
- Avoids walking in bare feet
- Trims toenails properly
- Reports nonhealing breaks in the skin of the feet to the health care provider

Interventions.

Patients with DM need intensive teaching about foot care. *Foot injury is the most common complication of diabetes leading to hospitalization.* Once a failure of tissue integrity has occurred and an ulcer has developed, there is an increased risk for wound progression that will eventually lead to amputation. Almost all lower extremity amputations are preceded by foot ulcers. The 5-year mortality rate after leg or foot amputation ranges from 39% to 67% (National Institute of Diabetes and Digestive and Kidney Diseases [NIDDK], 2011). Neuropathy is the main factor for development of a diabetic ulcer, and an inadequate vascular supply is the main cause of poor healing (Thomas, 2013).

Motor neuropathy damages the nerves of foot muscles, resulting in foot deformities. These deformities create pressure points that gradually cause reduced tissue integrity with skin breakdown and ulceration. Thinning or shifting of the fat pad under the metatarsal heads decreases cushioning and increases areas of pressure. In claw toe deformity, toes are hyperextended and increase pressure on the metatarsal heads ("ball"

of the foot). These changes predispose the patient to callus formation, ulceration, and infection. The Charcot foot is a type of diabetic foot deformity with many abnormalities, often including a hallux valgus (turning inward of the great toe) (Fig. 64-6). The foot is warm, swollen, and painful. Walking collapses the arch, shortens the foot, and gives the sole of the foot a "rocker bottom" shape.

FIG. 64-6 A "Charcot foot" type of diabetic foot deformity.

Autonomic neuropathy causes loss of normal sweating and skin temperature regulation, resulting in dry, thinning skin. Skin cracks and fissures increase the risk for infection. Sensory neuropathy may cause pain, tingling, or burning (Funnell, 2014). More often it produces numbness and reduced sensory perception. Without sensation, the patient does not

notice injuries and loss of tissue integrity in the foot and does not treat them. Peripheral arterial disease reduces the blood supply to the foot, increasing the risk for ulcer formation and reducing the rate of ulcer healing (McCance et al., 2014).

Foot injuries can be caused by walking barefoot, wearing ill-fitting shoes, sustaining thermal injuries from heat (e.g., hot water bottles, heating pads, baths), or chemical burns from over-the-counter corn treatments. These injuries can lead to loss of tissue integrity and to amputation.

Ulcers result from continued pressure. Plantar ulcers (on the sole, usually the ball) are from standing or walking. Those on the top or sides of the foot usually are from shoes. The increased pressure causes calluses. Ulcers usually form over or around the great toe, under the metatarsal heads, and on the tops of claw toes.

Loss of tissue integrity with broken skin increases the risk for infection. Skin tends to break in areas of pressure. Infection is common in diabetic foot ulcers and, once present, is difficult to treat. Infection also impairs glucose regulation, leading to higher blood glucose levels and reduced immune defenses, which further increases the risk for infection.

Prevention of High-Risk Conditions.

Neuropathy of the feet and legs can be delayed by keeping blood glucose levels as near to normal as possible. Poor blood glucose control increases the risk for neuropathy and amputation. Urge smoking cessation to reduce the risk for vascular complications.

The risk for ulcers or amputation increases with duration of diabetes. Other associated factors are male gender; poor glucose control; and cardiovascular, retinal, or kidney complications. Foot-related risks include poor gait and stepping mechanics, peripheral neuropathy, increased pressure (callus, erythema, hemorrhage under a callus, limited joint mobility, foot deformities, or severe nail pathology), peripheral vascular disease, and a history of ulcers or amputation.

Peripheral Neuropathy Management.

The feet should be evaluated closely at least annually. Chart 22-9 in Chapter 22 lists self-management activities for prevention of injury from peripheral neuropathy, and Table 64-10 lists foot risk categories.

TABLE 64-10

Foot Risk Categories

RISK CATEGORIES	MANAGEMENT CATEGORIES
Risk Category 0	*Management Category 0*
• Has protective sensation • No evidence of peripheral vascular disease • No evidence of foot deformity	• Comprehensive foot examination once a year • Patient education to include advice on appropriate footwear
Risk Category 1	*Management Category 1*
• Does not have protective sensation • May have evidence of foot deformity *Risk Category 2* • Does not have protective sensation • Evidence of peripheral vascular disease *Risk Category 3* • History of ulcer or amputation	• Evaluation every 3-6 months • Consider referral to a specialist to assess need for specialized treatment and follow-up • Patient education
	Management Categories 2 & 3
	• Evaluation every 1-3 months • Referral to a specialist • Prescription footwear • Consider vascular consultation for combined follow-up • Patient education

Complete a full foot assessment as outlined in Chart 64-5. Sensory examination with Semmes-Weinstein monofilaments is a practical measure of the risk for foot ulcers. The nylon monofilament is mounted on a holder standardized to exert a 10-g force. A person who cannot feel the 10-g pressure at any point is at increased risk for ulcers. To perform the examination:

Chart 64-5 Focused Assessment

The Diabetic Foot

Assess the patient for risk for diabetic foot problems:

- History of previous ulcer
- History of previous amputation
- Assess the foot for abnormal skin and nail conditions:
- Dry, cracked, fissured skin
- Ulcers
- Toenails: thickened, long nails; ingrown nails
- Tinea pedis; onychomycosis (mycotic nails)

Assess the foot for status of circulation:

- Manifestations of claudication
- Presence or absence of dorsalis pedis or posterior tibial pulse
- Prolonged capillary filling time (greater than 25 seconds)
- Presence or absence of hair growth on the top of the foot

Assess the foot for evidence of deformity:

- Calluses, corns

■ Prominent metatarsal heads (metatarsal head is easily felt under the skin)
■ Toe contractures: clawed toes, hammertoes
■ Hallux valgus or bunions
■ Charcot foot ("rocker bottom")

Assess the foot for loss of strength:

■ Limited ankle joint range of motion
■ Limited motion of great toe

Assess the foot for loss of protective sensation:

■ Numbness, burning, tingling
■ Semmes-Weinstein monofilament testing at 10 points on each foot

- Provide a quiet and relaxed setting. Ask the patient to close his or her eyes during the test.
- Test the monofilament on the patient's cheek so he or she knows what to expect.
- Test the sites noted in Fig. 64-7.

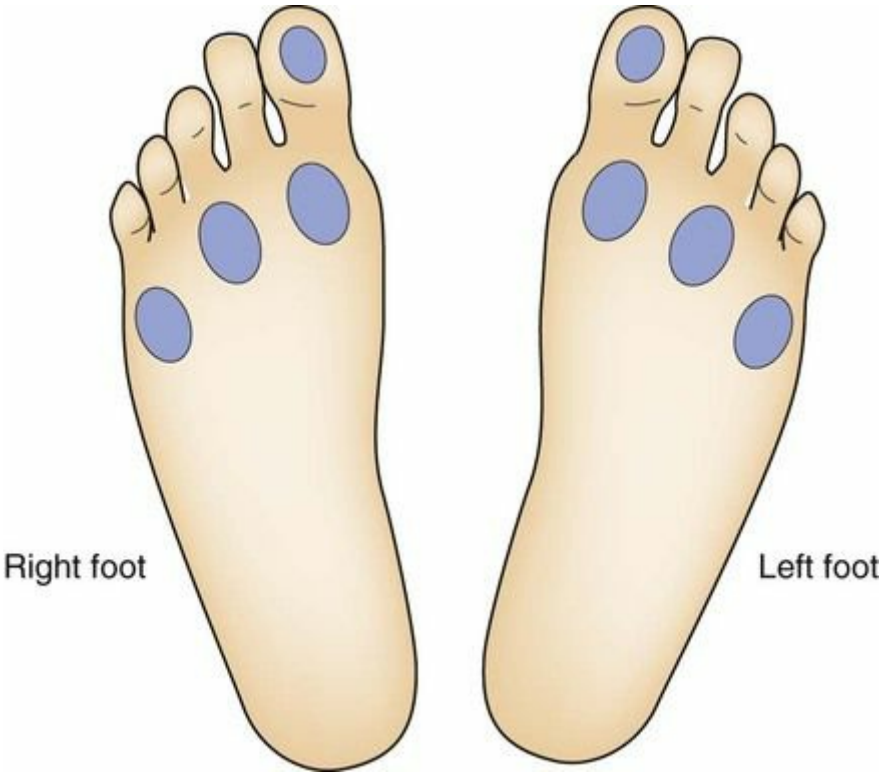

FIG. 64-7 Placement sites of monofilaments for testing of protective sensation.

- Apply the monofilament at a right angle to the skin surface.
- Apply enough force to bend the filament using a smooth, not jabbing, motion (Fig. 64-8).

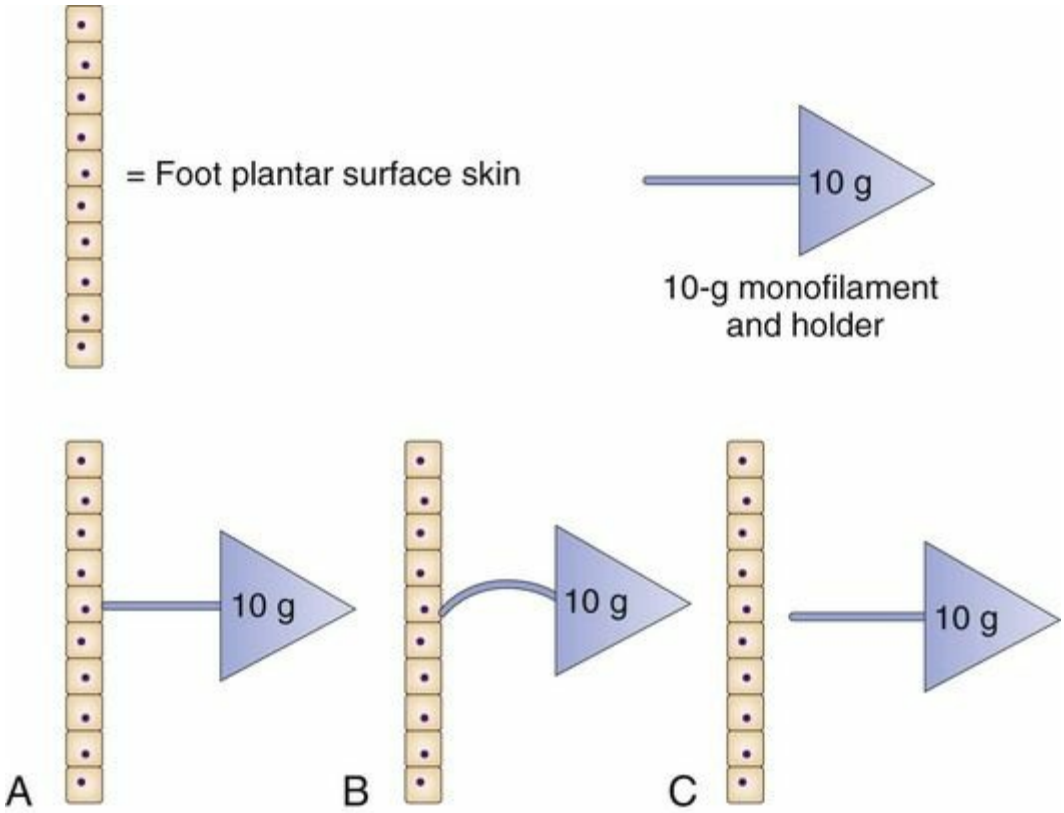

FIG. 64-8 Correct technique for sensation testing with 10-g monofilament. **A,** Apply monofilament to designated areas of the foot sole (intact skin only; see Fig. 64-7). **B,** Apply pressure to the filament either until the patient states he or she can feel the pressure or until the filament bends (see pp. 1326-1327). **C,** Quickly remove the filament without sliding it or touching other areas of the foot. *BUN,* Blood urea nitrogen; Ca^{2+}, calcium; HCO_3^-, bicarbonate; K^+, potassium; Mg^{2+}, magnesium; Na^+, sodium; PO_4, phosphate.

- The approach, contact, and removal of the filament at each site should take 1 to 2 seconds.
- Apply the filament along the perimeter and **not** on an ulcer site, callus, scar, or necrotic tissue. Do not slide the filament across the skin or make repeated contact at the test site.

Randomize the sequence of applying the filament throughout the examination. Have the patient identify where the filament touched rather than asking "Do you feel this?"

Footwear.

All patients with any degree of peripheral neuropathy are at risk for loss of tissue integrity and need to wear protective shoes. It is best to be fitted by an experienced shoe fitter, such as a certified podiatrist. The shoe should

be ½ to ⅝ inch longer than the longest toe. Heels should be less than 2 inches high. Shoes that are too tight damage tissue. Instruct the patient to change shoes by midday and again in the evening. Socks or stockings need to fit properly and be appropriate for the planned activity. Socks should feel soft and have no thick seams, creases, or holes. They should pad the foot and absorb excess moisture. Teach patients to avoid tight stockings or those that have constricting bands. Patients with toe deformities should buy custom shoes with high, wide toe boxes and extra depth. Those with severely deformed feet, such as Charcot feet, need specially molded shoes. All new shoes need a long break-in period with frequent inspection for irritation or blistering.

Foot Care.

Teach patients about preventive foot care and the need for examination of the feet and legs at each visit to a health care provider. Identify patients with high-risk foot conditions. Explain problems caused by loss of protective sensory perception, the importance of monitoring the feet daily, proper care of the feet (including nail and skin care), and how to select appropriate footwear.

Assess the patient's ability to inspect all areas of the foot and to perform foot care. Teach family members how to inspect and care for the patient's feet if the patient cannot. Chart 64-6 lists foot care instructions for self-management.

Chart 64-6 Patient and Family Education: Preparing for Self-Management

Foot Care Instructions

- Inspect your feet daily, especially the area between the toes.
- Wash your feet daily with lukewarm water and soap. Dry thoroughly.
- Apply moisturizing cream to your feet after bathing. Do not apply to the area between your toes.
- Change into clean cotton socks every day.
- Do not wear the same pair of shoes 2 days in a row, and wear only shoes made of breathable materials, such as leather or cloth.
- Check your shoes for foreign objects (nails, pebbles) before putting them on. Check inside the shoes for cracks or tears in the lining.
- Purchase shoes that have plenty of room for your toes. Buy shoes later in the day, when feet are normally larger. Break in new shoes gradually.
- Wear socks to keep your feet warm.

- Trim your nails straight across with a nail clipper. Smooth the nails with an emery board.
- See your physician or nurse immediately if you have blisters, sores, or infections. Protect the area with a dry, sterile dressing. Do not use adhesive tape to secure dressing to the skin.
- Do not treat blisters, sores, or infections with home remedies.
- Do not smoke.
- Do not step into the bathtub without checking the temperature of the water with your wrist or thermometer. Optimal temperature is 95° F (35° C). Maximum temperature is 110° F (43° C).
- Do not use very hot or cold water. Never use hot water bottles, heating pads, or portable heaters to warm your feet.
- Do not treat corns, blisters, bunions, calluses, or ingrown toenails yourself.
- Do not go barefooted.
- Do not wear sandals with open toes or straps between the toes.
- Do not cross your legs or wear garters or tight stockings that constrict blood flow.
- Do not soak your feet.

Wound Care.

The standards of care for diabetic ulcers are a moist wound environment, débridement of necrotic tissue, and elimination of pressure (offloading). Proper wound care and débridement are presented in Chapter 25.

Eliminating pressure on an infected area is essential to wound healing. Teach patients with foot ulcers to not wear a shoe on the affected foot while the ulcer is healing. Those with poor sensory perception may keep walking on an ulcer because it does not hurt. This results in pressure necrosis that delays healing and increases ulcer size. Pressure is reduced by specialized orthotic devices, custom-molded shoe inserts, or shoe adjustments that redistribute weight.

Offloading redistributes force away from ulcer sites and pressure points to wider areas of the foot. Available products include total-contact casting, half shoes, removable cast walkers, wheelchairs, and crutches. Total-contact casts redistribute pressure over the bottom of the foot. Casting material is molded to the foot and leg to spread pressure along the entire surface of contact, reducing vertical force. The almost complete elimination of motion of the total-contact cast reduces plantar shear forces. The cast is removed 24 to 48 hours after application to inspect the foot and cast fit. The cast is replaced and then removed and reapplied weekly until the ulcer is healed. *Teach the patient that foot ulcers will recur*

unless weight is permanently redistributed.

NCLEX Examination Challenge

Health Promotion and Maintenance

While assessing the client who has had diabetes for 15 years, the nurse finds that he has decreased sensory perception in both feet. What is the nurse's best first action?
A Document the finding as the only action.
B Examine the feet for manifestations of injury.
C Test the sensory perception of the client's hands.
D Tell the client that he now has peripheral neuropathy.

Managing Pain

Planning: Expected Outcomes.

The patient with neuropathic pain is expected to experience relief of pain. Indicators include these consistent behaviors:
- Uses preventive measures
- Uses available resources to increase comfort
- Reports that pain is controlled

Interventions.

Neuropathic pain results from damage anywhere along the nerve. Many patients with diabetes suffer from the painful neuropathy. Manifestations of diabetic neuropathy include:
- Burning
- Muscle cramps
- Piercing, stabbing, or darting pain
- Metatarsalgia (feeling as if you are walking on marbles)
- Hyperalgesia (exaggerated pain response)
- Allodynia (pain in response to normally nonpainful stimuli)
- Tingling, numbness, and loss of proprioception in lower extremities

Maintaining normal blood glucose levels and avoiding extreme fluctuations prevent neuropathy and relieve manifestations. Rapid improvement in blood glucose control may actually trigger acute peripheral neuropathy.

Several pharmacologic agents are used to manage neuropathic pain. The anticonvulsants *gabapentin* (Neurontin) and *pregabalin* (Lyrica) and the serotonin-norepinephrine reuptake inhibitor (SNRI) *duloxetine*

(Cymbalta) are used in management of neuropathic pain. Tricyclic antidepressants such as amitriptyline hydrochloride (Elavil, Levate) and nortriptyline (Pamelor) are widely used for pain but are not approved for this purpose and have some significant side effects. Their use is contraindicated for older adults and those with cardiovascular disease.

The burning of neuropathy may respond to capsaicin cream 0.075% (Axsain, Zostrix-HP). Teach the patient to apply it 4 times daily for several weeks. The pain may worsen for several days after therapy is started before improving.

Unpleasant symptoms are noted with abrupt discontinuation of many of these drugs. A gradual reduction in the dose is recommended to prevent side effects.

Provide support and information on measures to reduce pain. Even having a bed cradle to lift bed clothes off hypersensitive skin can be beneficial. Assist the patient to maintain stable glucose control. *All patients with neuropathy are at increased risk for foot ulcers and require more frequent assessment and education in routine foot management.*

Preventing Injury from Reduced Vision

Planning: Expected Outcomes.

The patient with diabetes is expected to be free of injury related to reduced visual sensory perception and to maintain current level of vision. Indicators include:

- No further reduction of visual fields
- No double vision

Interventions

Blood Glucose Control.

Poor blood glucose regulation (control), proteinuria, diastolic hypertension, and long duration of diabetes are risk factors for vision loss among people with diabetes (ADA, 2014a). Surgical intervention for retinal hemorrhage or new retinal blood vessel growth can reduce vision loss.

Besides regular eye examinations to evaluate retinopathy, urge the patient with impaired vision to have an optometrist or ophthalmologist assess the remaining vision and prescribe appropriate vision support. A functional vision assessment, performed by a low-vision technician, rehabilitation teacher, or diabetes educator, determines the patient's use of lighting, contrast, non-optical and low-vision devices, large-print

options, and use of central or peripheral vision. Many low-vision reading aids are available as described in Chapter 47. The American Foundation for the Blind maintains a list of services for visually impaired people that is organized by type of service and geographic area. More information is available at (800) 232-5463 and www.afb.org.

Environmental Management.

Not all visually impaired patients need special devices. Adjustments in lighting, contrast, color, distance, type size of printed materials, and eye movement often improve visual abilities. Chapter 47 describes general methods of enhancing vision. For the patient with diabetes and low vision, coding objects such as vials of insulin with bright colors or with felt-tipped markers helps identify the correct bottle. Bringing the blood glucose lancet or insulin syringe close to the eye makes it easier to see.

Prefilled insulin pens are not approved for use by people with severe visual impairment unless they are assisted by a person with good vision who is trained to use the pen correctly. Adaptive devices can help the patient self-administer insulin independently. Some syringes may have a magnifier attached to the syringe. Other devices include preset dose gauges (which measure the space between the end of the syringe barrel and the plunger) to help the patient draw up the correct amount of insulin by feeling this distance. The blind patient can accurately measure insulin by using products such as the Count-A-Dose Insulin Measuring Device. This device is designed to be used with the BD Lo-Dose syringe. It holds two insulin vials and has a slot to direct the syringe needle into the vials' rubber stoppers. The patient draws insulin into the syringe by turning a thumb-wheel, which clicks for each unit (clicks can be both heard and felt). (See the *Consumer Guide* published yearly in the January edition of *Diabetes Forecast* [forecast.diabetes.org] for information to help patients determine which adaptive devices best meet their needs.) When teaching the patient to use an adaptive device, stress:

- Differentiating between bottles of fast-acting and slower-acting insulin by wrapping a rubber band around the fast-acting insulin bottle
- Ensuring proper placement of the device on the syringe
- Holding the insulin bottle upright when measuring insulin
- Avoiding air bubbles in the syringe by pulling a small amount of insulin into the syringe, moving the plunger in and out 3 times, and measuring insulin on the fourth draw

Design a system to determine how many doses can be drawn from a bottle so the patient does not inject air from an empty bottle instead of insulin.

Specialized adaptive equipment also is available to assist with blood glucose monitoring techniques. Assist the patient to select a blood glucose monitoring device best suited to his or her level of visual impairment. Some monitors have large display screens and easy-to-use features. Fully audio systems are available for patients who are visually impaired. The monitor uses no coding, has automatic turn-on with test strip insertion, and has a button for repeating the last message. Assess the ability of the patient to obtain an adequate blood sample and to apply it to the test strip. Commercially made blood drop guides can assist with this task.

Clinical Judgment Challenge

Patient-Centered Care QSEN

During a clinic visit, you are reviewing the records of a 39-year-old patient who was diagnosed 5 years ago with type 2 diabetes. You discover that, although he has always been extremely near-sighted, he has not seen an ophthalmologist for 4 years. He has gained 12 lbs since his last visit a year ago. His laboratory values show a fasting blood glucose level of 96 mg/dL, an A1C of 8.2%, a total cholesterol of 322 mg/dL, and an LDL of 190 mg/dL. When you ask him about ophthalmology follow-up and point out his laboratory values, he replies that because he is taking prescribed antidiabetic medication, he believes that he won't have all the diabetes complications that his father had. He further tells you that he did have his eyes checked by an optometrist to make sure his prescription was accurate but that because he is younger than 40 years, he does not need intraocular pressure measurements.

1. How should you interpret his laboratory values in terms of his personal glucose regulation?
2. Should you address his weight gain? Why or why not?
3. Is he correct in thinking that an ophthalmologist visit is not necessary at this time? Explain your response.
4. Is he correct in believing that taking antidiabetic medication will prevent complications of diabetes? Explain your response.
5. How do you propose to assist this patient in managing his diabetes?

Reducing the Risk for Kidney Disease

Planning: Expected Outcomes.

The patient with diabetes is expected to maintain a normal urine

elimination pattern. Indicators include:

- Urine protein levels within normal limits
- 24-hour intake and output balance
- Blood urea nitrogen (BUN) and serum creatinine within the normal ranges
- Serum electrolytes within the normal ranges

Interventions

Prevention.

Diabetic kidney disease is more likely to develop in patients with poor blood glucose control. Progression to end-stage kidney disease (ESKD) can be delayed or prevented by normalizing blood pressure, correcting hyperlipidemia, and restricting dietary protein. Control of hypertension is essential for the reduction of diabetic nephropathy (ADA, 2014b). Both systolic and diastolic hypertension greatly accelerate the progression of diabetic kidney disease.

Stress the need for evaluation of kidney function according to the ADA Standards of Care. Serum creatinine should be measured at least annually for an estimation of GFR in all patients with diabetes (ADA, 2013). An annual test for microalbuminuria is performed for patients who have had type 1 DM for over 5 years and in all those with type 2 DM starting at diagnosis and during pregnancy.

Persistent albuminuria in the range of 30 to 299 mg/24 hr (formerly called *microalbuminuria*) is the earliest stage of nephropathy in type 1 DM and a marker for the development of nephropathy in type 2 DM. Patients with albumin levels greater than 300 mg/24 hr (formerly called *macroalbuminuria*) are likely to progress to end-stage kidney disease (ESKD) (ADA, 2014b). Screening for increased urinary albumin excretion is performed by measurement of the albumin-creatinine ratio in a spot collection.

Aggressive control of blood glucose and hypertension in patients without microalbuminuria can avoid nephropathy. Once microalbuminuria develops, management focuses on controlling blood pressure and blood glucose, restricting dietary protein, avoiding nephrotoxic agents, promptly treating urinary tract infections, and preventing dehydration.

Control of blood pressure and blood glucose levels requires the patient's participation and effort. Prescribed drugs must be taken according to schedules, and dietary restrictions must be maintained. Teach patients about the roles of blood pressure and blood glucose levels

in kidney disease. Help them maintain normal blood glucose levels and blood pressure levels below 140/80 mm Hg. Stress the need for yearly screening for microalbuminuria.

Smoking cessation is important in halting the progression of diabetic kidney disease for patients with type 1 and type 2 diabetes. Teach the patient about the risks of smoking, and refer him or her to appropriate resources for assistance in smoking cessation.

Any urinary tract infection (UTI) can lead to kidney infection and further reduce kidney function. Explain the manifestations of UTI. Urge the patient to take antibiotics exactly as prescribed, completing the entire course of treatment. Reinforce the need for follow-up urine cultures to reduce the risk for kidney damage. Avoid indwelling urinary catheters when possible.

Drugs can affect kidney function either through toxic effects on the kidney or by an acute but reversible reduction in function. The most common nephrotoxic drugs are antifungal agents and aminoglycoside antibiotics. Outside the hospital, the leading nephrotoxic agents are NSAIDs such as ibuprofen (Advil) or naproxen (Aleve), when used long-term. To prevent accidental ingestion of nephrotoxic drugs, teach the patient to check with a health care provider before taking over-the-counter drugs or herbal remedies.

Radiocontrast dyes can also affect kidney function, especially in patients with preexisting kidney problems. Monitor IV hydration before and after contrast is used to prevent contrast-induced nephropathy in patients with diabetes.

Drug Therapy.

Use of angiotensin-converting enzyme (ACE) inhibitors (ACEIs) or angiotensin receptor blockers (ARBs) is recommended for all patients with microalbuminuria or advanced stages of nephropathy (ADA, 2013). ACE inhibitors reduce the level of albuminuria and the rate of progression of kidney disease, although they do not appear to prevent microalbuminuria. Monitor serum potassium levels for development of hyperkalemia.

Nutrition Therapy.

Patients with nephropathy should restrict protein intake to 0.8 g/kg of body weight per day. Once the glomerular filtration rate (GFR) starts falling, further reducing protein may slow the decline in kidney function. Because lifelong dietary restrictions are difficult, provide ongoing teaching to encourage adherence.

Fluid and Electrolyte Management.

Fluid and electrolyte management can prevent more loss of kidney function. Avoiding dehydration is important for kidney perfusion and function. The most common cause of dehydration in patients with diabetes is overuse of diuretics. Teach patients to report edema or symptoms of orthostatic hypotension, and provide ongoing education to promote nutrition therapy.

Dialysis for patients with DM and kidney failure is the same as for patients without diabetes (see Chapter 68). The dosage of insulin needs to be adjusted when dialysis starts.

Preventing Hypoglycemia.

Hypoglycemia (low blood glucose level) induces specific manifestations and resolves when blood glucose concentration is raised. Once blood glucose levels fall below 70 mg/dL (3.88 mmol/L), a sequence of events begins with release of counterregulatory hormones, stimulation of the autonomic nervous system, and production of *neurogenic* and *neuroglycopenic* manifestations. Peripheral autonomic manifestations, including sweating, irritability, tremors, anxiety, tachycardia, and hunger, serve as an early warning system and occur before the manifestations of confusion, paralysis, seizure, and coma occur from brain glucose deprivation. *Neuroglycopenic symptoms* occur when brain glucose *gradually declines* to a low level. *Neurogenic symptoms* result from autonomic nervous activity triggered by a *rapid decline* in blood glucose (Table 64-11).

TABLE 64-11

Manifestations of Hypoglycemia

Neuroglycopenic Manifestations	Neurogenic Manifestations

• Weakness
• Fatigue
• Difficulty thinking
• Confusion
• Behavior changes
• Emotional instability
• Seizures
• Loss of consciousness
• Brain damage
• Death
	• Adrenergic:
	  ◦ Shaky/tremulous
	  ◦ Heart pounding
	  ◦ Nervous/anxious
	• Cholinergic:
	  ◦ Sweaty
	  ◦ Hungry
	  ◦ Tingling

Central nervous system (CNS) function depends on a continuous supply of glucose in the blood. The brain cannot make glucose and stores only a few minutes' supply as glycogen. This needed supply is not maintained when the blood glucose level falls below critical levels.

The first defense against falling blood glucose levels in the nondiabetic person is decreased insulin secretion, decreased glucose use, and increased glucose production. Normally, insulin secretion decreases when blood glucose levels drop to about 83 mg/dL (4.5 mmol/L). Counterregulatory hormones are activated at about 67 mg/dL (3.7 mmol/L), a level well above the threshold for manifestations of hypoglycemia. The main counterregulatory hormone is glucagon. Epinephrine also becomes important in patients with DM who are deficient in glucagon. Both glucagon and epinephrine raise blood glucose levels by stimulating liver glycogen breakdown and conversion of protein to glucose. Epinephrine also limits insulin secretion.

Type 1 DM disrupts the body's response to hypoglycemia, usually within 1 to 5 years of diagnosis. Regulation of circulating insulin levels is lost because insulin comes from an injection rather than from the pancreas. As blood glucose levels fall, insulin levels do not decrease. Over time, the pancreas loses its ability to secrete glucagon in response to hypoglycemia. After a few more years of type 1 DM, the response of epinephrine to falling blood glucose levels does not occur until the blood glucose level is very low. These problems greatly increase the risk for severe hypoglycemia.

A second problem with long-standing type 1 DM is *hypoglycemic unawareness,* in which patients no longer have the warning manifestations of impending hypoglycemia that should prompt them to take preventive action (Mompoint-Williams et al., 2012). This problem occurs most often in patients who have had type 1 DM for 30 years or longer.

The blood glucose level at which manifestations of hypoglycemia occur varies among patients. Thus clinical criteria used to categorize hypoglycemia are based on manifestation severity rather than blood glucose levels. In mild hypoglycemia, the patient remains alert and able to self-manage symptoms. In severe hypoglycemia, neurologic function is so impaired that he or she needs another person's help to increase blood glucose levels.

Planning: Expected Outcomes.

The patient with DM is expected to have decreased episodes of hypoglycemia and remain oriented to person, place, and time, as indicated by a Glasgow Coma Scale score above 7.

Interventions.

A blood glucose level below 70 mg/dL (3.9 mmol/L) alerts you to assess

for manifestations of hypoglycemia (Table 64-11; see also Table 64-12).

TABLE 64-12

Differentiation of Hypoglycemia and Hyperglycemia

FEATURE	HYPOGLYCEMIA	HYPERGLYCEMIA
Skin	Cool, clammy	Warm, moist
Dehydration	Absent	Present
Respirations	No particular or consistent change	Rapid, deep*; Kussmaul type; acetone odor ("fruity" odor) to breath
Mental status	Anxious, nervous,* irritable, mental confusion,* seizures, coma	Varies from alert to stuporous, obtunded, or frank coma
Manifestations	Weakness,* double vision, blurred vision, hunger, tachycardia, palpitations	None specific for DKA
		Acidosis; hypercapnia; abdominal cramps, nausea and vomiting
		Dehydration: decreased neck vein filling, orthostatic hypotension, tachycardia, poor skin turgor
Glucose	<70 mg/dL (3.9 mmol/L)	>250 mg/dL (13.8 mmol/L)
Ketones	Negative	Positive

DKA, Diabetic ketoacidosis.

*Classic symptoms.

Blood Glucose Management.

Monitor blood glucose levels before giving antidiabetic drugs, before meals, before bedtime, and when the patient is symptomatic. All patients who take insulin, those taking long-acting insulin secretagogues (glyburide [glibenclamide]), and those taking metformin in combination with glyburide (Glucovance) are at risk for hypoglycemia. This risk is increased if they are older, have liver or kidney impairment, or are taking drugs that enhance the effects of antidiabetic drugs. Proper patient selection, drug dosage, and instructions are important factors in avoiding severe hypoglycemia. Hypoglycemia may be difficult to recognize in those who take beta-blocking drugs. Manifestations are less intense and less obvious. Manifestations of hypoglycemia in older patients may be mistaken for other conditions.

The most common causes of hypoglycemia are:

- Too much insulin compared with food intake and physical activity
- Insulin injected at the wrong time relative to food intake and physical activity
- The wrong type of insulin injected at the wrong time
- Decreased food intake resulting from missed or delayed meals
- Delayed gastric emptying from gastroparesis
- Decrease liver glucose production after alcohol ingestion
- Increased insulin sensitivity as a result of regular exercise and weight loss
- Decreased insulin clearance from progressive kidney failure

Nutrition Therapy.

When the patient is hypoglycemic, start carbohydrate replacement per physician prescription or standing protocols—usually ingestion of 15 to 20 g of glucose. If the patient can swallow, give a liquid form of carbohydrate, although any carbohydrate source can be used. Ingestion of 15 to 20 g of glucose is the preferred management for blood glucose levels less than 70 mg/dL (3.9 mmol/L), repeated in about 15 minutes if manifestations have not improved or if blood glucose levels are still less than 70. The amount of carbohydrate should be increased to 30 g for glucose levels less than 50 mg/dL (2.8 mmol/L).

Ten grams (g) of oral glucose raises blood glucose levels by about 40 mg/dL over 30 minutes, and 20 g of oral glucose raises blood glucose levels by about 60 mg/dL over 45 minutes. Specific recommendations are listed in Chart 64-7.

Chart 64-7 Patient and Family Education: Preparing for Self-Management

Management of Hypoglycemia at Home

For *mild* hypoglycemia (hungry, irritable, shaky, weak, headache, fully conscious; blood glucose usually less than 60 mg/dL [3.4 mmol/L]):

- Treat the symptoms of hypoglycemia with 10 to 15 g of carbohydrate. You may use one of these:
  - Glucose tablets or glucose gel (dosage is printed on the package)
  - ½ cup of fruit juice
  - ½ cup of regular (nondiet) soft drink
  - 8 ounces of skim milk
  - 6 to 10 hard candies
  - 4 cubes of sugar
  - 4 teaspoons of sugar
  - 6 saltines
  - 3 graham crackers
  - 1 tablespoon of honey or syrup
- Re-test blood glucose in 15 minutes.
- Repeat this treatment if symptoms do not resolve.
- Eat a small snack of carbohydrate and protein if your next meal is more than an hour away.

For *moderate* hypoglycemia (cold, clammy skin; pale; rapid pulse; rapid, shallow respirations; marked change in mood; drowsiness; blood

glucose usually less than 40 mg/dL [2.2 mmol/L]):

- Treat the symptoms of hypoglycemia with 15 to 30 g of rapidly absorbed carbohydrate.
- Take additional food, such as low-fat milk or cheese, after 10 to 15 minutes.

For *severe* hypoglycemia (unable to swallow; unconsciousness or convulsions; blood glucose usually less than 20 mg/dL [1.0 mmol/L]):

- Treatment administered by family members:
  - Administer 1 mg of glucagon as intramuscular or subcutaneous injection.
  - Administer a second dose in 10 minutes if the person remains unconscious.
  - Notify a primary care provider immediately, and follow instructions.
  - If still unconscious, transport the person to the emergency department.
  - Give a small meal when the person wakes up and is no longer nauseated.

The blood glucose level determines the form and amount of glucose used. The response should be apparent in 10 to 20 minutes; however, test blood glucose again in about 60 minutes because additional management may be needed. Fluid is absorbed much more quickly from the GI tract than are solids. Concentrated sweet fluids, such as juice with sugar added or a soft drink, may slow absorption.

Management of hypoglycemia requires ingestion of glucose or glucose-containing foods. The blood glucose response correlates better with the glucose content rather than the carbohydrate content of the food. Adding protein to carbohydrate does NOT improve blood glucose response and does NOT prevent subsequent hypoglycemia. Adding fat may retard and then prolong the blood glucose response, resulting in post-treatment hyperglycemia. Commercially available products provide predictable glucose absorption.

Drug Therapy.

Glucagon given subcutaneously or IM and 50% dextrose given IV are used for patients who cannot swallow. Glucagon is the main counterregulatory hormone to insulin and is used as first-line therapy for severe hypoglycemia in DM. It converts liver glycogen to glucose but is not effective in severely starved patients. Take care to prevent aspiration in patients receiving glucagon, because it often causes vomiting. Give 50% dextrose carefully to avoid extravasation because it is hyperosmolar

and can damage tissue. The effects of glucagon and dextrose are temporary. After the patient responds and is no longer nauseated, give a simple sugar followed by a small snack or meal. IV glucose is used to maintain mild hyperglycemia. Diazoxide (Proglycem) or octreotide (Sandostatin) may be required to treat sulfonylurea-induced hypoglycemia. Evaluate response by monitoring blood glucose levels for several hours because manifestations may persist. A target blood glucose level is 70 to 110 mg/dL (3.9 to 6.2 mmol/L).

Nursing Safety Priority QSEN

Critical Rescue

For the patient with *severe* hypoglycemia (unable to swallow, unconscious or convulsing, blood glucose usually less than 20 mg/dL [1.0 mmol/L]), treat by:

1. Giving glucagon 1 mg subcutaneously or IM
2. Repeating the dose in 10 minutes if the patient remains unconscious
3. Notifying the primary health care provider immediately, and following instructions

Prevention Strategies.

Teach the patient how to prevent hypoglycemia by avoiding its four common causes: (1) excess insulin, (2) deficient intake or absorption of food, (3) exercise, and (4) alcohol intake.

Insulin excess from variable absorption of insulin can cause hypoglycemia even when insulin is injected correctly. Increased insulin sensitivity can occur with weight loss, exercise programs, and resolution of an infection. Differences in insulin formulation can result in hypoglycemia. Teach the patient to not change insulin brands without medical supervision.

Deficient food intake from inadequate or incorrectly timed meals can result in hypoglycemia. Changes in gastric absorption may cause hypoglycemia in patients with delayed gastric emptying, which is more severe with solid meals, and is made worse by illness or poor glucose control. Teach the patient the importance of regularity in timing and quantity of food eaten.

Exercise often causes blood glucose levels to fall in a patient with type 1 DM. Prolonged exercise increases cellular glucose uptake for several hours after exercise. Teach the patient about blood glucose monitoring and carbohydrate consumption before and during exercise.

Alcohol inhibits liver glucose production and leads to hypoglycemia. It interferes with the counterregulatory response to hypoglycemia and impairs glycogen breakdown, making exercise-induced hypoglycemia more severe. Teach the patient to ingest alcohol only with or shortly *after* eating a meal with enough carbohydrate to prevent hypoglycemia. Warn patients to avoid excess alcohol at bedtime to prevent nighttime hypoglycemia.

Patient and Family Education.

The cause of hypoglycemia may be subtle. At the onset of menses, a fall in hormone levels decreases insulin needs and contributes to hypoglycemia. When patients switch to a new bottle of insulin, hypoglycemia may occur because the fresh insulin has greater potency. Some patients have hypoglycemia when they change injection sites. Beta-blocking drugs mask manifestations that are warning signs and thus predispose patients to severe hypoglycemia. Some episodes of hypoglycemia occur without an obvious cause.

Many patients who have been treated in the emergency department for hypoglycemia do not receive adequate prevention instructions and are at continuing risk. Help each patient develop a personal treatment plan for hypoglycemia. The exact glucose rise from a set amount of carbohydrate varies; however, using the estimate that each 5 g of carbohydrate raises blood glucose about 20 mg/dL is a good starting plan. For example, the patient may be directed to take:

- 20 to 30 g of carbohydrate if the blood glucose level is 50 mg/dL (2.8 mmol/L) or less
- 10 to 15 g of carbohydrate if the blood glucose level is 51 to 70 mg/dL (2.9 to 3.9 mmol/L)

Use blood glucose monitoring results to revise or reinforce this plan.

Encourage the patient to wear a medical alert bracelet, and help him or her obtain one. This bracelet is helpful if the patient becomes hypoglycemic and is unable to provide self-care.

Teach the patient and family about the manifestations of hypoglycemia. Emphasize that delaying a meal for more than 30 minutes raises the risk for hypoglycemia when using some insulin regimens. Instruct him or her to keep a carbohydrate source nearby at all times. Teach the patient and family how to administer glucagon.

Hypoglycemia is a major risk for patients receiving intensive insulin protocols who engage in exercise programs. Explain that nightmares or headaches on days after prolonged or severe exercise may indicate hypoglycemia.

Establishing Treatment Plans.

Blood glucose monitoring directs hypoglycemia management. Treatment continues until blood glucose levels reach and stay in the target range. Once blood glucose control is regained, the patient should identify the specific cause of the episode and take specific measures to prevent recurrence.

Considerations for Older Adults

Patient-Centered Care QSEN

Patients in the older age-groups are especially vulnerable to hypoglycemia. Age-related declines in kidney function and liver enzyme activity may interfere with the metabolism of sulfonylureas and insulin, thereby potentiating their hypoglycemic effects. Older patients with diabetes have impaired epinephrine release and a diminished glucagon response to falling blood glucose levels. They often have a reduced awareness of hypoglycemic manifestations. Confusion and any impairment in psychomotor performance when blood sugars are low prevent the older adult from taking appropriate steps to return the blood sugar to normal.

Instruct the older patient and family to check blood glucose values when symptoms such as unsteadiness, light-headedness, poor concentration, trembling, or sweating occur. Assess eating patterns to make sure sufficient foods are eaten at appropriate times. Encourage a patient with a poor appetite to eat a small snack at bedtime to prevent hypoglycemia during the night.

The highest rates of severe and fatal episodes of hypoglycemia are associated with the use of glyburide in patients older than 70 years. Drug regimens that require that meals be eaten on time increase the potential for hypoglycemic reactions. Complex regimens that require multiple decision points should be simplified, especially for patients with decreased functional status (Seaquist et al., 2013).

Clinical Judgment Challenge

Safety; Quality Improvement; Teamwork and Collaboration QSEN

The patient is a 60-year-old-woman who is 1 day postoperative after a total knee replacement. She has type 2 diabetes and just recently was switched from oral antidiabetic drugs to an insulin regimen. She let her

nurse know that her on-demand lunch has been ordered. The nurse tests her blood and gives her the prescribed short-acting insulin dose. An hour later the physical therapist finds her pale, confused, and clammy. Her lunch tray is on her table and appears untouched.

1. Is her condition consistent with hyperglycemia or hypoglycemia? Explain your choice.
2. What is your first action? Provide a rationale.
3. What is the most likely cause leading to this problem?
4. What could be done on this nursing care unit to prevent such an incident from happening again?

Preventing Diabetic Ketoacidosis.

Diabetic ketoacidosis (DKA) is characterized by uncontrolled hyperglycemia, metabolic acidosis, and increased production of ketones. This condition results from the combination of insulin deficiency and an increase in hormone release that leads to increased liver and kidney glucose production and decreased glucose use in peripheral tissues (Fig. 64-9). Laboratory diagnosis of DKA is shown in Table 64-13. All of these changes increase ketoacid production with resultant ketonemia and metabolic acidosis.

TABLE 64-13

Differences Between Diabetic Ketoacidosis and Hyperglycemic-Hyperosmolar State

	DIABETIC KETOACIDOSIS (DKA)	HYPERGLYCEMIC-HYPEROSMOLAR STATE (HHS)
Onset	Sudden	Gradual
Precipitating factors	Infection	Infection
	Other stressors	Other stressors
	Inadequate insulin dose	Poor fluid intake
Manifestations	Ketosis: Kussmaul respiration, "rotting fruit" breath, nausea, abdominal pain	Altered central nervous system function with neurologic symptoms
	Dehydration or electrolyte loss: polyuria, polydipsia, weight loss, dry skin, sunken eyes, soft eyeballs, lethargy, coma	Dehydration or electrolyte loss: same as for DKA
Laboratory Findings		
Serum glucose	>300 mg/dL (16.7 mmol/L)	>600 mg/dL (33.3 mmol/L)
Osmolarity	Variable	>320 mOsm/L
Serum ketones	Positive at 1 : 2 dilutions	Negative
Serum pH	<7.35	>7.4
Serum HCO_3^-	<15 mEq/L	>20 mEq/L
Serum Na^+	Low, normal, or high	Normal or low
BUN	>30 mg/dL; elevated because of dehydration	Elevated
Creatinine	>1.5 mg/dL; elevated because of dehydration	Elevated
Urine ketones	Positive	Negative

BUN, Blood urea nitrogen; HCO_3^-, bicarbonate; Na^+, sodium.

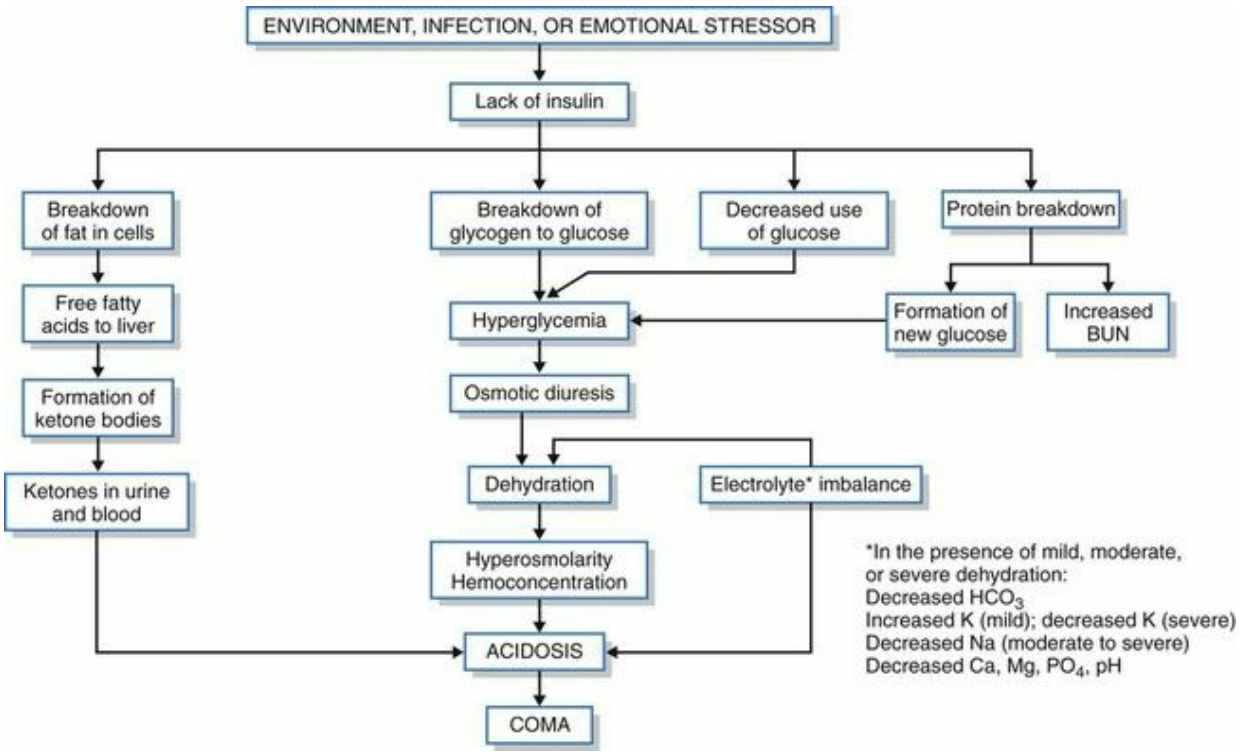

FIG. 64-9 The pathophysiologic mechanism of diabetic ketoacidosis (DKA).

DKA occurs most often in patients with type 1 DM but also can occur in those with type 2 DM who are under severe stress (e.g., trauma, surgery, infection). Some people with type 2 diabetes have a syndrome known as *ketosis-prone diabetes* or *KPD* (Palmer & Jessup, 2012). This problem is not yet fully characterized, and it is important to remember that regardless of whether the patient with DKA has type 1 or type 2 diabetes, management of the acute episode is the same. The most common precipitating factor for DKA is infection. *Death occurs in up to 10% of these cases even with appropriate treatment.*

Hyperglycemia leads to osmotic diuresis with dehydration and electrolyte loss. Classic manifestations of DKA include polyuria, polydipsia, polyphagia, vomiting, abdominal pain, dehydration, weakness, confusion, shock, and coma. Mental status can vary from total alertness to profound coma. As ketone levels rise, the pH of the blood decreases and acidosis occurs. **Kussmaul respirations** (very deep and rapid respirations) cause respiratory alkalosis in an attempt to correct metabolic acidosis by exhaling carbon dioxide. Initial serum sodium levels may be low or normal. Initial potassium levels depend on how long DKA existed before treatment. After therapy starts, serum potassium levels drop quickly.

Planning: Expected Outcomes.

The patient is expected to have few episodes of hyperglycemia and avoid diabetic ketoacidosis. Indicators include that the patient consistently demonstrates these behaviors:

- Maintains blood glucose levels within the prescribed target range
- Adjusts insulin doses to match eating patterns and blood glucose levels during illness
- Maintains easily digestible liquid diet containing carbohydrate and salt when nauseated
- Describes correct procedure for urine ketone testing
- Describes when to seek help from health care professional

Interventions

Blood Glucose Management.

Monitor for manifestations of DKA (see Table 64-13 and Fig. 64-9). Document and use these findings to determine therapy effectiveness. *First assess the airway, level of consciousness, hydration status, electrolytes, and blood glucose level.* Check the patient's blood pressure, pulse, and respirations every 15 minutes until stable. Record urine output,

temperature, and mental status every hour. When a central venous catheter is present, assess central venous pressure every 30 minutes or as prescribed. After treatment starts and these values are stable, monitor and record vital signs every 4 hours. Use blood glucose values to assess therapy and determine when to switch from saline to dextrose-containing solutions.

Fluid and Electrolyte Management.

Closely assess the patient's fluid status. Assess for acute weight loss, thirst, decreased skin turgor, dry mucous membranes, and oliguria with a high specific gravity. Also assess for weak and rapid pulse, flattened neck veins, increased temperature, decreased central venous pressure, muscle weakness, postural hypotension, and cool, clammy, and pale skin to determine if the patient is at risk for dehydration and shock.

Manifestations of fluid volume excess include acute weight gain, full and bounding pulses, distended neck veins, pulmonary crackles, peripheral edema, and elevated central venous pressure. Acute pulmonary edema can develop quickly. Hypertension is common, especially in patients with kidney failure.

Expected manifestations of fluid balance are altered by age-related changes, by other medical conditions, and by drugs. Age-related skin changes, such as loss of elasticity and dryness, make skin turgor an unreliable indicator of dehydration. With severe hyperglycemia, the kidneys are less able to respond to changes in pH or fluid and electrolyte balance, to concentrate urine, or to regulate blood osmolarity. The risk for kidney failure rises with age, and acidosis occurs more quickly. Cardiovascular disease can cause fluid retention. In patients with poor kidney function and excess fluid volume, assess for edema around the eyes and in the limbs, increasing blood pressure, jugular venous distention, and orthostatic hypotension. Edema occurs with excess interstitial fluid and often is not apparent until interstitial volume increases by 2 to 3 L. Jugular venous pressure increases with volume overload. In severe volume depletion, the jugular venous pulsation may not be visible even with the patient lying flat.

Tachycardia is a compensatory mechanism to increase cardiac output. Older adults may not exhibit tachycardia if they are taking beta blockers or calcium channel blockers. Dry mucous membranes may be caused by anticholinergic drugs, and postural hypotension may occur with antihypertensive therapy.

The first outcome of fluid therapy is to restore volume and maintain perfusion to the brain, heart, and kidneys. Typically, initial infusion rates of

0.9% sodium chloride are 15 to 20 mL/kg/hr during the first hour.

The second outcome of replacing total body fluid losses is achieved more slowly. The choice for fluid replacement depends on blood pressure, hydration, serum electrolyte levels, and urine output. In general, hypotonic fluids, such as 0.45% sodium chloride, are infused at 4 to 14 mL/kg/hr after the initial fluid bolus. When blood glucose levels reach 250 mg/dL (13.8 mmol/L), 5% dextrose in 0.45% saline is usually prescribed. This solution prevents hypoglycemia and cerebral edema, which can occur when serum osmolarity declines too rapidly.

During the first 24 hours of treatment, the patient needs enough fluids to replace the actual volume lost, as well as ongoing losses. This may be as much as 6 to 10 L. Assess cardiac, kidney, and mental status to avoid fluid overload. Watch for manifestations of congestive heart failure and pulmonary edema. Central venous pressure may be monitored for older patients and those with myocardial disease. Assess the status of fluid replacement by monitoring blood pressure, intake and output, and changes in daily weight.

Drug Therapy.

Insulin therapy is used to lower serum glucose by about 50 to 75 mg/dL/hr. Unless the episode of DKA is mild, regular insulin by continuous IV infusion is the usual management. Effective blood insulin levels are reached quickly when an IV bolus dose is given at the start of the infusion. An initial IV bolus dose of 0.1 unit/kg is followed by an IV infusion of 0.1 unit/kg/hr. Continuous insulin infusion is used because insulin half-life is short and subcutaneous insulin has a delayed onset of action. Subcutaneous insulin is started when the patient can take oral fluids and ketosis has stopped. DKA is considered resolved when blood glucose is less than 200 mg/mL along with a serum bicarbonate level higher than 18 mEq/L, venous pH higher than 7.3, and a calculated ion gap less than 12 mEq/L. Assess therapy effectiveness by hourly blood glucose measurements.

Acidosis Management.

The key feature of DKA is elevation in blood ketone concentration (measured as serum β-hydroxybutyrate). Accumulation of ketoacids results in an increased anion gap metabolic acidosis. A normal anion gap is between 7 and 9 mEq/L; an anion gap greater than 10 to12 mEq/L indicates metabolic acidosis.

Mild to moderate hyperkalemia is common in patients with hyperglycemia. Insulin therapy, correction of acidosis, and volume

expansion decrease serum potassium concentration. To prevent hypokalemia, potassium replacement is initiated after serum levels fall below the upper limit of normal (5.0 mEq/L). *Assess for manifestations of hypokalemia, including fatigue, malaise, confusion, muscle weakness, shallow respirations, abdominal distention or paralytic ileus, hypotension, and weak pulse.* An ECG shows conduction changes related to potassium. Hypokalemia is a common cause of death in the treatment of DKA.

Nursing Safety Priority QSEN

Critical Rescue

Before giving IV potassium-containing solutions, make sure the urine output is at least 30 mL/hr.

Bicarbonate is used only for severe acidosis. Sodium bicarbonate, given by slow IV infusion over several hours, is indicated when the arterial pH is 7.0 or less or the serum bicarbonate level is less than 5 mEq/L (5 mmol/L).

Patient and Family Education.

Exploring the factors leading to DKA helps in planning specific educational efforts. Teach the patient and family to check blood glucose levels every 4 to 6 hours as long as manifestations such as anorexia, nausea, and vomiting are present and as long as glucose levels exceed 250 mg/dL (13.8 mmol/L). Teach them to check urine ketone levels when blood glucose levels exceed 300 mg/dL (16.7 mmol/L).

Teach the patient to prevent dehydration by maintaining food and fluid intake. Unless another health problem is present that requires fluid restriction, suggest that he or she drink at least 2 L of fluid daily and increase this amount when infection is present. When nausea is present, instruct the patient to take liquids containing both glucose and electrolytes (e.g., soda pop, diluted fruit juice, and sports drinks [Gatorade]). Small amounts of fluid may be tolerated even when vomiting is present. When the blood glucose level is normal or elevated, the patient should take 8 to 12 ounces (240 to 360 mL) of calorie-free and caffeine-free liquids every hour while awake to prevent dehydration.

Liquids containing carbohydrate can be taken if the diabetic patient cannot eat solid food. Ingesting at least 150 g of carbohydrate daily reduces the risk for starvation ketosis. After consulting a primary care provider, urge the patient to take additional rapid-acting (lispro) or short-

acting (regular) insulin based on blood glucose levels.

Instruct the patient and family to consult the health care provider when these problems occur:

- Blood glucose exceeds 250 mg/dL (13.8 mmol/L).
- Ketonuria lasts for more than 24 hours.
- The patient cannot take food or fluids.
- Illness lasts more than 1 to 2 days.

Also instruct them to detect hyperglycemia by monitoring blood glucose whenever the patient is ill. Illness can result in dehydration with DKA, hyperglycemic-hyperosmolar state, or both. The sooner the patient seeks treatment, the less severe the metabolic alteration. He or she should not omit insulin therapy during illness. Chart 64-8 lists guidelines for the ill patient.

Chart 64-8 Patient and Family Education: Preparing for Self-Management

Sick-Day Rules

- Notify your health care provider that you are ill.
- Monitor your blood glucose at least every 4 hours.
- Test your urine for ketones when your blood glucose level is greater than 240 mg/dL (13.8 mmol/L).
- Continue to take insulin or oral antidiabetic agents.
- To prevent dehydration, drink 8 to 12 ounces of sugar-free liquids every hour that you are awake. If your blood glucose level is below your target range, drink fluids that contain sugar.
- Continue to eat meals at regular times.
- If unable to tolerate solid food because of nausea, consume more easily tolerated foods or liquids equal to the carbohydrate content of your usual meal.
- Call your primary care provider for any of these danger signals:
  - Persistent nausea and vomiting
  - Moderate or large ketones
  - Blood glucose elevation after two supplemental doses of insulin
  - High (101.5° F [38.6° C]) temperature or increasing fever; fever for more than 24 hours
- Treat symptoms (e.g., diarrhea, nausea, vomiting, fever) as directed by your primary care provider.
- Get plenty of rest.

Clinical Judgment Challenge

Prioritization, Delegation, and Supervision

The patient, a 21-year-old college student, was brought to the emergency department (ED) by his roommate. He reports abdominal pain, polyuria for the past 2 days, vomiting several times prior to arrival, and extreme thirst. He appears flushed, and his lips and mucous membranes are dry and cracked. His skin turgor is poor. He demonstrates deep, rapid respirations; there is a rotting fruit odor to his breath. He has type 1 diabetes and "may have skipped a few doses of insulin because of cramming for final exams." He is alert and talking but is having trouble focusing on questions.

Vital signs: Blood pressure, 110/60; Pulse, 110/min; Respirations, 32/min; Temperature, 100.8° F; Fingerstick glucose, 485 mg/dL; Oxygen saturation, 99%.

1. You have completed triage assessment and history. Should you now notify his parents for permission to treat him? Why or why not?
2. Should you apply oxygen at this time? Why or why not?
3. Should you call his primary care provider? Why or why not?
4. Your work plan includes checking hourly vital signs, assessing blood glucose levels, updating the roommate about the patient's condition, and measuring the patient's emesis. Which task(s) is (are) appropriate to assign to the new nursing assistant? Provide a rationale for your choices.
5. In caring for this patient, what immediate intervention do you anticipate the ED physician will order to be performed first? Provide a rationale for your choice.
6. What IV solution do you anticipate the ED physician will order for initial fluid replacement?

Preventing Hyperglycemic-Hyperosmolar State.

Hyperglycemic-hyperosmolar state (HHS) is a hyperosmolar (increased blood osmolarity) state caused by hyperglycemia. The processes of HHS are outlined in Fig. 64-10. Both HHS and diabetic ketoacidosis (DKA) are caused by hyperglycemia and dehydration. HHS differs from DKA in that ketone levels are absent or low and blood glucose levels are much higher. Blood glucose levels may exceed 600 mg/dL (33.3 mmol/L), and blood osmolarity may exceed 320 mOsm/L. Table 64-13 lists the differences between DKA and HHS.

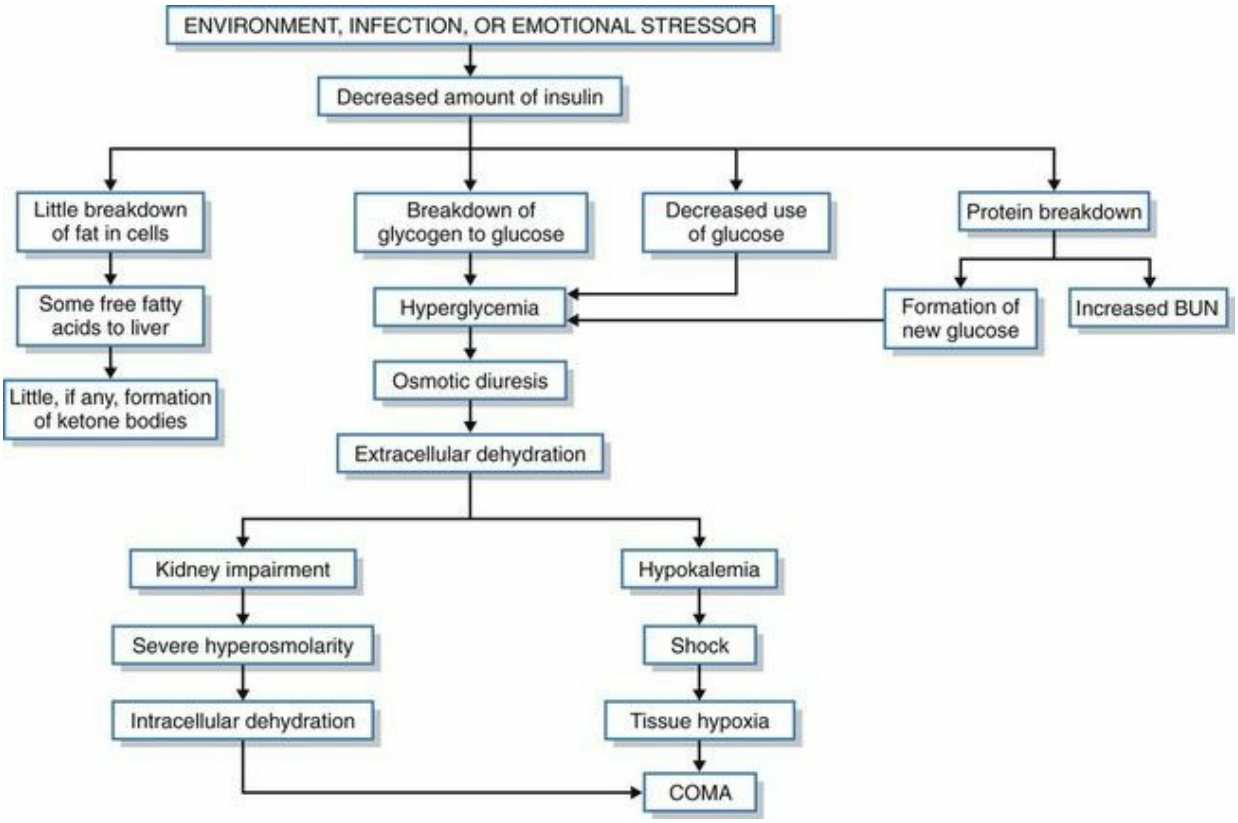

FIG. 64-10 The pathophysiologic mechanism of hyperglycemic-hyperosmolar state (HHS).
BUN, Blood urea nitrogen.

HHS results from a sustained osmotic diuresis. Kidney impairment in HHS allows for extremely high blood glucose levels. As blood concentrations of glucose exceed the renal threshold, the kidney's capacity to reabsorb glucose is exceeded.

Decreased blood volume, caused by osmotic diuresis, or underlying kidney disease, common in many older patients with diabetes, results in further deterioration of kidney function. The decreased volume further reduces glomerular filtration rate, causing the glucose level to increase. Decreased kidney perfusion from hypovolemia further impairs kidney function.

Considerations for Older Adults

Patient-Centered Care QSEN

HHS occurs most often in older patients with type 2 diabetes mellitus, many of whom did not know that they had diabetes. Mortality rates in older patients are as high as 40% to 70%. The onset of HHS is slow and may not be recognized. The older patient often seeks medical attention later and is sicker than the younger patient. HHS does not occur in adequately hydrated patients. Older patients are at greater risk for

dehydration and HHS because of age-related changes in thirst perception, poor urine-concentrating abilities, and use of diuretics. Stress to all older adults, especially those who have diabetes, the importance of maintaining hydration.

Myocardial infarction, sepsis, pancreatitis, stroke, and some drugs (glucocorticoids, diuretics, phenytoin [Dilantin], beta blockers, and calcium channel blockers) also may cause HHS. Central nervous system (CNS) changes range from confusion to complete coma. Unlike DKA, patients with HHS may have seizures and reversible paralysis. The degree of neurologic impairment is related to serum osmolarity, with coma occurring once serum osmolarity is greater than 350 mOsm/L (350 mmol/L).

The development of HHS rather than DKA is related to residual insulin secretion. In HHS, the patient secretes just enough insulin to prevent ketosis but not enough to prevent hyperglycemia. The hyperglycemia of HHS is more severe than that of DKA, greatly increasing blood osmolarity, leading to extreme diuresis with severe dehydration and electrolyte loss.

Planning: Expected Outcomes.

The patient with DM is expected to have few episodes of hyperglycemia and avoid HHS. Indicators include that the patient consistently demonstrates these behaviors:

- Maintains blood glucose levels within the target range
- Uses antidiabetic drugs appropriately
- Remains well hydrated
- Describes when to seek help from health care professionals

Interventions

Monitoring.

Assess for manifestations of HHS. (See Tables 64-12 and 64-13 for manifestations of hyperglycemia.) Continually assess fluid status.

Fluid Therapy.

The expected outcome of therapy is to rehydrate the patient and restore normal blood glucose levels within 36 to 72 hours. The choice of fluid replacement and the rate of infusion are critical in managing HHS. The severity of the CNS problems is related to the level of blood hyperosmolarity and cellular dehydration. Re-establishing fluid balance

in brain cells is a difficult and slow process, and many patients do not recover baseline CNS function until hours after blood glucose levels have returned to normal.

The *first* priority for fluid replacement in HHS is to increase blood volume. In shock or severe hypotension, normal saline is used. Otherwise, half-normal saline (0.45% sodium chloride) is used. Infuse fluids at 1 L/hr until central venous pressure or pulmonary capillary wedge pressure begins to rise or until blood pressure and urine output are adequate. The rate is then reduced to 100 to 200 mL/hr. Half of the estimated fluid deficit is replaced in the first 12 hours, and the rest is given over the next 36 hours. Body weight, urine output, kidney function, and the presence or absence of pulmonary congestion and jugular venous distention determine the rate of fluid infusion. In patients with congestive heart failure, kidney disease, or acute kidney injury, monitor central venous pressure. *Assess the patient hourly for signs of cerebral edema—abrupt changes in mental status, abnormal neurologic signs, and coma.* Lack of improvement in level of consciousness may indicate inadequate rates of fluid replacement or reduction in plasma (blood) osmolarity. Regression after initial improvement may indicate a too-rapid reduction in blood osmolarity. A slow but steady improvement in CNS function is the best evidence that fluid management is satisfactory.

Nursing Safety Priority QSEN

Critical Rescue

For patients being managed for hyperglycemic-hyperosmolar state, immediately report changes in the level of consciousness; changes in pupil size, shape, or reaction; or seizures.

Continuing Therapy.

IV insulin is administered after adequate fluids have been replaced. The typical intervention is an initial bolus dose of 0.15 unit per kg IV followed by an infusion of 0.1 unit per kg per hour until blood glucose levels fall to 250 mg/dL (13.9 mmol/L). A reduction of blood glucose of 50 to 70 mg/dL per hour is the expected outcome. Monitor the patient closely for hypokalemia. Total body potassium depletion is often unrecognized because the blood potassium level may be normal or high as a result of dehydration. The potassium level may drop quickly when insulin therapy is started. Potassium replacement is initiated once urine output is adequate. Serum electrolytes are checked every 1 to 2 hours until stable,

and the cardiac rhythm is monitored continuously for signs of hypokalemia or hyperkalemia. Patient education and interventions to minimize dehydration are similar to those for ketoacidosis.

Community-Based Care

Self-Management Education.

Diabetes is a self-managed chronic disease requiring those affected to be actively involved in their own care. The concept of diabetes self-management refers to the patient's daily responsibility for almost all tasks involved in diabetes care. Education about blood glucose control for those with or at risk for diabetes occurs in a variety of health care settings. Physicians, nurses, registered dietitians, pharmacists, social workers, and psychologists all participate in the education. People with diabetes are best able to learn through educational efforts that are tailored to their individual needs.

Assessing Learning Needs and Readiness to Learn.

First assess the patient's learning needs and readiness to learn. This assessment establishes what the patient already knows and what he or she needs to know. It also helps you determine the patient's ability and desire to learn. Assess the needs of both patient and family before teaching (Hughes, 2012b). Table 64-14 lists areas to include in this assessment.

TABLE 64-14

Assessment of Learning Needs for the Patient with Diabetes

- Health and medical history
- Nutrition history and practices
- Physical activity and exercise behaviors
- Prescription and over-the-counter medications and complementary and alternative therapies and practices
- Factors that influence learning such as education and literacy levels, perceived learning needs, motivation to learn, and health beliefs
- Diabetes self-management behaviors, including experience with self-adjusting the treatment plan
- Previous diabetes self-management training, actual knowledge, and skills
- Physical factors including age, mobility, visual acuity, hearing, manual dexterity, alertness, attention span, and ability to concentrate or special needs or limitations requiring adaptive support and use of alternative skills
- Psychosocial concerns, factors, or issues including family and social support
- Current mental health status
- History of substance use including alcohol, tobacco, and recreational drugs
- Occupation, vocation, education level, financial status, and social, cultural, and religious practices
- Access to and use of health care resources

Patients want information that applies directly to them. Find out what concerns the patient most about having diabetes, and ask what he or she wants to learn. Start with what the patient already knows, and build on that base. Make sure that the patient's knowledge is current and applies to his or her type of diabetes.

Your assessment may indicate that the patient is not ready to learn

needed self-management behaviors. With the patient's permission, you would then teach a family member or someone close to the patient about diabetes management. You would also provide written materials on diabetes management as well as telephone numbers for the patient to call when he or she is ready to learn.

Assessing Physical, Cognitive, and Emotional Limitations.

Assessing the patient's literacy is essential in developing a plan of care and providing self-management education. It is important to measure the patient's ability to read and understand written materials and conduct math calculations. Assess the patient's education and reading level to determine what level of information to present. It is important to match the literacy level of materials to the literacy level of the patient. Simplify the information you present by replacing technical terms with plain language (words people use in everyday conversation).

Assess the patient's ability to read printed information, insulin labels, and markings on syringes and equipment. Many with type 2 diabetes have age-related visual problems made worse by blurred vision caused by fluctuating blood glucose levels. Assess the patient's ability to reason with numbers. Determine whether the patient has the math skills needed to interpret a food label or to make adjustments in insulin doses based on glucose readings.

Assess manual dexterity for any physical limitations that may alter the teaching plan. A hand injury, tremors, or severe arthritis often leads to dosing errors with a standard syringe and may require a change in insulin preparation.

Individual learning styles vary. Visual learners think in terms of pictures and remember things best by seeing something written or by seeing visual aids. Auditory learners learn best through hearing. Kinesthetic or tactile learners learn best through touching, feeling, and experiencing what they are trying to learn. Tactile learners remember best by writing or physically manipulating the equipment. Successful diabetes self-management education uses all three learning styles by providing written handouts, discussing steps involved in a procedure such as insulin administration or self-monitoring of blood glucose, and encouraging the learner to touch and manipulate equipment. Confirm that the patient understands your instructions by having him or her "teach back" the information to you.

Tailor educational sessions to the time available and to the condition of the patient. Hospitalized people require only basic education when they are acutely ill. In these situations, it is appropriate to teach basic survival

skills or focused problem-solving skills while reserving more detailed education for follow-up sessions.

Survival Skills Information.

The initial phase of diabetes education involves teaching information necessary for the survival of anyone diagnosed with diabetes. Survival information includes:

- Simple information on pathophysiology of diabetes
- Learning how to prepare and administer insulin or how to take oral drugs for diabetes
- Recognition, treatment, and prevention of hypoglycemia and hyperglycemia
- Basic diet information
- Monitoring of blood glucose and ketones
- Sick-day management
- Where to buy diabetes supplies and how to store them
- When and how to notify the health care provider

In-Depth Education.

In-depth education and counseling involve teaching more detailed information about survival skills and about actions for avoiding long-term complications. Educational sessions with patient and family are needed to "patientize" the diabetes regimen for *their* needs and abilities.

The person with diabetes needs to understand the pathology of diabetes. He or she should be able to discuss the action of insulin in the body and the effects of insulin deficiency. He or she should also be able to explain the effects of diet, drugs, and activity on blood glucose. The patient should be able to relate maintaining normal blood glucose levels to preventing complications. This includes relating changes in glucose level to the possible need for a change in insulin dosage.

Provide education about the manifestations of hypoglycemia along with the prescribed treatment options if the patient takes any drugs that will lower blood glucose levels. Educate patients and their families about common causes of hypoglycemia such as changes in drug regimen, increase in physical activity, and delayed or missed meals. Review manifestations of hypoglycemia at each visit. Advise patients to check their blood glucose levels before driving and make sure they have easy-to-reach snacks or fast-acting sugars with them at all times. Encourage them to always wear a medical ID tag or bracelet and to contact their health care provider if they experience low blood glucose levels more than twice a week.

Many patients require combination drug therapy to achieve glucose regulation in addition to aspirin and drugs to lower lipids and blood pressure. If the patient takes an oral antidiabetic drug, ask him or her to identify the drugs and describe the prescribed schedule. Determine if the patient is able to administer insulin accurately by having him or her "teach back" injection techniques. Ask the patient to discuss the onset, peak, and duration of the insulin used. The patient must be able to state when insulin is to be injected, where insulin is injected, and how insulin is stored. Review formulas for self-adjustment in insulin (when permitted by the health care provider), and explain blood glucose monitoring requirements needed to evaluate the effects of additional insulin. Stress the dangers of skipping doses. Review drug interactions, especially with older patients taking oral antidiabetic drugs.

Teach patients receiving diet therapy alone, glucose-lowering drugs, or fixed insulin doses to eat consistent amounts of carbohydrate at meals and snacks. Patients who adjust mealtime doses of insulin or those on insulin pump therapy can be taught to match their insulin dose to the carbohydrate content of their diet. The patient needs to understand what to eat, how much to eat, and when to eat. Stress the importance of eating on time, the dangers of skipping meals, and how to maintain food intake during illness. Ask the patient to describe the meal plan and explain the adjustments needed to meet diabetic diet requirements. Include the family member usually responsible for buying groceries and preparing meals in this teaching.

Regular physical activity is important for physical fitness, weight management, and blood glucose control. Assist all patients to identify activities they can do to achieve the goal of moderate-intensity activity 3 or more days a week. For patients taking insulin and/or insulin secretagogues, physical activity can cause hypoglycemia if drug dosage or carbohydrate intake is not increased. Review how to perform physical activities safely. Instruct the patient on blood glucose levels that are safe for exercise, the frequency of glucose monitoring during exercise, drug adjustments before exercise, food required before exercise, and what food to have available during exercise. He or she should be aware of the risk for injury during exercise and be able to explain the importance of protective footwear.

Self-monitoring of blood glucose provides immediate information on a person's blood glucose level and provides feedback on the effects of recent activity, drugs, and meals. The nurse's role includes teaching skills of performing the test, educating how to interpret results, and problem solving to adjust behaviors and therapy based on the information. Teach

patients how to recognize when blood glucose levels are out of range, how to adjust therapy and behaviors based on self-monitoring of blood glucose (SMBG) results, and how to verify the effects of these adjustments by performing subsequent glucose testing. Also, show patients who use insulin how to use SMBG to adjust dosages to achieve glucose control while avoiding episodes of hypoglycemia.

Teach patients sick-day procedures when initially diagnosed with diabetes. Hyperglycemia often develops before infection manifestations and can serve as a warning that infection is developing. Provide guidelines for the frequency of glucose testing, for ketone testing, and for insulin adjustment for those patients able to self-adjust insulin doses.

Psychosocial Preparation.

The diagnosis of diabetes may represent a loss of control and flexibility. Life becomes ordered, and routines must be followed. Certain events surrounding diabetes are predictable. Taking an insulin injection and not eating for several hours causes hypoglycemia. Poorly controlled diabetes leads to complications and premature death. Tight control of blood glucose levels prevents complications.

The stress of diabetes is in addition to the demands of normal daily life. The patient must be able to integrate the demands of diabetes into daily and recreational schedules while keeping blood glucose stable.

Patients are more likely to adhere to disease management activities when the strategies make sense and seem effective. Other factors promoting adherence include the patient's belief that the activity is important, having confidence in himself or herself, and having support. Assist in healthy psychological adaptation to diabetes by providing successful educational experiences. Mastery of blood glucose monitoring helps the patient feel that he or she has control over the disease. Knowing the effects of extra activities, extra food, or extra insulin is helpful in learning to adjust the regimen.

Feeling a sense of control over the condition promotes a positive attitude about diabetes. Success in injecting insulin provides concrete evidence that he or she can master the disease. Teach by breaking a task into small, achievable units to ensure mastery. For example, a patient may begin learning how to inject insulin by first obtaining an accurate dose.

Devote as much teaching time as possible to insulin injection and blood glucose monitoring. Patients with newly diagnosed diabetes are often fearful of giving themselves injections. After this technique has been mastered, they become less anxious and are able to attend to other tasks.

Recognize that not everyone will adapt to diabetes. Some patients are unable to progress beyond the survival level. Major depression affects many patients with diabetes, having an impact on quality of life and all aspects of functioning, including self-management behaviors. Refer those who have significant problems coping with the day-to-day demands of diabetes to mental health counseling for appropriate treatment.

Home Care Management.

Patients with diabetes self-manage their disease. Each day they decide what to eat, whether to exercise, and whether to take prescribed drugs. Maintaining blood glucose control depends on the accuracy of self-management skills. The nurse provides support and education to empower the patient to make informed decisions. Self-management education allows patients to identify their problems and provides techniques to help them make decisions, take appropriate actions, and alter these actions as needed.

Provide information about resources. The patient must know whom to contact in case of emergency. Older adults who live alone need to have daily telephone contact with a friend or neighbor. The patient may also need help shopping and preparing meals. He or she may have limited access to transportation and may not have sufficient supplies of food, particularly in bad weather. Because of the likelihood of visual problems in older patients, they may need assistance in preparing insulin syringes for injection or in monitoring blood glucose. Make referrals to home care or public health agencies as needed. Chart 64-9 identifies areas for assessment during a home or clinic visit.

Chart 64-9 Focused Assessment

The Insulin-Dependent Patient with Diabetes During a Home or Clinic Visit

- Assess overall mental status, wakefulness, ability to converse.
- Take vital signs and weight:
  - Fever could indicate infection.
  - Are blood pressure and weight within target range? If not, why?
- Question patient regarding any change in visual acuity; check current visual acuity.
- Inspect oral mucous membranes, gums, and teeth.
- Question patient about injection areas used; inspect areas being used;

assess whether patient is using areas and sites appropriately.
- Inspect skin for intactness, wounds that have not healed, new sores, ulcers, bruises, or burns; assess any previously known wounds for infection, progression of healing.
- Question patient regarding foot care.
- Assess lower extremities and feet for peripheral pulses, lack of or decreased sensation, abnormal sensations, breaks in skin integrity, condition of toes and nails.
- Question patient regarding color and consistency of stools and frequency of bowel movements; assess abdomen for bowel sounds.
- Review patient's home health diary:
  - Is blood glucose within targeted range? If not, why?
  - Is glucose monitoring being recorded often enough?
  - Is the patient's food intake adequate and appropriate? If not, why?
  - Is exercise occurring regularly? If not, why?
- Assess patient's ability to perform self-monitoring of blood glucose.
- Assess patient's procedures for obtaining and storing insulin and syringes, cleaning equipment, disposing of syringes and needles.
- Assess patient's insulin preparation and injection technique.

Evaluation: Outcomes

Evaluate the care of the patient with diabetes based on the identified priority patient problems. Outcome success for diabetes education is the ability of the patient to maintain blood glucose levels within their established target range. General outcome criteria are listed below and in Table 64-15. More specific outcomes are listed with each priority patient problem. The expected outcomes include that the patient should:

TABLE 64-15

Outcome Criteria for Diabetes Teaching

Before being discharged to home, the patient with diabetes or the significant other should be able to:
• Tell why insulin or an oral hypoglycemic agent is being prescribed • Name which insulin or oral hypoglycemic agent is being prescribed, and name the dosage and frequency of administration • Discuss the relationship between mealtime and the action of insulin or the oral hypoglycemic agent • Discuss plans to follow diabetic diet instructions • Prepare and administer insulin accurately • Test blood for glucose, or state plans for having blood glucose levels monitored • Test urine for ketones, and state when this test should be done • Verbalize how to store insulin • List manifestations that indicate a hypoglycemic reaction • Tell what carbohydrate sources are used to treat hypoglycemic reactions • Tell what manifestations indicate hyperglycemia • Tell what dietary changes are needed during illness • Verbalize when to call the physician or the nurse (frequent episodes of hypoglycemia, manifestations of hyperglycemia) • Verbalize the procedures for proper foot care

- Achieve blood glucose control
- Avoid acute and chronic complications of diabetes
- Avoid injury
- Experience relief of pain
- Maintain optimal visual sensory perception
- Maintain a urine output in the expected range
- Have an optimal level of mental status functioning
- Have decreased episodes of hypoglycemia
- Have decreased episodes of hyperglycemia

Specific indicators for these outcomes are listed for each priority patient problem under the Planning and Implementation section (see earlier).

Nursing Concepts and Clinical Judgment Review

What might you NOTICE in a patient with diabetes mellitus who demonstrates adequate glucose regulation?

Vital signs:

- Blood pressure less than 140/80
- Heart rate and rhythm within the normal range
- Temperature within the normal range

Physical assessment:

- Skin intact, especially on the feet, no open wounds or sores that have failed to heal
- Weight proportionate to height; does not appear overweight or underweight
- Vision adequate for safety and participation in ADLs
- No report of pain, tingling, numbness, or burning in extremities

Psychological assessment:

- Oriented and not confused
- Willing to learn and participate in self-care
- Energy level good; can engage in desired work, recreational, and personal activities

Laboratory assessment:

- A1C levels are maintained at 6.5% or below.

- The majority of premeal blood glucose levels are 70 to 130 mg/dL (3.9 to 7.2 mmol/L).
- Peak after-meal blood glucose levels are less than 180 mg/dL (<10.0 mmol/L).
- Urine is free from ketone bodies and albumin.
- 24-hour intake and output balance.
- Blood urea nitrogen (BUN) and serum creatinine are within the normal ranges.
- Serum electrolytes are within the normal ranges.

Get Ready for the NCLEX® Examination!

Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Use aseptic technique during any invasive procedure when caring for a patient with diabetes. **Safety** QSEN
- Administer antidiabetic drugs and insulin in a safe manner. **Safety** QSEN
- Ensure that meals are available immediately after the patient receives an antidiabetic drug or insulin. **Safety** QSEN
- Use good handwashing techniques before providing any care to a patient who has diabetes. **Safety** QSEN

Health Promotion and Maintenance

- Encourage all patients to maintain weight within an appropriate range. **Evidence-Based Practice** QSEN
- Encourage all patients, including patients with diabetes, to participate regularly in exercise or physical activity appropriate to their health status. **Patient-Centered Care** QSEN
- Teach the patient and family about the manifestations of infection and when to seek medical advice.
- Instruct patients with diabetes to wear a medical alert bracelet. **Safety** QSEN
- Instruct patients to not share blood glucose monitoring equipment. **Evidence-Based Practice** QSEN
- Reinforce to all patients with diabetes that tight control over blood glucose levels reduces the risk for the vascular complications of diabetes. **Patient-Centered Care** QSEN
- Remind patients with diabetes to have yearly eye examinations by an ophthalmologist. **Evidence-Based Practice** QSEN
- Teach patients with peripheral neuropathy to use a bath thermometer to test water for bathing, to avoid walking barefoot, and to inspect their feet daily. **Safety** QSEN
- Assess patients' visual acuity and peripheral tactile sensation to determine needed adjustments in teaching self-medication and self-monitoring of blood glucose levels.
- Instruct all patients with diabetes to avoid becoming dehydrated and to drink at least 2 L of water each day unless another medical condition

requires fluid restriction. **Patient-Centered Care** QSEN
- Instruct patients who are taking sulfonylurea drugs about an increased risk for hypoglycemic reactions. **Patient-Centered Care** QSEN
- Teach patients who are taking metformin the clinical manifestations of lactic acidosis (fatigue, dizziness, difficulty breathing, stomach discomfort, irregular heartbeat). **Safety** QSEN
- Warn patients to not take over-the-counter drugs with their oral antidiabetic drugs without consulting their primary care provider.
- Teach patients to rotate insulin injection sites within one area rather than to other areas, to prevent changes in absorption. **Evidence-Based Practice** QSEN
- Use return demonstration and "teach-back" strategies when teaching the patient about drug regimen, insulin injection, blood glucose monitoring, and foot assessment. **Patient-Centered Care** QSEN
- Teach patients to administer an accurate dose of insulin using a prefilled or disposable insulin pen.
- Teach patients who experience Somogyi phenomenon (early morning hyperglycemia) to ensure an adequate dietary intake at bedtime.
- Instruct patients to always carry a glucose source.
- Teach patients who exercise to test urine for ketone bodies if blood glucose levels are greater than 250 mg/dL before engaging in strenuous exercise.
- Instruct patients in foot care as outlined in Chart 64-6.

Psychosocial Integrity

- Explore with the patient what the diagnosis of diabetes means to him or her. **Patient-Centered Care** QSEN
- Allow the patient the opportunity to express concerns about the diagnosis of diabetes or the treatment regimen.
- Explain all procedures, restrictions, drugs, and follow-up care to the patient and family.
- Instruct the patient and family on the manifestations of complications and when to seek assistance. **Safety** QSEN
- Pace your education sessions to match the learning needs and style of the patient. **Patient-Centered Care** QSEN

Physiological Integrity

- Never dilute or mix insulin glargine with any other insulin or solution. **Safety** QSEN

- Avoid injecting insulin within a 2-inch radius of the umbilicus.
- Avoid IM insulin injection.
- Assist patients who have pain from peripheral neuropathy to determine what pain-relieving drugs and techniques work best for them.
- Assess the patient's A1C level for indications of adherence to prescribed regimens and their effectiveness.
- Start carbohydrate replacement per physician prescription or standing protocols immediately on identifying a patient with hypoglycemia. **Safety** QSEN
- Give glucagon subcutaneously or IM and 50% dextrose IV to patients identified with hypoglycemia who cannot swallow. **Evidence-Based Practice** QSEN
- First assess the airway, level of consciousness, hydration status, electrolytes, and blood glucose level of any patient with diabetic ketoacidosis.
- Use blood glucose values to assess therapy effectiveness and determine when to switch from saline to dextrose-containing solutions in a patient with diabetic ketoacidosis.
- Continually assess fluid status and level of consciousness in a patient with hyperglycemic-hyperosmolar state (HHS) during the resuscitation period.
- Immediately report manifestations of cerebral edema (abrupt changes in mental status; changes in level of consciousness; changes in pupil size, shape, or reaction; seizures) in a patient with HHS to the health care provider. **Safety** QSEN
- Collaborate with the health care provider, diabetes nurse educator, registered dietitian, pharmacist, social worker, and case manager to individualize patient care for the person with diabetes in any care setting. **Teamwork and Collaboration** QSEN
- Refer patients newly diagnosed with diabetes to local resources and support groups.

UNIT XV

Problems of Excretion: Management of Patients with Problems of the Renal/Urinary System

OUTLINE

Concept Overview: Urinary Elimination

Adequate urinary elimination is essential for body fluid homeostasis—the ability of the body to maintain its internal environment at a "steady state" and within very narrow ranges of normal, regardless of external changes. Urinary elimination alone is defined as the passage of urine through the urinary tract by means of the urinary sphincter and urethra (Giddens, 2013). However, urine cannot be eliminated unless it is first formed in the kidneys from the blood. The kidneys perform the actual work of determining which substances in body fluid will be eliminated and which will be retained. So kidney function is critical for urinary elimination to be able to maintain homeostasis of all body fluids.

The body works best when blood and other extracellular fluids maintain volumes within the normal ranges and maintain the proper ranges of electrolytes. Serious health problems and death occur when these electrolytes are much higher or lower than normal ranges. When blood volume is too high, hypertension develops and damages vital organs. When blood volume is too low, hypotension can be so severe that vital organs are not perfused with oxygen and become hypoxic. In addition, protein waste products containing nitrogen, such as urea, act as a poison and must be prevented from getting too high. Humans ingest many foods and liquids that contain water, electrolytes, and substances that will be converted to waste products. Without control mechanisms to balance the intake of these substances with their elimination, we would

rapidly accumulate too much of everything and die.

As part of the renal/urinary system, the kidneys are responsible for maintaining this balance of what is taken into the body, what is allowed to remain in the body, and what is eliminated from the body. Although some products are eliminated in the stool, there is no discrimination or adjustment in bowel elimination. Urinary elimination, however, allows a person to eat and drink almost anything (except poisons and infectious organisms) in almost any amount without upsetting the homeostatic balance for body water, electrolytes, waste products, and blood pressure. For example, on one day a person may drink 2 L of fluids and eat food that contains 2 g of sodium and 5 g of potassium. The next day this same person may drink 3 L of fluids and eat food that contains 12 g of sodium and 10 g of potassium. Yet because the kidneys selectively adjust to change the amount of each substance that gets eliminated, the blood pressure, serum sodium, and serum potassium levels remain the same and within the normal ranges on both days. A "steady-state" or homeostatic balance of these substances is maintained because the kidneys adjust the output to match the intake (Fig. 1).

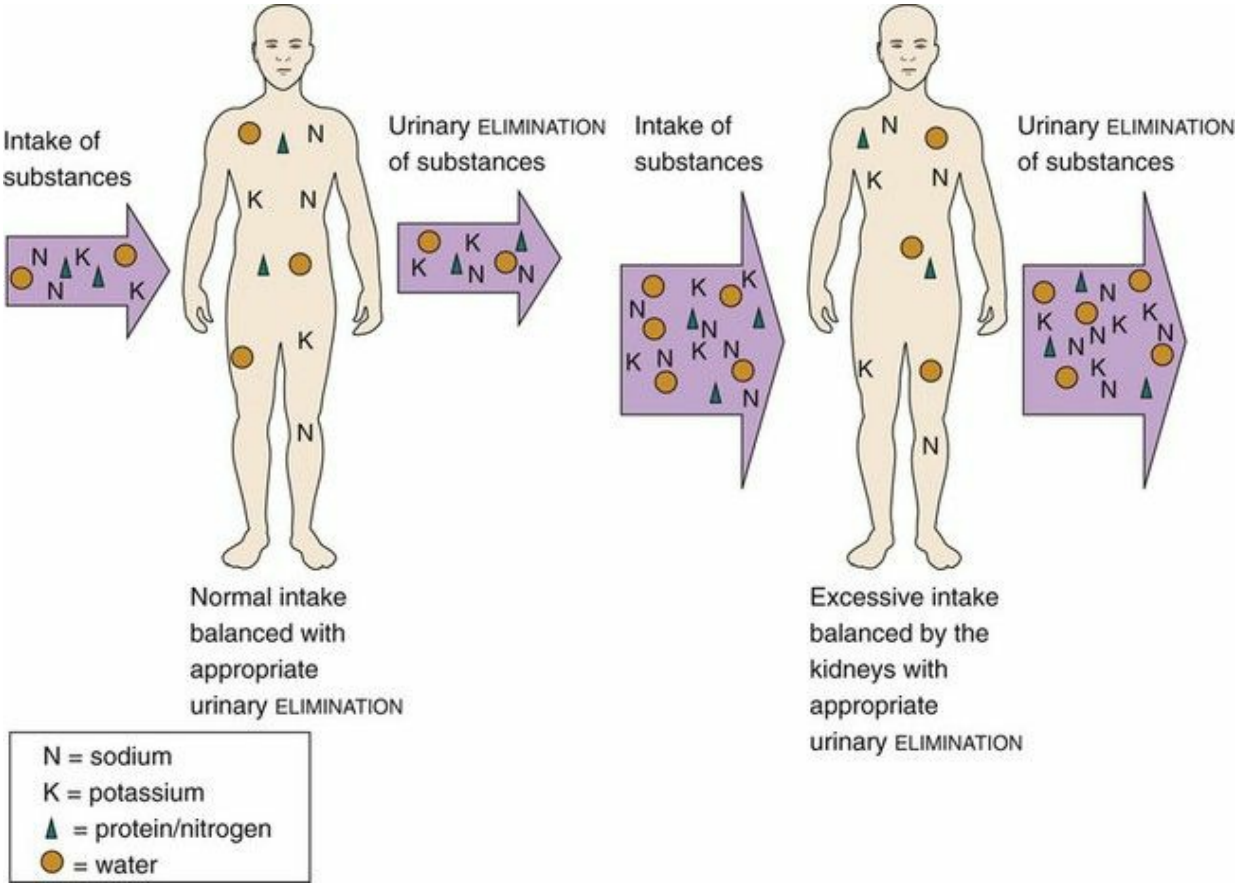

FIG. 1

When kidney function is impaired to any degree as a result of

renal/urinary problems, urinary elimination is not adequate and the steady-state homeostasis of water, electrolyte, and waste products is disrupted (Fig. 2). Without intervention, this lack of steady state leads to excesses of body water, electrolytes, and nitrogenous waste products that interfere with normal organ function and can cause death.

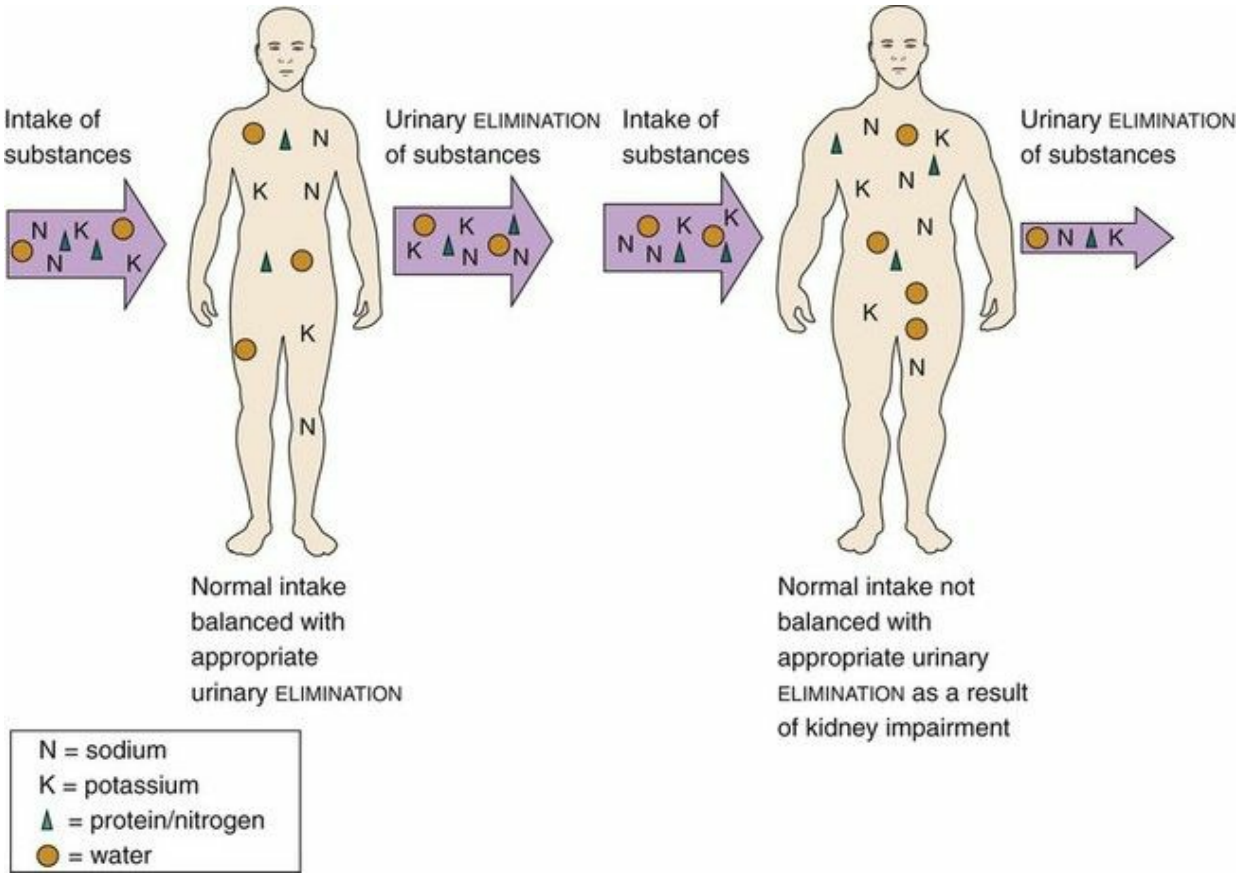

FIG. 2

CHAPTER 65

Assessment of the Renal/Urinary System

Chris Winkelman

PRIORITY CONCEPTS

- Elimination
- Fluid and electrolyte balance
- Acid-base balance

Learning Outcomes

Safe and Effective Care Environment

1. Use principles of infection control when assessing a patient's kidney and urinary elimination for adequate fluid and electrolyte balance and acid-base balance.

Health Promotion and Maintenance

2. Teach all people about the importance of maintaining an adequate oral fluid intake for fluid and electrolyte balance.
3. Teach about or assist with cleansing of the perineum or urinary meatus after using the toilet and during daily bathing or showering.
4. Teach all people how to protect the kidneys and urinary system from toxic substances.

Psychosocial Integrity

5. Reduce the psychological impact for the patient and family regarding the assessment and testing of the renal/urinary system.

Physiological Integrity

6. Perform a focused assessment of kidney and urinary function,

incorporating information from anatomy and physiology, including genetic risk and age-related changes affecting kidney and urinary function.

7. Coordinate appropriate care for patients after invasive and noninvasive testing of kidney and urinary function.
8. Use correct technique to assess the kidneys and urinary system.
9. Prioritize nursing care for the patient during the first 24 hours after invasive procedures, especially those requiring contrast material.

 http://evolve.elsevier.com/Iggy/

The renal system includes the kidneys and the entire urinary tract. The ureters, bladder, and urethra are the drainage route for the excretion of urine. Structural or functional problems in the kidneys or urinary tract may alter fluid and electrolyte balance and acid-base balance.

The kidneys help maintain health in many ways. *Most important, they maintain body fluid volume and composition and filter waste products for elimination.* The kidneys also help regulate blood pressure and acid-base balance, produce erythropoietin for red blood cell (RBC) synthesis, and convert vitamin D to an active form.

Assessment of the patient at risk for or with actual problems of the kidneys or urinary system begins with a history and physical assessment. Understanding the anatomy, physiology, and diagnostic tests of the renal system helps you in problem solving about kidney and urinary tract function in the clinical setting. It also assists you in teaching the patient about the purpose of procedures and in physically and emotionally preparing the patient for assessment.

Anatomy and Physiology Review

Kidneys

Structure

Gross Anatomy.

The two kidneys are located behind the peritoneum, not in the abdominal cavity, one on either side of the spine (Fig. 65-1). The adult kidney is 4 to 5 inches (10 to 13 cm) long, 2 to 3 inches (5 to 7 cm) wide, and about 1 inch (2.5 to 3 cm) thick. The left kidney is slightly longer and narrower than the right kidney. Larger-than-usual kidneys may indicate obstruction or polycystic disease. Smaller-than-usual kidneys may indicate chronic kidney disease (CKD).

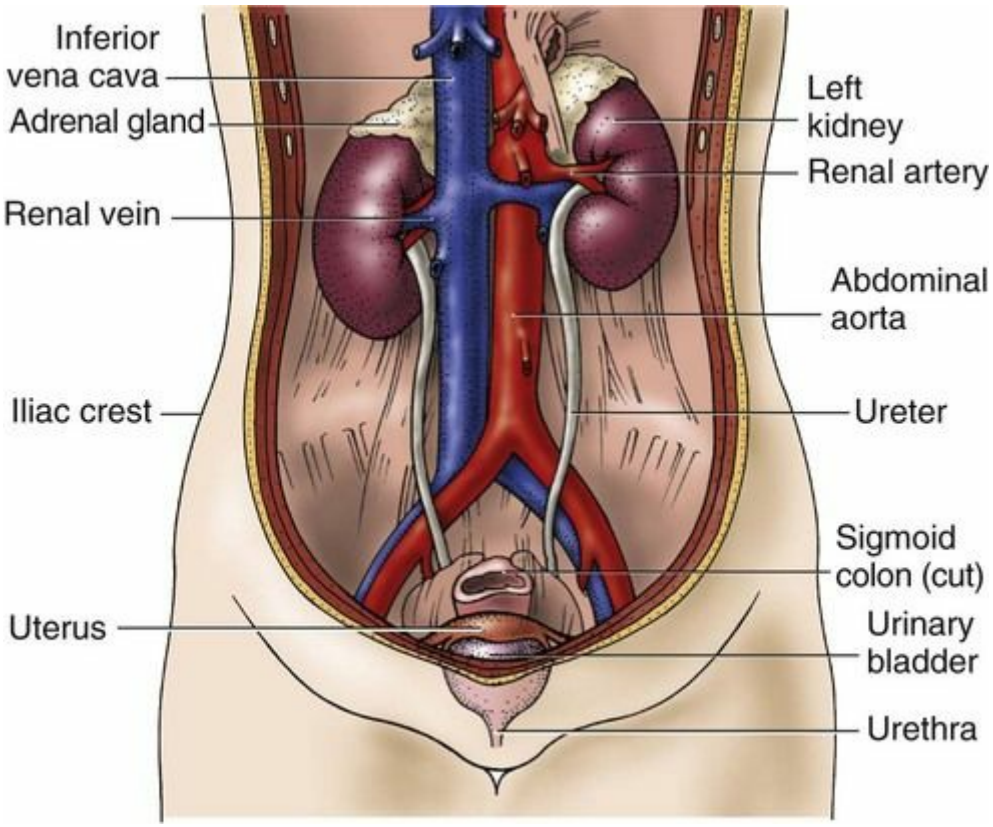

FIG. 65-1 Anatomic location of the kidneys and structures of the urinary system.

Variation in kidney shape and number is not uncommon and does not always indicate a problem in kidney function. Some people have more than two kidneys or may have only one large, horseshoe-shaped kidney. As long as tests of kidney function are normal, these variations are of no significance.

Several layers of tissue surround the kidney, providing protection and

support. The outer surface of the kidney is a layer of fibrous tissue called the **capsule** (Fig. 65-2). It covers most of the kidney except the **hilum**, which is the area where the kidney blood vessels and nerves enter and exit. It is also where the ureter exits. The capsule is surrounded by layers of fat and connective tissue.

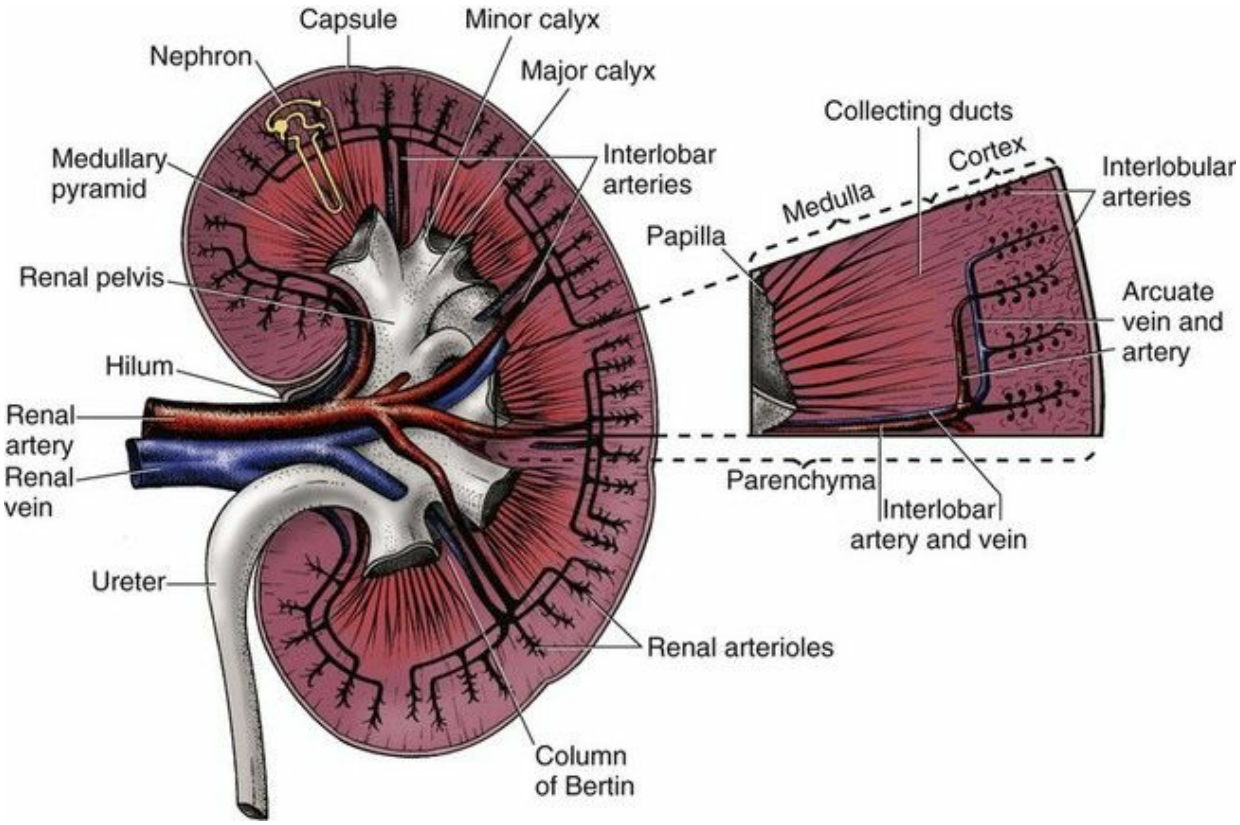

FIG. 65-2 Bisection of the kidney showing the major structures of the kidney.

Lying beneath the capsule are the two layers of functional kidney tissue—the cortex and the medulla. The **renal cortex** is the outer tissue layer. The **medulla** is the medullary tissue lying below the cortex in the shape of many fans. Each "fan" is called a *pyramid.* The **renal columns** are cortical tissue that dips down into the interior of the kidney and separates the pyramids.

The tip of each pyramid is called a **papilla**. The papillae drain urine into the collecting system. A cuplike structure called a **calyx** collects the urine at the end of each papilla. The calices join together to form the **renal pelvis**, which narrows to become the ureter.

The kidneys have a rich blood supply and receive a blood flow from 600 to 1300 mL/min. The blood supply to each kidney comes from the renal artery, which branches from the abdominal aorta. The renal artery divides into progressively smaller arteries, supplying all blood to areas of

the kidney tissue and the nephrons. The smallest arteries (**afferent arterioles**) feed the nephrons directly to form urine.

Venous blood from the kidneys starts with the capillaries surrounding each nephron. These capillaries drain into progressively larger veins, with blood eventually returned to the inferior vena cava through the renal vein.

Microscopic Anatomy.

The **nephron** is the functional unit of the kidney, which forms urine from blood. There are about 1 million nephrons per kidney, and each nephron separately makes urine from blood.

There are two types of nephrons: *cortical nephrons* and *juxtamedullary nephrons*. The cortical nephrons are short and lie totally within the renal cortex. The juxtamedullary nephrons (about 20% of all nephrons) are longer, and their tubes and blood vessels dip deeply into the medulla. The purpose of these longer nephrons is to concentrate urine during times of low fluid intake to allow continued excretion of body wastes with less fluid loss.

Blood supply to the nephron is delivered through the afferent arteriole —the smallest, most distal portion of the renal arterial system. From the afferent arteriole, blood flows into the **glomerulus**, which is a series of specialized capillary loops. It is through these capillaries that water and small particles are filtered from the blood to make urine. The remaining blood leaves the glomerulus through the **efferent arteriole**, which is the first vessel in the kidney's venous system. From the efferent arteriole, blood exits into either the *peritubular capillaries* around the tubular part of the cortical nephrons or the *vasa recta* around the tubular part of juxtamedullary nephrons.

Each nephron is a tubelike structure with distinct parts (Fig. 65-3). The tube begins with Bowman's capsule, a saclike structure that surrounds the glomerulus. The tubular tissue of Bowman's capsule narrows into the *proximal convoluted tubule (PCT)*. The PCT twists and turns, finally straightening into the descending limb of the *loop of Henle*. The descending loop of Henle dips in the direction of the medulla but forms a hairpin loop and comes back up into the cortex as the ascending loop of Henle.

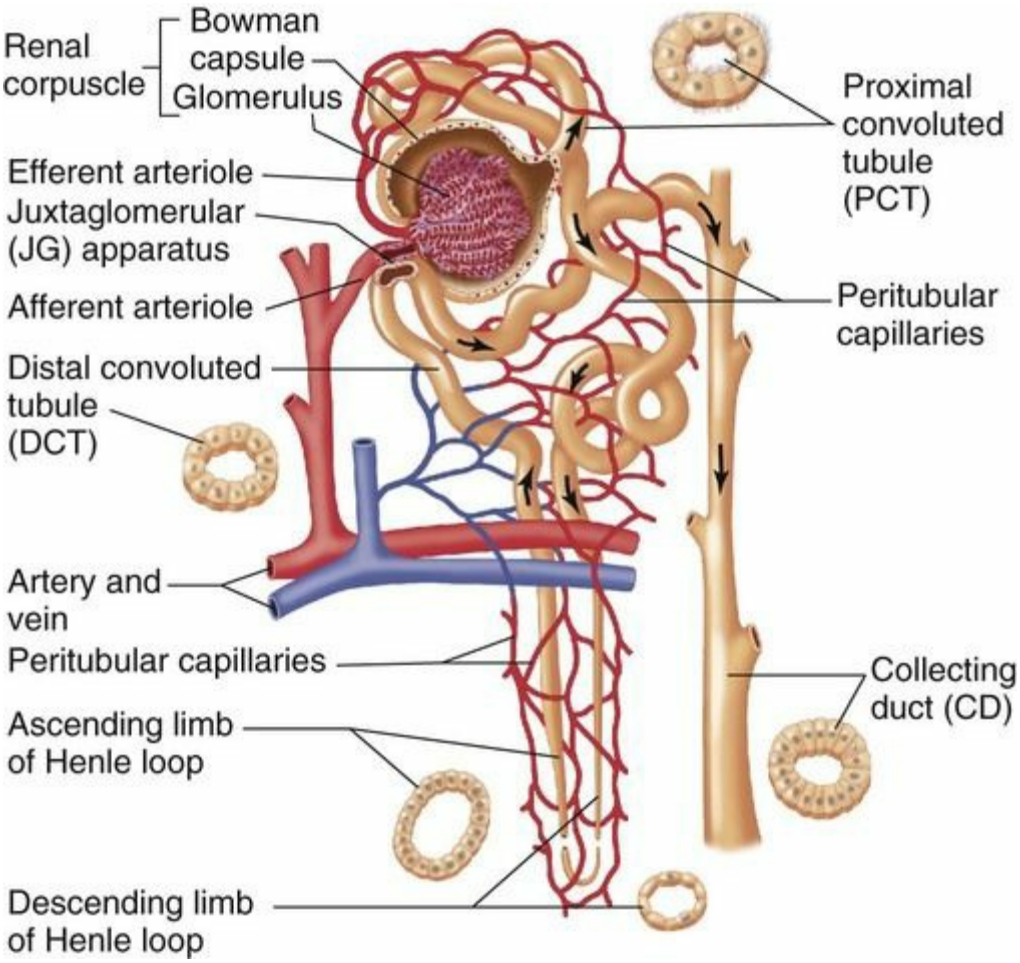

FIG. 65-3 Anatomy of the nephron—the functional unit of the kidney. The differences in appearance in tubular cells seen in a cross section reflect the differing functions of each nephron segment. Note that the particular nephron labeled here is a juxtamedullary nephron.

The two segments of the ascending limb of the loop of Henle are the thin segment and the thick segment. The *distal convoluted tubule (DCT)* forms from the thick segment of the ascending limb of the loop of Henle. The DCT ends in one of many collecting ducts located in the kidney tissue. The urine in the collecting ducts passes through the papillae and empties into the renal pelvis.

Special cells in the afferent arteriole, the efferent arteriole, and the DCT are known as the **juxtaglomerular complex** (Fig. 65-4). These cells produce and store **renin**, which is a hormone that helps regulate blood flow, glomerular filtration rate (GFR), and blood pressure. Renin is secreted when sensing cells in the DCT (called the *macula densa*) sense changes in blood volume and pressure. The macula densa lies next to the renin-producing cells. Renin is produced when the macula densa cells sense that blood volume, blood pressure, or blood sodium level is low. Renin then converts renin substrate (angiotensinogen) into angiotensin

I. This leads to a series of reactions that cause secretion of the hormone *aldosterone* (Fig. 65-5). Aldosterone helps regulate fluid and electrolyte balance by increasing kidney reabsorption of sodium and water and restoring blood pressure, blood volume, and blood sodium levels (McCance et al., 2014). It also promotes excretion of potassium (see Chapter 11).

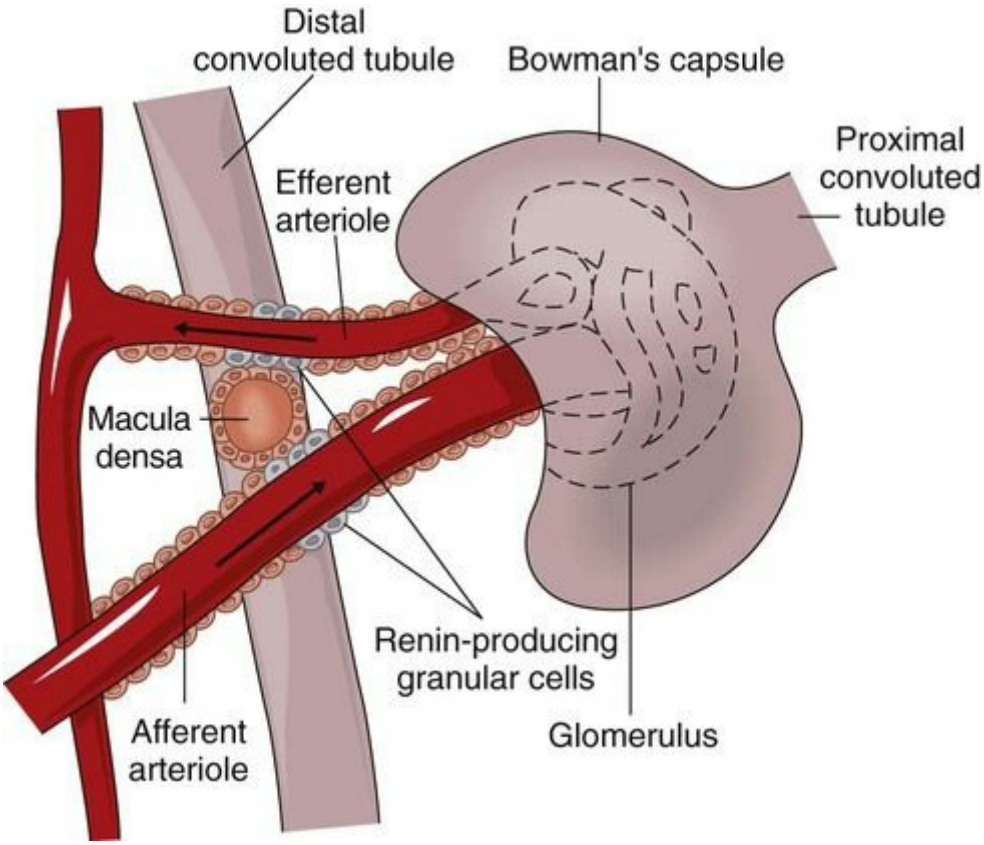

FIG. 65-4 The juxtaglomerular complex showing juxtaglomerular cells and the macula densa.

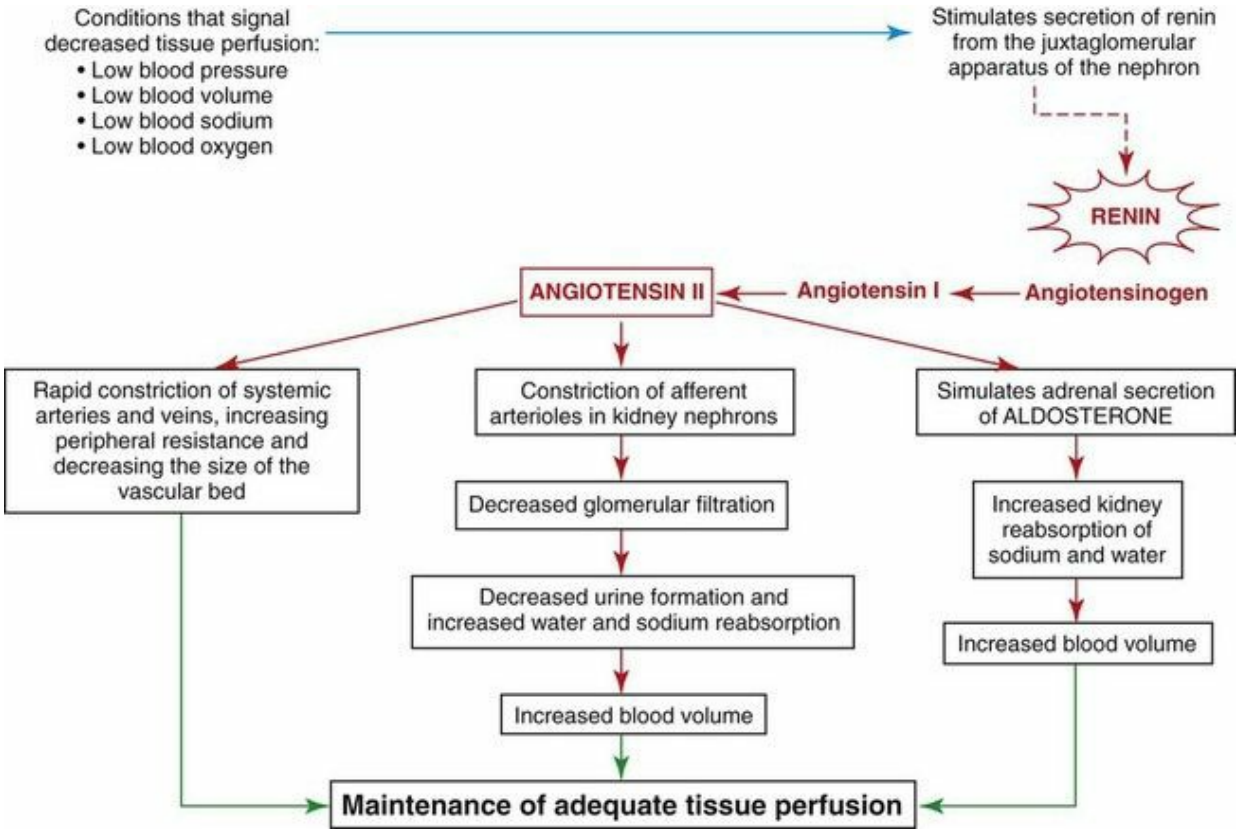

FIG. 65-5 The role of aldosterone, renin substrate (angiotensinogen), angiotensin I, and angiotensin II in the renal regulation of water and sodium.

The glomerular capillary wall has three layers (Fig. 65-6): the endothelium, the basement membrane, and the epithelium. The endothelial and epithelial cells lining these capillaries are separated by pores that filter water and small particles from the blood into Bowman's capsule. This fluid is called the “filtrate” or “early urine.”

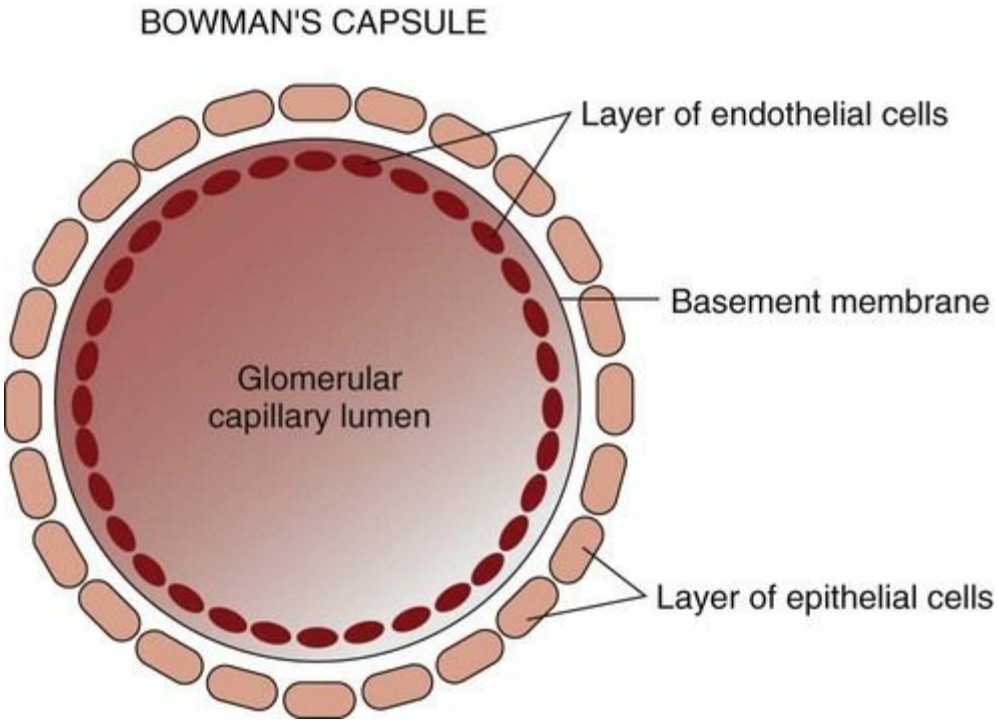

FIG. 65-6 Glomerular capillary wall.

Function

The kidneys have both regulatory and hormonal functions. The regulatory functions control fluid and electrolyte balance and acid-base balance. The hormonal functions control red blood cell (RBC) formation, blood pressure, and vitamin D activation.

Regulatory Functions.

The kidney processes that maintain fluid and electrolyte balance and acid-base balance are glomerular filtration, tubular reabsorption, and tubular secretion. These processes use filtration, diffusion, active transport, and osmosis. (See Chapter 11 for a review of these actions.) Table 65-1 lists the functions of nephron tubules and blood vessels.

TABLE 65-1

Vascular and Tubular Components of the Nephron

STRUCTURE	ANATOMIC FEATURES	PHYSIOLOGIC ASPECTS
Vascular Components		
Afferent arteriole	Delivers arterial blood from the branches of the renal artery into the glomerulus	Autoregulation of renal blood flow via vasoconstriction or vasodilation
		Renin-producing granular cells
Glomerulus	Capillary loops with thin, semipermeable membrane	Site of glomerular filtration
		Glomerular filtration occurs when hydrostatic pressure (blood pressure) is greater than opposing forces (tubular filtrate and oncotic pressure)
Efferent arteriole	Delivers arterial blood from the glomerulus into the peritubular capillaries or the vasa recta	Autoregulation of renal blood flow via vasoconstriction or vasodilation
		Renin-producing granular cells
Peritubular capillaries (PTCs) and vasa recta (VR)	PTCs: surround tubular components of cortical nephrons	Tubular reabsorption and tubular secretion allow movement of water and solutes to or from the tubules, interstitium, and blood
	VR: surround tubular components of juxtamedullary nephrons	
Tubular Components		
Bowman's capsule (BC)	Thin membranous sac surrounding $\frac{7}{8}$ of the glomerulus	Collects glomerular filtrate (GF) and funnels it into the tubule
Proximal convoluted tubule (PCT)	Evolves from and is continuous with Bowman's capsule	Site for reabsorption of sodium, chloride, water, glucose, amino acids, potassium, calcium, bicarbonate, phosphate, and urea
	Specialized cellular lining facilitates tubular reabsorption	
Loop of Henle	Continues from PCT	Regulation of water balance
	Juxtamedullary nephrons dip deep into the medulla	
	Permeable to water, urea, and sodium chloride	
Descending limb (DL)	Continues from the loop of Henle	Regulation of water balance
	Permeable to water, urea, and sodium chloride	
Ascending limb (AL)	Emerges from DL as it turns and is redirected up toward the renal cortex	Potassium and magnesium reabsorption in the thick segment
		Thin segment is impermeable to water
Distal convoluted tubule (DCT)	Evolves from AL and twists so the macula densa cells lie adjacent to the juxtaglomerular cells of afferent arteriole	Site of additional water and electrolyte reabsorption, including bicarbonate
		Potassium and hydrogen secretion
Collecting ducts	Collect formed urine from several tubules and deliver it into the renal pelvis	Receptor sites for antidiuretic hormone regulation of water balance

Glomerular filtration is the first process in urine formation. As blood passes from the afferent arteriole into the glomerulus, water, electrolytes, and other small particles (e.g., creatinine, urea nitrogen, glucose) are filtered across the glomerular membrane into the Bowman's capsule to form *glomerular* filtrate. As the filtrate enters the proximal convoluted tubule (PCT), it is called *tubular filtrate.*

Large particles, such as blood cells, albumin, and other proteins, are too large to filter through the glomerular capillary walls. *Therefore these substances are not normally present in the final urine.*

About 180 L of glomerular filtrate is formed from the blood each day. The rate of filtration is expressed in milliliters per minute. Normal glomerular filtration rate (GFR) averages 125 mL/min. If the entire amount of filtrate were excreted as urine, death would occur quickly from dehydration. Actually, only about 1 to 3 L is excreted each day as urine. The rest is reabsorbed back into the circulatory system (McCance et al., 2014).

GFR is controlled by blood pressure and blood flow. The kidneys self-regulate their own blood pressure and blood flow, which keeps GFR

constant. GFR is controlled by selectively constricting and dilating the afferent and efferent arterioles. When the afferent arteriole is constricted or the efferent arteriole is dilated, pressure in the glomerular capillaries falls and filtration decreases. When the afferent arteriole is dilated or the efferent arteriole is constricted, pressure in the glomerular capillaries rises and filtration increases. This way the kidney maintains a constant GFR, even when systemic blood pressure changes. When systolic pressure drops below 65 to 70 mm Hg, these self-regulation processes are not effective at maintaining GFR.

Tubular reabsorption is the second process in urine formation. This reabsorption of most of the filtrate keeps normal urine output at 1 to 3 L/day and prevents dehydration. As the filtrate passes through the tubular parts of the nephron, most of the water and electrolytes is reabsorbed from the tubular lumen of the nephron and into the peritubular capillaries. This process returns most water, electrolytes, and other particles to the blood.

The tubules return about 99% of all filtered water back into the body (Fig. 65-7). Most water reabsorption occurs in the PCT. Water reabsorption continues as the filtrate flows down the descending loop of Henle. The thin and thick segments of the ascending loop of Henle are *not* permeable to water, and water reabsorption does not occur here.

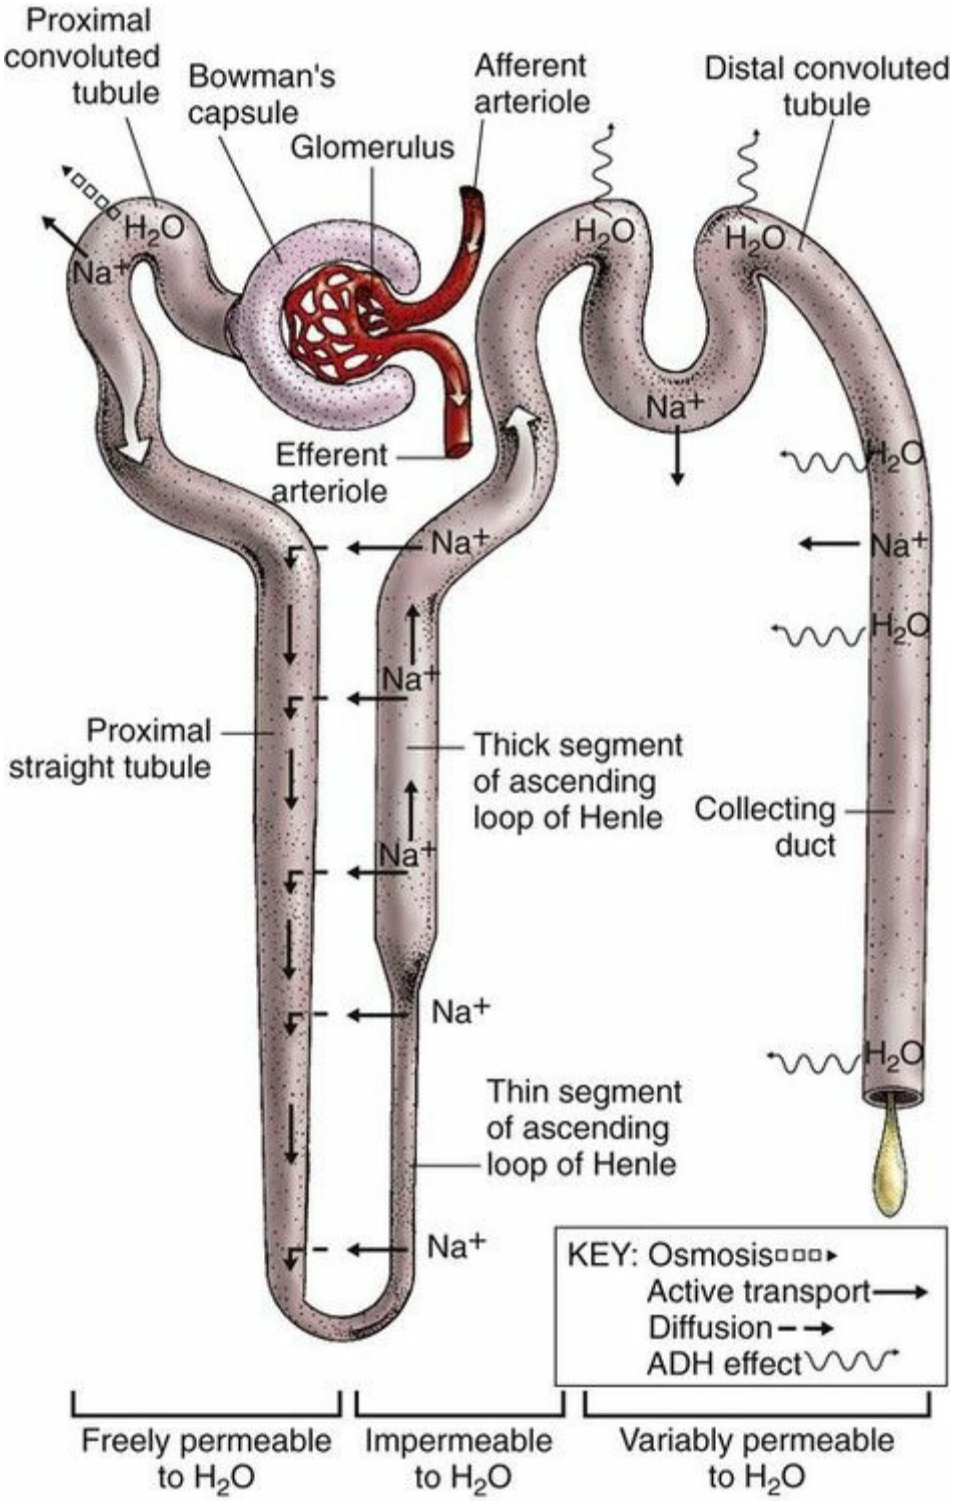

FIG. 65-7 Sodium and water reabsorption by the tubules of a cortical nephron. *ADH,* Antidiuretic hormone; *Na^+,* sodium.

The distal convoluted tubule (DCT) can be permeable to water, and some water reabsorption occurs as the filtrate continues to flow through the tubule. The membrane of the DCT may be made more permeable to water when *vasopressin,* also known as *antidiuretic hormone* (ADH), and aldosterone are present. Vasopressin increases tubular permeability to water, allowing water to leave the tube and be reabsorbed back into the

capillaries. Vasopressin also increases arteriole constriction. Arteriole constriction alters blood pressure, which then affects the amounts of fluid and particles that exit glomerular capillaries. Aldosterone promotes the reabsorption of sodium in the DCT. Water reabsorption occurs as a result of the movement of sodium (where sodium goes, water follows).

The ability of the kidneys to vary the volume or concentration of urine helps regulate water balance regardless of fluid intake. In this way, the healthy kidney can prevent dehydration when fluid intake is low and can prevent circulatory overload when fluid intake is high.

In addition to water, some types of particles in the tubular filtrate also are returned to the blood by *tubular reabsorption.* About 50% of all urea in the filtrate is reabsorbed, although creatinine is not reabsorbed.

Most sodium, chloride, and water reabsorption occurs in the PCT. The collecting ducts are the other site of sodium, chloride, and water reabsorption. Here reabsorption is caused by aldosterone. Potassium is mostly reabsorbed in the PCT and in the thick segment of the loop of Henle.

Bicarbonate, calcium, and phosphate are mostly reabsorbed in the PCT. Bicarbonate reabsorption helps acid-base balance and maintains a normal blood pH. Blood levels of calcitonin and parathyroid hormone (PTH) (see Chapters 11 and 63) control calcium balance.

The kidney reabsorbs some of the glucose filtered from the blood. However, there is a limit to how much glucose the kidney can reabsorb. This limit is called the **renal threshold** or **transport maximum (tm)** for glucose reabsorption. The usual renal threshold for glucose is about 220 mg/dL. This means that at a blood glucose level of 220 mg/dL or less, all glucose is reabsorbed and returned to the blood, with no glucose present in final urine. When blood glucose levels are greater than 220 mg/dL, some glucose stays in the filtrate and is present in the urine. Normally, almost all glucose and most proteins are reabsorbed and are not present in the urine.

Nursing Safety Priority QSEN

Action Alert

Report the presence of glucose or proteins in the urine of a patient undergoing a screening examination to the health care provider because this is an abnormal finding and requires further assessment.

Tubular secretion is the third process of urine formation. It allows

substances to move from the blood into the early urine. During tubular secretion, substances move from the peritubular capillaries in reverse, across capillary membranes, and into the cells that line the tubules. From the cells, these substances are moved into the urine and are excreted from the body. Potassium (K^+) and hydrogen (H^+) ions are some of the substances moved in this way to maintain fluid and electrolyte balance and acid-base balance (pH).

Hormonal Functions.

The kidneys produce renin, prostaglandins, erythropoietin, and activated vitamin D (Table 65-2). Other kidney products, such as the kinins, change kidney blood flow and capillary permeability. The kidneys also help break down and excrete insulin.

TABLE 65-2

Kidney Hormones and Hormones Influencing Kidney Function

	SITE	ACTION
Kidney Hormones		
Renin	Renin-producing granular cells	Raises blood pressure as result of angiotensin (local vasoconstriction) and aldosterone (volume expansion) secretion
Prostaglandins	Kidney tissues	Regulate intrarenal blood flow by vasodilation or vasoconstriction
Bradykinins	Juxtaglomerular cells of the arterioles	Increase blood flow (vasodilation) and vascular permeability
Erythropoietin	Kidney parenchyma	Stimulates bone marrow to make red blood cells
Activated vitamin D	Kidney parenchyma	Promotes absorption of calcium in the GI tract
Hormones Influencing Kidney Function		
Vasopressin (Antidiuretic hormone [ADH])	Released from posterior pituitary	Makes DCT and CD permeable to water to maximize reabsorption and produce a concentrated urine
Aldosterone	Released from adrenal cortex	Promotes sodium reabsorption and potassium secretion in DCT and CD; water and chloride follow sodium movement
Natriuretic hormones	Cardiac atria, cardiac ventricles, brain	Cause tubular secretion of sodium

CD, Collecting duct; *DCT*, distal convoluted tubule.

Renin, as discussed on p. 1346 in the Microscopic Anatomy section, assists in blood pressure control. It is formed and released when there is a decrease in blood flow, blood volume, or blood pressure through the renal arterioles or when too little sodium is present in kidney blood. These conditions are detected through the receptors of the juxtaglomerular complex.

Renin release causes the production of *angiotensin II* through a series of steps (see Fig. 65-5). Angiotensin II increases systemic blood pressure through powerful blood vessel constricting effects and triggers the release of aldosterone from the adrenal glands. Aldosterone increases the reabsorption of sodium in the distal tubule of the nephron. Therefore

more water is reabsorbed, which increases blood volume and blood pressure. When blood flow to the kidney is reduced, this system also prevents fluid loss and maintains circulating blood volume (see Chapter 11).

Prostaglandins are produced in the kidney and many other tissues. Those produced specifically in the kidney help regulate glomerular filtration, kidney vascular resistance, and renin production. They also increase sodium and water excretion.

Erythropoietin is produced and released in response to decreased oxygen tension in the kidney's blood supply. It triggers red blood cell (RBC) production in the bone marrow. When kidney function is poor, erythropoietin production decreases and the person develops anemia.

Vitamin D activation occurs through a series of steps. Some of these steps take place in the skin when it is exposed to sunlight, and then more processing occurs in the liver. From there, vitamin D is converted to its active form in the kidney. Activated vitamin D is needed to absorb calcium in the intestinal tract and to regulate calcium balance (McCance et al., 2014).

Ureters

Each kidney has a single ureter—a hollow tube that connects the renal pelvis with the urinary bladder. The ureter is about ½ inch (1.25 cm) in diameter and about 12 to 18 inches (30 to 45 cm) in length. The diameter of the ureter narrows in three areas:

- In the upper third of the ureter, at the point in which the renal pelvis becomes the ureter, is a narrowing known as the **ureteropelvic junction (UPJ)**.
- The ureter also narrows as it bends toward the abdominal wall (aortoiliac bend).
- Each ureter narrows at the point it enters the bladder; this point is called the **ureterovesical junction (UVJ)**.

The ureter tunnels through bladder tissue for a short distance and then opens into the bladder at the trigone (Fig. 65-8).

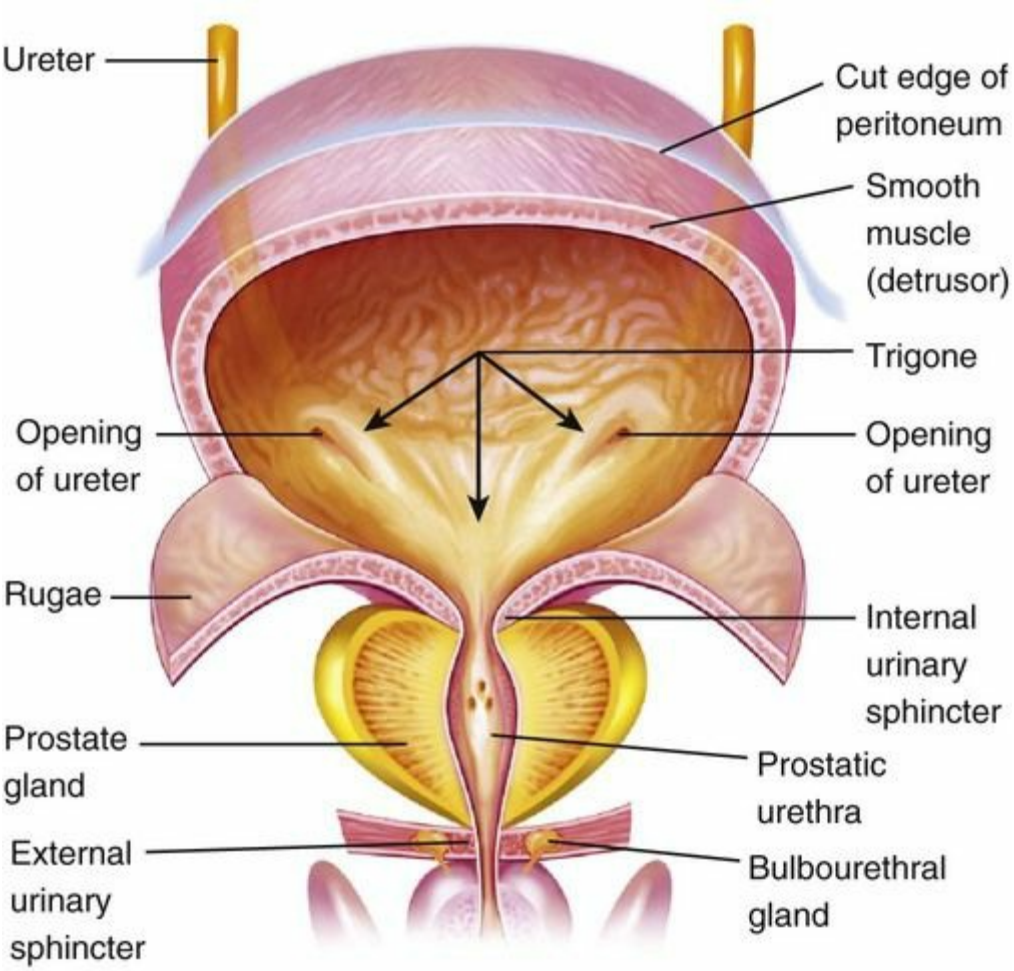

FIG. 65-8 Gross anatomy of the urinary bladder.

The ureter has three layers: an inner lining of mucous membrane *(urothelium)*, a middle layer of smooth muscle fibers, and an outer layer of fibrous tissue. The middle layer of muscle fibers is controlled by several nerve pathways from the lower spinal cord.

Contractions of the smooth muscle in the ureter move urine from the kidney pelvis to the bladder. Stretch receptors in the kidney pelvis regulate this movement. For example, a large volume of urine in the kidney pelvis triggers the stretch receptors, which respond by increasing ureteral contractions and ureter peristalsis.

Urinary Bladder

Structure

The urinary bladder is a muscular sac (see Fig. 65-8) that lies directly behind the pubic bone. In men, the bladder is in front of the rectum. In women, it is in front of the vagina.

The bladder is composed of the *body* (the rounded sac portion) and the *bladder neck* (posterior urethra), which connects to the bladder body. The

bladder has three linings—an inner lining of epithelial cells *(urothelium)*, middle layers of smooth muscle *(detrusor muscle)*, and an outer lining. The *trigone* is an area on the posterior wall between the points of ureteral entry (ureterovesical junctions [UVJs]) and the urethra.

The **internal urethral sphincter** is the smooth detrusor muscle of the bladder neck and elastic tissue. The **external urethral sphincter** is skeletal muscle that surrounds the urethra. In men, the external sphincter surrounds the urethra at the base of the prostate gland. In women, the external sphincter is at the base of the bladder. The pudendal nerve from the spinal cord controls the external sphincter.

Function

The bladder stores urine, provides continence, and enables voiding. The secretions of the urothelium lining the bladder resist bacteria.

Continence is the ability to voluntarily control bladder emptying. Continence occurs during bladder filling through the combination of detrusor muscle relaxation, internal sphincter muscle tone, and external sphincter contraction. As the bladder fills with urine, stretch sensations are transmitted to spinal sacral nerves.

Maintaining continence occurs by the interaction of the nerves that control the muscles of the bladder, bladder neck, urethra, and pelvic floor, as well as by factors that close the urethra. In the continent person, the smooth muscle of the detrusor remains relaxed during a period of urine filling and storage. Sympathetic nervous system fibers prevent detrusor muscle contraction. The control centers for voiding are located in the cerebral cortex, the brainstem, and the lower spinal cord. For urethral closure to be adequate for continence, the mucosal surfaces must be in contact and must be adhesive. Contact depends on the presence and proper function of the involved nerves and muscles. Adhesion depends on the adequate secretion of mucus-like substances.

Micturition (voiding) is a reflex of autonomic control that triggers contraction of the detrusor muscle (closing the ureter at the UVJ to prevent backflow) at the same time as relaxation of the external sphincter and the muscles of the pelvic floor. Voluntary voiding occurs as a learned response and is controlled by the cerebral cortex and the brainstem. Contraction of the external sphincter inhibits the micturition reflex and prevents voiding.

Urethra

The urethra is a narrow tube lined with mucous membranes. Its purpose

is to eliminate urine from the bladder. The **urethral meatus,** or opening, is the end point of the urethra. In men, the urethra is about 6 to 8 inches (15 to 20 cm) long, with the meatus located at the tip of the penis. The male urethra has three sections:

- The prostatic urethra, which extends from the bladder through the prostate gland
- The membranous urethra, which extends from the prostate to the wall of the pelvic floor
- The cavernous urethra, which is external and extends through the length of the penis

In women, the urethra is about 1 to 1½ inches (2.5 to 3.75 cm) long and exits the bladder through the pelvic floor. The meatus lies slightly below the clitoris and directly in front of the vagina and rectum.

Kidney and Urinary System Changes Associated with Aging

Kidney Changes

Changes occur in the kidney as a result of the aging process and can affect health (Chart 65-1) (Touhy & Jett, 2014). The kidney loses cortical tissue and gets smaller with age. This cortical loss is caused by reduced blood flow to the kidney. The medulla is not affected by aging, and the juxtamedullary nephron functions are preserved. The glomerular and tubular linings thicken. Both the number of glomeruli and their surface areas decrease with aging. Tubule length decreases. These changes reduce the ability of the older adult to filter blood and excrete waste products.

Chart 65-1 Nursing Focus on the Older Adult

Changes in the Renal System Related to Aging

PHYSIOLOGIC CHANGE	NURSING INTERVENTIONS	RATIONALES
Decreased glomerular filtration rate (GFR)	Monitor hydration status.	The ability of the kidneys to regulate water balance decreases with age.
	Ensure adequate fluid intake.	The kidneys are less able to conserve water when necessary.
	Administer potentially nephrotoxic agents or drugs carefully.	Dehydration reduces kidney blood flow and increases the nephrotoxic potential of many agents. Acute or chronic kidney failure may result.
Nocturia	Ensure adequate nighttime lighting and a hazard-free environment.	Falls and injuries are common among older patients seeking bathroom facilities.
	Ensure the availability of a bedside toilet, bedpan, or urinal.	Using these items instead of getting up to the bathroom can help prevent falls.
	Discourage excessive fluid intake for 2-4 hr before the patient goes to bed.	Excessive fluid intake at night may increase nocturia.
	Evaluate drugs and timing.	Some drugs increase urine output.
Decreased bladder capacity	Encourage the patient to use the toilet, bedpan, or urinal at least every 2 hr.	Emptying the bladder on a regular basis may avoid overflow urinary incontinence.
	Respond as soon as possible to the patient's indication of the need to void.	A quick response may alleviate episodes of urinary stress incontinence.
Weakened urinary sphincters and shortened urethra in women	Provide thorough perineal care after each voiding.	The shortened urethra increases the potential for bladder infections.
		Good perineal hygiene may prevent skin irritations and urinary tract infection (UTI).
Tendency to retain urine	Observe the patient for urinary retention (e.g., bladder distention) or urinary tract infection (e.g., dysuria, foul odor, confusion).	Urinary stasis may result in a UTI, which may lead to bloodstream infections, urosepsis, or septic shock.
	Provide privacy, assistance, and voiding stimulants such as warm water over the perineum as needed.	Nursing interventions can help initiate voiding.
	Evaluate drugs for possible contribution to retention.	Anticholinergic drugs promote urinary retention.

Blood flow to the kidney declines by about 10% per decade as blood vessels thicken. This means that blood flow to the kidney is not as adaptive in older adults, leaving nephrons more vulnerable to damage during episodes of either hypotension or hypertension.

Glomerular filtration rate (GFR) decreases with age. By age 65 years, the GFR is about 65 mL/min (half the rate of a young adult) and increases the risk for fluid overload. This decline is more rapid in patients with diabetes, hypertension, or heart failure. The combination of reduced kidney mass, reduced blood flow, and decreased GFR contributes to reduced drug clearance and a greater risk for drug reactions and kidney damage from drugs and contrast dyes in older adults.

Tubular changes with aging decrease the ability to concentrate urine, resulting in **urgency** (a sense of a nearly uncontrollable need to urinate) and **nocturnal polyuria** (increased urination at night). The regulation of sodium, acids, and bicarbonate is less efficient. Along with an age-related impairment in the thirst mechanism, these changes increase the risk for disturbances of fluid and electrolyte balance, such as dehydration and **hypernatremia** (increased blood sodium levels) in the older adult. Hormonal changes include a decrease in renin secretion, aldosterone levels, and activation of vitamin D.

Urinary Changes

Changes in detrusor muscle elasticity lead to decreased bladder capacity and reduced ability to retain urine. The urge to void may cause immediate bladder emptying because the urinary sphincters lose tone

and often become weaker with age. In women, weakened muscles in the pelvic floor shorten the urethra and promote incontinence. In men, an enlarged prostate gland makes starting the urine stream difficult and may cause urinary retention.

Cultural Considerations

Patient-Centered Care QSEN

African Americans have more rapid age-related decreases in GFR than do white people. Kidney excretion of sodium is less effective in hypertensive African Americans who have high sodium intake, and the kidneys have about 20% less blood flow as a result of anatomic changes in small blood vessels and intrarenal responses to renin. Thus African-American patients are at greater risk for kidney failure than are white patients (Jarvis, 2016). Remind African Americans that yearly health examinations should include urinalysis, checking for the presence of microalbuminuria, and evaluating serum creatinine.

Assessment Methods

Patient History

Demographic information, such as age, gender, race, and ethnicity, is important to consider as nonmodifiable risk factors in the patient with any kidney or urinary problem. A sudden onset of hypertension in patients older than 50 years suggests possible kidney disease. Clinical changes with adult polycystic kidney disease typically occur in patients in their 40s or 50s. In men older than 50 years, altered urine patterns accompany prostate disease.

Anatomic gender differences make some disorders worse or more common. For example, men rarely have ascending urinary tract infections. Women have a shorter urethra and more commonly develop **cystitis** (bladder inflammation, most often with infection) because bacteria pass more readily into the bladder.

Ask the patient about any previous kidney or urologic problems, including tumors, infections, stones, or urologic surgery. A history of any chronic health problems, especially diabetes mellitus or hypertension, increases the risk for development of kidney disease because these disorders damage kidney blood vessels.

Exposure to certain dyes during imaging can harm the kidneys. Iodinated contrast used for CT scans is associated with both acute and chronic kidney damage. High osmolarity contrast agents can also contribute to kidney function impairment. Exposure to gadolinium-enhanced MRI can result in nephrogenic systemic fibrosis.

Ask the patient about chemical exposures at the workplace or with hobbies. Exposure to hydrocarbons (e.g., gasoline, oil), heavy metals (especially mercury and lead), and some gases (e.g., chlorine, toluene) can impair kidney function. Use this opportunity to teach patients who come into contact with chemicals at work or during leisure-time activities to avoid direct skin or mucous membrane contact with these chemicals. Use of heroin, cocaine, methamphetamine, ecstasy, and volatile solvents (inhalants) has also been associated with kidney damage.

Specifically ask the patient whether he or she has ever been told about the presence of protein or albumin in the urine. The question "Have you ever been told that your blood pressure is high?" may prompt a response different from the one to the question "Do you have high blood pressure?" Ask women about health problems during pregnancy (e.g., proteinuria, high blood pressure, gestational diabetes, urinary tract infections). Obtain information about:

- Chemical or environmental toxin exposure in occupational, diagnostic, or other settings
- Recent travel to geographic regions that pose infectious disease risks
- Recent trauma or injury, particularly to the abdomen or pelvic or genital areas
- A history of altered patterns of urinary elimination

Socioeconomic status may influence health care practices. Prevention, early detection, and treatment of kidney or urinary problems may be limited by lack of insurance or access to health care, lack of transportation, and reduced income. Low income may also result in difficulty following medical advice, having prescriptions filled, adhering to dietary instructions, and keeping follow-up appointments.

Education level may affect health-seeking practices and the patient's understanding of a disease or its manifestations. Recurring urinary tract infections can result from not completing a course of antibiotic therapy or from not following up to ensure the infection is cleared and risks are well-managed.

The patient's health beliefs affect the approach to health and illness. Cultural background or religious affiliation may influence the belief system.

The language used by patients may be different from that used by the health care professional. When obtaining a history, listen to and explore the terms used by the patient. By using the patient's own terms, you may help him or her provide a more complete description of the problem and may decrease the patient's discomfort when discussing bodily functions.

Nutrition History

Ask the patient with known or suspected kidney or urologic disorders about his or her usual diet and any recent changes in the diet. Note any excessive intake or omission of certain food categories. Ask about food and fluid intake. Assess how much and what types of fluids the patient drinks daily, especially fluids with a high calorie or caffeine content. Use this opportunity to teach the patient the importance of drinking sufficient fluid to cause urine to be dilute (clear or very light yellow). If another medical problem does not require fluid restriction, health care providers recommend about 2 liters of fluid daily to prevent dehydration and cystitis. If the patient has followed a diet for weight reduction, the details of the diet plan are important and collaboration with a dietitian may be needed. A high-protein intake can result in temporary kidney problems. For example, a patient at risk for **calculi** (stone) formation who

ingests large amounts of protein or has a poor fluid intake may form new stones.

Ask about any change in appetite or taste. These manifestations can occur with the buildup of nitrogenous waste products from kidney impairment. Changes in thirst or fluid intake may also cause changes in urine output. Endocrine disorders may also cause changes in thirst, fluid intake, and urine output. (See Chapter 61 for a discussion of endocrine influences on fluid balance.)

Medication History

Identify all of the patient's prescription drugs because many can impair kidney function. Ask about the duration of drug use and whether there have been any recent changes in prescribed drugs. Drugs for diabetes mellitus, hypertension, cardiac disorders, hormonal disorders, cancer, arthritis, and psychiatric disorders are potential causes of kidney problems. Antibiotics, such as gentamicin (Garamycin, Cidomycin), may also cause acute kidney injury. Drug-drug interactions and drug–contrast dye interactions also may lead to kidney dysfunction.

Explore the past and current use of over-the-counter (OTC) drugs or agents, including dietary supplements, vitamins and minerals, herbal agents, laxatives, analgesics, acetaminophen, and NSAIDs. Many of these agents affect kidney function. For example, dietary supplementation with synthetic creatine, used to increase muscle mass, has been associated with compromised kidney function. High-dose or long-term use of NSAIDs or acetaminophen can seriously reduce kidney function. Some agents are associated with hypertension, hematuria, or proteinuria, which may occur before kidney dysfunction.

Family History and Genetic Risk

The family history of the patient with a suspected kidney or urologic problem is important because some disorders have a familial inheritance pattern. Ask whether his or her siblings, parents, or grandparents have had kidney problems. Past terms used for kidney disease include *Bright's disease, nephritis,* and *nephrosis.* Although nephritis is a current term describing an inflammatory process in the kidney and nephrosis is a current term describing a degenerative process in the kidney, these terms have been used by lay people for years to describe any kidney problem. Adult polycystic kidney disease, which is a genetic disorder, can occur in either gender.

Current Health Problem

The effects of severe kidney impairment are evident in all body systems. Therefore document all of the patient's current health problems. Ask him or her to describe all health concerns, because some kidney disorders cause systemic problems or problems in other body systems. Recent upper respiratory problems, achy muscles or joints, or GI problems may be related to problems of kidney function.

Assess the kidney and urologic system by asking about any changes in the appearance (color, odor, clarity) of the urine, pattern of urination, ability to initiate or control voiding, and other unusual manifestations. For example, urine that is reddish, dark brown or black, greenish, or different from the usual yellowish color usually prompts the patient to seek health care assistance. Urine typically has a mild but distinct odor of ammonia. An increase in the intensity of color, a change in odor quality, or a decrease in urine clarity may suggest infection.

Ask about changes in urination patterns, such as **incontinence** (involuntary bladder emptying), **nocturia** (urination at night), frequency, or an increase or decrease in the amount of urine. The normal urine output for adults is about 1500 to 2000 mL/day or within 500 mL of the volume of fluid ingested daily. Ask about how close the urine output is to the volume of fluid ingested. The patient usually does not know the exact amount of urine produced. A bladder diary may provide useful data. Also ask whether:

- Initiating urine flow is difficult
- A burning sensation or other discomfort occurs with urination
- The force of the urine stream is decreased (in men)
- Persistent dribbling of urine is present

The onset of pain in the flank, in the lower abdomen or pelvic region, or in the perineal area usually triggers concern and may prompt the patient to seek assistance. Ask about the onset, intensity, and duration of the pain, its location, and its association with any activity or event.

Pain associated with kidney or ureteral irritation is often severe and spasmodic. Pain that radiates into the perineal area, groin, scrotum, or labia is described as *renal colic*. This pain occurs with distention or spasm of the ureter, such as in an obstruction or the passing of a stone. Renal colic pain may be intermittent or continuous and may occur with pallor, diaphoresis, and hypotension. These general manifestations occur because of the location of the nerve tracts near or in the kidneys and ureters.

Because the kidneys are close to the GI organs and the nerve pathways

are similar, GI manifestations may occur with kidney problems. These renointestinal reflexes often complicate the description of the kidney problem.

Uremia is the buildup of nitrogenous waste products in the blood as a result of some degree of kidney impairment. Manifestations include anorexia, nausea and vomiting, muscle cramps, **pruritus** (itching), fatigue, and lethargy.

Physical Assessment

The physical assessment of the patient with a known or suspected kidney or urologic disorder includes general appearance, a review of body systems, and specific structure and functions of the kidney and urinary system.

Assess the patient's general appearance, and check the skin for the presence of any rashes, bruising, or yellowish discoloration. The skin and tissues may show edema, especially in the **pedal** (foot), **pretibial** (shin), and sacral tissues and around the eyes. Use a stethoscope to listen to the lungs to determine whether fluid is present. Weigh the patient and measure blood pressure as a baseline for later comparisons.

Assess the level of consciousness and level of alertness. Record any deficits in memory, concentration, or thought processes. Family members may report subtle changes. Cognitive changes may be the result of the buildup of waste products when kidney disease is present.

Assessment of the Kidneys, Ureters, and Bladder

Assess the kidneys, ureters, and bladder during an abdominal assessment (Jarvis, 2016). Auscultate before percussion and palpation because these activities can enhance bowel sounds and obscure abdominal vascular sounds.

Inspect the abdomen and the flank regions with the patient in both the supine and the sitting positions. Observe the patient for asymmetry (e.g., swelling) or discoloration (e.g., bruising or redness) in the flank region, especially in the area of the costovertebral angle (CVA). The CVA is located between the lower portion of the twelfth rib and the vertebral column.

Listen for a bruit by placing a stethoscope over each renal artery on the midclavicular line. A **bruit** is an audible swishing sound produced when the volume of blood or the diameter of the blood vessel changes. It often occurs with blood flow through a narrowed vessel, as in renal artery stenosis.

Kidney palpation is usually performed by a physician or advanced practice nurse. It can help locate masses and areas of tenderness in or around the kidney. Lightly palpate the abdomen in all quadrants. Ask about areas of tenderness or pain, and examine nontender areas first. The outline of the bladder may be seen as high as the umbilicus in patients with severe bladder distention. *If tumor or aneurysm is suspected, palpation may harm the patient.*

Because the kidneys are located deep and posterior, palpation is easier in thin patients who have little abdominal musculature. For palpation of the right kidney, the patient is in a supine position while the examiner places one hand under the right flank and the other hand over the abdomen below the lower right part of the rib cage. The lower hand is used to raise the flank, and the upper hand depresses the abdomen as the patient takes a deep breath (Fig. 65-9) (Jarvis, 2016). The left kidney is deeper and often cannot be palpated. A transplanted kidney is readily palpated in either the lower right or left abdominal quadrant. The normal kidney is smooth, firm, and nontender.

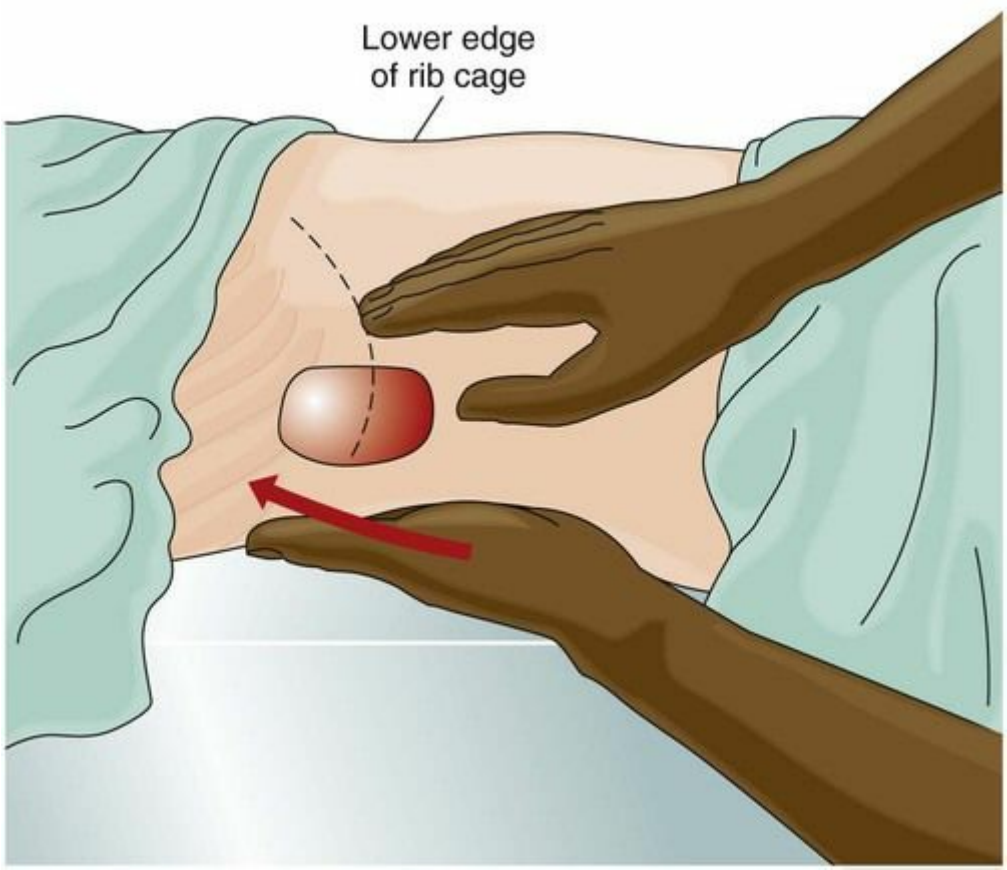

FIG. 65-9 Advanced technique for palpation of the kidney.

A distended bladder sounds dull when percussed. After gently palpating to determine the outline of the distended bladder, begin

percussion on the lower abdomen and continue in the direction of the umbilicus until dull sounds are no longer produced. If you suspect bladder distention, use a portable bladder scanner to determine the amount of retained urine.

If the patient reports flank pain or tenderness, percuss the nontender flank first. Have the patient assume a sitting, side-lying, or supine position, and then form one of your hands into a clenched fist. Place your other hand flat over the CVA of the patient. Then quickly deliver a firm thump to your hand over the CVA area (Jarvis, 2016). Costovertebral tenderness often occurs with kidney infection or inflammation. Patients with inflammation or infection in the kidney or nearby structures may describe their pain as severe or as a constant, dull ache.

Assessment of the Urethra

Using a good light source and wearing gloves, inspect the urethra by examining the meatus and the tissues around it. Record any unusual discharge such as blood, mucus, or pus. Inspect the skin and mucous membranes of surrounding tissues. Record the presence of lesions, rashes, or other abnormalities of the penis or scrotum or of the labia or vaginal opening. Urethral irritation is suspected when the patient reports discomfort with urination. Use this opportunity to remind women to clean the perineum by wiping from front to back, never from back to front. Teach them that the front-to-back technique keeps organisms in stool from coming close to the urethra and decreases the risk for infection.

Gender Health Considerations

Patient-Centered Care QSEN

Women from other cultures may have undergone female circumcision. This procedure alters the anatomic appearance of the vulvar-perineal area and increases the risk for urinary tract infections. It also makes urethral inspection or catheterization difficult. Document any noted anatomic changes, and ask the patient to describe her hygiene practices for this area.

Psychosocial Assessment

Concerns about the urologic system may evoke fear, anger, embarrassment, anxiety, guilt, or sadness in the patient. Childhood learning often includes privacy with regard to toilet habits. Urologic

disorders may bring up forgotten memories of difficult toilet training and bedwetting or of childhood experiences of exploring one's body. The patient may ignore manifestations or delay seeking health care because of emotional responses or cultural taboos about the urogenital area.

NCLEX Examination Challenge

Health Promotion and Maintenance

The client arrives at the primary health care clinic with a problem of new abdominal pain and blood in her urine. She is afebrile. Which information is most important for the nurse to obtain from this client's history?
A Kidney cancer in the client's family
B Injury or trauma to the abdomen or pelvis
C Treatment for a urinary tract infection in the past 12 months
D Recent exposure to heavy metals, drugs, or other nephrotoxins

Diagnostic Assessment

Laboratory Assessment

Blood Tests.

Serum creatinine is produced when muscle and other proteins are broken down. Because protein breakdown is usually constant, the serum creatinine level is a good indicator of kidney function. Serum creatinine levels are slightly higher in men than in women because men tend to have a larger muscle mass than do women. Similarly, people with greater muscle mass or muscle mass turnover (e.g., athletes) may have a slightly-higher-than-average serum creatinine level. Muscle mass and the amount of creatinine produced decrease with age. Because of decreased rates of creatinine clearance, however, the serum creatinine level remains relatively constant in older adults unless kidney disease is present.

No common pathologic condition other than kidney disease increases the serum creatinine level. The serum creatinine level does not increase until at least 50% of the kidney function is lost, and therefore *any* elevation of serum creatinine values is important and should be assessed further. Creatinine is excreted by the kidneys.

Nursing Safety Priority QSEN

Action Alert

A serum creatinine of 1.5 mg/dL or greater places a patient at risk for acute kidney injury (AKI) from iodinated contrast dyes and some drugs. Monitor both baseline and trend values to determine risk for and actual kidney damage, especially among patients exposed to agents that can cause kidney dysfunction. Promptly inform the health care provider of increases in serum creatinine greater than 1.5 times the baseline and urine output values of less than 0.5 mL/kg/hr for 6 or more hours.

Blood urea nitrogen (BUN) measures the effectiveness of kidney excretion of urea nitrogen, a by-product of protein breakdown in the liver. Urea nitrogen is produced mostly from liver metabolism of food sources of protein. The kidneys filter urea nitrogen from the blood and excrete the waste in urine.

Other factors influence the BUN level, and an elevation does not always mean kidney disease is present (Chart 65-2). For example, rapid cell destruction from infection, cancer treatment, or steroid therapy may elevate BUN level. In addition, blood is a protein. Blood in the tissues rather than in the blood vessels is reabsorbed as if it were a general protein. Thus reabsorbed blood protein is processed by the liver and increases BUN levels. This means that injured tissues can result in increased BUN levels even when kidney function is normal. Also, BUN is increased by protein turnover in exercising muscle and is elevated as a result of concentration during dehydration.

Chart 65-2 Laboratory Profile

Kidney Function Blood Studies

TEST	NORMAL RANGE FOR ADULTS	SIGNIFICANCE OF ABNORMAL FINDINGS
Serum creatinine	*Males:* 0.6-1.2 mg/dL (0.053-0.106 mmol/L; 53-106 µmol/L) *Females:* 0.5-1.1 mg/dL (0.044-0.097 mmol/L; 44-97µmol/L) *Older adults:* may be decreased	An *increased level* indicates kidney impairment. A *decreased level* may be caused by a decreased muscle mass.
Blood urea nitrogen (BUN)	10-20 mg/dL (3.6-7.1 mmol/L) *Older adults:* 60-90 yr: 8-23 mg/dL (2.9-8.2 mmol/L) Older than 90 yr: 10-31 mg/dL (3.6-11.1 mmol/L)	An *increased level* may indicate liver or kidney disease, dehydration or decreased kidney perfusion, a high-protein diet, infection, stress, steroid use, GI bleeding, or other situations in which blood is in body tissues. A *decreased level* may indicate malnutrition, fluid volume excess, or severe hepatic damage.
BUN/creatinine ratio	6-25 (BUN divided by creatinine)	An *increased ratio* may indicate fluid volume deficit, obstructive uropathy, catabolic state, or a high-protein diet. A *decreased ratio* may indicate fluid volume excess.

Data from Pagana, K., & Pagana, T. (2014). *Mosby's manual of diagnostic and laboratory tests* (5th ed.). St. Louis: Mosby.

The liver must function properly to produce urea nitrogen. When liver and kidney dysfunction are present, urea nitrogen levels are actually *decreased* because the liver failure limits urea production. The BUN level is not always elevated with kidney disease and is not the best indicator of kidney function. However, an elevated BUN level suggests kidney dysfunction.

Blood urea nitrogen to serum creatinine ratio can help determine whether non–kidney-related factors, such as low cardiac output or red blood cell destruction, are causing the elevated BUN level. When blood volume is deficient (e.g., dehydration) or cardiac output is low, the BUN level rises more rapidly than the serum creatinine level. As a result, the ratio of BUN to creatinine is *increased.*

When both the BUN and serum creatinine levels increase at the same rate, the BUN/creatinine ratio remains normal. However, elevations of ***both*** serum creatinine and BUN levels suggest kidney dysfunction that is not related to dehydration or poor perfusion.

Blood osmolarity is a measure of the overall concentration of particles in the blood and is a good indicator of hydration status. The kidneys excrete or reabsorb water to keep blood osmolarity in the range of 285 to 295 mOsm/L. Osmolarity is slightly higher in older adults (285 to 301 mOsm/L). When blood osmolarity is decreased, the release of vasopressin (antidiuretic hormone [ADH]) is inhibited. Without vasopressin, the distal tubule and collecting ducts are *not* permeable to water. As a result, water is *excreted,* not reabsorbed, and blood osmolarity increases. When blood osmolarity increases, vasopressin is released. Vasopressin increases the permeability of the distal tubule to water. Then water is reabsorbed and blood osmolarity decreases.

Urine Tests

Urinalysis.

Urinalysis is a part of any complete physical examination and is especially useful for patients with suspected kidney or urologic disorders (Chart 65-3). Ideally, the urine specimen is collected at the morning's first voiding. Specimens obtained at other times may be too dilute. The specimen may be collected by several techniques (Table 65-3).

Chart 65-3 Laboratory Profile

Urinalysis

TEST	NORMAL RANGE FOR ADULTS	SIGNIFICANCE OF ABNORMAL FINDINGS
Color	Yellow	*Dark amber* indicates concentrated urine.
		Very pale yellow indicates dilute urine.
		Dark red or *brown* indicates blood in the urine. Brown may indicate increased bilirubin level. Red also may indicate the presence of myoglobin.
		Other color changes may result from diet or drugs.
Odor	Specific aroma, similar to ammonia	*Foul smell* indicates possible infection, dehydration, or ingestion of certain foods or drugs.
Turbidity	Clear	*Cloudy urine* indicates infection, sediment, or high levels of urine protein.
Specific gravity	Usually 1.005-1.030; possible range 1.000-1.040	*Increased* in decreased kidney perfusion, inappropriate ADH secretion, or heart failure. *Decreased* in chronic kidney disease, diabetes insipidus, malignant hypertension, diuretic administration, and lithium toxicity.
	Older adult: Decreased	
pH	Average: 6; possible range: 4.6-8	*Changes* are caused by diet, drugs, infection, age of specimen, acid-base imbalance, and kidney disease.
Glucose	Fresh specimen, negative 50-300 mg/day in a 24-hour specimen	*Presence* reflects hyperglycemia or a decrease in the kidney threshold for glucose.
Ketones	None	*Presence* occurs with diabetic ketoacidosis, prolonged fasting, anorexia nervosa.
Protein	0-0.8 mg/dL 50-80 mg in a 24-hour specimen at rest <250 mg in a 24-hour specimen with exercise	*Increased* amounts may indicate stress, infection, recent strenuous exercise, or glomerular disorders.
Bilirubin (urobilinogen)	None	*Presence* suggests liver or biliary disease or obstruction.
Red blood cells (RBCs)	0-2 per high-power field	*Increased* is normal with catheterization or menses but may reflect tumor, stones, trauma, glomerular disorders, cystitis, or bleeding disorders.
White blood cells (WBCs)	0-4 per low-power field	*Increased* may indicate an infection or inflammation in the kidney and urinary tract, kidney transplant rejection, or exercise.
Casts	None	*Increased* indicates bacteria, protein, or urinary calculi.
Crystals	None	*Presence* may indicate that the specimen has been allowed to stand.
Bacteria	<1000 colonies/mL	*Increased* indicates the need for urine culture to determine the presence of urinary tract infection.
Parasites	None	*Presence* of *Trichomonas vaginalis* indicates infection, usually of the urethra, prostate, or vagina.
Leukoesterase	None	*Presence* suggests urinary tract infection.
Nitrites	None	*Presence* suggests urinary *Escherichia coli*.

ADH, Antidiuretic hormone.

Data from Pagana, K., & Pagana, T. (2014). *Mosby's manual of diagnostic and laboratory tests* (5th ed.). St. Louis: Mosby.

TABLE 65-3

Collection of Urine Specimens

NURSING INTERVENTIONS	RATIONALES
Voided Urine	
Collect the first specimen voided in the morning.	Urine is more concentrated in the early morning.
Send the specimen to the laboratory as soon as possible.	After urine is collected, cellular breakdown results in more alkaline urine.
Refrigerate the specimen if a delay is unavoidable.	Refrigeration delays the alkalinization of urine. Bacteria are more likely to multiply in an alkaline environment.
Clean-Catch Specimen	
Explain the purpose of the procedure to the patient.	Correct technique is needed to obtain a valid specimen.
Instruct the patient to self-clean before voiding: Instruct the female patient to separate the labia and use the sponges and solution provided to wipe with three strokes over the urethra. The first two wiping strokes are over each side of the urethra; the third wiping stroke is centered over the urethra (from front to back). Instruct the male patient to retract the foreskin of the penis and to similarly clean the urethra, using three wiping strokes with the sponge and solution provided (from the head of the penis downward).	Surface cleaning is necessary to remove secretions or bacteria from the urethral meatus.
Instruct the patient to initiate voiding after cleaning. The patient then stops and resumes voiding into the container. Only 1 ounce (30 mL) is needed; the remainder of the urine may be discarded into the commode.	A midstream collection further removes secretions and bacteria because urine flushes the distal portion of the internal urethra.
Ensure that the patient understands the procedure.	An improperly collected specimen may result in inappropriate or incomplete treatment.
Assist the patient as needed.	The patient's understanding and the nurse's assistance ensure proper collection.
Catheterized Specimen	
For non-indwelling (straight) catheters:	The one-time passage of a urinary catheter may be necessary to obtain an uncontaminated specimen for analysis or to measure the volume of residual urine.
Avoid routine use.	
Follow the facility's procedures for catheterization technique.	These procedures minimize bacterial entry.
For indwelling catheters:	Urine is collected from an indwelling catheter or tubing when patients have catheters for continence or long-term urinary drainage.
Apply a clamp to the drainage tubing, distal to the injection port.	Clamping allows urine to collect in the tubing at the location where the specimen is obtained.
Clean the injection port cap of the catheter drainage tubing with an appropriate antiseptic. Povidone-iodine solution or alcohol is acceptable.	Surface contamination is prevented by following the cleaning procedures.
Attach a sterile 5-mL syringe into the port, and aspirate the quantity of urine required.	A minimum of 5 mL is needed for culture and sensitivity (C&S) testing.
Inject the urine sample into a sterile specimen container.	A sterile container is used for C&S specimens.
Remove the clamp to resume drainage.	
Properly dispose of the syringe.	
24-Hour Urine Collection	
Instruct the patient thoroughly.	A 24-hr collection of urine is necessary to quantify or calculate the rate of clearance of a particular substance.
Provide written materials to assist in instruction.	Instructional materials for patients, signs, etc. remind patients and staff to ensure that the total collection is completed.
Place signs appropriately.	
Inform all personnel or family caregivers of test in progress.	
Check laboratory or procedure manual on proper technique for maintaining the collection (e.g., on ice, in a refrigerator, or with a preservative).	Proper technique prevents breakdown of elements to be measured.
On initiation of the collection, ask the patient to void, discard the urine, and note the time. If a Foley catheter is in use, empty the tubing and drainage bag at the start time and discard the urine.	Proper techniques ensure that *all* urine formed within the 24-hr period is collected.
Collect all urine of the next 24 hr.	
Twenty-four hours after initiation, ask the patient to empty the bladder and add that urine to the container.	
Do not remove urine from the collection container for other specimens.	Urine in the container is not considered a "fresh" specimen and may be mixed with preservative.

Urine color comes from urochrome pigment. Color variations may result from increased levels of urochrome or other pigments, changes in the concentration or dilution of the urine, and the presence of drug metabolites in the urine. Urine smells faintly like ammonia and is normally clear without *turbidity* (cloudiness) or haziness.

Specific gravity is the concentration of particles, including electrolytes and wastes, in urine. A high specific gravity indicates concentrated urine, such as might occur from dehydration, decreased kidney blood flow, or excess vasopressin associated with stress, surgery, anesthetic agents, and certain drugs (e.g., morphine, some oral antidiabetic drugs) or syndrome of inappropriate antidiuretic hormone (SIADH) (see Chapter 62). A low specific gravity indicates dilute urine that may occur from high fluid intake, diuretic drugs, or diabetes insipidus (DI) (see Chapter 62).

Specific gravity refers to the density of urine compared with distilled water, which has a specific gravity of 1.000. The normal specific gravity of urine ranges from 1.005 to about 1.030. Kidney disease diminishes the concentrating ability of the kidney, and chronic kidney disease (CKD) may be associated with a low (dilute) specific gravity.

pH is a measure of urine acidity or alkalinity. A pH value less than 7 is acidic, and a value greater than 7 is alkaline. Urine pH is affected by diet, drugs, systemic disturbances of acid-base balance, and kidney tubular function. For example, a high-protein diet produces acidic urine, whereas a high intake of citrus fruit produces alkaline urine.

Urine specimens become more alkaline when left standing unrefrigerated for more than 1 hour, when bacteria are present, or when a specimen is left uncovered. Alkaline urine increases cell breakdown; thus the presence of red blood cells may be missed on analysis. In addition, alkalinity promotes bacterial overgrowth. Ensure that urine specimens are covered and delivered to the laboratory promptly or refrigerated. During systemic acidosis or alkalosis, the kidneys, along with blood buffers and the lungs, normally respond to keep serum pH normal. Chapter 12 discusses acid-base balance and imbalance.

Protein is not normally present in the urine. Levels greater than 30 mg/hr, or 200 mcg/min, are abnormal. Protein molecules are too large to pass through intact glomerular membranes. When glomerular membranes are not intact, protein molecules pass through and are excreted in the urine. Increased membrane permeability is caused by infection, inflammation, or immunologic problems. Some systemic problems cause production of abnormal proteins, such as globulin. Detection of abnormal protein types requires electrophoresis.

A random finding of **proteinuria** (usually albumin in the urine) followed by a series of negative (normal) findings does not imply kidney disease. If infection is the cause of the proteinuria, urinalyses after resolution of the infection should be negative for protein. Persistent proteinuria needs further investigation.

Microalbuminuria is the presence of albumin in the urine that is not

measurable by a urine dipstick or usual urinalysis procedures. Specialized assays are used to quickly analyze a freshly voided urine specimen for microscopic levels of albumin. The normal microalbumin levels in a freshly voided specimen should range between 2.0 and 20 mg/mmol for men and between 2.8 and 28 mg/mmol for women. Higher levels indicate microalbuminuria and could mean mild or early kidney disease, especially in patients with diabetes mellitus. In 24-hour urine specimens, levels of 30 to 300 mg/24 hr, or 20 to 200 mcg/min, indicate microalbuminuria.

Glucose is filtered by the glomerulus and is reabsorbed in the proximal tubule of the nephron. When the blood glucose level rises above 220 mg/dL, the renal threshold for reabsorption is exceeded and glucose "spills over" into urine. Changes in the renal threshold for glucose occur in many patients, such as those with infection or severe stress.

Ketone bodies are formed from the incomplete metabolism of fatty acids. Three types of ketone bodies are acetone, acetoacetic acid, and beta-hydroxybutyric acid. *Normally there are no ketones in urine.* Ketone bodies are produced when fat is used instead of glucose for cellular energy. Ketones present in the blood are partially excreted in the urine.

Leukoesterase is an enzyme found in some white blood cells, especially neutrophils. When the number of these cells increases in the urine or they are broken (lysed), the urine then contains leukoesterase. The presence of leukoesterase and nitrites in the urine is a sensitive screen for assessing urinary tract infections. A normal reading is no leukoesterase in the urine. A positive test (+ sign) is an indication of a urinary tract infection.

Nitrites are not usually present in urine. Many types of bacteria, when present in the urine, convert nitrates (normally found in urine) into nitrites. A positive test enhances the sensitivity of the leukoesterase test to detect urinary tract infection.

Sediment is precipitated particles in the urine. These particles include cells, casts, crystals, and bacteria. Normally, urine contains few, if any, cells. Types of cells abnormally present in the urine include tubular cells (from the tubule of the nephron), epithelial cells (from the lining of the urinary tract), red blood cells (RBCs), and white blood cells (WBCs). WBCs may indicate a urinary tract or kidney infection. RBCs may indicate *glomerulonephritis*, *acute tubular necrosis*, *pyelonephritis,* kidney trauma, or kidney cancer.

Casts are clumps of materials or cells. When cells, bacteria, or proteins are present in the urine, minerals and sticky materials clump around them and form a cast of the distal renal tubule and collecting duct. Casts

are described by the type of particle they have surrounded (e.g., hyaline [protein-based] or cellular [from RBCs, WBCs, or epithelial cells]) or the stage of cast breakdown (whole cell or granular from cell breakdown). Although an isolated urinalysis with sediment from casts may be the result of strenuous exercise, repeated findings with sediment are more likely to be associated with disease.

Urine crystals come from mineral salts as a result of diet, drugs, or disease. Common salt crystals are formed from calcium, oxalate, urea, phosphate, magnesium, or other substances. Some drugs, such as the sulfates, can also form crystals.

Bacteria multiply quickly, so the urine specimen must be analyzed promptly to avoid falsely elevated counts of bacterial colonization. Normally urine is sterile, but it is easily contaminated by perineal bacteria during collection.

Recent advances in technology and molecular biology are leading to new diagnostic tests using urine, including identification of biomarkers of disease and profiling for specific proteins. Markers are being used in investigation to identify early-onset kidney dysfunction, target therapy, and predict responsiveness to intervention. Markers for angiogenesis and kidney cell adhesion, regulation, and apoptosis will likely contribute to clinical diagnostics in the future.

Urine for Culture and Sensitivity.

Urine is analyzed for the number and types of organisms present. Manifestations of infection and unexplained bacteria in a urine specimen are indications for urine culture and sensitivity testing. Bacteria from urine are placed in a medium with different antibiotics. In this way we can know which antibiotics are effective in killing or stopping the growth of the organisms (organisms are "sensitive") and which are not effective (organisms are "resistant"). A clean-catch or catheter-derived specimen is best for culture and sensitivity testing.

Composite Urine Collections.

Some urine collections are made for a specified number of hours (e.g., 24 hours) for more precise analysis of one or more substances. These collections are often used to measure urine levels of creatinine or urea nitrogen, sodium, chloride, calcium, catecholamines, or other components (Chart 65-4). For a composite urine specimen, *all* urine within the designated time frame must be collected (see Table 65-3). If other urine must be obtained while the collection is in progress, measure and record the amount collected but not added to the timed collection.

Chart 65-4 Laboratory Profile

24-Hour Urine Collections

COMPONENT	NORMAL RANGE FOR ADULTS	SIGNIFICANCE OF ABNORMAL FINDINGS
Creatinine	*Males:* 1-2 g/24 hr or 14-26 mg/kg/24 hr (124-230 µmol/kg/24 hr or 7.1-17.7 mmol/24 hr) *Females:* 0.6-1.8 g/24 hr or 11-20 mg/kg/24 hr (97-177 µmol/kg/24 hr or 5.3-15.9 mmol/24 hr) *Older adults:* 10 mg/kg/24 hr (88.4 µmol/kg/24 hr) at 90 yr	*Decreased amounts* indicate a deterioration in function caused by kidney disease. *Increased amounts* occur with infections, exercise, diabetes mellitus, and meat meals.
Urea nitrogen	12-20 g/24 hr (0.43-0.71 mmol/24 hr)	*Decreased amounts* occur when kidney damage or liver disease is present. *Increased amounts* commonly result from a high-protein diet, dehydration, trauma, or sepsis.
Sodium	40-220 mEq/24 hr (40-220 mmol/24 hr)	*Decreased* in hemorrhage, shock, hyperaldosteronism, and prerenal acute kidney injury. *Increased* with diuretic therapy, excessive salt intake, hypokalemia, and acute tubular necrosis.
Chloride	110-250 mEq/24 hr (110-250 mmol/24 hr) *Older adults:* 95-195 mEq/24 hr (95-195 mmol/24 hr)	*Decreased* in certain kidney diseases, malnutrition, pyloric obstruction, prolonged nasogastric tube drainage, diarrhea, diaphoresis, heart failure, and emphysema. *Increased* with hypokalemia, adrenal insufficiency, and massive diuresis.
Calcium	100-400 mg/24 hr (2.50-7.50 mmol/kg/24 hr)	*Decreased* with hypocalcemia, hypoparathyroidism, nephrosis, and nephritis. *Increased* with calcium kidney stones, hyperparathyroidism, sarcoidosis, certain cancers, immobilization, and hypercalcemia.
*Total catecholamines	<100 mcg/24 hr (<591 mmol/24 hr)	*Increased* with pheochromocytoma, neuroblastomas, stress, or heavy exercise.
Protein	1-14 mg/dL (10-140 mg/L) or 50-80 mg/24 hr at rest	*Increased* in glomerular disease, nephrotic syndrome, diabetic nephropathy, urinary tract malignancies, and irritations.

*Epinephrine and norepinephrine only; dopamine is not measured.

Data from Pagana, K., & Pagana, T. (2014). *Mosby's manual of diagnostic and laboratory tests* (5th ed.). St. Louis: Mosby.

The urine collection may need to be refrigerated or stored on ice to prevent changes in the urine during the collection time. Follow the procedure from the laboratory for urine storage, including whether a preservative is to be added. The urine collection must be free from fecal contamination. Menstrual blood and toilet tissue also contaminate the specimen and can invalidate the results.

The collection of urine for a 24-hour period is often more difficult than it seems. With hospitalized patients, the cooperation of staff personnel, the patient, family members, and visitors is essential. Placing signs in the bathroom, instructing the patient and family, and emphasizing the need to save the urine are helpful.

Creatinine Clearance.

Creatinine clearance is a calculated measure of glomerular filtration rate (GFR) and kidney function. The patient's age, gender, height, weight, diet, and activity level influence the expected amount of excreted creatinine. Thus these factors are considered when interpreting creatinine clearance test results. Decreases in the creatinine clearance rate may require reducing drug doses and often signifies the need to further explore the cause of kidney deterioration.

Commonly, creatinine clearance is calculated from serum creatinine, age, weight, urine creatinine, gender, and race. Current guidelines suggest clinical laboratories report an estimate of GFR whenever a serum creatinine is ordered, based on the modified diet in renal disease (MDRD) study equation (National Kidney Disease Education Program, 2012). The MDRD equation does not require urine to estimate GFR. The estimated GFR (eGFR) for the MDRD equation is >60 mL/min/1.73 m^2 (Pagana & Pagana, 2014). An alternate approach for calculation is the Cockcroft-Gault equation, and this equation has traditionally been used to determine the need for drug dose adjustment (Dong & Quan, 2010).

While expensive and time consuming, creatinine clearance to estimate GFR can be based on a 24-hour urine collection, although urine can be collected for shorter periods (e.g., 8 or 12 hours). The analysis compares the urine creatinine level with the blood creatinine level, and therefore a blood specimen for creatinine must also be collected. The range for normal creatinine clearance is 107 to 239 mL/min for men and 87 to 107 mL/min for women tested with a 24-hour urine collection. Values decrease 6.5 mL/min per decade of life for adults older than 40 years because of age-related decline in GFR.

Urine Electrolytes.

Urine samples can be analyzed for electrolyte levels (e.g., sodium, chloride). Normally the amount of sodium excreted in the urine is nearly equal to that consumed. Urine sodium levels of less than 10 mEq/L indicate that the tubules are able to conserve (reabsorb) sodium.

Urine Osmolarity.

Osmolarity measures the concentration of particles in solution. The particles in urine contributing to osmolarity include electrolytes, glucose, urea, and creatinine. Urine osmolarity can vary from 50 to 1400 mOsm/L, depending on the patient's hydration status and kidney function. With average fluid intake, the range for urine osmolarity is 300 to 900 mOsm/L. Electrolytes, acids, and other wastes of normal metabolism are continually produced. These particles are the solute load that must be excreted in the urine on a regular basis. This is referred to as *obligatory solute excretion.* If the patient loses excessive fluids, the kidney response is to save water while ridding the body of wastes by excreting small amounts of highly concentrated urine. Diet, drugs, and activity can change urine osmolarity. Thus urine with an increased osmolarity is concentrated urine with less water and more solutes. Urine with a

decreased osmolarity is dilute urine with more water and fewer solutes.

NCLEX Examination Challenge

Physiological Integrity

The client's urinalysis shows all of these abnormal results. Which result does the nurse report to the health care provider immediately?
A pH 7.8
B Protein 31 mg
C Sodium 15 mEq/L
D Leukoesterase and nitrate positive

Bedside Sonography/Bladder Scanners.

The use of portable ultrasound scanners in the hospital and rehabilitation setting by nurses is a noninvasive method of estimating bladder volume (Fig. 65-10). Bladder scanners are used to screen for post-void residual volumes and to determine the need for intermittent catheterization based on the amount of urine in the bladder rather than the time between catheterizations. There is no discomfort with the scan, and no patient preparation beyond an explanation of what to expect is required.

FIG. 65-10 The "BladderScan" BVI 9400, a handheld portable bladder scanner.

Explain why the procedure is being done and what sensations the patient might experience during the procedure. For example, "This test will measure the amount of urine in your bladder. I will place a gel pad just above your pubic area and then place the probe, which is a little bigger and heavier than a stethoscope, on the gel."

Before scanning, select the male or female icon on the bladder scanner. Using the female icon allows the scanner software to subtract the volume of the uterus from any measurement. Use the male icon on all men and on women who have undergone a hysterectomy.

Place an ultrasound gel pad right above the symphysis pubis (pubic bone), or moisten the round dome of the scan head area with 5 mL of conducting gel to improve ultrasound conduction. Use gel on the scanner head for obese patients and those with heavy body hair in the area to be scanned. Place the probe midline over the abdomen about $1\frac{1}{2}$ inches (4 cm) above the pubic bone. Aim the scan head so the ultrasound is projected toward the expected location of the bladder, typically toward

the patient's coccyx. Press and release the scan button. The scan is complete with the sound of a beep, and a volume is displayed. Two readings are recommended for best accuracy. An aiming icon on the portable bladder scanner indicates whether the bladder image is centered on the crosshairs of the scan head. If the crosshairs on the aiming icon are not centered on the bladder, the measured volume may not be accurate.

Imaging Assessment

Many imaging procedures are used to diagnose abnormalities within the urinary system (Table 65-4). Explain the procedures thoroughly to the patient, prepare him or her, and provide follow-up care. Patient education materials for many urologic tests have been developed by professional organizations such as the Society for Urologic Nurses and Associates and are freely available.

TABLE 65-4

Radiologic and Special Diagnostic Tests for Patients with Disorders of the Kidney and Urinary System

TEST	PURPOSE
Radiography of kidneys, ureters, and bladder (KUB) (plain film of abdomen)	To screen for the presence of two kidneys
	To measure kidney size
	To detect gross obstruction in kidneys or urinary tract
Computed tomography (CT)	To measure kidney size
	To evaluate contour to assess for masses or obstruction in kidneys or the urinary tract
	To assess renal blood flow
Magnetic resonance imaging (MRI)	Similar to CT
	Useful for staging of cancers
Ultrasonography (US) Can be used with a dye	To identify the size of the kidneys or obstruction (e.g., tumors, stones) in the kidneys or the lower urinary tract
(Nuclear) Renal scan	To evaluate renal perfusion
	To estimate glomerular filtration rate
	To provide functional information without exposing the patient to iodinated contrast dye
Cystoscopy	To identify abnormalities of the bladder wall and urethral and ureteral occlusions
	To treat small obstructions or lesions via fulguration, lithotripsy, or removal with a stone basket
Cystography and cystourethrography	To outline bladder's contour when full and examine structure during voiding
	To examine the structure of the urethra
	To detect backward urine flow
Metabolic imaging with positron emission tomography (PET)	To evaluate cysts, tumors, and other lesions, eliminating the need for biopsy in some patients

Kidney, Ureter, and Bladder X-rays.

An x-ray of the kidneys, ureters, and bladder (KUB) is a plain film of the abdomen obtained without any specific patient preparation. The KUB study shows gross anatomic features and obvious stones, strictures,

calcifications, or obstructions in the urinary tract. This test identifies the shape, size, and relationship of the organs to other parts of the urinary tract. Other tests are needed to diagnose functional or structural problems.

There is no discomfort or risk from this procedure. Tell the patient that the x-ray will be taken while he or she is in a supine position. No specific follow-up care is needed.

Computed Tomography.

Inform the patient that a CT scan provides three-dimensional information about the kidneys, ureters, bladder, and surrounding tissues. The CT scan is performed in a special room, usually in the radiology department. It is usually performed after other diagnostic procedures and can provide information about tumors, cysts, abscesses, other masses, and obstruction. CT can also be used to image the kidney's vascular system (i.e., CT angiography). Some hospitals require patients having CT scans to be NPO for some period before the scan, although there is no specific evidence guiding this practice.

Determine whether the scan requires administration of a dye. Oral or injected contrast dye is usually given before starting the imaging procedure. Dye use may be omitted in patients at risk for contrast-induced acute kidney injury, but the images produced are less distinct.

When a dye is used, ensure that there is sufficient oral or intravenous intake to dilute and excrete the dye. Typically, the radiologist will specify a total fluid intake of 1 liter or a variable rate to maintain urine output at 1 to 2 mL/kg/hr for up to 6 hours. When no contrast or dye is used, there is no special postprocedure care.

The contrast dye is potentially kidney-damaging (nephrotoxic). *Contrast-induced nephropathy* is the onset of *acute kidney failure* within 24 to 72 hours after the administration of iodinated contrast medium (Wood, 2012). The risk for *contrast-induced nephropathy* is greatest in patients who are older, dehydrated, have pre-existing renal insufficiency (e.g., serum creatinine levels greater than 1.5 mg/dL or estimated GFR <45 mL/min), or are also taking other nephrotoxic drugs (Davenport et al., 2014). Chart 65-5 lists assessment questions to ask before a patient undergoes testing that uses contrast material.

Chart 65-5 Best Practice for Patient Safety & Quality Care QSEN

Assessing the Patient About to Undergo a Kidney Test or Procedure Using Contrast Medium

Before the procedure:

- Ask the patient if he or she has ever had a reaction to contrast media. (Such a patient has the highest risk for having another reaction.)
- Ask the patient about a history of asthma. (Patients with asthma have been shown to be at greater risk for contrast reactions than the general public. When reactions do occur, they are more likely to be severe.)
- Ask the patient about known hay fever or food or drug allergies, especially to seafood, eggs, milk, or chocolate. (Contrast reactions have been reported to be as high as 15% in these patients.)
- Ask the patient to describe any specific allergic reactions (e.g., hives, facial edema, difficulty breathing, bronchospasm).
- Assess for a history of renal impairment and for conditions that have been implicated in increasing the chance of developing kidney failure after contrast media (e.g., diabetic nephropathy, class IV heart failure, dehydration, concomitant use of potentially nephrotoxic drugs such as the aminoglycosides or NSAIDs, and cirrhosis).
- Ask the patient if he or she is taking metformin (Glucophage). (Metformin must be discontinued at least 24 hours before any study using contrast media because the life-threatening complication of lactic acidosis, although rare, could occur.)
- Assess hydration status by checking blood pressure, heart and respiratory rates, mucous membranes, skin turgor, and urine concentration.
- Ask the patient when he or she last ate or drank anything.

In addition, patients taking metformin are at risk for lactic acidosis when they receive iodinated contrast media. Metformin should be discontinued at least 24 hours before the time of a procedure and for at least 48 hours after the procedure. Kidney function should be re-evaluated before the patient resumes metformin therapy.

Nursing Safety Priority QSEN

Drug Alert

Ensure that the patient who is prescribed metformin does not receive the drug after a procedure requiring IV contrast material until adequate kidney function has been determined.

All patients at risk for contrast-induced nephrotoxicity need regular assessment and collaboration with the health care provider to maintain hydration and decrease the risk for kidney damage following a dye-enhanced CT scan. Sodium bicarbonate in a liter of intravenous fluid or oral acetylcysteine (an antioxidant) may be used preprocedure to prevent contrast-induced nephrotoxic effects in radiologic procedures; however, protection provided to the kidneys is not consistent in clinical trials (Lameire & Kellum, 2013). Diuretics may be given immediately after the dye is injected to enhance dye excretion in patients who are well hydrated.

Magnetic Resonance Imaging of the Kidney.

MRI provides improved contrast between normal and abnormal tissue in the renal system compared with a CT scan. As with all MRIs, the patient with metal implants (pins, pacemaker, joint replacement, aneurysmal clips, or other cosmetic or medical devices) is not eligible for this test because the magnet can move the metal implant. Gadolinium-based contrast agents have been linked with nephrogenic systemic fibrosis (Pagana & Pagana, 2014) and should not be used in patients with renal impairment, usually defined as a serum creatinine above 1.5 mg/dL or an estimated GFR less than 45 mL/min. Adults older than 60 years should be carefully evaluated for renal impairment (see the Kidney and Urinary System Changes Associated with Aging section on p. 1351).

Kidney Ultrasonography.

Inform the patient that ultrasonography does not cause discomfort and is without risk. This test usually requires a full bladder. Ask the patient to drink water, if needed, to help fill the bladder. This test applies sound waves to structures of different densities to produce images of the kidneys, ureters, and bladder and surrounding tissues. Ultrasonography allows assessment of kidney size, cortical thickness, and status of the calices. The test can identify obstruction in the urinary tract, tumors, cysts, and other masses without the use of contrast dye.

The patient undergoing kidney ultrasound is usually placed in the prone position. Sonographic gel is applied to the skin over the back and flank areas to enhance sound-wave conduction. A transducer in contact with and moving across the skin delivers sound waves and measures the echoes. Images of the internal structures are produced. Skin care to remove the gel is all that is needed after ultrasonography.

Renal Scan.

This imaging test is used to examine the perfusion, function, and structure of the kidneys, using the IV administration of a radioisotope. It does not use an iodinated dye and so may be used in preference to a CT scan when the patient is allergic to iodine or has impaired kidney function that places him or her at risk for kidney injury from contrast dyes.

Patient Preparation and Procedural Care.

No fasting or sedation is used. A peripheral IV catheter is inserted to give the radioisotope. While the patient lies in a prone or sitting position, a camera is passed over the kidney area and records the isotope uptake on film, minutes after it is given. After initial images, the patient may be given furosemide or captopril to better visualize kidney function and blood flow. The isotope is eliminated 6 to 24 hours after the procedure. Encourage the patient to drink fluids to aid in excretion of the isotope. Because only tracer doses of radioisotopes are used, no precautions are needed related to radioactive exposure.

Renal Arteriography (Angiography).

Renal arteriography allows dye to enter the renal blood vessels and generates images to determine blood vessel size and abnormalities. This test has largely been replaced by other imaging techniques (e.g., nuclear renal scans, ultrasonography, computed tomography) and is seldom used as a stand-alone diagnostic procedure. The most common use of renal arteriography is at the time of a renal angioplasty or other intervention.

Cystoscopy and Cystourethroscopy

Patient Preparation.

Cystoscopy and cystourethroscopy are endoscopic procedures and require completion of a preoperative checklist and a signed informed consent statement. The urologist provides a complete description of and reasons for the procedure, and the nurse reinforces this information. Cystoscopy may be performed for diagnosis or treatment. This test is used to examine for bladder trauma (cystoscopy) or urethral trauma (cystourethroscopy) and to identify causes of urinary tract obstruction. Cystoscopy also may be used to remove bladder tumors or to plant radium seeds into a tumor, dilate the urethra and ureters with or without stent placement, stop areas of bleeding, or resect an enlarged prostate gland.

Cystoscopy may be performed under general anesthesia or under local

anesthesia with sedation. The patient's age and general health and the expected duration of the procedure are considered in the decision about anesthesia. A light evening meal may be eaten. Usually the patient is NPO after midnight on the night before the cystoscopy. A bowel preparation with laxatives or enemas is performed the evening before the procedure.

Procedure.

The cystoscopy is performed in a designated cystoscopic examination room. If the procedure is performed in a surgical suite under general anesthesia, the usual surgical support personnel are present (see Chapter 15). This procedure is often performed in clinics, ambulatory surgery or short-procedure units, or a urologist's office.

Assist the patient onto a table, and after sedation, place him or her in the lithotomy position. After the anesthesia is given and the area cleansed and draped, the urologist inserts a cystoscope through the urethra into the urinary bladder. This examination commonly includes the use of both the cystoscope and the urethroscope.

Follow-up Care.

After this procedure with general anesthesia, the patient is returned to a postanesthesia care unit (PACU) or area. If local anesthesia and sedation were used, he or she may be returned directly to the hospital room. Ambulatory care patients undergoing cystoscopic examinations are transferred to an area for monitoring before discharge to home. Monitor for airway patency and breathing, changes in vital signs (including temperature), and changes in urine output. Also observe for the complications of bleeding and infection.

A catheter may or may not be present after cystoscopy. The patient without a catheter has urinary frequency as a result of irritation from the procedure. The urine may be pink tinged, but gross bleeding is not expected. Bleeding or the presence of clots may obstruct the catheter and decrease urine output. Monitor urine output, and notify the urologist of obvious blood clots or a decreased or absent urine output. Irrigate the Foley catheter with sterile saline, if prescribed. Notify the urologist if the patient has a fever (with or without chills) or an elevated white blood cell (WBC) count, which suggests infection. Urge the patient to take oral fluids to increase urine output (which helps prevent clotting) and to reduce the burning sensation on urination.

Cystography and Cystourethrography.

These tests are a series of x-rays or a continuous radiographic visualization by fluoroscopy. During the imaging, a dye fills the bladder and the bladder is emptied. Images show structure and function of the bladder and urethra. Tumors, rupture or perforation of the bladder and urethra, abnormal backflow of urine, and distortion from trauma or other pelvic masses can be seen.

Patient Preparation and Procedural Care.

Explain the procedure to the patient. A urinary catheter is temporarily needed to instill contrast dye directly into the bladder for both procedures. The dye is needed to enhance x-ray visibility of the lower urinary tract and is not absorbed into the bloodstream, which reduces the risk for contrast-induced kidney injury.

After bladder filling, x-rays are taken from the front, back, and side positions. For the voiding cystourethrogram (VCUG), the patient is requested to void and x-rays are taken during the voiding. A VCUG is obtained to determine whether urine refluxes (flows backward) into the ureter. The cystogram is used in cases of trauma when urethral or bladder injury is suspected or for patients with recurrent *pyelonephritis* (kidney infection).

Monitor for infection as a result of catheter placement. In this test, the dye is not nephrotoxic because it does not enter the bloodstream and does not reach the kidney. Encourage fluid intake to dilute the urine and reduce the burning sensation from catheter irritation after removal. Monitor for changes in urine output because pelvic or urethral trauma may be present.

Retrograde Procedures.

Retrograde means going against the normal flow of urine. A retrograde examination of the ureters and the pelvis of both kidneys *(pyelogram),* the bladder *(cystogram),* and the urethra *(urethrogram)* involves instilling dye into the lower urinary tract. Because the dye is instilled directly to obtain an outline of the structures of interest, the dye does not enter the bloodstream. Therefore the patient is not at risk for dye-induced acute kidney injury (AKI) or a systemic allergic response.

The patient is prepared for retrograde procedures (retrograde pyelography, retrograde cystography, and retrograde urethrography) in the same way as for cystoscopy. Retrograde x-rays are obtained during the cystoscopy. After placement of the cystoscope by the urologist, catheters are placed into each ureter and contrast dye is instilled into each ureter and kidney pelvis. The catheters are removed by the urologist, and x-rays

are taken to outline these structures as the dye is excreted. The procedure identifies obstruction or structural abnormalities.

For patients undergoing retrograde cystoscopy or urethrography, contrast dye is instilled similarly into the bladder or urethra. Cystography and urethrography identify structural problems, such as fistulas, diverticula, and tumors.

After retrograde procedures, monitor the patient for infection caused by placing instruments in the urinary tract. Because these procedures are performed during cystoscopic examination, follow-up care is the same as that for cystoscopy.

Other Diagnostic Assessments

Urodynamic Studies.

Urodynamic studies examine the processes of voiding and include:

- Tests of bladder capacity, pressure, and tone
- Studies of urethral pressure and urine flow
- Tests of perineal voluntary muscle function

These tests are often used along with voiding urographic or cystoscopic procedures to evaluate problems with urine flow and disorders of the lower urinary tract (Gray, 2011; Gray, 2012a; Gray, 2012b).

Cystometrography (CMG) can determine how well the bladder wall (detrusor) muscle functions and how sensitive it is to stretching as the bladder fills. This test provides information about bladder capacity, bladder pressure, and voiding reflexes.

Explain the procedure, and inform the patient that a urinary catheter will be needed temporarily during the procedure. Ask the patient to void normally. Record the amount and time of voiding. Insert a urinary catheter to measure the residual urine volume. The cystometer is attached to the catheter, and fluid is instilled via the catheter into the bladder. The point at which the patient first notes a feeling of the urge to void and the point at which he or she notes a strong urge to void are recorded. Bladder capacity and bladder pressure readings are recorded graphically. The patient is asked to void when the bladder instillation is complete (about 500 mL). The residual urine after voiding is recorded, and the catheter is removed. Electromyography of the perineal muscles may be performed during this examination.

For any procedure that involves inserting instruments into the urinary tract, monitor for infection. Record the patient's temperature, the character of the urine, and urine output volume.

Urethral pressure profile (also called a *urethral pressure profilometry*

[UPP]) can provide information about the nature of urinary incontinence or urinary retention.

Explain the procedure, and inform the patient that a urinary catheter will be needed temporarily during the procedure. A special catheter with pressure-sensing capabilities is inserted into the bladder. Variations in the pressure of the smooth muscle of the urethra are recorded as the catheter is slowly withdrawn.

As with any study involving inserting instruments into the urinary tract, monitor the patient for manifestations of infection.

Urine stream testing is used to evaluate pelvic muscle strength and the effectiveness of pelvic muscles in stopping the flow of urine. It is useful in assessing urinary incontinence.

Explain the procedure, and reassure the patient that efforts will be made to ensure privacy. The patient is asked to begin urinating. Three to five seconds after urination begins, the examiner gives the patient a signal to stop urine flow. The length of time required to stop the flow of urine is recorded.

Cleaning the perineal area, as after any voiding, is all that is necessary after the urine stream test.

Electromyography (EMG) of the perineal muscles tests the strength of the muscles used in voiding. This information may help identify methods of improving continence. Inform the patient that some mild, temporary discomfort may accompany placement of the electrodes. In EMG of the perineal muscles, electrodes are placed in either the rectum or the urethra to measure muscle contraction and relaxation. After the completion of EMG, administer analgesics as prescribed to promote the patient's comfort.

NCLEX Examination Challenge

Safe and Effective Care Environment

Which assessments are most important for the nurse to perform when monitoring a client who returns to the medical-surgical unit after a dye-enhanced CT scan?

A Body temperature and urine odor
B Kidney tenderness and flank pain
C Urine volume and color
D Specific gravity and pH

Kidney Biopsy

Patient Preparation.

Explain that a kidney biopsy can help determine a cause of unexplained kidney problems and can help direct or change therapy. Most kidney biopsies are performed **percutaneously** (through skin and other tissues) using ultrasound or CT guidance. The patient signs an informed consent and is NPO for 4 to 6 hours before the procedure.

Because of the risk for bleeding after the biopsy, coagulation studies such as platelet count, activated partial thromboplastin time (aPTT), prothrombin time (PT), and bleeding time are performed before surgery. Hypertension is aggressively managed before and after the procedure because high blood pressure can make stopping the bleeding after the biopsy more difficult. Uremia also increases the risk for bleeding, and dialysis may be prescribed before a biopsy. A blood transfusion may be needed to correct anemia before biopsy.

Procedure.

In a percutaneous biopsy, the nephrologist or radiologist obtains tissue samples without an incision. Patients receive sedation and are monitored throughout the procedure. The patient is placed in the prone position on the procedure table. The entry site is selected after taking preliminary images. The area is prepped and sterilely draped. A local anesthetic is injected, and the physician then inserts the biopsy device into the tissues toward the kidney. Needle depth and placement are confirmed by ultrasound or CT. While the patient holds his or her breath, the needle is advanced into the renal cortex. Samples are then taken with a spring-loaded coring biopsy needle and sent for pathologic study.

Follow-up Care.

After a percutaneous biopsy, the major risk is bleeding from the biopsy site. For 24 hours after the biopsy, monitor the dressing site, vital signs (especially fluctuations in blood pressure), urine output, hemoglobin level, and hematocrit. Even if the dressing is dry and there is no hematoma, the patient could be bleeding from the site. An internal bleed is not readily visible but is suspected with flank pain, decreasing blood pressure, decreasing urine output, or other signs of hypovolemia or shock.

The patient follows a plan of strict bedrest, lying in a supine position with a back roll for additional support for 2 to 6 hours after the biopsy. The head of the bed may be elevated, and the patient may resume oral intake of food and fluids. After bedrest, the patient may have limited

bathroom privileges if there is no evidence of bleeding.

Monitor for hematuria, the most common complication of kidney biopsy. Hematuria occurs microscopically in most patients, but 5% to 9% have gross hematuria. This problem usually resolves without treatment in 48 to 72 hours after the biopsy but can persist for 2 to 3 weeks. In rare cases, transfusions and surgery are required. There should be no obvious blood clots in the urine.

The patient may have some local pain after the biopsy. If aching originates at the biopsy site and begins to radiate to the flank and around the front of the abdomen, bleeding may have started or a hematoma is forming around the kidney. This pattern of discomfort with bleeding occurs because blood in the tissues around the kidney increases pressure on local nerve tracts.

If bleeding occurs, IV fluid, packed red blood cells, or both may be needed to prevent shock. In general, a small amount of bleeding creates enough pressure to compress bleeding sites. This is called a "tamponade effect." If tamponade does not occur and bleeding is extensive, surgery for hemostasis or even nephrectomy may be needed. A hematoma in, on, or around the kidney may become infected, requiring treatment with antibiotics and surgical drainage.

If no bleeding occurs, the patient can resume general activities after 24 hours. Instruct him or her to avoid lifting heavy objects, exercising, or performing other strenuous activities for 1 to 2 weeks after the biopsy procedure. Driving may also be restricted. Refer to Chapter 16 for general postoperative care for the patient who has undergone an open kidney biopsy.

Clinical Judgment Challenge

Safety; Patient-Centered Care QSEN

At the start of the shift, you are assessing an 86-year-old patient who is awaiting surgery for a hip repair after a fall 12 hours ago at home. You are collecting a clean-catch urine specimen, using a bedpan, as part of the preoperative preparation. You observe that when she voids, the urine odor is foul and the urine is cloudy and full of sediment. She reports some urgency but notes that she had urgency before her fall.

1. What assessment information will you document in the chart?
2. What additional information should you ask the patient and what else should you consider?
3. Organize your thoughts into a SBAR communication (Chapter 1)

4. Who should you notify and why?

Nursing Concepts and Clinical Judgment Review

In addition to normal ranges indicating fluid and electrolyte balance and acid-base balance, what might you NOTICE in a patient with adequate urinary elimination?

Vital signs:

- Body temperature is within normal range.
- Blood Pressure is within normal range.

Physical assessment:

- Daily urine output is within 500 mL of daily fluid intake.
- Skin texture is normal (no edema or superficial crystals present).
- Skin color is appropriate for ethnicity with no excessive yellowing, bruising, or petechiae.
- Urine is clear and some variation of yellow in color.
- Patient voids 300 to 500 mL per voiding.
- Patient does not report pain or burning on urination.
- Patient has no difficulty starting or stopping the stream of urine.
- Patient is continent of urine and can maintain continence without sensation of urgency.
- Patient is alert and oriented.

Psychological assessment:

- Patient is able to communicate concerns about the urinary tract system.
- Patient is aware and informed about kidney function and diagnostic tests.

Laboratory assessment:

- Hematocrit and hemoglobin are within normal limits (no anemia).
- BUN and creatinine are within normal limits.
- Serum electrolytes are within normal ranges.
- Urinalysis shows no bacteria, blood, sediment, or protein.

Get Ready for the NCLEX® Examination!

Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Use sterile technique when inserting a catheter or any other instrument into the urinary system. **Safety** QSEN
- Use Contact Precautions with any patient who has drainage from the genitourinary tract. **Safety** QSEN
- Wear gloves when testing or handling urine. **Safety** QSEN
- Evaluate risk for kidney injury from diagnostic testing by asking about allergy to contrast dye or iodine and adverse reactions following the use of diagnostic agents such as gadolinium in MRI.
- Ask the patient about the use of prescribed and over-the-counter drugs that increase risk for kidney dysfunction.
- Verify that informed consent has been obtained and that the patient has a clear understanding of the potential risks before he or she undergoes invasive procedures to assess the kidneys and urinary function. **Safety** QSEN

Health Promotion and Maintenance

- Teach patients to clean the perineal area after voiding, after having a bowel movement, and after sexual intercourse. **Evidence-Based Practice** QSEN
- Urge all patients to maintain an adequate fluid intake (sufficient to dilute urine to a light yellow color). A minimum of 2 L/day may be recommended unless another health problem requires fluid restriction.
- Teach patients who come into contact with chemicals in their workplaces or for leisure-time activities to avoid direct skin or mucous membrane contact with these chemicals. **Safety** QSEN

Psychosocial Integrity

- Allow the patient the opportunity to express fear or anxiety about tests of the kidneys and urinary tract or about a potential change in kidney function. **Patient-Centered Care** QSEN
- Assess the patient's level of comfort in discussing issues related to elimination and the urogenital area.

- Explain all diagnostic procedures, restrictions, and follow-up care to the patient scheduled for tests.
- Provide as much privacy as possible for patients undergoing examination or testing of the kidney/urinary tract. **Patient-Centered Care** QSEN
- Use language and terminology that the patient can understand during discussions of kidney/urinary assessment. **Patient-Centered Care** QSEN

Physiological Integrity

- Ask the patient about kidney problems in any other members of the family, because some problems have a genetic component.
- Ask the patient about current and past drug use (prescribed, over-the-counter, and illicit), and evaluate drug use for potential nephrotoxicity.
- Use laboratory data to distinguish between dehydration and kidney impairment. **Evidence-Based Practice** QSEN
- Describe how to obtain a sterile urine specimen from a urinary catheter.
- Assess urine output closely after any procedure in which contrast dye is used IV. **Evidence-Based Practice** QSEN
- Assess the patient for bleeding or manifestations of infection after any invasive test of kidney/urinary function.
- Inform health care providers about any manifestations of complications following invasive or noninvasive tests of urinary and kidney structure or function.

CHAPTER 66

Care of Patients with Urinary Problems

Chris Winkelman

PRIORITY CONCEPTS

- Elimination
- Pain
- Infection
- Inflammation

Learning Outcomes

Safe and Effective Care Environment

1. Assess the appropriateness for continuing therapy with indwelling urinary catheters.
2. Prevent infection when caring for a patient with a urinary problem.

Health Promotion and Maintenance

3. Encourage everyone to have adequate fluid intake daily.
4. Teach people how to reduce or prevent urinary tract infection and injury and urinary incontinence.

Psychosocial Integrity

5. Reduce the psychological impact of urinary problems for the patient and family.

Physiological Integrity

6. Coordinate care to prevent urinary tract infection among hospitalized patients.

7. Compare the pathophysiology and manifestations of stress incontinence, urge incontinence, overflow incontinence, mixed incontinence, and functional incontinence.
8. Coordinate nursing care for the patient who has invasive bladder cancer.

http://evolve.elsevier.com/Iggy/

The ureters, bladder, and urethra make up the urinary system. Their functions are to store the urine made by the kidney and eliminate it from the body. Problems in the urinary system can interfere with urinary elimination when the mechanics of moving urine out of the body are disrupted. Such problems can reduce control of fluids, electrolytes, nitrogenous wastes, and blood pressure.

Urinary problems affect the storage or elimination of urine. Both acute and chronic urinary problems are common and costly. More than 20 million people in the United States are treated annually for urinary tract infections, cystitis, kidney and ureter stones, or urinary incontinence (U.S. Renal Data Systems, 2012). Although life-threatening complications are rare with urinary problems, patients may have functional, physical, and psychosocial changes that reduce quality of life. Nursing interventions are directed toward prevention, detection, and management of urologic disorders.

Infectious Disorders

Infections of the urinary tract and kidneys are common, especially among women. Manifestations of urinary tract infection (UTI) account for more than 7 million health care visits and 1 million hospital admissions annually in the United States (U.S. Renal Data Systems, 2012). Total direct and indirect costs for adult urinary tract infections are estimated at $1.6 billion each year. UTIs are the most common health care–associated infection (Dudeck et al., 2013).

Urinary tract infections are described by their location in the tract. Acute infections in the lower urinary tract include *urethritis* (urethra), *cystitis* (bladder), and *prostatitis* (prostate gland). Acute *pyelonephritis* is an upper urinary tract (kidney) infection. Although the vocabulary for these infected sites reflects an inflammatory condition *(-itis),* the most common cause of inflammation in the urinary tract is infection. Thus these terms are often used interchangeably to refer to either an infectious process or a noninfectious inflammatory process. Several risk factors are associated with occurrence of UTIs (Table 66-1).

TABLE 66-1

Factors Contributing to Urinary Tract Infections

FACTOR	MECHANISM
Obstruction	Incomplete bladder emptying creates a continuous pool of urine in which bacteria can grow, prevents flushing out of bacteria, and allows bacteria to ascend more easily to higher structures. Bacteria have a greater chance of multiplying the longer they remain in residual urine. Overdistention of the bladder damages the mucosa and allows bacteria to invade the bladder wall.
Stones (calculi)	Large stones can obstruct urine flow. The rough surface of a stone irritates mucosal surfaces and creates a spot where bacteria can establish and grow. Bacteria can live within stones and cause re-infection.
Vesicoureteral reflux	Bacteria-laden urine is forced backward from the bladder up into the ureters and kidneys, where pyelonephritis can develop. Reflux of sterile urine can cause kidney scarring, which may promote kidney dysfunction.
Diabetes mellitus	Excess glucose in urine provides a rich medium for bacterial growth. Peripheral neuropathy affects bladder innervation and leads to a flaccid bladder and incomplete bladder emptying.
Characteristics of urine	Alkaline urine promotes bacterial growth. Concentrated urine promotes bacterial growth.
Gender	**Women** Susceptibility to periurethral colonization with coliform bacteria is increased, especially as estrogen levels fall during menopause. Use of douches, perfumed pads or toilet tissue, diaphragms, or spermicide (including spermicide-coated condoms) in women can inflame periurethral tissue and contribute to colonization. Bladder displacement during pregnancy predisposes women to cystitis and the development of pyelonephritis. A diaphragm or pessary that is too large can obstruct urine flow or traumatize the urethra.
	Men With increased age, the prostate enlarges and may obstruct the normal flow of urine, producing stasis. With increased age, prostatic secretions lose their antibacterial characteristics and predispose to bacterial proliferation in the urine. Sexually transmitted diseases may cause urethral strictures that obstruct the flow of urine and predispose to urinary stasis.
Age	Urinary stasis may be caused by incomplete bladder emptying as a result of an enlarged prostate in men and cystocele and vaginal prolapse in women. Neuromuscular conditions that cause incomplete bladder emptying, such as Parkinson disease and stroke, affect older adults more frequently. The use of drugs with intentional or unintentional anticholinergic properties in older adults contributes to delayed bladder emptying. Fecal incontinence contributes to periurethral contamination. Low estrogen in menopausal women adversely affects the cells of the vagina and urethra, making them more susceptible to infections.
Sexual activity	Sexual intercourse is the strongest risk factor for uncomplicated cystitis, particularly in young women. Irritation of the perineum and urethra during intercourse can promote migration of bacteria from the perineal area to the urinary tract in some women. Inadequate vaginal lubrication may exacerbate potential urethral irritation. Bacteria may be introduced into the man's urethra during anal intercourse or during vaginal intercourse with a woman who has a bacterial vaginitis.
Recent use of antibiotics	Antibiotics change normal protective flora, providing opportunity for pathogenic bacterial overgrowth and colonization.

The presence of bacteria in the urine is **bacteriuria** and can occur with any urologic infection. When bacteriuria is without manifestations of infection, it is called *colonization,* or *asymptomatic bacterial urinary tract infection or ABUTI,* and is more common in older adults. This problem may progress to acute infection or renal insufficiency when the patient has other conditions, and only then does it require treatment.

Urinary tract infections are typically categorized as *uncomplicated* or *complicated.* An acute, uncomplicated UTI is usually cystitis or pyelonephritis in premenopausal, nonpregnant, otherwise healthy women. With an uncomplicated UTI, there is no anatomic or functional abnormality of the urinary tract. Complicated UTIs are associated with conditions that increase the risk for treatment failure or serious outcomes. These conditions or factors include obstruction, pregnancy, male gender, diabetes, neurogenic bladder, renal insufficiency, and immunosuppression (Hooton, 2012). Complicated UTIs require greater vigilance to avoid or to detect adverse events from the infection and a longer course of antimicrobial treatment. They also may require

additional diagnostics to identify and manage other related health problems (comorbidities).

Cystitis

Pathophysiology

Cystitis is an inflammatory condition of the bladder. Commonly, it refers to inflammation from an infection of the bladder. However, cystitis can be caused by inflammation without infection. Drugs, chemicals, or radiation, for example, cause bladder inflammation without an infecting organism. Irritants, such as feminine hygiene spray, spermicidal jellies, or long-term use of a catheter can cause cystitis without infection. Cystitis may sometimes occur as a complication of other disorders, such as gynecologic cancers, pelvic inflammatory disorders, endometriosis, Crohn's disease, diverticulitis, lupus, or tuberculosis. **Interstitial cystitis** is an inflammatory disease that has no known cause.

Microbes, most commonly bacteria, move up the urinary tract from the external urethra to the bladder to cause infectious cystitis. Less commonly, spread of infection through the blood and lymph fluid can occur. Mucin produced by cells lining the bladder helps maintain mucosal integrity and prevents cellular damage. Mucin may also prevent bacteria from adhering to urothelial cells. Bladder irritating factors, like concentrated urine, may interfere with the production and effectiveness of mucin.

Etiology and Genetic Risk

UTIs, like other infections, are the result of interactions between a pathogen and the host. Usually, a high bacterial *virulence* (ability to invade and infect) is needed to overcome normal host resistance. However, a compromised host is more likely to become infected even with bacteria that have low virulence. Invading bacteria with special adhesions are more likely to cause ascending UTIs that start in the urethra or bladder and move up into the ureter and kidney. Patient-specific genetic factors such as innate inflammatory response may influence the risk for UTI.

Infectious cystitis is most commonly caused by pathogens from the bowel or, in some cases, the vagina (Hooton, 2012). About 90% of UTIs are caused by *Escherichia coli*. Less common organisms include *Staphylococcus saprophyticus, Klebsiella pneumoniae,* and organisms from the *Proteus* and *Enterobacter* species (Brusch, 2013). Other infecting microbes causing infectious cystitis are viruses, mycobacteria, parasites, and yeast (fungus), especially *Candida* species.

In most cases, organisms adhere to the perineal area and move into the urethra as a result of irritation, trauma, or instrumentation of the urinary tract. Infecting organisms then migrate to the bladder. Small urine volume or infrequent voiding, sexual intercourse, urinary tract obstruction, instrumentation, use of catheters not drained to gravity, and *vesicoureteral reflux* (backward flow of urine at the ureteral-bladder junction) are all associated with the ascending migration of infecting organisms.

Catheters are the most common factor placing patients at risk for UTIs in the hospital and long-term care settings (Mori, 2014). Within 48 hours of catheter insertion, bacterial colonization along the urethra and the catheter itself begins. About 50% of patients with indwelling catheters become infected within 1 week of catheter insertion.

How a catheter-related infection occurs varies between genders. Bacteria from a woman's perineal area are more likely to ascend to the bladder by moving along the urethra. The shorter urethra in women aids in the ascending organism migration. In men, bacteria tend to gain access to the bladder from the catheter itself. Any break in the closed urinary drainage system allows bacteria to move through the lumen of the catheter. The external catheter surface also provides route for migration. Best practices to reduce the risk for catheter contamination and catheter-related UTIs are listed in Chart 66-1.

Chart 66-1

Best Practice for Patient Safety & Quality Care QSEN

Minimizing Catheter-Related Infection

- Maintain good hand hygiene.
- Insert urinary catheters for appropriate use only, including:
  - Acute urinary retention or bladder obstruction
  - Accurate measurement of urine volume in critically ill patients
  - Perioperative situations that involve urologic surgery
  - Monitor urine output when large-volume infusions or diuretics are used
  - Patient requires immobilization from unstable spine or pelvic fractures
- Assess patients daily to determine the need for an indwelling catheter; the strongest predictor of a catheter-associated urinary tract infection (CAUTI) is the length of time the catheter dwells in a patient.
- Consider appropriate alternatives to an indwelling catheter such as an

external device in men.
- Use sterile technique when inserting the urinary catheter.
- When emptying the urine bag, do not allow the tip of the outflow tube to touch the urine collection container. Use a dedicated container for each patient or resident.
- Select a small-size catheter, and do not overfill the balloon.
- Maintain a closed system by ensuring that catheter tubing connections are sealed securely; disconnections can introduce pathogens into the urinary tract.
- Maintain unobstructed urine flow by keeping the tubing patent and urine collection bags below the level of the bladder at all times; elevating the collection bag above the bladder causes reflux from the bag into the urinary tract.
- Monitor and report CAUTI rates, and promote ongoing best practices.
- Secure the catheter to the patient's thigh (women) or lower abdomen (men); catheter movement can cause urethral friction and irritation.
- Perform daily catheter care by washing the perineum and proximal portion of the catheter with soap and water and drying gently (removes pathogens and reduces pathogenic population).
- Consider the use of coated catheters for patients requiring indwelling catheters for more than 3 to 5 days. This coating reduces bacterial colonization along the catheter.

Application of antiseptic solutions or antibiotic ointments to the perineal area of catheterized patients has not been demonstrated to have any beneficial effect.

Adapted from Dumont, C., & Wakeman, J. (2010). Preventing catheter-associated UTIs: Survey report. *Nursing2010, 40*(12), 24-30.

Organisms other than bacteria cause cystitis. Fungal infections, such as those caused by *Candida*, can occur during long-term antibiotic therapy, because antibiotics change normal protective flora that reduce the adherence and virulence of pathogenic bacteria. Patients who are severely immunosuppressed, are receiving corticosteroids or other immunosuppressive agents, or have diabetes mellitus or acquired immune deficiency syndrome (AIDS) are at higher risk for fungal UTIs.

Viral and parasitic infections are rare and usually are transferred to the urinary tract from an infection at another body site. For example, *Trichomonas,* a parasite found in the vagina, can also be found in the urine. Treatment of the vaginal infection also resolves the UTI.

Noninfectious cystitis may result from chemical exposure, such as to drugs (e.g., cyclophosphamide [Cytoxan, Procytox]); from radiation

therapy; and from immunologic responses, as with systemic lupus erythematosus (SLE).

Interstitial cystitis is a rare, chronic inflammation of the entire lower urinary tract (bladder, urethra, and adjacent pelvic muscles) that is not a result of infection. The condition affects women 10 times more often than men, and the diagnosis is difficult to make. Manifestations are pain associated with bladder filling or voiding, usually accompanied by frequency, urgency, and nocturia (McCance et al., 2014). Pain occurs in suprapubic or pelvic areas, sometimes radiating to the groin, vulva, or rectum. Results from urinalysis and urine culture are negative for infection (Quillin & Erickson, 2012).

Although cystitis is not life threatening, infectious cystitis can lead to life-threatening complications, including pyelonephritis and sepsis. Severe kidney damage from an ascending infection that began as cystitis is a rare complication unless the patient also has other predisposing factors, such as anatomic abnormalities, pregnancy, obstruction, reflux, calculi, or diabetes.

The urinary tract is the infection source of severe sepsis or septic shock in about 10% to 30% of cases (Wagenlehner et al., 2013). The spread of the infection from the urinary tract to the bloodstream is termed **urosepsis**. Urosepsis is associated with complicated urinary tract infections and is more common among older adults. Sepsis is a systemic reaction to infection that can lead to overwhelming organ failure, shock, and death. Sepsis has a high mortality and prolongs hospitalization (see Chapter 37).

Incidence and Prevalence

The incidence of UTI is second only to that of upper respiratory infections in primary care. Patients who have **frequency** (an urge to urinate frequently in small amounts), **dysuria** (pain or burning with urination), and **urgency** (the feeling that urination will occur immediately) account for more than 8 million health care visits annually (Foxman, 2010). About 60% of these patients will have a confirmed UTI (Lowe & Ryan-Wenger, 2012).

Considerations for Older Adults

Patient-Centered Care QSEN

The prevalence of UTIs varies with age and gender. Women of any age are more commonly affected with UTIs than are men. In men, the incidence of UTI greatly increases after 73 years of age. In women, the

prevalence of UTIs increases from 20% among all women to 50% among those older than 80 years (U.S. Renal Data Systems, 2012). Skin and mucous membrane changes from a lack of estrogen appear to account for much of the increased risk in older women. Prostate disease increases risk for UTIs in men. Ask about manifestations of UTI whenever you are assessing an older adult.

Health Promotion and Maintenance

Although cystitis is common, in many cases it is preventable. In the health care setting, reducing the use and duration of indwelling urinary catheters is a major prevention strategy. When catheters must be used in institutional settings, strict attention to sterile technique during insertion is essential to reduce the risk for UTIs (see Chart 66-1). Long-term placement of urinary catheters requires aseptic technique for insertion. When *intermittent catheterization* is used in the home setting, a clean technique may be used (Newman & Willson, 2011).

Nursing Safety Priority QSEN

Action Alert

Ensuring that urinary catheters are used appropriately and discontinued as early as possible is everyone's responsibility. Do not allow catheters to remain in place for staff convenience.

Certain changes in fluid intake patterns, urinary elimination patterns, and hygiene patterns can help prevent or reduce cystitis in the general population. For example, a liberal water intake of 2.2 L for women and 3 L for men can promote general health. Another strategy to promote health is to have sufficient fluid intake to cause 1.5 L of clear or light yellow urine daily. Other strategies to prevent cystitis and other UTIs are listed in Chart 66-2. Although these strategies do not have consistent or high-quality evidence to support a reduced risk for UTI when followed, they are low risk and reasonable (Hooton, 2012).

Chart 66-2

Patient and Family Education: Preparing for Self-Management

Preventing a Urinary Tract Infection

- Drink fluid liberally, as much as 2 to 3 liters daily if not contraindicated by health conditions.
- Be sure to get enough sleep, rest, and nutrition daily to maintain immunologic health.
- If spermicides are used, consider changing to another method of contraception.
- *[For women]* Clean your perineum (the area between your legs) from front to back.
- *[For women]* Avoid using or wearing irritating substances such as douches, scented lubricants for intercourse, bubble bath, tight-fitting underwear, and scented toilet tissue. Wear loose-fitting cotton underwear.
- *[For women]* Empty your bladder before and after intercourse.
- *[For both women and men]* Gently wash the perineal area before intercourse.
- Do not routinely delay urination because the flow of urine can help remove bacteria that may be colonizing the urethra or bladder.
- If you experience burning when you urinate, if you have to urinate frequently, or if you find it difficult to begin urinating, notify your physician or other health care provider right away, especially if you have a chronic medical condition (e.g., diabetes) or are pregnant.
- Consider using one or more of these therapies to reduce the risk for developing a urinary tract infection:
  - Taking cranberry substances (juice, capsules, or tablets) daily. Avoid high fructose cranberry juice to minimize calories and high glucose urine favorable to bacterial reproduction.
  - Ingesting apple cider vinegar, 2 tablespoons 3 times daily in juice.
  - Applying topical estrogen to the perineal area, if postmenopausal. Topical estrogen normalizes vaginal flora. Oral estrogens are not effective.
  - Ingesting D-mannose 500 mg tablet or 0.5-1 teaspoon of powder; D-mannose is thought to block adhesion of *E. coli* to the epithelium in the urinary tract.

Adapted from Hooton, T.M. (2012). Clinical practice: Uncomplicated urinary tract infection. *New England Journal of Medicine, 366*(11), 1028-1037.

Patient-Centered Collaborative Care

Assessment

Physical Assessment/Clinical Manifestations.

Frequency, urgency, and dysuria are the common manifestations of a urinary tract infection (UTI), but other manifestations may be present (Chart 66-3). Urine may be cloudy, foul smelling, or blood tinged. Ask the patient about risk factors for UTI during the assessment (see Table 66-1). For noninfectious cystitis, the Pelvic Pain and Urgency/Frequency (PUF) patient symptom scale can identify patients with interstitial cystitis (Richmond, 2010).

Chart 66-3 Key Features

Urinary Tract Infection

Common Clinical Manifestations

- Frequency
- Urgency
- Dysuria
- Hesitancy or difficulty in initiating urine stream
- Low back pain
- Nocturia
- Incontinence
- Hematuria
- Pyuria
- Bacteriuria
- Retention
- Suprapubic tenderness or fullness
- Feeling of incomplete bladder emptying

Rare Clinical Manifestations

- Fever
- Chills
- Nausea or vomiting
- Malaise
- Flank pain

Clinical Manifestations that May Occur in the Older Adult

- The only manifestation may be something as vague as increasing mental confusion or frequent, unexplained falls.
- A sudden onset of incontinence or a worsening of incontinence may be the only manifestation of an early urinary tract infection (UTI).
- Fever, tachycardia, tachypnea, and hypotension, even without any urinary manifestations, may be signs of urosepsis.

• Loss of appetite, nocturia, and dysuria are common manifestations.

Before performing the physical assessment, ask the patient to void so that the urine can be examined and the bladder emptied before palpation. Assess vital signs to help identify the presence of infection (e.g., fever, tachycardia, and tachypnea). Inspect the lower abdomen, and palpate the bladder. Distention after voiding indicates incomplete bladder emptying.

Using Standard Precautions, record any lesions around the urethral meatus and vaginal opening. To help differentiate between a vaginal and a urinary tract infection, note whether there is any vaginal discharge. Vaginal discharge and irritation are more indicative of vaginal infection. Women often report burning with urination when normal acidic urine touches labial tissues that are inflamed or ulcerated by vaginal infections or sexually transmitted diseases (STDs). Maintain privacy with drapes during the examination.

The prostate is palpated by digital rectal examination (DRE) for size, change in shape or consistency, and tenderness. The physician or advanced practice nurse performs the DRE.

Laboratory Assessment.

Laboratory assessment for a UTI is a urinalysis with testing for leukocyte esterase and nitrate. The combination of a positive leukocyte esterase and nitrate is 68% to 88% sensitive in the diagnosis of a UTI (Lowe & Ryan-Wenger, 2012). However, when a urinalysis includes a microscopic count of bacteria, white blood cells (WBCs), and red blood cells (RBCs), the additional testing is more expensive and may not improve diagnostic accuracy. The presence of more than 20 epithelial cells/high-power field (hpf) suggests contamination. The presence of 100,000 colonies/mL or the presence of three or more WBCs (**pyuria**) with RBCs (**hematuria**) indicates infection.

A urinalysis is performed on a clean-catch midstream specimen. If the patient cannot produce a clean-catch specimen, you may need to obtain the specimen with a small-diameter (6 Fr) catheter. For a routine urinalysis, 10 mL of urine is needed; smaller quantities are sufficient for culture.

A urine culture confirms the type of organism and the number of colonies. Urine culture is expensive, and initial results take at least 48 hours. It is indicated when the UTI is complicated, when it does not respond to usual therapy, or when the diagnosis is uncertain. A UTI is confirmed when more than 10^5 colony-forming units are in the urine

from any patient. In patients who also have manifestations of UTI, as few as 10^3 colony-forming units may be used to confirm the infection. The presence of many different types of organisms in low colony counts usually indicates that the specimen is contaminated. Sensitivity testing follows culture results when complicating factors are present (e.g., stones or recurrent infection), when the patient is older, or to ensure the appropriate antibiotics are prescribed.

Occasionally the serum WBC count may be elevated, with the differential WBC count showing a "left shift" (see Chapter 17). This shift indicates that the number of immature WBCs is increasing in response to the infection. As a result, the number of bands, or immature WBCs, is elevated. Left shift most often occurs with urosepsis and rarely occurs with uncomplicated cystitis, which is a local rather than a systemic infection.

Other Diagnostic Assessment.

The diagnosis of cystitis is based on the history, physical examination, and laboratory data. If urinary retention and obstruction of urine outflow are suspected, pelvic ultrasound or CT may be needed to locate the site of obstruction or the presence of calculi. Voiding cystourethrography (see Chapter 65) is needed when urine reflux is suspected.

Cystoscopy (see Chapter 65) may be performed when the patient has recurrent UTIs (more than three or four a year). A urine culture is performed first to ensure that no infection is present. If infection is present, the urine is sterilized with antibiotic therapy before the procedure to reduce the risk for sepsis. Cystoscopy identifies abnormalities that increase the risk for cystitis. Such abnormalities include bladder calculi, bladder diverticula, urethral strictures, foreign bodies (e.g., sutures from previous surgery), and **trabeculation** (an abnormal thickening of the bladder wall caused by urinary retention and obstruction). Retrograde pyelography, along with the cystoscopic examination, shows outlines and images of the drainage tract.

Cystoscopy is needed to accurately diagnose interstitial cystitis. A urinalysis usually shows WBCs and RBCs but no bacteria. Common findings in interstitial cystitis are a small-capacity bladder, the presence of Hunner's ulcers (a type of bladder lesion), and small hemorrhages after bladder distention.

◆ Interventions

Nonsurgical Management.

The expected outcome is to maintain an optimal urine elimination pattern. Nursing interventions for the management of cystitis focus on comfort and teaching about drug therapy, fluid intake, and prevention measures.

Drug Therapy.

Drugs used to treat bacteriuria and promote patient comfort include urinary antiseptics or antibiotics, analgesics, and antispasmodics. Cure of a UTI depends on the antimicrobial levels achieved in the urine. Fluconazole is the drug of choice for treatment of *Candida* (fungal) infections. Antispasmodic drugs decrease bladder spasm and promote complete bladder emptying.

Antibiotic therapy is used for bacterial UTIs (Chart 66-4). Guidelines for uncomplicated cystitis recommend nitrofurantoin, trimethoprim/sulfamethoxazole, or fosfomycin as first-line therapy (Brusch, 2013; Hooton, 2012; Hopkins et al., 2014). Longer antibiotic treatment (7 to 21 days) and sometimes different agents are required for hospitalized patients and those with complicated UTIs (e.g., pregnant women and patients with anatomic, functional or metabolic derangements that affect the urinary tract).

Chart 66-4 Common Examples of Drug Therapy

Urinary Tract Infections

DRUG/DOSAGE	NURSING INTERVENTIONS	RATIONALES
Antimicrobials		
Sulfonamides*—*Reduce Bacteria in the Urinary Tract By Direct Killing (Trimethoprim) and By Inhibiting Bacterial Reproduction (Sulfamethoxazole).		
Trimethoprim*/ sulfamethoxazole (Bactrim, Bacter-Aid, Septra, Sulfatrim, Sultrex, Roubac 🍁) 160 mg trimethoprim/800 mg sulfamethoxazole orally every 12 hr	Ask patients about drug allergies, especially to sulfa drugs, before beginning drug therapy.	Allergies to sulfa drugs are common and require changing the drug therapy.
	Teach patients to drink a full glass of water with each dose and to have an overall fluid intake of 3 L daily.	Sulfamethoxazole can form crystals that precipitate in the kidney tubules. Fluid intake prevents this complication.
	Teach patients to keep out of the sun or to wear protective clothing outdoors and use a sunscreen.	This drug increases skin sensitivity to the sun and can lead to severe sunburns, even in darker-skinned patients.
	Caution patients to complete the drug regimen even if the symptoms improve or disappear sooner.	Not completing the drug regimen can lead to an infection recurrence and to bacterial drug resistance.
Fluoroquinolones*—*Reduce Bacteria in the Urinary Tract By Direct Killing (Bactericidal Actions) and By Inhibiting Bacterial Reproduction (Bacteriostatic Actions).		
Ciprofloxacin (Cipro, ProQuin) 250 mg orally twice daily Levofloxacin (Levaquin) 400 mg orally daily	Teach patients taking the extended-release drugs to swallow them whole, not to crush or chew the tablets.	Crushing or chewing the tablet releases all the drug at once, ruining the extended effect.
	Warn patients to not take the drug within 2 hours of taking an antacid.	Many antacids (especially those containing magnesium or aluminum) interfere with drug absorption.
	Teach patients how to take their pulse, to monitor it twice daily while on this drug, and to notify the prescriber if new-onset irregular heartbeats occur.	This class of drugs can induce serious cardiac dysrhythmias.
	Teach patients to keep out of the sun or to wear protective clothing outdoors and use a sunscreen.	Most quinolones increase skin sensitivity to the sun and can lead to severe sunburns even in darker-skinned patients.
	Caution patients to complete the drug regimen even if the symptoms improve or disappear sooner.	Not completing the drug regimen can lead to an infection recurrence and to bacterial drug resistance.
Penicillins*—*Reduce Bacteria in the Urinary Tract By Direct Killing (Bactericidal Actions) As a Result of Interrupting Bacterial Cell Wall Synthesis.		
Amoxicillin (Amoxil) 500 mg orally every 12 hr Amoxicillin/ clavulanate (Augmentin, Clavulin 🍁) 500 mg/125 mg orally every 12 hr	Ask patients about drug allergies to penicillin before beginning drug therapy.	Allergies to penicillin are common and require changing the drug therapy.
	Teach patients to take the drug with food.	Taking it with food reduces the risk for GI upset.
	Instruct patients to call the prescriber if severe or watery diarrhea develops.	A complication of penicillin therapy is pseudomembranous colitis, which may require discontinuing the drug.
	Suggest that women who take oral contraceptives use an additional method of birth control while taking this drug.	Penicillin appears to reduce the effectiveness of estrogen-containing oral contraceptives.
	Caution patients to complete the drug regimen even if the symptoms improve or disappear sooner.	Not completing the drug regimen can lead to an infection recurrence and to bacterial drug resistance.
Cephalosporins*—*Reduce Bacteria in the Urinary Tract By Direct Killing (Bactericidal Actions) As a Result of Interrupting Bacterial Cell Wall Synthesis.		
Cefdinir, cefaclor, or cefpodoxime 250-500 mg orally daily	Ask about drug allergies to penicillin or cephalosporins before beginning drug therapy.	Drugs in this class are structurally similar to penicillin. Anyone with allergies to penicillin is likely to be allergic to the cephalosporins.
	Instruct patients to call the prescriber if severe or watery diarrhea develops.	A complication of penicillin therapy is pseudomembranous colitis, which may require discontinuing the drug.
	Caution patients to complete the drug regimen even if the symptoms improve or disappear sooner.	Not completing the drug regimen can lead to an infection recurrence and to bacterial drug resistance.
Other		
Fosfomycin (Monurol)—Reduces bacteria in the urinary tract by direct killing (bactericidal actions) as a result of interrupting bacterial cell wall synthesis.		
3 g orally as a one-time dose	Instruct patients to mix the contents of a package in about ½ cup of cold water, stir well, and drink all the liquid.	This oral drug is available as granules that must be dissolved before taking.
	Avoid taking this drug when also taking metoclopramide or any other drug that increases GI motility.	Drugs that increase GI motility reduce the absorption of fosfomycin.
Nitrofurantoin (Furadantin, Macrobid, Macrodantin, Nephronex 🍁, Urotoin)—Usually reduce bacteria in the urinary tract by inhibiting bacterial reproduction (bacteriostatic actions).		
100 mg orally every 12 hr	Teach patients to shake the bottle well before measuring the drug.	Drug is a suspension and requires shaking to ensure homogeneity.
	Suggest that patients obtain a calibrated spoon for liquid drugs and to not use household spoons.	Household spoons are not accurate for measuring drugs.
	Teach patients to drink a full glass of water with each dose and to have an overall fluid intake of at least 3 L daily.	Drug precipitates in the kidney tubules and damages the kidney. Fluid intake prevents this complication.
	Caution patients to complete the drug regimen even if the symptoms improve or disappear sooner.	Not completing the drug regimen can lead to an infection recurrence and to bacterial drug resistance.

DRUG/DOSAGE	NURSING INTERVENTIONS	RATIONALES
Bladder Analgesics—*Reduce Bladder Pain and Burning on Urination by Exerting a Topical Analgesic or Local Anesthetic Effect on the Mucosa of the Urinary Tract.*		
Phenazopyridine (Azo-Dine, Prodium, Pyridiate, Pyridium, Uristat, Phenazo 🍁) 200 mg orally 3 times daily, after meals	Remind patients that this drug will not treat an infection, only the symptoms.	Drug does not have any antibacterial actions.
	Teach patients to take the drug with or immediately after a meal.	Food reduces the risk for GI disturbances.
	Warn patients that urine will turn red or orange.	This expected response to the drug may stain clothing or toilets.
Antispasmodics—*Relieve Bladder Spasms by Inhibiting Nerve Stimulation to the Bladder Muscle.*		
Hyoscyamine (Anaspaz, Cystospaz, many others) 0.125-0.25 mg orally 3 to 4 times daily	Teach patients to notify the prescriber if blurred vision or other eye problems, confusion, dizziness or fainting spells, fast heartbeat, fever, or difficulty passing urine occurs.	These are manifestations of drug toxicity.
	Teach patients to wear dark glasses in sunlight or other bright-light areas.	Drug dilates the pupil and increases eye sensitivity to light.

*Trimethoprim can be given alone to patients with a sulfa allergy.

Nursing Safety Priority QSEN

Drug Alert

Two of the fluoroquinolone antibiotics, Tequin and Noroxin, are designated as sound-alike, look-alike agents with other drugs and could easily be administered in error. Take care to not confuse Tequin with Tegretol, an oral anticonvulsant, or with Ticlid, a platelet inhibitor. Take care to not confuse Noroxin with Neurontin, an oral anticonvulsant.

NCLEX Examination Challenge

Safe and Effective Care Environment

A client in the community health clinic is prescribed trimethoprim/sulfamethoxazole for cystitis. The client reports developing hives to "something called Septra." What is the nurse's best action?

A Reassure the client that Septra is not trimethoprim/sulfamethoxazole.
B Highlight this important information in the client's medical record.
C Place an allergy alert band on the client's wrist.
D Notify the prescriber immediately.

Long-term, low-dose antibiotic therapy is sometimes used for chronic, recurring infection caused by structural abnormalities or stones. Trimethoprim 100 mg daily may be used for long-term management of the older patient with frequent UTIs. For women who have recurrent UTIs after intercourse, antibiotics may be prescribed to be taken after intercourse. The three most common drug treatment regimens are (1) one low-dose tablet of trimethoprim (TMP) (Proloprim, Trimpex),(2) TMP/sulfamethoxazole (half or single-strength Bactrim, Cotrim, Septra),

or (3) nitrofurantoin (Macrodantin, Nephronex, Novo Furantoin).

Gender Health Considerations

Patient-Centered Care QSEN

Pregnant women with a bacterial UTI require prompt and aggressive treatment because cystitis can lead to acute pyelonephritis during pregnancy. Pyelonephritis in pregnancy can cause preterm labor and adversely affect the fetus. Remind pregnant patients to contact their health care provider whenever manifestations of UTI are present.

Fluid Intake.

Urge patients to drink enough fluid to maintain a diluted urine throughout the day and night unless fluid restriction is needed for another health problem. Some urologists recommend sufficient fluid intake to result in at least 1.5 L of urine output or 7 to 12 voidings daily. Food can provide 20% or more of fluid intake, particularly the intake of fruits and vegetables.

Drinking 50 mL of concentrated cranberry juice daily appears to decrease the ability of bacteria to adhere to the epithelial cells lining the urinary tract, decreasing the incidence of recurrent symptomatic UTIs in some patients. Cranberry juice, tablets, or capsules must be consumed for more than 4 weeks to affect the ability of *E. coli* to adhere to the urinary tract (Stapleton et al., 2012). Cranberry products have not consistently demonstrated effectiveness but are a low-cost and low-risk intervention (Hooton, 2012). It is important to note that cranberry juice is an irritant to the bladder with interstitial cystitis and should be avoided by patients with this condition. Avoiding caffeine, carbonated beverages, and tomato products may decrease bladder irritation during cystitis.

Comfort Measures.

A warm sitz bath 2 or 3 times a day for 20 minutes may provide comfort and some relief of local symptoms. If burning with urination is severe or urinary retention occurs, teach the patient to sit in the sitz bath and urinate into the warm water. Urinary tract analgesics or antispasmodics may also provide comfort (see Chart 66-4).

Surgical Management.

Surgery for cystitis treats the conditions that increase the risk for recurrent UTIs (e.g., removal of obstructions and repair of vesicoureteral

reflux). Procedures may include cystoscopy (see Chapter 65) to identify and remove calculi or obstructions.

Community-Based Care

Assess the patient's level of understanding of the problem. His or her knowledge about factors that promote the development of cystitis determines the teaching interventions planned.

Teach the patient how to take prescribed drugs. Stress the need for correct spacing of doses throughout the day and the need to complete all of the prescribed antibiotics. If the drug will change the color of the urine, as it does with phenazopyridine (Pyridium, Urogesic, Phenazo), inform the patient to expect this change.

Patients may associate discomfort with sexual activities and have feelings of guilt and embarrassment. Open and sensitive discussions with a woman who has recurrences of UTI after sexual intercourse can help her find techniques to handle the problem (see Chart 66-2). Explore with her the factors that contribute to her infections, such as sexual penetration when the bladder is full, diaphragm use, and her general resistance to infection. Some positions during intercourse may reduce urethral irritation and subsequent cystitis. Remind the patient that vigorous cleaning of the perineum with harsh soaps and vaginal douching may irritate the perineal tissues and *increase* the risk for UTI. At the patient's request, discuss the problem with her and her partner to help them find ways of maintaining their intimate relationship.

Urethritis

Pathophysiology

Urethritis is an inflammation of the urethra. In men, manifestations include burning or difficulty urinating and a discharge from the urethral meatus. The most common cause of urethritis in men is sexually transmitted diseases (STDs). These include gonorrhea or nonspecific urethritis caused by *Ureaplasma* (a gram-negative bacterium), *Chlamydia* (a sexually transmitted gram-negative bacterium), or *Trichomonas vaginalis* (a protozoan found in both the male and female genital tract).

In women, urethritis causes manifestations similar to those of cystitis. Urethritis is known by several other terms: *pyuria-dysuria syndrome, frequency-dysuria syndrome, trigonitis syndrome,* and *urethral syndrome.* Urethritis is most common in postmenopausal women and is probably caused by tissue changes related to low estrogen levels.

Patient-Centered Collaborative Care

Ask the patient about a history of STD, painful or difficult urination, discharge from the penis or vagina, and discomfort in the lower abdomen. Urinalysis may show **pyuria** (white blood cells [WBCs] in the urine) without a large number of bacteria. However, results of urethral culture may indicate an STD. In women, the diagnosis may be made when urinalysis and urethral culture are negative for bacteria and there is no evidence of interstitial cystitis but manifestations persist. In such cases, pelvic examination may reveal tissue changes from low estrogen levels in the vagina. Urethroscopy may show low estrogen changes with inflammation of urethral tissues.

STDs and infection are treated with antibiotic therapy. More information on STDs can be found in Chapter 74.

Postmenopausal women often have improvement in their urethral symptoms with the use of estrogen vaginal cream. Estrogen cream applied locally to the vagina increases the amount of estrogen in the urethra as well, and irritating manifestations are reduced.

Noninfectious Disorders

Urethral Strictures

Urethral strictures are narrowed areas of the urethra. These problems may be caused by complications of an STD (usually gonorrhea) and by trauma during catheterization, urologic procedures, or childbirth. About one third of urethral strictures have no obvious cause. Strictures occur more often in men than in women. They may be a factor in other urologic problems, such as recurrent UTIs, urinary incontinence, and urinary retention.

The most common manifestation of urethral stricture is obstruction of urine flow. Strictures rarely cause pain. Because urine stasis can result when flow is obstructed, the patient is at risk for developing a UTI and may have overflow incontinence. **Overflow incontinence** is the involuntary loss of urine when the bladder is overdistended. Assess the patient for these two problems.

A urethral stricture is treated surgically. Dilation of the urethra (using a local anesthetic) is only a temporary measure, not a curative one. Stent placement can be used in some patients. The best chance of long-term cure is with **urethroplasty**, which is the surgical removal of the affected area with or without grafting to create a larger opening. The recurrence rate after surgery is still high, and most patients need repeated procedures. The urethral stricture location and length are the most important factors affecting choice of interventions and recovery.

Urinary Incontinence

❖ Pathophysiology

Continence is the control over the time and place of urination and is unique to humans and some domestic animals. It is a learned behavior in which a person can suppress the urge to urinate until a socially appropriate location is available (e.g., a toilet). Efficient bladder emptying (i.e., coordination between bladder contraction and urethral relaxation) is needed for continence.

Incontinence is an involuntary loss of urine severe enough to cause social or hygienic problems. It is *not* a normal consequence of aging or childbirth and often is a stigmatizing and an underreported health problem. Many people suffer in silence, are socially isolated, and may be unaware that treatment is available. In addition, the cost of incontinence can be enormous.

Continence occurs when pressure in the urethra is greater than

pressure in the bladder. For normal voiding to occur, the urethra must relax and the bladder must contract with enough pressure and duration to empty completely. Voiding should occur in a smooth and coordinated manner under a person's conscious control. Incontinence has several possible causes and can be either temporary or chronic (Table 66-2). Temporary causes usually do not involve a disorder of the urinary tract. The most common types of adult urinary incontinence are stress incontinence, urge incontinence, overflow incontinence, functional incontinence, and a mixed form.

TABLE 66-2

Types of Urinary Incontinence

TYPE	DEFINITION/DESCRIPTION	CAUSE	CLINICAL MANIFESTATIONS
Stress incontinence	The involuntary loss of urine during activities that increase abdominal and detrusor pressure. Patients cannot tighten the urethra sufficiently to overcome the increased detrusor pressure; leakage of urine results.	Weakening of bladder neck supports; associated with childbirth. Intrinsic sphincter deficiency caused by such congenital conditions as epispadias (abnormal location of the urethra on the dorsum of the penis) or myelomeningocele. Acquired anatomic damage to the urethral sphincter (from repeated incontinence surgeries, prostatectomy, radiation therapy, and trauma).	Urine loss with physical exertion, cough, sneeze, or exercise. Usually only small amounts of urine are lost with each exertion. Normal voiding habits (≤8 times per day, ≤2 times per night). Post-void residual usually ≤50 mL. Pelvic examination shows hypermobility of the urethra or bladder neck with Valsalva maneuvers.
Urge incontinence	The involuntary loss of urine associated with a strong desire to urinate. Patients cannot suppress the signal from the bladder muscle to the brain that it is time to urinate.	Unknown.	An abrupt and strong urge to void. May have loss of large amounts of urine with each occurrence.
Detrusor hyperreflexia (reflex incontinence)	The abnormal detrusor contractions result from neurologic abnormalities.	Central nervous system (CNS) lesions from stroke, multiple sclerosis, and parasacral spinal cord lesions. Local irritating factors such as caffeine, medications, or bladder tumor.	Post-void residual ≤50 mL.
Overflow incontinence	The involuntary loss of urine associated with overdistention of the bladder when the bladder's capacity has reached its maximum. The urethra is obstructed, so it fails to relax sufficiently to allow urine to flow, resulting in incomplete bladder emptying or complete urinary retention, causing overflow incontinence.	Diabetic neuropathy; side effects of medication; after radical pelvic surgery or spinal cord damage; outlet obstruction. Causes external to the mechanism of the urethra: an enlarged prostate (male patients) and large genital prolapse (female patients). When the cause is intrinsic to the urethra, abnormal contraction of the skeletal muscle occurs, causing obstruction. This condition, called *detrusor dyssynergia*, is seen in patients with spinal cord injuries and multiple sclerosis.	Bladder distention, often up to the level of the umbilicus. Constant dribbling of urine.
Mixed incontinence	A combination of stress, urge, and overflow incontinence.	As with each separate disorder.	As with each separate disorder.
Functional incontinence	Leakage of urine caused by factors other than disease of the lower urinary tract.		Quantity and timing of urine leakage vary; patterns are difficult to discern.
Transient causes	Transient causes improve with treatment of the underlying condition.	Loss of cognitive functioning. Loss of awareness that urination is to occur in a socially acceptable place.	Altered mental state, as in delirium, confusion, depression, dementia, sepsis, mental illness, or severe psychological stress.
		Abnormal openings in the urinary tract, such as a fistula or diverticulum.	Urinary drainage noted from areas other than the urinary meatus.
		Drugs, such as sedatives, hypnotics, diuretics, anticholinergics, decongestants, antihypertensives, and calcium channel blockers.	Some drugs cause altered mental state; others cause increased urine production.
		Diabetes insipidus or psychogenic polydipsia.	Increased urine output.
		Inability to get to toileting facilities.	Restraints, restricted mobility.
		Direct bladder pressure or urethral obstruction.	Constipation or fecal impaction.
Permanent causes	Permanent causes are organic but may be improved with treatment.	Cognitive impairment. Traumatic or surgical effects. Those factors contributing to stress incontinence, urge incontinence, and overflow incontinence. Structural or functional defects of the bladder or the sphincters. Injuries or diseases of the spinal cord, brainstem, or cerebral cortex (neurogenic bladder). Congenital defects, including exstrophy of the bladder (bladder turned "inside out") and spina bifida.	Clinical manifestations depend on the cause.

Stress incontinence is the most common type. Its main feature is the loss of small amounts of urine during coughing, sneezing, jogging, or lifting. In the continent person, the urethra can be relaxed and tightened under conscious control because skeletal muscles of the pelvic floor surround it. When a person feels the urge to urinate, the conscious contraction of

the urethra can override a bladder contraction if the urethral contraction is strong enough.

Patients with *stress incontinence* cannot tighten the urethra enough to overcome the increased bladder pressure caused by contraction of the detrusor muscle. This is common after childbirth, when the pelvic muscles are stretched and weakened. The weakened pelvic floor allows the urethra to move during exertion. If the pelvic muscles are not strengthened, this condition continues. Low estrogen levels after menopause also contribute to stress incontinence. Vaginal, urethral, and pelvic floor muscles become thin and weak without estrogen.

Urge incontinence is the perception of an urgent need to urinate as a result of bladder contractions regardless of the urine volume in the bladder. Normally when the bladder is full, contraction of the smooth muscle fibers of the bladder detrusor muscle signals the brain that it is time to urinate. Continent people override that signal and relax the detrusor muscle for the time it takes to locate a toilet. Those who suffer from urge incontinence cannot suppress the signal and have a sudden strong urge to void and often leak large amounts of urine at this time. Urge incontinence is also known as an *overactive bladder* (OAB). Overactivity may have no known cause or may be the result of abnormal detrusor contractions related to other problems. Such problems include stroke and other neurologic problems, other urinary tract problems, and irritation from concentrated urine, artificial sweeteners, caffeine, alcohol, and citric intake. Drugs, such as diuretics, and nicotine can also irritate the bladder.

Mixed incontinence is the presence of more than one type of incontinence. Often urine loss is related to both stress and urge incontinence. The manifestations mimic more than one subtype. This category is more common in older women.

Overflow incontinence occurs when the detrusor muscle fails to contract and the bladder becomes overdistended. This type of incontinence (also known as *reflex incontinence* or *underactive bladder*) occurs when the bladder has reached its maximum capacity and some urine must leak out to prevent bladder rupture. Causes for the underactive (acontractile) bladder may or may not be determined.

The urethra can be obstructed and fail to relax enough to allow urine flow. Incomplete bladder emptying or urinary retention from urethral obstruction results in overflow incontinence.

Functional incontinence is incontinence occurring as a result of factors other than the abnormal function of the bladder and urethra. A common factor is the loss of cognitive function in patients affected by dementia.

To maintain continence, a person must be aware that urination needs to occur in a socially acceptable place. Patients with dementia may not have that awareness.

Etiology

Incontinence may have temporary or permanent causes. Evaluation of the incontinent patient means considering all possible causes, beginning with those that are temporary and correctable. Surgical and traumatic causes of urinary incontinence are related to procedures or surgery in the lower pelvic structures, which are areas that contain complex nerve pathways. Radical urologic, prostatic, and gynecologic procedures for treatment of pelvic cancers may result in urinary incontinence. Injury to segments S2 to S4 of the spinal cord may cause incontinence from impairment of normal nerve pathways.

Inappropriate bladder contraction may result from disorders of the brain and nervous system or from bladder irritation due to chronic infection, stones, chemotherapy, or radiation therapy. Other causes of bladder contraction failure include the neuropathies associated with diabetes mellitus and syphilis. Constipation can lead to temporary urinary incontinence. Some drugs, such as anticholinergics, calcium channel blockers, diuretics, and sedatives, can cause or worsen urinary incontinence.

Considerations for Older Adults

Patient-Centered Care QSEN

Many factors contribute to urinary incontinence in older adults (Chart 66-5). An older person may have decreased mobility from many causes. In inpatient settings, mobility is limited when the older patient is placed on bedrest. Vision and hearing impairments may also prevent the patient from locating a call light to notify the nurse or assistive personnel of the need to void. Assess for these factors, and minimize them to prevent urinary incontinence. Getting out of bed to urinate is a common cause of falls among older adults.

Chart 66-5 Nursing Focus on the Older Adult

Factors Contributing to Urinary Incontinence*

Drugs

- Central nervous system depressants, such as opioid analgesics, decrease the patient's level of consciousness and the urge to void, and they contribute to constipation.
- Diuretics cause frequent voiding, often of large amounts of urine.
- Multiple drugs can contribute to changes in mental status or mobility, and they can irritate the bladder.
- Anticholinergic drugs or drugs with anticholinergic side effects are especially challenging because they affect both cognition and the ability to void. Monitor patient responses to these drugs early in treatment.

Disease

- Cerebrovascular accidents and other neurologic disorders decrease mobility, sensation, or cognition.
- Arthritis decreases mobility and causes pain.
- Parkinson disease causes muscle rigidity and an inability to initiate movement.

Depression

- Depression decreases the energy necessary to maintain continence.
- Decreased self-esteem and feelings of self-worth decrease the importance to the patient of maintaining continence.

Inadequate Resources

- Patients who need assistive devices (e.g., eyeglasses, cane, walker) may be afraid to ambulate without them or without personal assistance.
- Products that help patients manage incontinence are often costly.
- No one may be available to assist the patient to the bathroom or help with incontinence products.

*These factors are in addition to the physiologic changes of aging given in Chapter 2.

Incidence and Prevalence

Incontinence is a major health problem. As many as 25% to 45% of woman report some degree of urinary incontinence with roughly half as many men reporting this condition (Buckley et al., 2010). It is most common in older adults and in at least one half of all nursing home residents.

Increased risk for urinary incontinence occurs with pregnancy,

childbirth, diabetes mellitus, and increased body mass (Buckley et al., 2010). Urinary incontinence can occur as an isolated condition or with other chronic health problems. In addition, impairments from central nervous system diseases (i.e., dementia, stroke, multiple sclerosis, Parkinson disease) and musculoskeletal disorders (i.e., osteoporosis, osteoarthritis, low back pain) contribute to reduced leg strength and mobility limitations resulting in the onset and severity of urinary incontinence (McCance et al., 2014). More than 35% of adults admitted to the hospital develop urinary incontinence (Dowling-Castronovo & Bradway, 2012). Because the problem is so common among older adults, it is recommended that all people older than 65 years be screened for urinary incontinence (DuBeau, 2013).

Patient-Centered Collaborative Care

Assessment

History.

Effective screening includes asking patients to respond "always," "sometimes," or "never" to these questions:

- Do you ever leak urine or water when you don't want to?
- Do you ever leak urine or water when you cough, laugh, or exercise?
- Do you ever leak urine or water on the way to the bathroom?
- Do you ever use pads, tissue, or cloth in your underwear to catch urine?

If any answer is "always" or "sometimes," proceed with a focused assessment (Chart 66-6). Incontinence may be underreported because health care professionals do not ask patients about urine loss. *Do not assume that patients will volunteer the information without specifically being asked.*

Chart 66-6 Focused Assessment

The Patient with Urinary Incontinence

Note the presence of risk factors for urinary incontinence:

- Age
- If female, menopausal status
- Neurologic disease:
  - Parkinson disease
  - Dementia
  - Multiple sclerosis

- Stroke
- Spinal injury
- Diabetes mellitus
- Childbirth
- Urologic procedures
- Prescribed and over-the-counter drugs
- Bowel patterns
- Stress/anxiety level

Detail the symptoms of urinary incontinence:

- Leakage
- Frequency
- Urgency
- Nocturia
- Sensation of full bladder before leakage

Obtain a 24-hour intake-and-output record or a voiding diary:

- Time and amount of oral intake and continent voiding
- Time and estimated amount of incontinent leakages
- Activity around the time of leakage

Assess the patient's:

- Mobility
- Self-care ability
- Cognitive ability
- Communication patterns

Assess the environment for barriers to toileting:

- Privacy
- Restrictive clothing
- Access to toilet

Physical Assessment/Clinical Manifestations.

Assess the abdomen to estimate bladder fullness, to rule out palpable hard stool, and to evaluate bowel sounds. Urinary incontinence is confirmed by evaluating the force and character of the urine stream during voiding. Asking the patient to cough while wearing a perineal pad is useful in evaluating stress incontinence; a wet pad on forceful coughing may indicate stress incontinence.

For women, inspect the external genitalia to determine whether there is apparent urethral or uterine prolapse, **cystocele** (herniation of the bladder into the vagina), or rectocele. These conditions occur with pelvic floor muscle weakness. A health care provider puts on an examination glove and inserts two fingers into the vagina to assess the strength of these muscles. Strength is described as *weak*, *adequate,* or *strong* based on

the amount of pressure felt by the health care provider as the patient tightens her vaginal muscles. Describe and document the color, consistency, and odor of any secretions from the genitourinary orifices. The urine stream interruption test (i.e., asking a patient to voluntarily start and stop urine flow during a void at least twice) is another method of determining pelvic muscle strength. For men, inspect the urethral meatus for any discharge.

A digital rectal examination (DRE) is performed by the health care provider on both male and female patients. It provides information about the nerve integrity to the bladder. The examiner determines whether there is tactile sensation in the anal area by observing whether the rectal sphincter is relaxed or contracted on digital insertion. Because nerve supply to the bladder is similar to nerve supply to the rectum, the presence of tactile sensation and a rectal sphincter that contracts suggest that the nerve supply to the bladder is intact. Impaction of stool is a cause of transient urinary incontinence and can be detected during a rectal examination. The health care provider assesses for prostate enlargement in men as a possible cause of incontinence.

Laboratory Assessment.

A urinalysis is useful to rule out infection. This test is the first step in the assessment of incontinent patients of any age. The presence of red blood cells (RBCs), white blood cells (WBCs), leukocyte esterase, or nitrites is an indication for culturing the urine. Any infection is treated before further assessment of incontinence.

Imaging Assessment.

Determine the amount of post-void residual urine (urine remaining in the bladder immediately after voiding) by portable ultrasound. With a health care provider's order, catheterizing the patient immediately after voiding can also be used to assess residual volume. Additional imaging is rarely needed unless surgery is being considered. CT is most useful for locating abnormalities in kidneys and ureters. A voiding cystourethrogram (VCUG) or urodynamic testing may be performed to assess the size, shape, support, and function of the urinary tract system. Urodynamic testing (see Chapter 65) may take several hours and more than one visit. Electromyography (EMG) of the pelvic muscles may be a part of the urodynamic studies.

Analysis

The priority NANDA-I nursing diagnoses and collaborative problems for

patients with urinary incontinence include:
1. Stress Urinary Incontinence related to weak pelvic muscles and structural supports (NANDA-I)
2. Urge Urinary Incontinence related to decreased bladder capacity, bladder spasms, diet, and neurologic impairment (NANDA-I)
3. Reflex Urinary Incontinence related to neurologic impairment (NANDA-I)
4. Functional Urinary Incontinence related to impaired cognition or neuromuscular limitations (NANDA-I)
5. Total urinary incontinence (mixed) related to many causes

Planning and Implementation

Several interventions are useful for each type of incontinence in addition to drugs, surgical repair, and nutrition therapy.

Reducing Stress Urinary Incontinence

Planning: Expected Outcomes.

With appropriate therapy, the patient with stress urinary incontinence is expected to develop urinary continence. Indicators include that the patient rarely or never demonstrates these problems:
- Urine leakage between voidings
- Urine leakage with increased abdominal pressure (e.g., sneezing, laughing, lifting)

Interventions.

Initial interventions for patients with stress incontinence include keeping a diary, behavioral interventions, and drugs. Surgery also may be an option if other interventions are not effective. Explain the purpose of a detailed diary in which the patient records times of urine leakage, activities, and foods eaten. The diary is then used by the health care provider to plan and evaluate interventions. Collection devices, absorbent pads, and undergarments may be used during the sometimes lengthy process of assessment and treatment and by those patients who elect not to pursue further interventions.

Nonsurgical Management.

Drug therapy and behavioral interventions (primarily diet and exercise) for stress incontinence require the patient's active participation for success. Nursing interventions focus on teaching patients about the drugs and behavioral strategies and on providing ongoing

encouragement, clarification, and support to maximize intervention effects.

Pelvic floor (Kegel) exercise therapy for women with stress incontinence strengthens the muscles of the pelvic floor (circumvaginal muscles). These muscles become strengthened, as any other skeletal muscle does, by frequent, systematic, and repeated contractions. Pelvic floor muscle training improves not only continence but also quality of life in women with urinary incontinence (Fan et al., 2013).

The most important step in teaching pelvic muscle exercises is to help the patient learn which muscle to exercise. During the pelvic examination in women and the rectal examination in men or women, instruct the patient to tighten the pelvic muscles around your fingers. Then provide feedback about the strength of the contraction. Starting and stopping the urine stream or stopping the passage of flatus indicates that the patient has correctly identified the pelvic muscles. Biofeedback devices, such as electromyography or perineometers, measure the strength of contraction. A perineometer is a tampon-shaped instrument inserted into the vagina to measure the strength of pelvic muscle contractions. The graph shows the amplitude of muscle contraction to the patient as a method of biofeedback. Alternatively, retention of a vaginal weight also shows that the patient has identified the proper muscle (see discussion on vaginal cone therapy below).

Instructions for pelvic muscle exercises are given in Chart 66-7. Although improvement may take several months, most patients notice a positive change after 6 weeks. Teach patients to continue the exercises 10 times daily to improve and maintain pelvic muscle strength.

Chart 66-7 Patient and Family Education: Preparing for Self-Management

Pelvic Muscle Exercises

- The pelvic muscles are composed of a sling of muscles that support your bladder, urethra, and vagina. Like any other muscles in your body, you can make your pelvic muscles stronger by alternately contracting (tightening) and relaxing them in regular exercise periods. By strengthening these muscles, you will be able to stop your urine flow more effectively.
- To identify your pelvic muscles, sit on the toilet with your feet flat on the floor about 12 inches apart. Begin to urinate, and then try to stop the urine flow. Do not strain down, lift your bottom off the seat, or

squeeze your legs together. When you start and stop your urine stream, you are using your pelvic muscles.

- To perform pelvic muscle exercises, tighten your pelvic muscles for a slow count of 10 and then relax for a slow count of 10. Do this exercise 15 times while you are lying down, sitting up, and standing (a total of 45 exercises). Repeat—and this time rapidly contract and relax the pelvic muscles 10 times. This should take no more than 10 to 12 minutes for all three positions, or 3 to 4 minutes for each set of 15 exercises.
- Begin with 45 exercises a day in three sets of 15 exercises each. You will notice faster improvement if you can do this twice a day, or a total of 20 minutes each day. Remember to exercise in all three positions so your muscles learn to squeeze effectively despite your position. At first, it is helpful to have a designated time and place to do these exercises because you will have to concentrate to do them correctly. After you have been doing them for several weeks, you will notice improvement in your control of urine. However, many people report that improvement may take as long as 3 months.

Nutrition therapy in the form of weight reduction is helpful for obese patients because stress incontinence is made worse by increased abdominal pressure from obesity (Wilde et al., 2014). Teach the patient to avoid bladder irritants in the diet that can contribute to urgency and frequency. For example, caffeine is a bladder irritant (Jura et al., 2011). Stress the importance of maintaining an adequate fluid intake, especially water. Refer the patient to a registered dietitian as needed.

Drug therapy can be useful for some people with stress incontinence. Because bladder pressure is greater than urethral resistance in patients with stress incontinence, drugs may be used to improve urethral resistance (Chart 66-8).

Chart 66-8 Common Examples of Drug Therapy

Urinary Incontinence

DRUG/DOSAGE	NURSING INTERVENTIONS	RATIONALES
Hormones—Thought to Enhance Nerve Conduction to the Urinary Tract, Improve Blood Flow, and Reduce Tissue Deterioration of the Urinary Tract.		
*Estrogen vaginal cream daily or an estrogen-containing ring inserted monthly	Teach patients that a thin application of the cream is all that is needed. Teach patients that it takes 4-6 wks to achieve continence benefits and that benefits disappear after about 4 weeks after discontinuing regular use.	Topical use minimizes the amount of estrogen absorbed and distributed in the body. A thick application increases risk for systemic distribution. Topical administration via a cream or ring avoids systemic adverse drug effects from this hormone but also takes longer for effects.
Antispasmodics—Reduce Incontinence By Causing Bladder Muscle Relaxation.		
Oxybutynin (Ditropan) 5 mg orally 3-4 times daily; (Ditropan XL) 5-10 mg orally daily	Ask whether the patient has glaucoma before starting the drug.	Anticholinergics can increase intraocular pressure and make glaucoma worse.
	Suggest that patients increase fluid intake and use hard candy to moisten the mouth.	Dry mouth is a common side effect of drugs in this category.
	Teach patients to increase fluid intake and the amount of dietary fiber.	Constipation is a common side effect of drugs in this category.
	Teach patients to monitor urine output and to report an output significantly lower than intake to the health care provider.	Drugs in this category can cause urinary retention.
	Instruct patients taking the extended-release forms of these drugs not to chew or crush the tablet/capsule.	Crushing or chewing the tablet/capsule releases all the drug at once, ruining the extended effect and increasing the possibility of side effects.
Anticholinergics—Suppress Involuntary Bladder Contraction, Increase Urine Volume and May Increase the Bladder Capacity.		
Tolterodine (Detrol) 2 mg orally twice daily; (Detrol LA) 4 mg orally daily Propantheline (Pro-Banthine, Propanthel) 7.5-30 mg orally 3-4 times daily Dicyclomine (Bamine, Bentyl) 10-40 mg orally 3-4 times daily Trospium (Sanctura) 20 mg orally every 12 hr Darifenacin (Enablex) 7.5-15 mg orally daily Solifenacin (Vesicare) 5-10 mg orally daily Fesoterodine (Toviaz) 4-8 mg orally daily	Ask whether the patient has glaucoma before starting the drug.	These drugs can increase intraocular fluid and pressure.
	Do not use these drugs if prostate hypertrophy co-exists.	These drugs can worsen urinary retention from prostate hypertrophy.
	Teach patients to avoid dehydration and increase the amount of dietary fiber to avoid constipation.	These drugs can cause significant constipation.
	Evaluate kidney function before starting and at least annually.	These drugs may have decreased renal clearance and should either be avoided or administered in a reduced dose in patients with renal insufficiency.
	Instruct the patient to avoid crushing or chewing tablets.	Most of the once-daily drugs are a long-acting formulation and should not be crushed or chewed.
Alpha Adrenergic Agonists—Increase Contractile Force of the Urethral Sphincter, Increasing Resistance to Urine Outflow.		
*Midorine (ProAmatine, Orvaten) 2.5-5 mg orally every 8-12 hr *Pseudoephedrine (Sudafed, SudoGest) 30 mg orally; also comes in an extended-release formulation	Teach the patient to monitor his or her blood pressure periodically when starting the drug.	These drugs can cause a supine hypertension; do not use with severe cardiac disease.
Beta$_3$ Blockers—Relax the Detrusor Smooth Muscle to Increase Bladder Capacity and Urine Storage.		
Mirabegron (Myrbetriq) 25 mg orally daily	Teach the patient to periodically obtain a blood pressure and to inform the health care provider if the systolic or diastolic values increase more than 10 mm Hg or above 180/110.	Because it is a selective beta blocker, there is some potential to increase blood pressure.
	If the patient is taking warfarin, avoid this drug or schedule additional blood testing for potential increased risk for bleeding.	This drug may interact with warfarin due to similar metabolic pathways, resulting in prolonged international normalized ratio (INR), the test to evaluate warfarin effects.
Antidepressants: Tricyclics and Serotonin-Norepinephrine Reuptake Inhibitors (SNRIs)—Increase Norepinephrine and Serotonin Levels, Which Are Thought to Strengthen the Urinary Sphincters. They Also Have Anticholinergic Actions.		
Tricyclics Imipramine (Tofranil, Novo-Pramine) 25-100 mg orally 4 times daily Amitriptyline (Elavil, Levate) 10-25 mg orally daily *SNRI* *Duloxetine (Cymbalta) 20-60 mg orally daily	Warn patients not to combine these drugs with other antidepressant drugs. Instruct patients to inform their provider if they take drugs to manage hypertension.	These drugs have significant drug-drug interactions with other antidepressants and with some antihypertensive drugs, leading to hypertensive crisis.
	Teach patients to change positions slowly, especially in the morning.	These drugs cause dizziness and orthostatic hypotension and can increase the risk for falls.
	Teach patients the same interventions as for anticholinergic agents.	These drugs have anticholinergic activity and produce the same side effects.

*These drugs are used off-label and do not have United States Food and Drug Administration (FDA) approval for use. However, they are commonly used to manage incontinence syndromes.

Topical estrogen to the perineal and vaginal orifice is used to treat postmenopausal women with stress incontinence, although it is not known exactly how this drug helps improve continence. Estrogen may increase the blood flow and tone of the muscles around the vagina and urethra, thus improving the patient's ability to contract those muscles

during times of increased intra-abdominal stress.

Vaginal cone therapy involves using a set of five small, cone-shaped weights. They are of equal size but of varying weights and are used together with pelvic muscle exercise. The woman inserts the lightest cone, labeled *1*, into her vagina (Fig. 66-1), with the string to the outside, for a 1-minute test period. If she can hold the first cone in place without its slipping out while she walks around, she proceeds to the second cone, labeled *2*, and repeats the procedure. The patient begins her treatment with the heaviest cone she can comfortably hold in her vagina for the 1-minute test period. Treatment periods are 15 minutes twice a day. When the patient can comfortably hold the cone in her vagina for the 15-minute period, she progresses to the next heaviest weight. Treatment is completed with the cone labeled *5*.

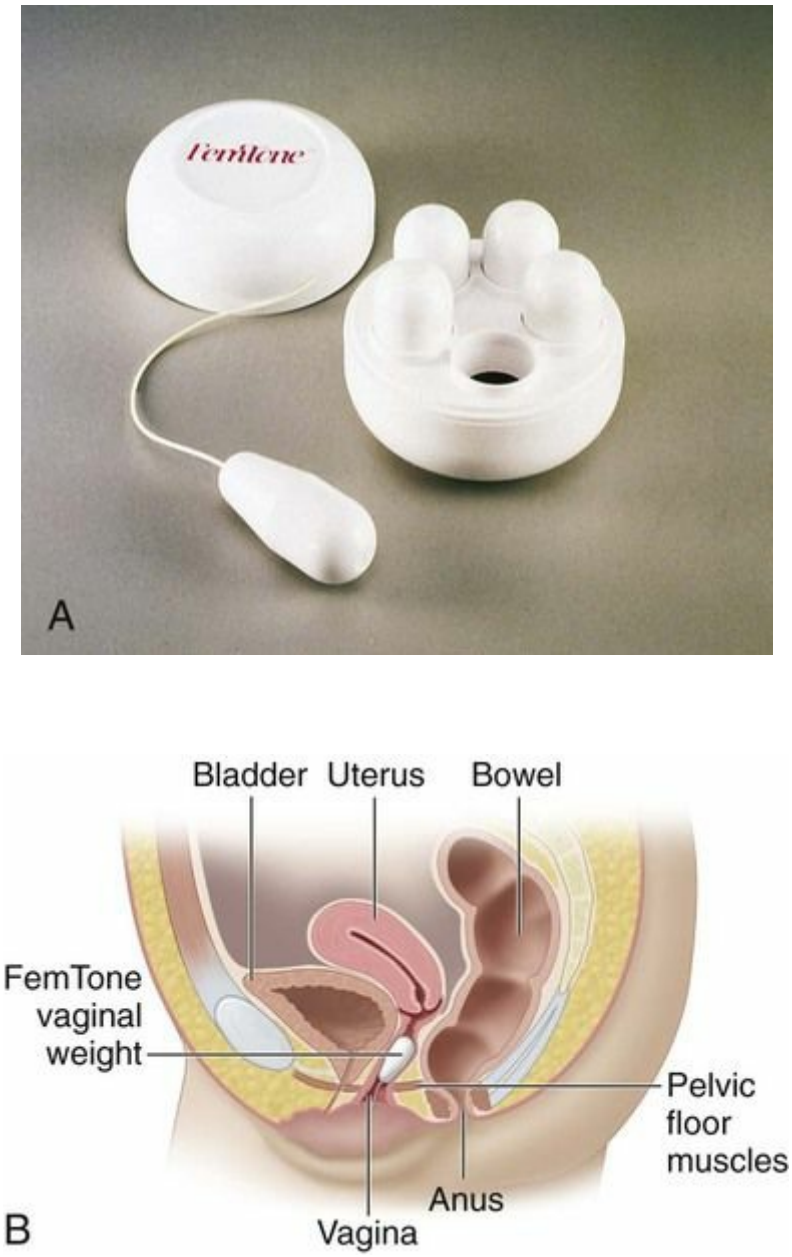

FIG. 66-1 **A,** FemTone vaginal weights, or cones. The number on the top of each cone represents increasing weight up to the heaviest cone, a *5*. **B,** Diagram showing the correct positioning of a vaginal weight, or cone, in place.

Weighted vaginal cones can help strengthen the pelvic muscles and decrease stress incontinence but may not help pelvic prolapse. Vaginal cones do not require a prescription.

Other interventions for stress incontinence include behavior modification, psychotherapy, and electrical stimulation devices to strengthen urethral contractions. Many intravaginal and intrarectal electrical stimulation devices have been used with varying degrees of success.

A ring-shaped *pessary* inserted into the vagina may help with a prolapsed uterus or bladder when this condition is contributing to

urinary incontinence. A prolapse occurs when the supportive tissue in the vagina weakens and stretches, allowing pelvic organs to protrude into the vaginal lumen. The pessary presses against the wall of the vagina to reposition pelvic organs. Generally, a pessary is removed and cleaned with soap and water on a monthly basis by the patient but can be done by the nurse for adults with cognitive or musculoskeletal impairment.

Urethral occlusion devices can be particularly helpful for activity-induced incontinence. One device, the Reliance insert, is like a tiny tampon that the patient inserts into the urethra. After insertion, the patient inflates a tiny balloon, which rests at the bladder neck and prevents the flow of urine. To void, the patient pulls a string to deflate the balloon and removes the device. The applicator is reusable, although the tampon part is disposed of after each void.

Electrical stimulation with either an intravaginal or intrarectal electrical stimulation device is available to treat both urge and stress incontinence. Treatment consists of stimulating sensory nerves to decrease the sensation of urgency. It is done as an office-based procedure 1 to 3 times weekly for 6 to 8 weeks.

Magnetic resonance therapy involves targeted urinary tract nerves and muscles for depolarization. The patient sits on a chair containing a magnetic device, which induces depolarization and helps reduce stress-induced incontinence similar to drug-induced relaxation of muscle and nerves.

Surgical Management.

Stress incontinence may be treated by a surgical sling or bladder suspension procedure (Table 66-3). A sling procedure creates a sling around the bladder neck and urethra using strips of body tissue or synthetic material (mesh). Bladder suspension procedures are more extensive, and the surgeon sutures tissue near the bladder neck to a pubic bone ligament to provide support and prevent sagging. A third surgical procedure is the injection of bulking agents into the urethral wall to provide resistance to urine outflow. Bulking agents include collagen, carbon-coated zirconium beads, and silicone implants (Shultz, 2012).

TABLE 66-3

Surgical Procedures for Stress Incontinence

PROCEDURE	PURPOSE	NURSING CONSIDERATIONS
Anterior vaginal repair (colporrhaphy)	Elevates the urethral position and repairs any cystocele.	Because the operation is performed by vaginal incision, it is often done in conjunction with a vaginal hysterectomy. Recovery is usually rapid, and a urethral catheter is in place for 24-48 hr.
Retropubic suspension (Marshall-Marchetti-Krantz or Burch colposuspension)	Elevates the urethral position and provides longer-lasting results.	The operation requires a low abdominal incision and a urethral or suprapubic catheter for several days postoperatively. Recovery takes longer, and urinary retention and detrusor instability are the most frequent complications.
Needle bladder neck suspension (Pereyra or Stamey procedure)	Elevates the urethral position and provides longer-lasting results without a long operative time.	The combined vaginal approach with a needle and a small suprapubic skin incision does not allow direct vision of the operative site; however, the high complication rates may be due to the selection of patients who, because of their medical condition, are not good candidates for longer retropubic procedures.
Pubovaginal sling procedures	A sling made of synthetic or fascial material is placed under the urethrovesical junction to elevate the bladder neck.	The operation uses an abdominal, vaginal, or combined approach to treat intrinsic sphincter deficiencies. Temporary or permanent urinary retention is common postoperatively.
Midurethral sling procedures	A tensionless vaginal sling is made from polypropylene mesh (or other materials) and placed near the urethrovesical junction to increase the angle, which inhibits movement of urine into the urethra with lower intravesicular pressures.	This ambulatory surgery procedure uses a vaginal approach to improve symptoms of stress incontinence. Temporary or permanent urinary retention is common postoperatively.
Artificial sphincters	A mechanical device to open and close the urethra is placed around the anatomic urethra.	The operation is done more frequently in men. The most common complications include mechanical failure of the device, erosion of tissue, and infection.
Periurethral injection of collagen or Siloxane	Implantation of small amounts of an inert substance through several small injections provides support around the bladder neck.	The procedure can be done in an ambulatory care setting and can be repeated as often as necessary. Certain compounds may migrate after injection; an allergy test to bovine collagen must be performed before implantation.

Preoperative Care.

Teach the patient about the procedure, and clarify the surgeon's

explanation of events surrounding the surgery. Extensive urodynamic testing (see Chapter 65) is often performed before surgery, and you must explain the need for such thorough assessment to the patient and family.

Postoperative Care.

After surgery, assess for and intervene to prevent or detect complications. For prevention of movement or traction on the bladder neck, secure the urethral catheter with tape or a tube holder. If a suprapubic catheter is used instead of a urethral catheter, monitor the dressing for urine leakage and other drainage. Catheters are usually in place until the patient can urinate easily and has residual urine volume after voiding of less than 50 mL. (See Chapters 14 and 16 for a discussion of general care before and after surgery.)

Reducing Urge Urinary Incontinence

Planning: Expected Outcomes.

The patient with urinary incontinence is expected to use techniques to prevent or manage urge incontinence. Indicators include that the patient often or consistently demonstrates these behaviors:

- Responds to urge in a timely manner
- Gets to toilet between urge and passage of urine
- Avoids substances that stimulate the bladder (e.g., caffeine, alcohol)

Interventions.

Interventions for patients with urge incontinence or overactive bladder (OAB) include neuromodulation, drugs, and behavioral interventions. *Neuromodulation* therapy, which involves stimulation of the nerves to the bladder, can be used to manage urge incontinence. The device requires minor surgery to place the device. Other types of surgery are not the recommended treatment of this condition.

Drug Therapy.

Because the hypertonic bladder contracts involuntarily in patients with urge incontinence, drugs that relax the smooth muscle and increase the bladder's capacity are prescribed (see Chart 66-8). The most effective drugs are anticholinergics, such as propantheline (Pro-Banthine, Propanthel), and anticholinergics with smooth muscle relaxant properties, such as oxybutynin (Ditropan and Ditropan XL), tolterodine (Detrol and Detrol LA), and dicyclomine hydrochloride (Baramine, Bentyl, Spasmoban). This class of drugs has serious side effects and is

used along with behavioral interventions. These drugs inhibit the nerve fibers that stimulate bladder contraction. Tricyclic antidepressants with anticholinergic and alpha-adrenergic agonist activity, such as imipramine (Tofranil, Novopramine), have been used successfully. The effectiveness of other drugs, such as flavoxate (Urispas) and the antihistamines, NSAIDs, beta-adrenergic agonists, and calcium channel blockers, has yet to be determined.

Another drug therapy for urge incontinence is onabotulinumtoxinA (Botox), which received approval in 2013 from the U.S. Food and Drug Administration (FDA) for this use. The drug is injected during cystoscopy into multiple areas of the detrusor muscle of the bladder. Usually, 10 to 30 different sites are injected during one treatment session. This treatment relaxes the detrusor muscle and relieves the urge to urinate. Some patients have had relief of incontinence for as long as 6 to 9 months after injection. Side effects may include urinary retention, painful urination, and an increased incidence of urinary tract infections. For most patients who experience urinary retention, the condition is temporary but does require intermittent self-catheterization.

Nursing Safety Priority QSEN

Drug Alert

Teach patients taking the extended-release forms of anticholinergic drugs to swallow the tablet or capsule whole without chewing it or crushing it. Chewing or crushing the tablet/capsule ruins the extended-release feature, allowing the entire dose to be absorbed quickly, which increases drug side effects.

Nutrition Therapy.

Teach the patient to avoid foods that irritate the bladder such as caffeine and alcohol. Spacing fluids at regular intervals throughout the day (e.g., 120 mL every hour or 240 mL every 2 hours) and limiting fluids after the dinner hour (e.g., only 120 mL at bedtime) help avoid fluid overload on the bladder and allow urine to collect at a steady pace.

Behavioral Interventions.

Behavioral interventions for urge incontinence include bladder training, habit training, exercise therapy, and electrical stimulation. Interventions for urinary bladder training and urinary habit training are listed in Chart 66-9. Behavioral interventions involve a great deal of patient

participation. Provide ongoing encouragement, clarification, and support to increase the effects of all interventions. Behavioral interventions are often combined with drug therapy for greatest effect.

Chart 66-9 Best Practice for Patient Safety & Quality Care QSEN

Bladder Training and Habit Training to Reduce Urinary Incontinence

Bladder Training

- Assess patient's awareness of bladder fullness and ability to cooperate with training regimen.
- Assess the patient's 24-hour voiding pattern for 2 to 3 consecutive days.
- Base the initial interval of toileting on the voiding pattern (e.g., 45 minutes).
- Teach the patient to void every 45 minutes on the first day and to ignore or suppress the urge to urinate between the 45-minute intervals.
- Take the patient to the toilet or remind him or her to urinate at the 45-minute intervals.
- Provide privacy for toileting and run water in the sink to promote the urge to urinate at this time.
- If the patient is not consistently able to resist the urge to urinate between the intervals, reduce the intervals by 15 minutes.
- Continue this regimen for at least 24 hours or for as many days as it takes for the patient to be comfortable with this schedule and not urinate between the intervals.
- When the patient remains continent between the intervals, increase the intervals by 15 minutes daily until a 3- to 4-hour interval is comfortable for the patient.
- Praise successes. If incontinence occurs, work with the patient to re-establish an acceptable toileting interval.

Habit Training

- Assess the patient's 24-hour voiding pattern for 2 to 3 days.
- Base the initial interval of toileting on the voiding pattern (e.g., 2 hours).
- Assist the patient to the toilet or provide a bedpan/urinal every 2 hours (or whatever has been determined to be an appropriate toileting interval for the individual patient).
- During the toileting, remind the patient to void and provide cues such

as running water.
- If the patient is incontinent between scheduled toileting, reduce the time interval by 30 minutes until the patient is continent between voidings.
- Assist the patient to toilet and prompt to void at prescribed intervals.
- Do not leave the patient on the toilet or bedpan for longer than 5 minutes.
- Ensure that all nursing staff members comply with the established toileting schedule and do not apply briefs or encourage the patient to "just wet the bed."
- Reduce toileting interval by 30 minutes if there are more than two incontinence episodes in 24 hours.
- If the patient remains continent at the toileting interval, attempt to increase the interval by 30 minutes until a 3- to 4-hour continence interval is reached.
- Praise the patient for successes, and spend extra time socializing with the patient.
- When incontinence occurs, ensure that the patient and bed are cleaned appropriately but do not spend extra time socializing with the patient.
- Discuss daily record of continence with staff to provide reinforcement and encourage compliance with toileting schedule.
- Include unlicensed assistive personnel in all aspects of the habit training.

Bladder training is an education program for the patient that begins with a thorough explanation of the problem of urge incontinence. Instead of the bladder being in control of the patient, the patient learns to control the bladder. For the program to succeed, he or she must be alert, aware, and able to resist the urge to urinate (Wilde et al., 2014).

Start a schedule for voiding, beginning with the longest interval that is comfortable for the patient, even if the interval is only 30 minutes. Instruct the patient to void every 30 minutes and to ignore any urge to urinate between the set intervals. Once he or she is comfortable with the starting schedule, increase the interval by 15 to 30 minutes. Instruct the patient to follow the new schedule until he or she achieves success again. As the interval increases, the bladder gradually tolerates more volume. Teach him or her relaxation and distraction techniques to maximize success in the retraining. Provide positive reinforcement for maintaining the prescribed schedule.

Habit training (scheduled toileting) is a type of bladder training that is successful in reducing incontinence in cognitively impaired patients. To

use habit training, caregivers assist the patient in voiding at specific times (e.g., every 2 hours on the even hours). The goal is to get the patient to the toilet before incontinence occurs. The focus is on reducing incontinence. When that has been achieved, the focus may change to increase bladder capacity by gradually lengthening the voiding intervals, but this is only secondary.

Nursing Safety Priority QSEN

Action Alert

Habit training is undermined when absorbent briefs are used in place of timed toileting. Do not tell patients to "just wet the bed." A common cause of falls in health care facilities is related to patient efforts to get out of bed unassisted to use the toilet. Work with all staff members, including unlicensed assistive personnel (UAP), to implement consistently the toileting schedule for habit training.

Prompted voiding, a supplement to habit training, attempts to increase the patient's awareness of the need to void and to prompt him or her to ask for toileting assistance. Habit training otherwise relies completely on a time schedule.

Exercise therapy with pelvic muscle exercises for urge incontinence is helpful and is taught in the same way as for stress incontinence (see Chart 66-7). Improved urethral resistance helps the patient overcome abnormal detrusor contractions long enough to get to the toilet.

Reducing Reflex Urinary Incontinence

Planning: Expected Outcomes.

With appropriate intervention, the patient with reflex incontinence is expected to achieve continence. Indicators include that the patient often or consistently demonstrates these behaviors:

- Recognizes the urge to void
- Maintains a predictable pattern of voiding
- Responds to urge in a timely manner
- Empties bladder completely
- Keeps urine volume in the bladder under 300 mL

Interventions.

Interventions for the patient with reflex (overflow) incontinence caused

by obstruction of the bladder outlet may include surgery to relieve the obstruction. The most common procedures are prostate removal (see Chapter 72) and repair of uterine prolapse (see Chapter 71).

Drug Therapy.

Drugs are prescribed for short-term management of urinary retention, often after surgery. They are not used in long-term management of overflow incontinence caused by a hypotonic bladder. The most commonly used drug is bethanechol chloride (Urecholine), an agent that increases bladder pressure.

Behavioral Interventions.

The most effective common behavioral interventions are bladder compression and intermittent self-catheterization.

Bladder compression uses techniques that promote bladder emptying and include the Credé method, the Valsalva maneuver, double-voiding, and splinting.

For the Credé method, teach the patient how to press over the bladder area, increasing its pressure, or to trigger nerve stimulation by tugging at pubic hair or massaging the genital area. These techniques manually assist the bladder in emptying. In the Valsalva maneuver, breathing techniques increase chest and abdominal pressure. This increased pressure is then directed toward the bladder during exhalation. With the technique of double-voiding, the patient empties the bladder and then, within a few minutes, attempts a second bladder emptying.

For women who have a large *cystocele* (prolapse of the bladder into the vagina), a technique called *splinting* both compresses the bladder and moves it into a better position. The woman inserts her fingers into her vagina, gently lifts the cystocele, and begins to urinate. A *pessary,* described earlier, can also provide relief from cystocele-related incontinence.

Intermittent self-catheterization is often used to help patients with long-term problems of incomplete bladder emptying. It is effective, can be learned fairly easily, and remains the preferred method of bladder emptying in patients who have incontinence as a result of a neurogenic bladder (Newman & Willson, 2011). These points are important in teaching the technique:

- Proper handwashing and cleaning of the catheter reduce the risk for infection.
- A small lumen and good lubrication of the catheter prevent urethral trauma.

- A regular schedule for bladder emptying prevents distention and mucosal trauma.

Patients must be able to understand instructions and have the manual dexterity to manipulate the catheter. Caregivers or family members in the home can also be taught to perform straight catheterization using clean (rather than sterile) technique with good outcomes (Kannankeril et al., 2011).

Reducing Functional Urinary Incontinence

Planning: Expected Outcomes.

The patient with functional urinary incontinence is expected to remain dry. Indicators include that the patient often or consistently demonstrates these behaviors:

- Uses urine containment or collection measures to ensure dryness
- Manages clothing independently

Interventions.

Causes of functional (or chronic intractable) incontinence vary greatly. Some are reversible, and others are not. The focus of intervention is treatment of reversible causes. When incontinence is not reversible, urinary habit training (see Chart 66-9) is used to establish a predictable pattern of bladder emptying to prevent incontinence. A final strategy focuses on containment of the urine and protection of the patient's skin. Nonsurgical interventions include applied devices, containment, and catheterization.

Applied devices include intravaginal pessaries for women and penile clamps for men. The intravaginal pessary supports the uterus and vagina and helps maintain the correct position of the bladder. (See Chapter 71 for further discussion of pessaries.) The penile clamp is applied around the outside of the penis to compress the urethra and prevent urine leakage.

Adverse outcomes from pessaries and penile clamps include damage to the tissues from pressure and infection from colonization of damaged tissues. Both devices require that the patient have either manual dexterity or a caregiver to apply and remove the device. Instruct the patient or caregivers in the use of these devices. Male patients may use an external collecting device, such as a condom catheter. Design of an effective external collecting device for women has not been as successful.

Containment is achieved with absorbent pads and briefs designed to collect urine and keep the patient's skin and clothing dry. Many types and

sizes of pads are available:
- Shields or liners inserted inside a panty
- Undergarments that are full-size pads with waist straps
- Plastic-lined protective underpants
- Combination pad and pant systems
- Absorbent bed pads

A major concern with the use of protective pads is the risk for skin breakdown. Materials and costs vary. Some are reusable; others are disposable. The disposal of these products raises ecologic concerns. Avoid use of the word "diaper" when discussing these adult protective pants, however, because of the association of diapers with a baby.

Catheterization for control of incontinence may be intermittent or involve an indwelling catheter. Intermittent catheterization is preferred to an indwelling catheter because of the reduced risk for infection. An indwelling urinary catheter is appropriate for patients with skin breakdown who need a dry environment for healing, for those who are terminally ill and need comfort, and for those who are critically ill and require precise measurement of urine output.

Reducing Total or Mixed Urinary Incontinence.

Mixed or total urinary incontinence is a combination of two or more types of involuntary urine loss syndromes. For example, stress incontinence and urge incontinence often occur together in women during and after menopause. For the patient with mixed or total incontinence, combinations of assessment techniques (as discussed under each syndrome) are used. Interventions are also combined to promote continence. The problems and interventions for mixed incontinence are the same as for each specific type of incontinence separately. After identifying the specific types of incontinence an individual patient has, apply the appropriate priority patient problems, interventions, and expected outcomes discussed earlier with each incontinence type.

Cultural Considerations

Patient-Centered Care QSEN

Compared with white women, Asian and black women are less likely to report urinary incontinence. In addition, black women are more likely to report remission or cessation of urinary incontinence and Asian women are more likely to report improvement or a decrease of

manifestations over a 2-year period when compared with white women. These cultural differences in urinary incontinence and recovery may be a result of differences in pelvic floor anatomy and function, including smaller pelvic floor area and higher urethral closure pressure in black women (Townsend et al., 2011).

Clinical Judgment Challenge

Patient-Centered Care; Evidence-Based Practice QSEN

The patient is a 52-year-old perimenopausal woman who reports a small loss of urine with coughing, laughing, and occasionally bending over. Recently she has started to leak urine just as she arrives in the bathroom but before she sits on the toilet. She states her mother has had a continuing problem with incontinence for years and seldom leaves her home. The patient wants to continue to lead an active lifestyle and wants to discuss options for preventing progression of this embarrassing condition.

1. What other information should you obtain from this patient?
2. What type or types of incontinence is she most likely to have from the information she has provided thus far?
3. Is this problem likely to be genetic? Why or why not?
4. What will you tell her regarding options for care?
5. She asks if there is anything she can do now to help reduce her urine leakage. How do you respond?

Community-Based Care

Community-based care for the patient with urinary incontinence considers his or her personal, physical, emotional, and social resources. Important personal resources for self-care include mobility, vision, and manual dexterity. When planning care, consider who will be the primary caregiver and what factors may influence the effectiveness of the plan. A recent comparative effectiveness review from the Agency for Healthcare Research and Quality (AHRQ) (2012) reports that some drugs for urinary incontinence can provide benefit but that adverse drug events, overall, lead to poor adherence. This report also provides information that nonpharmacologic and nonsurgical treatments provide significant clinical benefit with low risk for adverse effects but that these interventions are also associated with poor adherence. Ongoing relationships with health care providers may improve adherence.

Home Care Management.

Assess the home environment for barriers that limit access to the bathroom. Eliminate hazards that might slow walking or lead to a fall. Such hazards include throw rugs, furniture with legs that extend into the walking area, slippery waxed or polished floors, and poor lighting.

If the patient must climb stairs to reach a bathroom, handrails should be installed and stairs kept free of obstacles. Toilet seat extenders may help provide the right level and height of seating so that maximal abdominal pressure may be applied for voiding. Portable commodes may be obtained when ambulatory access to toilets is impractical. Physical and occupational therapists are valuable resources for assisting with home care management.

Self-Management Education.

Teach the patient and family about the cause of the specific type of incontinence, and discuss available treatment options for its management. The teaching plan addresses the prescribed drugs (purpose, dosage, method and route of administration, and expected and potential side effects). Instruct the patient and family about the importance of weight reduction and dietary modification to help control incontinence. Remind the patient who smokes that nicotine can contribute to bladder irritation and that coughing can cause urine leakage.

When external devices or protective pads are needed, describe the possible options and help the patient make a selection best for his or her lifestyle and resources. For patients who will use intermittent catheterization or those with artificial urinary sphincters, demonstrate the correct technique to the patient or caregiver. Evaluate return demonstrations for correct technique. Chart 66-10 also addresses teaching.

Chart 66-10 Patient and Family Education: Preparing for Self-Management

Urinary Incontinence

- Maintain a normal body weight to reduce the pressure on your bladder.
- Do not try to control your incontinence by limiting your fluid intake. Adequate fluid intake is necessary for kidney function and health maintenance.
- If you have a catheter in your bladder, follow the instructions given to

you about maintaining the sterile drainage system.
- If you are discharged with a suprapubic catheter in your bladder, inspect the entry site for the tube daily, clean the skin around the opening gently with warm soap and water, and place a sterile gauze dressing on the skin around the tube. Report any redness, swelling, drainage, or fever to your physician.
- Do not put anything into your vagina, such as tampons, drugs, hygiene products, or exercise weights, until you check with your physician at your 6-week checkup after surgery.
- Do not have sexual intercourse until after your 6-week postoperative checkup.
- Do not lift or carry anything heavier than 5 pounds or participate in any strenuous exercise until your physician gives you postoperative clearance. In some cases, this could be as long as 3 months.
- Avoid exercises, such as running, jogging, step or dance aerobic classes, rowing, cross-country ski or stair-climber machines, and mountain biking. Brisk walking without any additional hand, leg, or body weights is allowed. Swimming is allowed after all drains and catheters have been removed and your incision is completely healed.
- If Kegel exercises are recommended, ask your nurse for specific instructions.

Psychosocial Preparation.

The embarrassment of incontinence can be devastating to self-esteem, body image, and relationships. Sexual intimacy is often adversely affected by incontinence. The unpredictable nature of incontinence creates anxiety. Patients may be embarrassed to seek help, and even when resources are identified, they may need help to feel comfortable in using the resources. Buying supplies at a local store may threaten privacy.

Accept and acknowledge the personal concerns of the patient and caregiver. Never make their concerns seem trivial. As he or she learns the specifics of the plan that will allow control of urinary incontinence, the confidence to resume social interactions should return. Many continence supplies can be purchased online and delivered directly to the home to maintain privacy.

Health Care Resources.

Referral to home care agencies for help with personal care and to continence clinics that specialize in evaluation and treatment may be helpful. In many continence clinics, nurses collaborate with physicians

and other health care professionals to evaluate and manage patients. The treatment plan is specific for each patient; supplies and products are custom selected.

Patients may benefit from education and from the support of others who experience similar concerns. The National Association for Continence (NAFC) (www.nafc.org), Access to Continence Care and Treatment (www.wellweb.com/INCONT/acct/contents.htm), and the Wound, Ostomy, and Continence Nurses (www.wocn.org) publish newsletters and educational materials written with easy-to-understand explanations. The American Foundation for Urologic Disease (www.afud.com) provides information on many areas of bladder dysfunction. Local hospitals often have local NAFC-approved support groups.

NCLEX Examination Challenge

Safe and Effective Care Environment

For which hospitalized client does the nurse recommend the ongoing use of a urinary catheter?

A 36-year-old woman who is blind and is receiving diuretics

B 46-year-old man who has paraplegia and is admitted for asthma management

C 56-year-old woman who is admitted with a vaginal-rectal fistula and has diabetes

D 66-year-old man who has severe osteoarthritis and is a high risk for falling

Evaluation: Outcomes

Evaluate the care of the patient with urinary incontinence based on the identified priority patient problems. The expected outcomes are that the patient will:

- Describe the type of urinary incontinence experienced
- Demonstrate knowledge of proper use of drugs and correct procedures for self-catheterization, use of the artificial sphincter, or care of an indwelling urinary catheter
- Demonstrate effective use of the selected exercise or bladder-training program
- Select and use incontinence interventions, devices, and products
- Have a reduction in the number of incontinence episodes

Specific indicators for these outcomes are listed for each priority

patient problem under the Planning and Implementation section (see earlier).

Urolithiasis

Pathophysiology

Urolithiasis is the presence of *calculi* (stones) in the urinary tract. Stones often do not cause manifestations until they pass into the lower urinary tract, where they can cause excruciating pain. **Nephrolithiasis** is the formation of stones in the kidney. Formation of stones in the ureter is **ureterolithiasis**.

Urologic stones are caused by many disorders. However, the exact mechanism of stone formation is not entirely understood. Everyone excretes crystals in the urine at some time, but fewer than 10% of people form stones. Most stones contain calcium as one part of the stone complex. Struvite (15%), uric acid (8%), and cystine (3%) are more rare compositions of stones. Formation of stones involves three conditions:

- Slow urine flow, resulting in supersaturation of the urine with the particular element (e.g., calcium) that first becomes crystallized and later becomes the stone
- Damage to the lining of the urinary tract (e.g., abrasion from crystals)
- Decreased amounts of inhibitor substances in the urine that would otherwise prevent supersaturation and crystal aggregation

High urine acidity (as with uric acid and cystine stones) or alkalinity (as with calcium phosphate and struvite stones), as well as drugs (e.g., triamterene, indinavir, acetazolamide), contributes to stone formation.

One example of a metabolic problem causing stone formation begins when excessive amounts of calcium are absorbed through the intestinal tract leading to hypercalciuria. As blood circulates through the kidneys, the excess calcium is filtered into the urine, causing supersaturation of calcium in the urine. If fluid intake is poor, such as when a patient is dehydrated, supersaturation is more likely to occur and the risk for calcium combining with another compound to form a larger molecule increases. Calcium complexes often serve as a center for other deposits, and eventually a stone forms.

Stones that form in the kidney and then pass into the ureter often lodge in areas where the ureter bends or slightly changes shape. When the stone occludes the ureter and blocks the flow of urine, the ureter dilates. Enlargement of the ureter is called **hydroureter**.

The pain associated with ureteral spasm is excruciating and may cause the patient to go into shock from stimulation of nearby nerves.

Hematuria (bloody urine) may result from damage to the urothelial lining. If the obstruction is not removed, urinary stasis can cause infection and impair kidney function on the side of the blockage. As the blockage persists, **hydronephrosis** (enlargement of the kidney caused by blockage of urine lower in the tract and filling of the kidney with urine) and permanent kidney damage may develop.

Etiology and Genetic Risk

The cause of urolithiasis is unknown. At least 90% of patients who form stones have a metabolic risk factor. Table 66-4 lists some metabolic problems that cause stone formation. Patients who are white, older, obese, or have diabetes or gout (hyperuricemia) have increased risk for stone formation (Rodgers, 2013). Other conditions associated with stone formation and recurrence are hyperparathyroidism, urinary tract obstruction, inflammatory bowel diseases, and a history of GI problems (Fink et al., 2013).

TABLE 66-4

Metabolic Defects That Commonly Cause Kidney Stones

METABOLIC DEFICIT	ETIOLOGY
Hypercalcemia	
Primary	Absorptive: increased intestinal calcium absorption Renal: decreased kidney tubular excretion of calcium
Secondary	Resorptive: hyperparathyroidism, vitamin D intoxication, kidney tubular acidosis, prolonged immobilization
Hyperoxaluria	
Primary	Genetic: autosomal recessive trait resulting in high oxalate production
Secondary	Dietary: excess oxalate from foods such as spinach, rhubarb, Swiss chard, cocoa, beets, wheat germ, pecans, peanuts, okra, chocolate, and lime peel
Hyperuricemia	
Primary	Gout is an inherited disorder of purine metabolism (20% of patients with gout have uric acid calculi)
Secondary	Increased production or decreased clearance of purine from myeloproliferative disorders, thiazide diuretics, carcinoma
Struvite	Made of magnesium ammonium phosphate and carbonate apatite; formed by urea splitting by bacteria, most commonly, *Proteus mirabilis;* needs an alkaline urine to form
Cystinuria	Autosomal recessive defect of amino acid metabolism that precipitates insoluble cystine crystals in the urine

Diet is not considered a risk for stone formation. However, calcium and vitamin D supplementation as well as high-dose ascorbic acid (vitamin C) intake have been implicated in stone formation (Fletcher, 2013; Rosa et al., 2013). Conversely, high intake of fluids, fruits, and vegetables, low consumption of protein, and a balanced intake of calcium, fats, and carbohydrates are prescribed to prevent and treat recurrent urolithiasis (Fink et al., 2013).

Genetic/Genomic Considerations

Patient-Centered Care QSEN

Family history has a strong association with stone formation and recurrence. More than 30 genetic variations are associated with the formation of kidney stones. Single gene disorders are rare. More commonly, nephrolithiasis is a complex disease, with genetic variation in intestinal calcium absorption, kidney calcium transport, or kidney phosphate transport all associated with stone formation. Always ask a patient with a renal stone whether other family members have also had this problem.

Incidence and Prevalence

The incidence of stone disease is high and varies with geographic location, race, and family history. About 12% of adults will have at least one episode of renal stone disease. The incidence is higher in men; however, struvite stones are twice as common in women. Recurrence rates vary depending on the type of treatment. The recurrence rate of untreated calcium oxalate stones is 35% to 50% in 5 to 10 years. A higher recurrence of stones occurs in patients with a family history of stone disease and in those who had their first occurrence by age 25 years.

Cultural Considerations

Patient-Centered Care QSEN

The incidence of stone disease is most common in the southeastern United States, Japan, and western Europe. Calcium stone disease is more common in men than in women and tends to occur in young adults or during early middle adulthood. Kidney stone disease occurs more often in younger adults than older adults and more commonly among white people (Rodgers, 2013). For patients in these higher-risk groups, nursing care includes teaching family members, as well as patients, about the manifestations of a stone and interventions to reduce stone formation.

Patient-Centered Collaborative Care

Assessment

Ask the patient about a personal or family history of urologic stones. Obtain a diet history, focusing on fluid intake patterns and supplemental vitamin or mineral intake. If he or she has a history of stone formation, ask about past treatment, whether chemical analysis of the stone was performed, and what preventive measures are followed.

The major manifestation of stones is severe pain, commonly called **renal colic**. Flank pain suggests that the stone is in the kidney or upper ureter. Flank pain that extends toward the abdomen or to the scrotum and testes or the vulva suggests that stones are in the ureters or bladder. Pain is most intense when the stone is moving or when the ureter is obstructed.

Renal colic begins suddenly and is often described as "unbearable." Nausea, vomiting, pallor, and diaphoresis often accompany the pain. A large stationary stone in the kidney (staghorn calculus), however, rarely causes much pain because it is not moving. Frequency and dysuria occur when a stone reaches the bladder. **Oliguria** (scant urine output) or **anuria** (absence of urine output) suggests obstruction, possibly at the bladder neck or urethra. *Urinary tract obstruction is an emergency and must be treated immediately to preserve kidney function.*

Assess the patient for bladder distention. He or she may appear pale, ashen, and diaphoretic and may suffer from excruciating pain. Vital signs may be moderately elevated with pain; body temperature and pulse are elevated with infection. Blood pressure may decrease if the severe pain causes shock.

Urinalysis is performed in patients with suspected stones. Hematuria is common, and blood may make the urine appear smoky or rusty. RBCs are usually caused by stone-induced trauma on the lining of the ureter, bladder, or urethra. WBCs and bacteria may be present as a result of urinary stasis. Increased *turbidity* (cloudiness) and odor indicate that infection may also be present. Microscopic examination of the urine may identify crystals from which stones could form. Urinary pH is measured to determine acidity or alkalinity.

The serum WBC count is elevated with infection. Increases in the serum calcium, serum phosphate, or serum uric acid levels indicate excess minerals are present and may contribute to stone formation.

Stones are easily seen on x-rays of the kidneys, ureters, and bladder (KUB) (Fig. 66-2), CT, and ultrasound, with ultrasound being used most commonly for screening. Noncontrast CT is the most sensitive procedure to identify urinary tract stones and can confirm the presence, shape, and location of the stones.

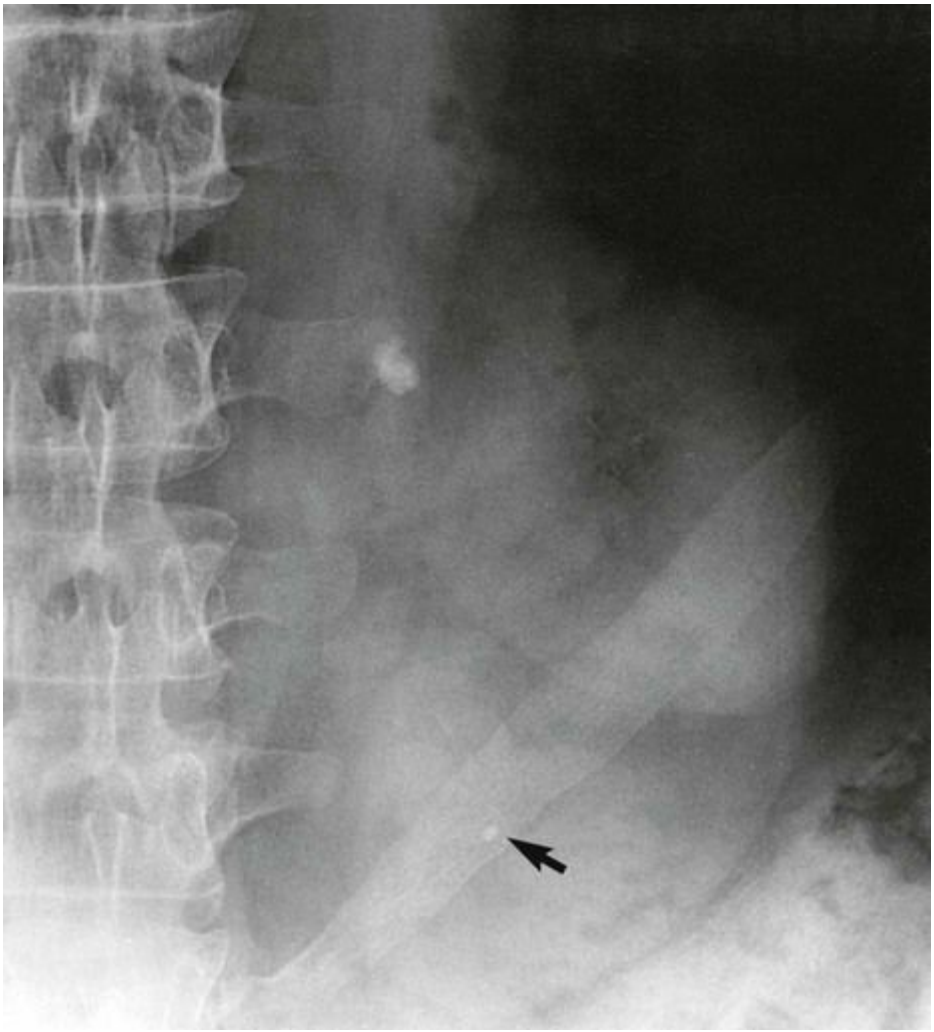

FIG. 66-2 Urinary stones on x-ray of the kidneys, ureters, and bladder (KUB).

Interventions

Nursing interventions focus on pain management and prevention of infection and urinary obstruction. Most patients can expel the stone without invasive procedures. The most important factors regarding whether a stone will pass on its own are its composition, size, and location. The larger the stone and the higher up in the urinary tract it is, the less likely it is to be passed. When the stone is passed, it should be captured and sent to the laboratory for analysis. Other interventions are needed when the patient does not pass the stone spontaneously (Fig. 66-3).

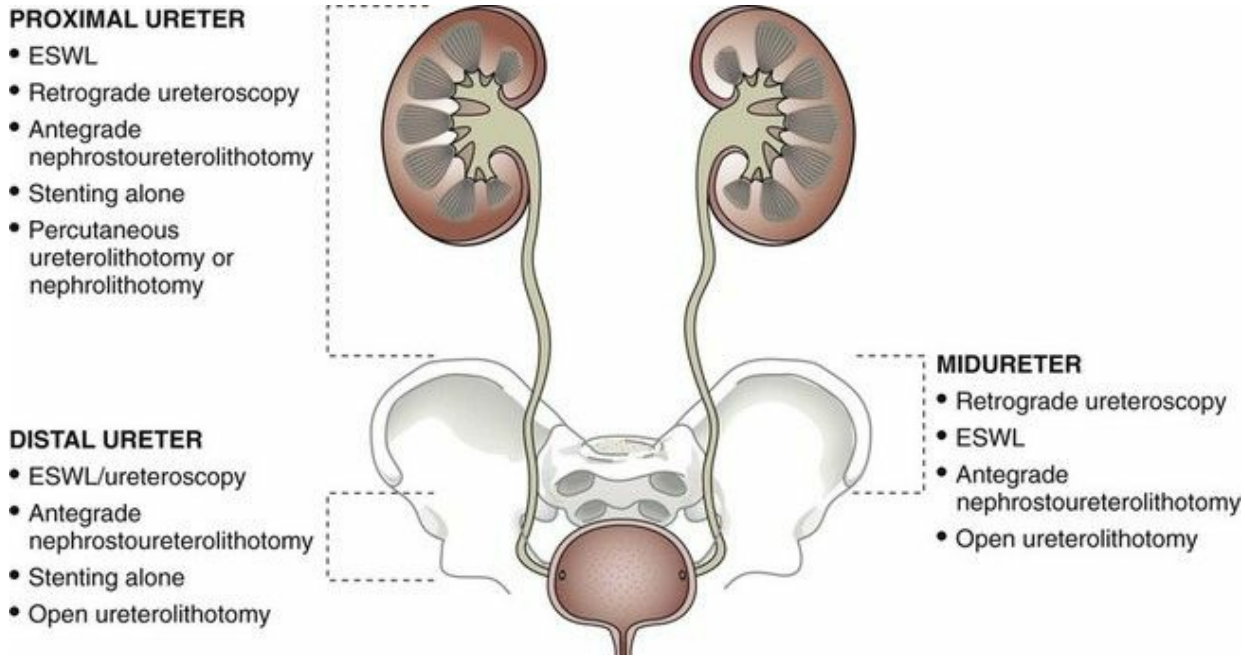

FIG. 66-3 Treatment options for ureteral stones. *ESWL,* Extracorporeal shock wave lithotripsy.

Managing Pain.

Nonsurgical and surgical approaches are used to assist the patient with a kidney stone achieve an acceptable degree of pain relief.

Nonsurgical Management.

Nonsurgical measures to relieve pain include strategies to enhance stone passing, as well as direct pain management.

Drug therapy is needed in the first 24 to 36 hours when pain is most severe. Opioid analgesics are used to control the severe pain caused by stones in the urinary tract and may be given IV for rapid pain relief. NSAIDs such as ketorolac (Toradol) or ketoprofen (Nexcede) in the acute phase may be quite effective. When NSAIDs are used, the risk for bleeding is increased and the use of extracorporeal shock wave lithotripsy is delayed.

Control of pain is more effective when drugs are given at regularly scheduled intervals or by a constant delivery system (e.g., skin patch) instead of PRN. Spasmolytic drugs, such as oxybutynin chloride (Ditropan) and propantheline bromide (Pro-Banthine, Propanthel), are important for control of pain (see Chart 66-8). Give the drugs, and assess the response by asking the patient to rate the discomfort on a pain-rating scale.

Other management techniques include avoiding overhydration and underhydration in the acute phase to help make the passage of a stone

less painful. Strain the urine and teach the patient to strain it to monitor for stone passage. Send any stone passed to the laboratory for analysis because preventive therapy is based on stone composition.

Two drugs may be used to aid in stone expulsion: a thiazide diuretic and allopurinol. These drugs, combined with a high fluid intake, increase urine volume or decrease urine pH and help increase the excretion of stones or stone fragments (Rosa et al., 2013). Citrate may be used to alter urine pH and interrupt intrarenal conditions that promote stone production.

Lithotripsy, also known as *shock wave lithotripsy (SWL),* is the use of sound, laser, or dry shock waves to break the stone into small fragments. The patient receives moderate sedation and lies on a flat table with the lithotriptor aimed at the stone, which is located by fluoroscopy. A local anesthetic cream is applied to the skin site over the stone 45 minutes before the procedure. During the procedure, cardiac rhythm is monitored by electrocardiography (ECG) and the shock waves are delivered in synchrony with the R wave. Shock waves at the rate of 60 to 120/min are applied over 30 to 45 minutes (Li et al., 2013). Continuous ECG monitoring for dysrhythmia and fluoroscopic observation for stone destruction are maintained.

After lithotripsy, strain the urine to monitor the passage of stone fragments. Bruising may occur on the flank of the affected side. Occasionally a stent is placed in the ureter before SWL to ease passage of the stone fragments.

Surgical Management.

Minimally invasive surgical and open surgical procedures are used if urinary obstruction occurs or if the stone is too large to be passed.

Minimally Invasive Surgical Procedures.

Minimally invasive surgical (MIS) procedures include stenting, ureteroscopy, percutaneous ureterolithotomy, and percutaneous nephrolithotomy.

Stenting is performed with a **stent**—a small tube that is placed in the ureter by ureteroscopy. The stent dilates the ureter and enlarges the passageway for the stone or stone fragments. This totally internal procedure prevents the passing stone from coming in contact with the ureteral mucosa, thereby reducing pain, bleeding, and infection risk, all of which could block the ureter. A Foley catheter may be placed to facilitate passage of the stone through the urethra.

Ureteroscopy is an endoscopic procedure. The ureteroscope is passed

through the urethra and bladder into the ureter. Once the stone is seen, it is removed using grasping baskets, forceps, or loops. Lithotripsy also can be performed through the ureteroscope. A Foley catheter may be placed to facilitate passage of the stone fragments through the urethra.

Percutaneous ureterolithotomy or nephrolithotomy is the removal of a stone in the ureter or kidney through the skin. The patient lies prone or on the side and receives local or general anesthesia. The physician identifies the ideal entry point with fluoroscopy and then passes a needle into the collecting system of the kidney. Once a tract has been made in the kidney, other equipment, such as an **intracorporeal** (inside the body) ultrasonic or laser lithotriptor, can be used to break up and remove the stone. An endoscope with a special attachment to grasp and extract the stone can be used. Often a nephrostomy tube is left in place at first to prevent the stone fragments from passing through the urinary tract.

Monitor the patient for complications after the procedure. Complications include bleeding at the site or through the tube, pneumothorax, and infection. Monitor nephrostomy tube drainage for volume and the presence of blood in the urine, which is normal for the first 24 to 48 hours after tube placement. Provide routine nephrostomy tube care, with sterile dressing changes and tube flushing (if ordered).

Open Surgical Procedures.

When other stone removal attempts have failed or when risk for a lasting injury to the ureter or kidney is possible, an *open ureterolithotomy* (into the ureter), *pyelolithotomy* (into the kidney pelvis), or *nephrolithotomy* (into the kidney) procedure may be performed. These procedures are used for a large or impacted stone.

Preoperative Care.

Explain to the patient how, when, and where the procedure will be performed. Describe what he or she can expect to see, hear, and feel before and after the procedure. The patient is given nothing by mouth and also receives a bowel preparation before the procedure. (See Chapter 14 for routine care before surgery.)

Operative Procedures.

The retroperitoneal area is entered through a large flank incision, as for nephrectomy (see Chapter 67), pyelolithotomy, or nephrolithotomy and through a lower abdominal incision for ureterolithotomy. The urinary tract is entered surgically, and the stone is removed. Before closure, tubes and drains may be placed (e.g., nephrostomy tube, ureteral stent,

Penrose or other wound drainage device, and Foley catheter).

Postoperative Care.

Follow routine procedures for assessment of the patient who has received anesthesia. (See Chapter 16 for routine care after surgery.) Monitor the amount of bleeding from incisions and in the urine. Maintain adequate fluid intake. Strain the urine to monitor the passage of stone fragments. Teach the patient how to prevent future stones through dietary changes, including consistent daily fluid intake to avoid dehydration and supersaturation.

Preventing Infection.

Control of infection before invasive procedures is critical for the prevention of urosepsis. Interventions include giving appropriate antibiotics, either to eliminate an existing infection or to prevent new infections, and maintaining adequate nutrition and fluid intake. Because infection always occurs with struvite stone formation, the health care team plans for long-term infection prevention.

Drug therapy involves the use of broad-spectrum antibiotics, such as the aminoglycosides (e.g., gentamicin [Garamycin]) and cephalosporins (e.g., cephalexin [Keflex, Novo-Lexin]). The broad coverage is effective against gram-negative organisms. After the results of the culture and sensitivity (C&S) studies are obtained, more specific antibiotics may be prescribed. C&S studies are often done 48 hours after the start of antibiotic therapy and again 48 hours after completion of the prescribed course of therapy.

Blood levels of antibiotics may be measured to ensure that adequate levels have been reached. If the blood level of the antibiotic is not adequate, organisms may not be completely eliminated. Evidence of a new infection (e.g., chills, fever, and altered mental status) warrants the collection of a urine sample for repeat C&S tests.

For the patient with struvite stones, periodic and long-term monitoring of the urine for infection is needed. Urine cultures are checked monthly for 3 months and then quarterly for 1 year. Drugs that prevent bacteria from splitting urea, such as acetohydroxamic acid (Lithostat) and hydroxyurea (Hydrea), are often prescribed long-term for patients with struvite stones. Serum creatinine levels are monitored in patients receiving acetohydroxamic acid, and the drug is stopped if creatinine levels are above 2 mg/dL. Review interventions aimed at preventing urinary tract infection (UTI). (See Health Promotion discussion on p. 1369 in the Cystitis section.)

Nutrition therapy ideally includes adequate calorie intake with a balance of all food groups. Encourage a fluid intake sufficient to dilute urine to a light color throughout the 24-hour day (typically 2 to 3 L/day) unless another health problem requires fluid restriction.

Preventing Obstruction.

Measures to prevent urinary obstruction by stones include a high intake of fluids (3 L/day or more) and accurate measures of intake and output. Fluid intake sufficient to provide diluted urine helps prevent dehydration, promotes urine flow, and decreases the chance of crystals forming a stone. Interventions also depend on the type of stone the patient has formed. Drugs, diet modification, and fluid intake are the major strategies used to prevent future stones.

Drug therapy to prevent obstruction depends on what is causing stone formation and the type of stone formed. Teach the patient the reason for the drug, and assess for side effects or adverse drug reactions. Some drugs may need to be avoided because they may contribute to stone formation.

Drugs to treat *hypercalciuria* (high levels of calcium in the urine) include thiazide diuretics (e.g., chlorothiazide [Diuril] or hydrochlorothiazide [HydroDIURIL, Urozide]). These drugs promote calcium reabsorbtion from the renal tubules back into the body, thereby reducing urine calcium loads. For patients with *hyperoxaluria* (high levels of oxalic acid in the urine), allopurinol (Zyloprim) or febuxostat (Uloric) is used.

For patients with hyperuricemia or chronic gout, both allopurinol and febuxostat help prevent the formation of urate (uric acid) stones. To alkalinize the urine, drugs such as potassium citrate, 50% sodium citrate, and sodium bicarbonate are used. Lemon or orange juice may also be ingested as a daily source of citrate. The desired urine pH is 6 to 6.5. Because the normal urine pH averages 5 to 6, the desired values are termed *alkaline.*

For patients with *cystinuria* (high levels of cystine in the urine), both alpha-mercaptopropionylglycine (AMPG) and captopril (Capoten) lower urine cystine levels. They are used when hydration and urine alkalinization have not been successful.

Statins, drugs used to manage hypercholesterolemia, have also been found to reduce the incidence of stone recurrence (Sur et al., 2013). In general, with one stone, patients are advised to increase fluid intake. With two or more stones, drug therapy is advised based on the type of stone as described above (Fink et al., 2013).

Nutrition therapy depends on the type of stone formed (Table 66-5). Collaborate with the dietitian to plan for and teach the appropriate diet to the patient (Türk et al., 2011).

TABLE 66-5

Dietary Treatment for Kidney and Urinary Stones

STONE TYPE	DIETARY INTERVENTIONS	RATIONALES
Calcium oxalate	Avoid oxalate sources, such as spinach, black tea, and rhubarb.	Reduction of urinary oxalate content may help prevent these stones from forming. Urinary pH is not a factor.
	Decrease sodium intake.	High sodium intake reduces kidney tubular calcium reabsorption.
Calcium phosphate	Limit intake of foods high in animal protein to 5-7 servings per week and never more than 2 per day.	Reduction of protein intake reduces acidic urine and prevents calcium precipitation.
	Some patients may benefit from a reduced calcium intake (milk, other dairy products).	Reduction of urine calcium concentration may prevent calcium precipitation and crystallization.
	Decrease sodium intake.	High sodium intake reduces kidney tubular calcium reabsorption.
Struvite (magnesium ammonium phosphate)	Limit high-phosphate foods, such as dairy products, organ meats, and whole grains.	Reduction of urinary phosphate content may help prevent these stones from forming.
Uric acid (urate)	Decrease intake of purine sources, such as organ meats, poultry, fish, gravies, red wines, and sardines.	Reduction of urinary purine content may help prevent these stones from forming.
Cystine	Limit animal protein intake (as above).	Reduces urinary uric acid.
	Encourage oral fluid intake (500 mL every 4 hours while awake and 750 mL at night).	Increased fluid helps dilute the urine and prevents the cystine crystals from forming.

Other measures can help the stone pass more quickly. Urge the patient to walk as often as possible. Walking promotes passage of stones and reduces bone calcium resorption. Check the urine pH daily, and strain all urine with filter paper or a special urine sieve/strainer to collect passed stones and fragments.

Self-management education includes the key points listed in Chart 66-11. Follow-up care to evaluate effects of intervention includes a 24-hour urine collection and serum chemical analysis. The patient often has great anxiety and fear that a stone and its pain may recur. In addition to anxiety about the pain, the risk for repeated surgical interventions or permanent and serious kidney damage is of major concern. Psychosocial preparation is enhanced when patients know what to expect and what actions to take if problems develop. Reassure the patient that preventive and health promotion activities help prevent recurrence.

Chart 66-11 Patient and Family Education: Preparing for Self-Management

Urinary Calculi

- Finish your entire prescription of antibiotics to ensure that you will not get a urinary tract infection.
- You may resume your usual daily activities.

- Remember to balance regular exercise with sleep and rest.
- You may return to work 2 days to 6 weeks after surgery, depending on the type of intervention, your personal tolerance, and your physician's directives.
- Depending on the type of stone you had, your diet may be restricted to prevent further stone formation.
- Remember to drink at least 3 L of fluid a day to dilute potential stone-forming crystals, prevent dehydration, and promote urine flow.
- Monitor urine pH as directed (possibly up to 3 times per day).
- Expect bruising after lithotripsy. The bruising may be quite extensive and may take several weeks to resolve.
- Your urine may be bloody for several days after surgery.
- Pain in the region of the kidneys or bladder may signal the beginning of an infection or the formation of another stone. Report any pain, fever, chills, or difficulty with urination immediately to your physician or nurse.
- Keep follow-up appointments to check on infection, and have repeat cultures done.

NCLEX Examination Challenge

Health Promotion and Maintenance

The client passes a urinary stone that laboratory analysis indicates is composed of calcium oxalate. Based on this analysis, which instruction does the nurse specifically include for dietary prevention of the problem?

A "Increase your intake of meat, fish, and cranberry juice."
B "Avoid citrus fruits and citrus juices such as oranges."
C "Avoid dark green leafy vegetables such as spinach."
D "Decrease your intake of dairy products, especially milk."

Urothelial Cancer

Pathophysiology

Urothelial cancers are malignant tumors of the *urothelium*—the lining of transitional cells in the kidney, renal pelvis, ureters, urinary bladder, and urethra. Most urothelial cancers occur in the bladder, and the term *bladder cancer* describes this condition.

In North America, most urinary tract cancers are transitional cell carcinomas of the bladder (ACS, 2014; Canadian Cancer Society, 2014).

The second most common site of urinary tract cancer is the kidney and renal pelvis. Urothelial cancers are usually low grade, have multiple points of origin *(multifocal),* and are recurrent. Once the cancer spreads beyond the transitional cell layer, it is highly invasive and can spread beyond the bladder. Because of the nature of this cancer, patients may have recurrence up to 10 years after being cancer free (ACS, 2014).

Tumors confined to the bladder mucosa are treated by simple excision, whereas those that are deeper but not into the muscle layer are treated with excision plus **intravesical** (inside the bladder) chemotherapy. Cancer that has spread deeper into the bladder muscle layer is treated with more extensive surgery, often a **radical cystectomy** (removal of the bladder and surrounding tissue) with urinary diversion. Chemotherapy and radiation therapy are used in addition to surgery. If untreated, the tumor invades surrounding tissues, spreads to distant sites (liver, lung, and bone), and ultimately leads to death.

Exposure to toxins, especially chemicals used in hair dyes and the rubber, paint, electric cable, and textile industries, increases the risk for bladder cancer. The greatest risk factor for bladder cancer is tobacco use. Other risks include *Schistosoma haematobium* (a parasite) infection, excessive use of drugs containing phenacetin, and long-term use of cyclophosphamide (Cytoxan, Procytox).

In the United States and Canada, about 82,690 new cases of bladder cancer are diagnosed each year, and about 17,780 deaths occur each year from the disease (ACS, 2014; Canadian Cancer Society, 2014). This cancer is rare in adults younger than 40 years and is most common after 60 years of age.

Health Promotion and Maintenance

Many people believe that tobacco use is associated with cancers only of organs that come into direct contact with it, such as the lungs. However, many compounds in tobacco enter the bloodstream and affect other organs, such as the bladder. Therefore encourage everyone who smokes to quit and nonsmokers not to start (see the Health Promotion and Maintenance section of Chapter 27 on pp. 494-496). Just as important, encourage anyone who comes into contact with dry, liquid, or gaseous chemicals to take precautions. Some people work with chemicals, and others may come into contact with them while engaging in hobbies. Many chemicals and fumes can enter the body through contact with skin and with mucous membranes in the respiratory tract. Use of personal protective equipment, such as gloves and masks, can reduce this contact.

Also encourage anyone who works with chemicals to shower or bathe and change clothing as soon as contact is completed.

NCLEX Examination Challenge

Physiological Integrity

A 65-year-old client is seeing his primary care provider for an annual examination. Which assessment finding alerts the nurse to an increased risk for bladder cancer?
A Smoking
B Urine with a high specific gravity
C Recurrent urinary tract infections
D History of cancer in another organ or tissue

Patient-Centered Collaborative Care

Assessment

Physical Assessment/Clinical Manifestations.

Ask about the patient's perception of his or her general health. Document the gender and age of the patient. Ask about active and passive exposure to cigarette smoke. To detect exposure to harmful environmental agents, ask the patient to describe his or her occupation and hobbies in detail. Also ask the patient to describe any change in the color, frequency, or amount of urine and any abdominal discomfort.

Observe the patient's overall appearance, especially skin color and nutrition status. Inspect, percuss, and palpate the abdomen for asymmetry, tenderness, and bladder distention.

Examine the urine for color and clarity. Blood in the urine is often the first manifestation of bladder cancer. It may be gross or microscopic and is usually painless and intermittent. Dysuria, frequency, and urgency occur when infection or obstruction is also present.

Psychosocial Assessment.

Assess the patient's emotions, including his or her response to a tentative diagnosis of bladder cancer, and note anxiety, fear, sadness, anger, or guilt. Early manifestations are painless, and many patients ignore the blood in the urine because it is intermittent. They also may be reluctant to seek treatment because they suspect a sexually transmitted disease (STD). As a result, they may have guilt or anger about their own

delays in seeking medical attention.

Assess the patient's coping methods and available support from family members. Social support may provide motivation and improve coping during recovery from treatment.

Diagnostic Assessment.

The only significant finding on a routine urinalysis is gross or microscopic hematuria. Cytologic testing on voided urine specimens usually is not helpful. Bladder-wash specimens and bladder biopsies are the most specific tests for cancer.

Cystoscopy is usually performed to evaluate painless hematuria. A biopsy of a visible bladder tumor can be performed during cystoscopy. This is essential for staging and is usually performed in an ambulatory care surgery center. Cystoureterography may be used to identify obstructions, especially where the ureter joins the bladder. CT scans show tumor invasion of surrounding tissues. Ultrasonography shows masses but is less valuable for tumor staging. MRI may help assess deep, invasive tumors.

Interventions

Therapy for the patient with bladder cancer usually begins with surgical removal of the tumor for diagnosis and staging of disease. For tumors extending beyond the mucosa, surgery is followed by intravesical chemotherapy or immunotherapy. High-grade or recurrent tumors are treated with more radical surgery plus intravesical chemotherapy, radiotherapy, or both. Systemic chemotherapy is reserved for patients with distant metastases. (See Chapter 22 for general care of the patient receiving chemotherapy or radiation therapy.)

Nonsurgical Management.

Prophylactic immunotherapy with intravesical instillation of bacille Calmette-Guérin (BCG), a live virus compound, is used to prevent tumor recurrence of superficial cancers. This procedure is more effective than single-agent chemotherapy. Usually the agent is instilled in an outpatient cancer clinic and allowed to dwell in the bladder for a specified length of time, usually 2 hours. When the patient urinates, live virus is excreted with the urine.

Teach patients receiving this treatment to prevent contact of the live virus with other members of the household by not sharing a toilet with others for at least 24 hours after instillation. Instruct men to urinate while sitting down to avoid splashing the urine. After 24 hours, the toilet

should be completely cleaned using a solution of 10% liquid bleach. If only one toilet is available in the household, teach the patient to flush the toilet after use and follow this by adding one cup of undiluted bleach to the bowl water. The bowl is then flushed after 15 minutes and the seat and flat surfaces of the toilet wiped with a cloth containing a solution of 10% liquid bleach. Instruct the patient to wear gloves during the cleaning and to dispose of the cloth after sealing it in a plastic bag.

Underwear or other clothing that has come into contact with the urine during the immediate 24 hours after instillation should be washed separately from other clothing in a solution of 10% liquid bleach. Sexual intercourse is avoided for 24 hours after the instillation.

Multiagent chemotherapy is successful in prolonging life after distant metastasis has occurred but rarely results in a cure. Radiation therapy is also useful in prolonging life.

Surgical Management.

The type of surgery for bladder cancer depends on the type and stage of the cancer and the patient's general health. Complete bladder removal *(cystectomy)* with additional removal of surrounding muscle and tissue offers the best chance of a cure for large, invasive bladder cancers. Four alternatives for urine elimination are used after cystectomy: ileal conduit; continent pouch; bladder reconstruction, also known as *neobladder;* and ureterosigmoidostomy.

Preoperative Care.

Specific patient education depends on the type and extent of the planned surgical procedure. Coordinate education before surgery with the patient, surgeon, and enterostomal therapist (ET) or wound, ostomy, and continence nurse. Discuss the type of planned urinary diversion and the selection of a site for the stoma. Including the patient in this planning improves the chances for the patient to have a positive attitude about body image and a positive self-image. Use educational counseling to ensure understanding about self-care practices, methods of pouching, control of urine drainage, and management of odor.

The site selected for the stoma should be visible to the patient and avoid folds of skin, bones, and scar tissue. When possible, the waistline or belt area is avoided. Prepare the patient for the number and type of drains that will be present after surgery. General care before surgery is discussed in Chapter 14.

Operative Procedures.

Transurethral resection of the bladder tumor (TURBT) or partial cystectomy is performed for small, early, superficial tumors. In a partial (segmental) cystectomy, a portion of the bladder is removed when there is only a single isolated bladder tumor.

When the entire bladder must be removed (complete cystectomy), the ureters are diverted into a collecting reservoir. Techniques for urinary diversion are shown in Fig. 66-4. With an ileal conduit, the ureters are surgically placed in the ileum and urine is collected in a pouch on the skin around the stoma. More often, continent reservoirs or "neobladders" are created from an intestinal graft. With cutaneous ureterostomy or ureteroureterostomy, the ureter opening is brought out onto the skin. The cutaneous ureterostomies may be located on either side of the abdomen or side by side.

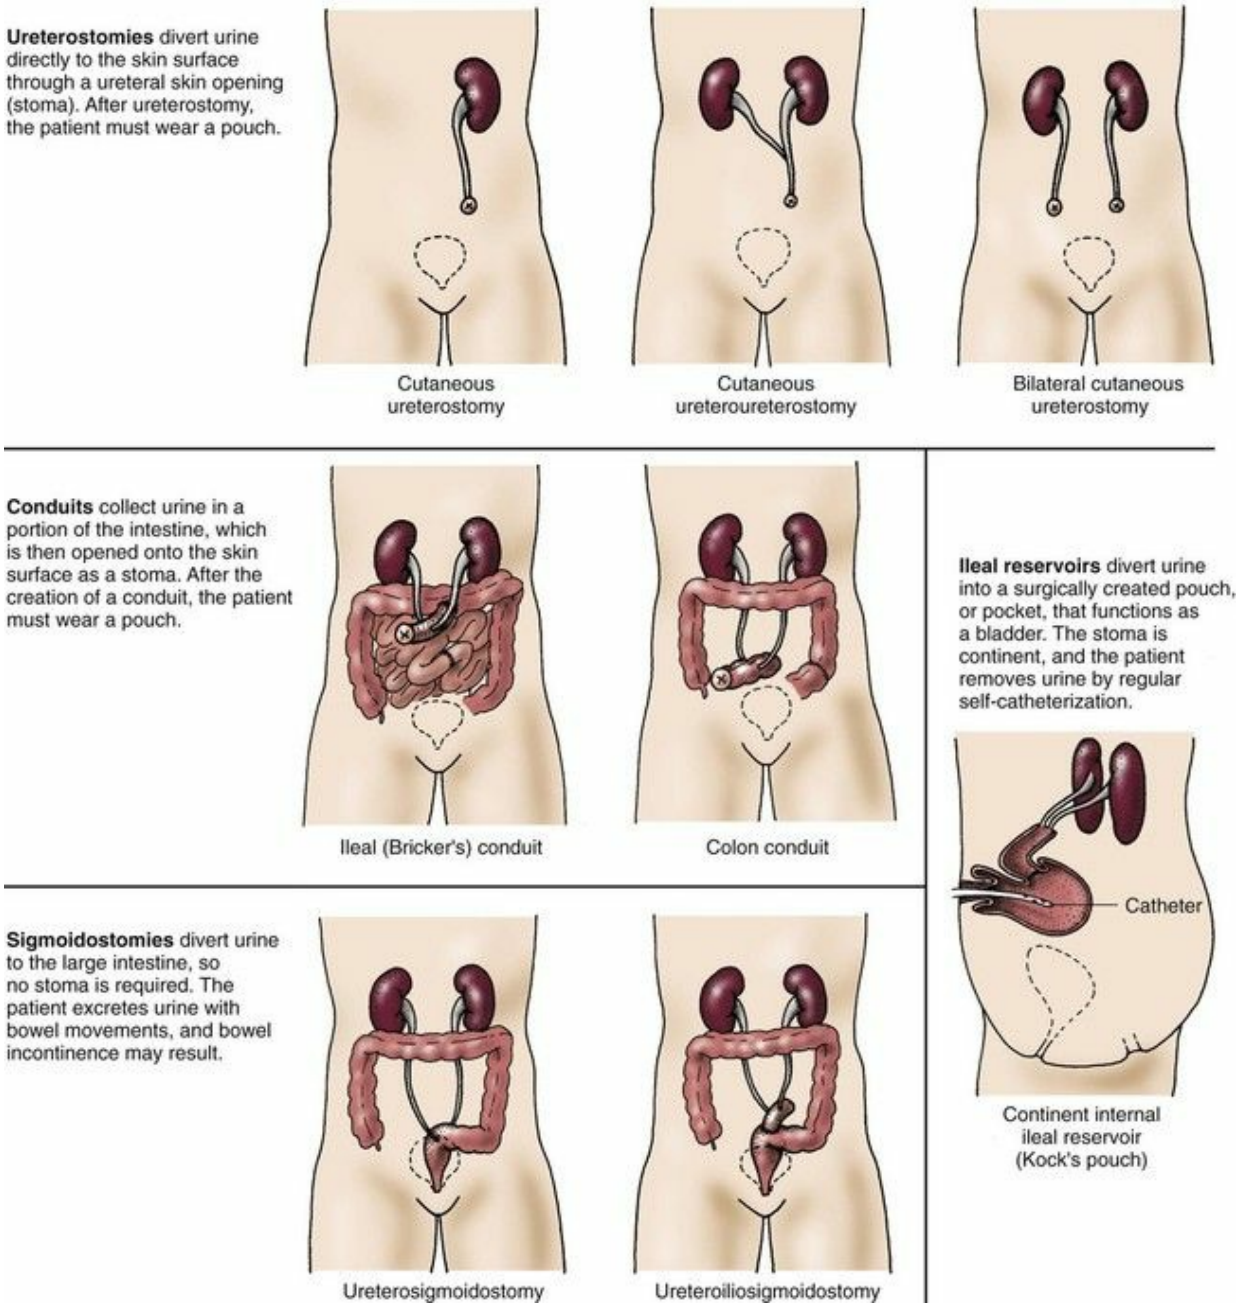

FIG. 66-4 Urinary diversion procedures used in the treatment of bladder cancer.

Postoperative Care.

After cutaneous ureterostomy, an external pouch covers the ostomy to collect urine. Work with the ET to focus care on the wound, the skin, and urinary drainage. (See Chapter 56 for ostomy care.)

The patient with a Kock's pouch, a continent reservoir, may have a Penrose drain and a plastic Medena catheter in the stoma. The drain removes lymphatic fluid or other secretions; the catheter ensures urine drainage so that incisions can heal. The patient with a neobladder usually requires 2 to 4 days in the intensive care unit (ICU) and will have a drain at first in the event the neobladder requires irrigation. Later, irrigation

can be performed with intermittent catheterization. Irrigation is performed to ensure patency. There is no sensation of bladder fullness with a neobladder because sensory nerves are not attached. As a result, the patient will need to learn new cues to void, such as prescribed times or noticing a feeling of neobladder pressure. General care after surgery is discussed in Chapter 16.

Different types of drains and nephrostomy catheters are used, sometimes on a temporary basis, to drain urine from the kidney. Some are totally internal, with no drainage to the outside. Others may drain exclusively to the outside and urine is collected in a pouch or bag. For this type of drainage system, urine output remains constant. Decreased or no drainage is cause for concern and must be reported to the surgeon or nephrologist, as is leakage around the catheter. Some nephrostomy tubes are connected both to the new bladder (internal drainage) and to an external drainage system. With this type of system, urine output from the external portion of the catheter is variable. With any drainage system, intervention is needed if the external catheter is partially or completely pulled out accidentally. Immediately notify the surgeon or nephrologist. If the catheter remains partially in place, secure it from further movement. This action may result in a re-insertion process rather than a total replacement.

Community-Based Care

Self-Management Education.

Teach the patient and family about drugs, diet and fluid therapy, the use of external pouching systems, and the technique for catheterizing a continent reservoir.

With some procedures, the patient may need electrolyte replacement to prevent long-term deficits. Teach him or her to avoid foods that are known to produce gas if the urinary diversion uses the intestinal tract. When intestinal production of gas is excessive, flatus can induce incontinence.

Patients who have a neobladder created often have extreme weight loss during the first few weeks after surgery. Collaborate with a dietitian to develop a diet plan specific to the patient to meet his or her caloric needs.

Nursing Safety Priority QSEN

Action Alert

Infection is common in patients who have a neobladder. Teach patients and family members the manifestations of infection and the importance of reporting them immediately to the surgeon.

Instruct the patient and family about any changes in self-care activities related to the urinary diversion. In collaboration with the enterostomal therapist, demonstrate external pouch application, local skin care, pouch care, methods of adhesion, and drainage mechanisms. If a Kock's pouch has been created, teach the patient how to use a catheter to drain the pouch. For all instruction, observe at least one return demonstration or "teach-back" session by the patient or the caregiver. Ideally, the patient assumes responsibility for self-care before discharge.

Assist the patient to prepare for the impact of urinary diversion on self-image, body image, sexual functioning, and self-esteem. Counseling provides information and support to reduce feelings of powerlessness.

Through discussions with the patient about common social situations, help him or her gain control over new toileting practices. Men with a urinary diversion into the sigmoid colon need to learn the habit of sitting to urinate. For patients of either gender, promote confidence in social situations by encouraging frequent emptying of urinary collection devices before traveling or attending social functions. Resumption of sexual activity is a major concern for many, regardless of age. Address this topic openly and with sensitivity. Cystectomy causes impotence in men, but treatment is available (see Chapter 72).

Health Care Resources.

The United Ostomy Association and the American Cancer Society have educational materials that may be useful to patients. Refer patients and family members to local chapters or units of these organizations. In some areas, local support groups have meetings to assist others and to send visitors to provide peer counseling and support. Home care personnel may assist with follow-up, easing the transition from hospital to home. The Wound, Ostomy, and Continence Nurses Society has educational programs and a journal for the care of patients with ostomies.

Bladder Trauma

❖ Pathophysiology

Bladder trauma can be caused by penetrating or blunt injury to the lower abdomen. Penetrating injury may occur by stabbing, gunshot wound, or other trauma in which objects pierce the abdominal wall. A fractured pelvis with puncture of the bladder by bone fragments is the most common cause of bladder trauma. Bladder trauma may also be a result of sexual assault.

Blunt trauma compresses the abdominal wall and the bladder. A seat belt may compress the bladder hard enough to cause injury, especially when the bladder is full or distended.

Patient-Centered Collaborative Care

Patients with a penetrating bladder wound often have anuria or hematuria. In the emergency department, initial assessment includes inspection of the urinary meatus for blood.

Bladder trauma, other than a simple contusion, requires surgical intervention. When bone fractures are present, they are stabilized before bladder repair to prevent further bladder damage. Surgical interventions include repairing the bladder wall and peritoneal membrane. Usually, repairs of the bladder are procedures to close the abnormal opening(s) caused by the trauma.

Patients with an anterior bladder wall injury usually have a Penrose drain and a Foley catheter in place after surgery. Those with a posterior bladder wall injury have a Penrose drain and Foley or suprapubic catheter after surgery. In some instances, vaginal or rectal fistulas may also require repair.

Psychosocial support is critical for patients who have sustained traumatic injuries. Refer them to counseling resources to assist in dealing with psychosocial issues.

Nursing Concepts and Clinical Judgment Review

What might you NOTICE if the patient is experiencing urinary elimination problems, inflammation, or infection from cystitis?

- Patient urinates frequently in small amounts.
- Patient reports pain and burning on urination.
- Patient reports suprapubic pain.
- Urine is cloudy and foul-smelling.
- Urine may be darker or smoky in appearance or have obvious blood in it.

What should you INTERPRET and how should you RESPOND to a

patient experiencing infection, inflammation, and urinary elimination problems as a result of a UTI?

Perform and interpret physical assessment, including:

- Asking how long manifestations have been present
- Asking about low back pain (midline in men) or flank pain
- Asking whether he or she has had a UTI in the past; how long ago; how it was treated; and if antibiotics were prescribed, whether the drug course was completed
- Asking about pregnancy or the presence of any chronic health problem, especially diabetes
- Determining fluid intake and output volumes
- Assessing for bladder distention by palpation or with a bedside bladder ultrasound scanner (see Chapter 65)
- Examining the meatus for irritation
- If a Foley catheter is in place, determining why it is in use and how long it has been present
- Interpreting laboratory values:
  - Is the complete blood count within normal limits?
  - Is the urinalysis positive for bacteria, leukocyte esterase, nitrate, red blood cells, or white blood cells?

Respond by:

- Assessing the need for continuing indwelling catheter
- Teaching the patient comfort measures
- Teaching the patient the importance of completing the prescribed drug regimen

On what should you REFLECT?

- Observe patient for evidence of improved urinary output (see Chapter 65).
- Think about what may have caused this infection in a hospitalized patient (or long-term care resident) and what steps could be taken to prevent a similar episode.
- Think about what patient-teaching focus could help reduce the risk for future UTI.

Get Ready for the NCLEX® Examination!

Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Use sterile technique when inserting a catheter or any other instrument into the urinary system. **Safety** QSEN
- Use Contact Precautions with any drainage from the genitourinary tract. **Safety** QSEN
- Determine whether there is an ongoing need for an indwelling catheter. **Evidence-Based Practice** QSEN

Health Promotion and Maintenance

- Teach patients to clean the perineal area daily, after voiding, after having a bowel movement, and after sexual intercourse. **Patient-Centered Care** QSEN
- Encourage all patients to maintain an adequate fluid intake.
- Instruct women who have stress incontinence the proper way to perform pelvic floor strengthening exercises. **Patient-Centered Care** QSEN
- Urge anyone who smokes to stop smoking.
- Teach patients who come into contact with chemicals in their workplaces or with leisure-time activities to avoid direct skin and mucous membrane contact with these chemicals. **Safety** QSEN

Psychosocial Integrity

- Allow the patient the opportunity to express feelings or concerns regarding a potential chronic urinary tract disorder or a cancer diagnosis. **Patient-Centered Care** QSEN
- Use a nonjudgmental approach in caring for patients with urinary incontinence.
- Avoid referring to protective pads or pants as “diapers.”
- Recognize the need for the patient undergoing cystectomy and urinary diversion to grieve about the body image change. **Patient-Centered Care** QSEN
- Assess the patient's level of comfort in discussing issues related to elimination and the urogenital area. **Patient-Centered Care** QSEN
- Use language and terminology during kidney/urinary assessment that

the patient is comfortable using. **Patient-Centered Care** QSEN
- Refer patients to community resources and support groups.

Physiological Integrity

- Identify hospitalized patients at risk for bacteriuria and urosepsis.
- Report immediately any condition that obstructs urine flow.
- Instruct patients with UTI to complete all prescribed antibiotic therapy even when manifestations of infection are absent.
- Evaluate daily the indications for maintaining indwelling catheters and discontinue their use as soon as possible. **Evidence-Based Practice** QSEN
- Teach patients the expected side effects and any adverse reactions to prescribed drugs.
- Assess the patient's manual dexterity and cognitive awareness before teaching a regimen of intermittent self-catheterization. **Patient-Centered Care** QSEN

CHAPTER 67

Care of Patients with Kidney Disorders

Chris Winkelman

PRIORITY CONCEPTS

- Elimination
- Pain
- Fluid and Electrolyte Balance
- Acid-Base Balance
- Inflammation
- Infection

Learning Outcomes

Safe and Effective Care Environment

1. Collaborate with members of the health care team when providing care to patients with various types of kidney disorders.
2. Prioritize collaborative interventions for patients with kidney disorders and after nephrectomy.
3. Assess presence and extent of pain and suffering for patients with kidney disease.

Health Promotion and Maintenance

4. Teach patients who have other health problems that affect kidney function and elimination to manage these problems and maintain kidney health.
5. Instruct patients who are at risk for or who have kidney changes involving infection or inflammation to manage kidney health appropriately.

Psychosocial Integrity

6. Reduce the psychological impact of kidney disorders for the patient and family.

Physiological Integrity

7. Identify adults at highest risk for development of an acute or chronic kidney disorder that affects fluid and electrolyte balance.
8. Perform focused kidney/urinary assessment and re-assessment.

http://evolve.elsevier.com/Iggy/

The role of the kidneys in urinary elimination is to filter wastes and maintain fluid and electrolyte balance, as well as acid-base balance. Any problem that disrupts kidney function limits the ability to meet these roles and has the potential to impair general homeostasis (Fig. 67-1). The kidneys work together with many other organ systems. Thus kidney disorders affect systemic health and can lead to life-threatening outcomes. Kidney disorders are classified as congenital, obstructive, infectious, glomerular, and degenerative. Kidney tumors and kidney trauma are also described in this chapter. Acute kidney injury (AKI) and chronic kidney disease (CKD) are discussed in Chapter 68.

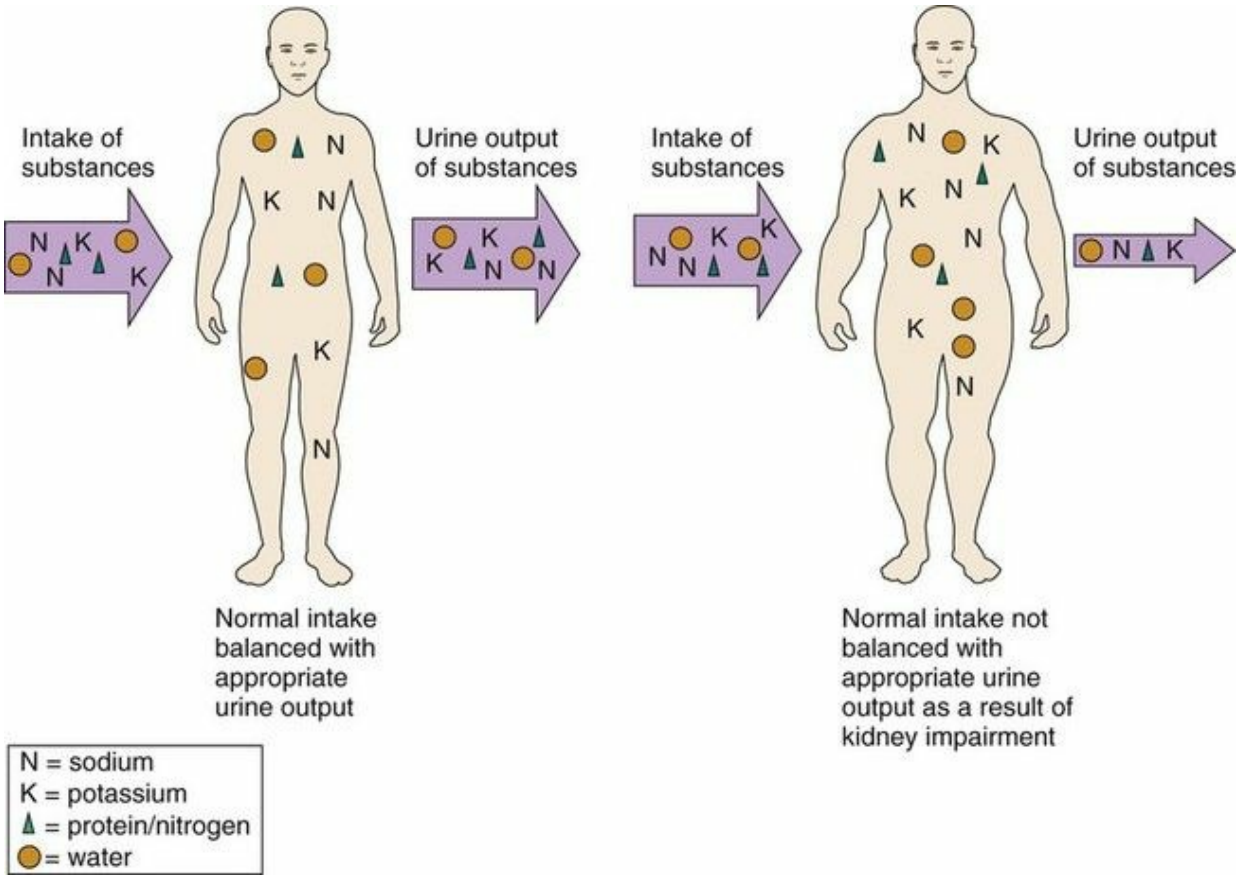

FIG. 67-1 Unbalanced body water, electrolytes, and waste products as a result of kidney problems that prevent adjustments in urinary elimination.

Congenital Disorders

Polycystic Kidney Disease

Pathophysiology

Polycystic kidney disease (PKD) is an inherited disorder in which fluid-filled cysts develop in the nephrons (Fig. 67-2). In the dominant form, only a few nephrons have cysts until the person reaches his or her 30s. In the recessive form of the disease, nearly all nephrons have cysts from birth. Cysts develop throughout the nephron as a result of abnormal cell division.

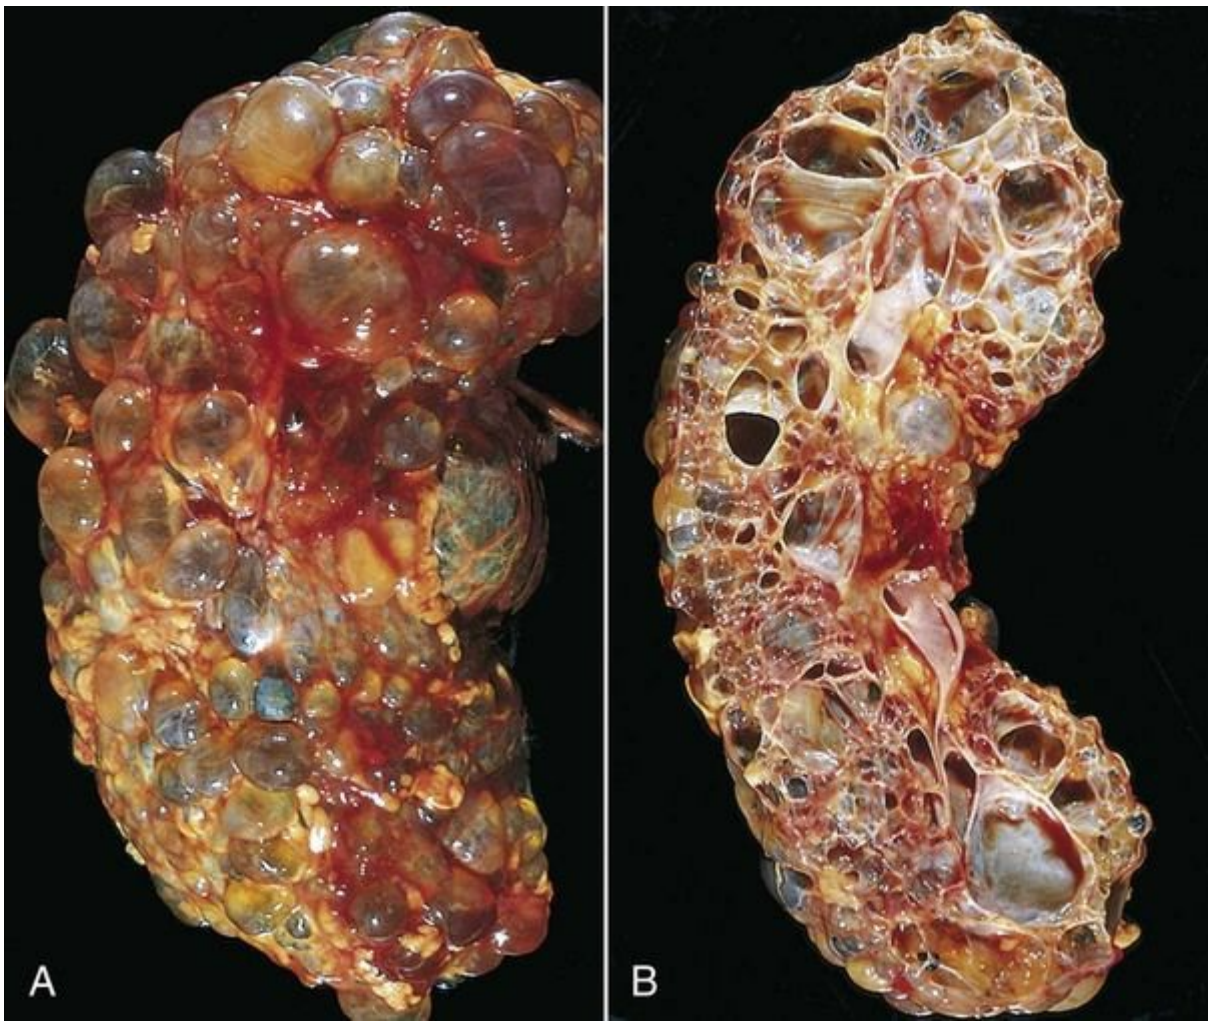

FIG. 67-2 External surface **(A)** and internal surface **(B)** of a polycystic kidney.

Over time, small cysts become much larger (up to centimeters in diameter) and more widely distributed. The growing cysts damage the glomerular and tubular membranes. As the cysts fill with fluid and enlarge, the nephron and kidney function become less effective.

The kidney tissue is eventually replaced by nonfunctioning cysts, which look like clusters of grapes (see Fig. 67-2). The kidneys become very large. Each cystic kidney may enlarge to 2 or 3 times its normal size, becoming as large as a football, and may weigh 10 pounds or more each. Other abdominal organs are displaced, and the patient has pain. The fluid-filled cysts are also at increased risk for infection, rupture, and bleeding, which increase pain.

Most patients with PKD have high blood pressure. The cause of hypertension is related to kidney ischemia from the enlarging cysts. As the vessels are compressed and blood flow to the kidneys decreases, the renin-angiotensin system is activated, raising blood pressure. Control of hypertension is a top priority because proper treatment can disrupt the process that leads to further kidney damage.

Cysts may occur also in other tissues, such as the liver and blood vessels. They may reduce liver function. In addition, the incidence of cerebral *aneurysms* (outpouching and thinning of an artery wall) is higher in patients with PKD. These aneurysms may rupture, causing bleeding and sudden death. For reasons as yet unknown, kidney stones occur in many patients with PKD. Heart valve problems (e.g., mitral valve prolapse), left ventricular hypertrophy, and colonic diverticula also are common in patients with PKD (McCance et al., 2014).

Etiology and Genetic Risk

PKD has several forms and can be inherited as either an autosomal dominant trait or, less commonly, as an autosomal recessive trait. People who inherit the recessive form of PKD usually die in early childhood. The 5% to 10% incidence of PKD in patients with no family history occurs as a result of a new gene mutation.

Genetic/Genomic Considerations

Patient-Centered Care QSEN

The autosomal dominant form of PKD (ADPKD) is the most common form of polycystic disease. Children of parents who have the autosomal dominant form of PKD have a 50% chance of inheriting the gene mutation that causes the disease (*PKD1*). Fig. 67-3 shows a typical pedigree for a family with ADPKD. Presentation of ADPKD can vary for age of onset, manifestations, and illness severity, even within one family. However, it is fully penetrant, meaning that nearly 100% of people who inherit a PKD gene mutation will develop kidney cysts by age 30 (Online

Mendelian Inheritance in Man [OMIM], 2014). Half of these people develop chronic kidney disease (CKD) by age 50 years. ADPKD-1 is the most common and most severe form of the autosomal dominant disease. ADPKD-2 has a slower rate of cyst formation, so manifestations occur later in life and progression to end-stage kidney disease (ESKD) and other complications is delayed.

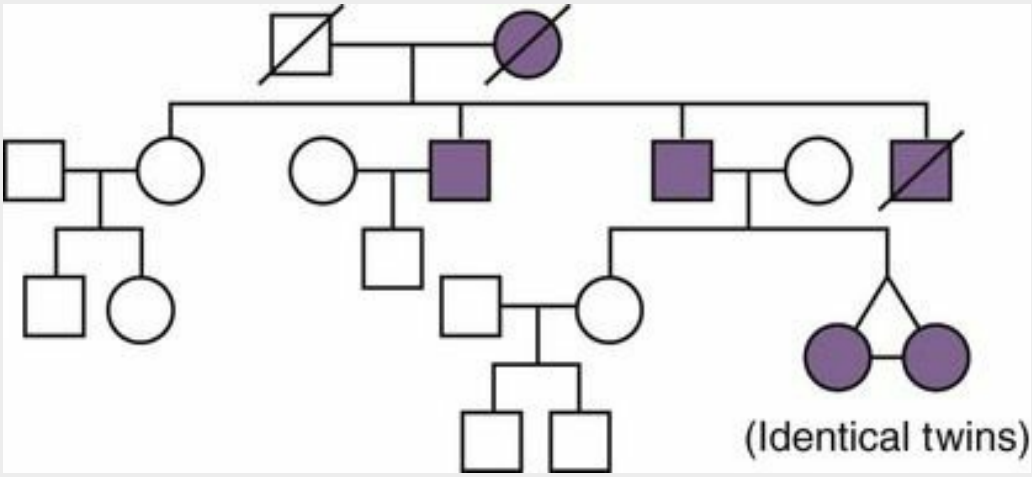

FIG. 67-3 Four-generation pedigree for autosomal dominant polycystic kidney disease (ADPKD). *Colored-in symbols* indicate family members with ADPKD. *Slashes* indicate the person has died.

There is no way to prevent PKD among people who have the genetic mutation, although early detection and management of hypertension may slow the progression of kidney damage. Genetic counseling may be useful for adults who have a parent with PKD. Family history analysis is a simple assessment that can be used to help identify people at risk for PKD (see Fig. 67-3).

Incidence and Prevalence

PKD is a common disorder, affecting about 600,000 people in the United States (National Kidney Foundation, 2013). It is more common in white people than in people of other races. Men and women have an equal chance of inheriting the disease because the gene responsible for PKD is not located on the sex chromosomes.

❖ Patient-Centered Collaborative Care

◆ Assessment

History.

Explore the family history of a patient with suspected or actual PKD, and ask whether either parent was known to have PKD or whether there is any family history of kidney disease. Important information to obtain is the age at which the problem was diagnosed in the parent and any related complications. Ask about constipation, abdominal discomfort, a change in urine color or frequency, high blood pressure, headaches, and a family history of sudden death from a stroke.

Physical Assessment/Clinical Manifestations.

Chart 67-1 lists key features of PKD. Pain is often the first manifestation. Inspect the abdomen. A distended abdomen is common as the cystic kidneys swell and push the abdominal contents forward. Polycystic kidneys are easily palpated because of their increased size. Proceed with *gentle* abdominal palpation because the cystic kidneys and nearby tissues may be tender and palpation is uncomfortable.

Chart 67-1 Key Features

Polycystic Kidney Disease

- Abdominal or flank pain
- Hypertension
- Nocturia
- Increased abdominal girth
- Constipation
- Bloody or cloudy urine
- Kidney stones
- Sodium wasting and inability to concentrate urine in early stage
- Progression to kidney failure with anuria

The patient also may have flank pain as a dull ache or as sharp and intermittent discomfort. Dull, aching pain is caused by increased kidney size with distention or by infection within the cyst. Sharp, intermittent pain occurs when a cyst ruptures or a stone is present. When a cyst ruptures, the patient may have bright red or cola-colored urine. Infection is suspected if the urine is cloudy or foul smelling or if there is **dysuria** (pain on urination).

Nocturia (the need to urinate excessively at night) is an early manifestation and occurs because of decreased urine concentrating ability. Patients with early PKD waste sodium and water. As kidney

function further declines, the patient has increasing hypertension, edema, and uremic manifestations such as anorexia, nausea, vomiting, pruritus, and fatigue (see Chapter 68). Because berry aneurysms often occur in patients with PKD, a severe headache with or without neurologic or vision changes requires attention.

Psychosocial Assessment.

As an inherited disorder, PKD may cause psychosocial responses. The patient often has seen the effects and problems of the disease in close family members. He or she may have had a parent who died or close relatives who required dialysis or transplantation. While obtaining the family history, listen carefully for spoken and unspoken feelings of anger, resentment, futility, sadness, or anxiety. Such feelings may need further exploration. The focus of the feelings may be one or both parents or the process of diagnosis and treatment. Feelings of guilt and concern for the patient's children may also complicate the issue.

Diagnostic Assessment.

Urinalysis shows **proteinuria** (protein in the urine) once the glomeruli are involved. **Hematuria** (blood in the urine) may be gross or microscopic. Bacteria in the urine indicate infection, usually in the cysts. Obtain a urine sample for culture and sensitivity testing when there is evidence of infection. As kidney function declines, serum creatinine and blood urea nitrogen (BUN) levels rise. With decreasing kidney function, creatinine clearance decreases. Changes in kidney handling of sodium may cause either sodium losses or sodium retention.

Diagnostic studies to detect cysts include renal ultrasound, CT, and MRI.

Interventions

Interventions for the patient with PKD include pain management and prevention of infection, constipation, hypertension, and chronic kidney disease. Newer drug therapies are being evaluated to interrupt the pathways that promote malignant cyst formation such as molecular signaling for cell division or endothelial growth (Aguiari et al., 2013). When the disease progresses and the kidneys no longer function to clear wastes, care becomes similar to that needed for the patient with end-stage kidney disease (ESKD) (see Chapter 68).

Managing Pain.

Pain management strategies include drug therapy and complementary

approaches. A combination may be most effective. NSAIDs are used cautiously because they can reduce kidney blood flow. Aspirin-containing compounds are avoided to reduce the risk for bleeding.

If cyst infection causes discomfort, antibiotics such as trimethoprim/sulfamethoxazole (Bactrim, Septra, Trimpex) or ciprofloxacin (Cipro) are prescribed. (See Chart 66-4 in Chapter 66.) These drugs enter the cyst wall. Monitor the serum creatinine levels because antibiotic therapy can be nephrotoxic. Apply dry heat to the abdomen or flank to promote comfort when kidney cysts are infected. When pain is severe, cysts can be reduced by needle aspiration and drainage; however, they usually refill.

Teach the patient methods of relaxation and comfort using deep breathing, guided imagery, or other strategies. The expected outcome is patient self-management. (See Chapter 3 for pain management.)

Preventing Constipation.

Teach the patient who has adequate urine output how to prevent constipation by maintaining adequate fluid intake, increasing dietary fiber when fluid intake is more than 2500 mL/24 hr, and exercising regularly. Explain that pressure on the large intestine may occur as the polycystic kidneys increase in size. The patient should know that these recommendations for bowel management might change, particularly if ESDK also develops. Advise him or her about the use of stool softeners and bulk agents, including the careful use of laxatives, to prevent chronic constipation.

Controlling Hypertension and Preventing End-Stage Kidney Disease.

Blood pressure control is necessary to reduce cardiovascular complications and slow the progression of kidney dysfunction. Nursing interventions include education to promote self-management and understanding. When kidney impairment results in decreased urine concentration with nocturia and low urine specific gravity, urge the patient to drink at least 2 L of fluid per day to prevent dehydration, which can further reduce kidney function. Restricting sodium intake may help control blood pressure. See Chapter 36 for a detailed discussion about the causes and management of hypertension.

Drug therapy for blood pressure control includes antihypertensive agents and diuretics. Antihypertensive agents include angiotensin-converting enzyme (ACE) inhibitors, calcium channel blockers, beta blockers, and vasodilators (see Chapter 36). ACE inhibitors may help control the cell growth aspects of PKD and reduce microalbuminuria.

Teach the patient and family how to measure and record blood pressure. Help the patient establish a schedule for self-administering drugs, monitoring daily weights, and keeping blood pressure records (Chart 67-2). Explain the potential side effects of the drugs. Make available written materials, such as drug teaching cards and booklets.

Chart 67-2 Patient and Family Education: Preparing for Self-Management

Polycystic Kidney Disease

- Measure and record your blood pressure daily, and notify your health care provider for consistent changes in blood pressure.
- Take your temperature if you suspect you have a fever. If a fever is present, notify your physician or nurse.
- Weigh yourself every day at the same time of day and with the same amount of clothing; notify your physician or nurse if you have a sudden weight gain.
- Limit your intake of salt to help control your blood pressure.
- Notify your physician or nurse if your urine smells foul or has blood in it.
- Notify your physician or nurse if you have a headache that does not go away or if you have visual disturbances.
- Monitor bowel movements to prevent constipation.

Many patients may have salt wasting and should not follow a sodium-restricted diet. As the disease progresses, the protein intake may be limited to slow the development of ESKD. Assist the patient and family in understanding the diet plan and why it was prescribed. Work closely with the dietitian to foster the patient's understanding. Also refer the patient for nutrition counseling.

Health Care Resources

The Polycystic Kidney Research Foundation (www.pkdcure.org) and the National Kidney & Urologic Diseases Clearinghouse (NKUDIC) of the National Institute of Diabetes and Digestive and Kidney Diseases (www2.niddk.nih.gov) conduct research and provide education about PKD. Many pamphlets are available; there is a fee for some materials. Chapters of the National Kidney Foundation (NKF) and the American Association of Kidney Patients (AAKP) also have resources for information and support.

NCLEX Examination Challenge

Health Promotion and Maintenance

Which statement made by the client who is newly diagnosed with polycystic kidney disease (PKD) indicates to the nurse that additional teaching for self-management is needed?

A "I will need to increase my daily water intake."
B "I will restrict my sodium to less than 2 g daily."
C "Now I will need to take a blood pressure drug daily."
D "If I become sexually active or plan to have a family, I will seek genetic counseling."

Obstructive Disorders

Hydronephrosis, Hydroureter, and Urethral Stricture

Pathophysiology

Hydronephrosis and hydroureter are problems of urine outflow obstruction. Urethral strictures also obstruct urine outflow. Prompt recognition and treatment are crucial to prevent permanent kidney damage.

In **hydronephrosis**, the kidney enlarges as urine collects in the renal pelvis and kidney tissue. Because the capacity of the renal pelvis is normally 5 to 8 mL, obstruction in the renal pelvis or at the point where the ureter joins the renal pelvis quickly distends the renal pelvis. Kidney pressure increases as the volume of urine increases. Over time, sometimes in only a matter of hours, the blood vessels and kidney tubules can be damaged extensively (Fig. 67-4).

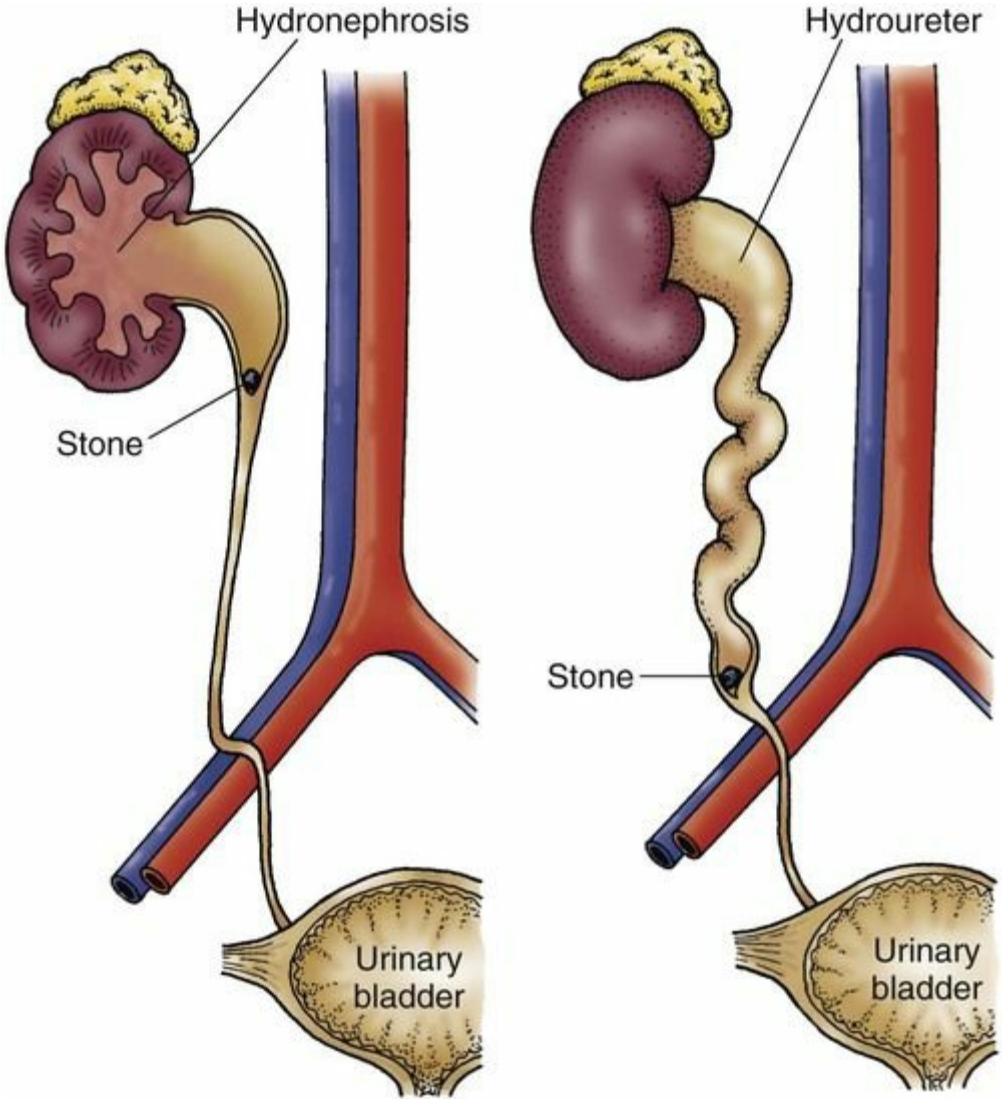

FIG. 67-4 Hydronephrosis is caused by obstruction in the upper part of the ureter. Hydroureter is caused by obstruction in the lower part of the ureter.

In patients with **hydroureter** (enlargement of the ureter), the effects are similar but the obstruction is in the ureter rather than in the kidney. The ureter is most easily obstructed where the iliac vessels cross or where the ureters enter the bladder. Ureter dilation occurs above the obstruction and enlarges as urine collects (see Fig. 67-4).

In patients with a **urethral stricture**, the obstruction is very low in the urinary tract, causing bladder distention before hydroureter and hydronephrosis. The problems and kidney damage are similar without prompt treatment.

Urinary obstruction causes damage when pressure builds up directly on kidney tissue. Tubular filtrate pressure also increases in the nephron as drainage through the collecting system is impaired. With this added pressure, glomerular filtration decreases or ceases. Necrosis of the affected kidney can occur. Nitrogen waste products (urea, creatinine, and

uric acid) and *electrolytes* (sodium, potassium, chloride, and phosphorus) are retained, and acid-base balance is impaired.

Causes of hydronephrosis or hydroureter include tumors, stones, trauma, structural defects, and fibrosis (Pengo et al., 2013). In patients with cancer, obstructed ureters may result from the tumors themselves, pelvic radiation, or surgical treatment. Early treatment of the causes can prevent hydronephrosis and hydroureter and prevent permanent kidney damage. The time needed to prevent permanent damage depends on the patient's kidney health. Permanent damage can occur in less than 48 hours in some patients and after several weeks in other patients.

Patient-Centered Collaborative Care

Assessment

Obtain a history from the patient, focusing on known kidney or urologic disorders. A history of childhood urinary tract problems may indicate previously undiagnosed structural defects. Ask about his or her usual pattern of urine elimination, especially amount, frequency, color, clarity, and odor. Ask about recent flank or abdominal pain. Chills, fever, and malaise may be present with a urinary tract infection (UTI).

Inspect each flank to identify asymmetry, which may occur with a kidney mass, and *gently* palpate the abdomen to locate areas of tenderness. Palpate and percuss the bladder to detect distention, or use a bedside bladder scanner. Gentle pressure on the abdomen may cause urine leakage, which reflects a full bladder and possible obstruction.

Urinalysis may show bacteria or white blood cells if infection is present. When urinary tract obstruction is prolonged, microscopic examination may show tubular epithelial cells. Blood chemistries are normal unless glomerular filtration has decreased. Blood creatinine and blood urea nitrogen (BUN) levels increase with a reduced glomerular filtration rate (GFR). Serum electrolyte levels may be altered with elevated blood levels of potassium, phosphorus, and calcium along with a metabolic acidosis (bicarbonate deficit).

Urinary outflow obstruction can be seen with ultrasound (US) or CT.

Interventions

Urinary retention and potential for infection are the primary problems. Failure to treat the cause of obstruction leads to infection and ESKD.

Urologic Interventions.

If the stricture is caused by a stone, it can be located and removed using cystoscopic or retrograde urogram procedures. The urologist uses a cystoscope to guide a stone basket over the stone and removes it through the bladder. After stone removal, a plastic stent is usually left in the ureter for a few weeks to improve urine flow in the area irritated by the stone. The stent is later removed by another cystoscopic procedure.

Radiologic Interventions.

When a stricture is causing hydronephrosis and cannot be corrected with urologic procedures, a **nephrostomy** is performed. Most nephrostomy drains provide only external drainage (diversion). Other styles of nephrostomy drains enter the kidney but extend to the bladder. These tubes can drain urine out to a bag or past a ureteral stricture and into the bladder, so there is both an internal and external component to the nephrostomy tubing. Externally, a fully external or an internal/external diversion drain appears the same. The urine output will fluctuate more if all urine goes to the bladder before external drainage.

Patient Preparation.

If possible, the patient is kept NPO for 4 to 6 hours before the procedure. Clotting studies (e.g., international normalized ratio [INR], prothrombin time [PT], and partial thromboplastic time [PTT]) should be normal or corrected. Drugs are used to reduce hypertension. The patient receives moderate sedation for the procedure.

Procedure.

The patient is placed in the prone position. The kidney is located under ultrasound or fluoroscopic guidance, and a local anesthetic is given. A needle is placed into the kidney, a soft-tipped guidewire is placed through the needle, and then a catheter is placed over the wire. The catheter tip remains in the renal pelvis, and the external end is connected to a drainage bag. The procedure immediately relieves the pressure and prevents further damage. The nephrostomy tube remains in place until the obstruction is resolved (with or without further intervention).

Follow-up Care.

Assess the amount of drainage in the collection bag. The amount of drainage depends on whether a ureteral catheter is also being used (with a separate drainage bag). Patients with ureteral tubes may have all urine pass through to the bladder or may have urine drain into the collection bags. The type of urine drainage expected should be clearly

communicated in the chart. If urine is expected to drain into the collection bag, assess the amount of drainage hourly for the first 24 hours. When urine drains only into the collection bag and not into the bladder, the minimum expected drainage is 30 mL/hr. If the amount of drainage decreases and the patient has back pain, the tube may be clogged or dislodged.

Monitor the nephrostomy site for leaking urine or blood. Urine drainage may be red-tinged for the first 12 to 24 hours after the procedure and should gradually clear. Assess the patient for manifestations of infection, including fever or a change in urine character.

Nursing Safety Priority QSEN

Critical Rescue

After nephrostomy, notify the physician immediately when the drainage decreases or stops, drainage becomes cloudy or foul-smelling, the nephrostomy site leaks blood or urine, or the patient has back pain.

NCLEX Examination Challenge

Physiological Integrity

When providing care to a client who has undergone a nephrostomy for hydronephrosis, which observation alerts the nurse to a possible complication?

A Urine output of 15 mL/hr
B Tenderness at the surgical site
C Blood urea nitrogen (BUN) of 23 mg/dL
D Pink-tinged urine draining from the nephrostomy

Infectious Disorders: Pyelonephritis

In the healthy person, urine is normally sterile and remains sterile if there is no obstruction to urine passage in the kidney and urinary tract. When any structural abnormality is present, the risk for damage as a result of infection is greatly increased. **Urinary tract infection (UTI)** is an infection in this normally sterile system. **Pyelonephritis** is a bacterial infection in the kidney and renal pelvis.

Pathophysiology

Pyelonephritis is either the presence of active organisms in the kidney or the effects of kidney infection. **Acute pyelonephritis** is the active bacterial infection, whereas **chronic pyelonephritis** results from repeated or continued upper urinary tract infections or the effects of such infections. Chronic pyelonephritis often occurs with a urinary tract defect, with obstruction, or, most commonly, when urine refluxes from the bladder back into the ureters. **Reflux** is the reverse or upward flow of urine toward the renal pelvis and kidney.

In pyelonephritis, organisms move up from the urinary tract into the kidney tissue. Descending infection transmitted by organisms in the blood may occur, but not often. Bacteria trigger the inflammatory response, and local edema results.

Acute pyelonephritis involves acute tissue inflammation, tubular cell necrosis, and possible abscess formation. **Abscesses**, which are pockets of infection, can occur anywhere in the kidney. The infection is scattered within the kidney; healthy tissues can lie next to infected areas. Fibrosis and scar tissue develop from the inflammation. The calices thicken, and scars develop in the interstitial tissue.

Reflux of infected urine from the bladder into the ureters and kidney is responsible for most cases of chronic pyelonephritis. Reflux within the kidney can occur when some papillae in the kidney do not close properly. Inflammation and fibrosis lead to deformity of the renal pelvis and calices. Repeated or continuous infection creates additional scar tissue, changing blood vessel, glomerular, and tubular structure. As a result, filtration, reabsorption, and secretion are impaired and kidney function is reduced (Fig. 67-5).

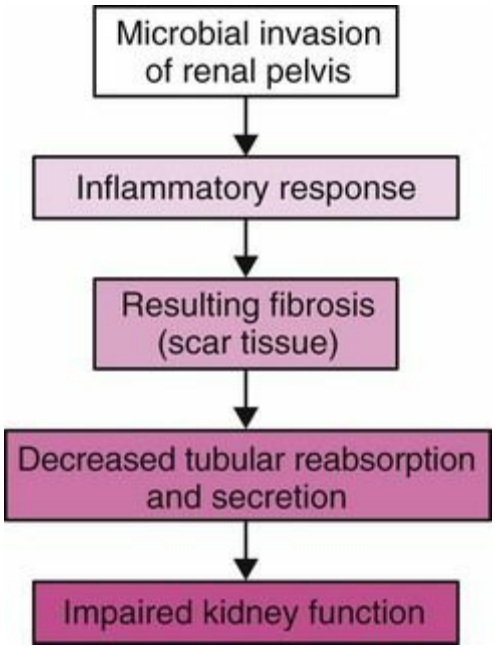

FIG. 67-5 Pathophysiology of pyelonephritis.

Etiology and Genetic Risk

Single episodes of *acute pyelonephritis* result from bacterial infection, with or without obstruction or reflux. *Chronic pyelonephritis* usually occurs with structural deformities, urinary stasis, obstruction, or reflux. Conditions that lead to urinary stasis include prolonged bedrest and paralysis. Obstruction can be caused by stones, kidney cancer, scarring from pelvic radiotherapy or surgery, recurrent infection, or injury. Reflux may occur from scarring or as a result of anatomic anomalies. Reflux also results from bladder tumor, prostate enlargement, or urinary tract stones. Reduced bladder tone from diabetic neuropathy, spinal cord injury, and neurodegenerative diseases (e.g., spina bifida, multiple sclerosis) contributes to reflux and increases the risk for pyelonephritis.

Pyelonephritis from an ascending infection may follow manipulation of the urinary tract (e.g., placement of a urinary catheter), particularly in patients who are immunosuppressed or who have diabetes mellitus. In patients with chronic kidney stone disease, stones may retain organisms, resulting in ongoing infection and kidney scarring. Drug use can also contribute to pyelonephritis. In particular, high-dose or prolonged use of NSAIDs can lead to papillary necrosis and reflux.

The most common pyelonephritis-causing infecting organism is *Escherichia coli*. *Enterococcus faecalis* is common in hospitalized patients. Both organisms are in the intestinal tract. Other organisms that cause pyelonephritis in hospitalized patients include *Proteus mirabilis*, *Klebsiella* species, and *Pseudomonas aeruginosa*. When the infection is

bloodborne, common organisms include *Staphylococcus aureus* and the *Candida* and *Salmonella* species.

Other causes of kidney scarring contributing to increased risk for pyelonephritis are inflammation and inflammatory responses resulting from antibody reactions, cell-mediated immunity against the bacterial antigens, or autoimmune reactions.

Incidence and Prevalence

About 250,000 cases of acute pyelonephritis occur each year, resulting in more than 100,000 hospitalizations in the United States (U.S. Renal Data Systems, 2012). Chronic pyelonephritis is more common in women, although the exact incidence and prevalence are not known. After 65 years of age, rates of pyelonephritis for men increase greatly because of the increased incidence of prostatitis.

Patient-Centered Collaborative Care

Assessment

History.

Ask about a history of urinary tract infections (UTIs), diabetes mellitus, stone disease, and defects of the genitourinary tract. Determine whether the UTIs occurred with pregnancy, and ask the patient about any previous episodes of pyelonephritis or similar problems. Ask about disease or treatment that causes immunosuppression, because they can also increase risk for pyelonephritis. Recurrences are common and may lead to a decline of kidney function. Ensure that a woman is not pregnant before radiographic imaging.

Physical Assessment/Clinical Manifestations.

Ask about specific manifestations of acute pyelonephritis (Chart 67-3). Chronic pyelonephritis has a less dramatic presentation, with manifestations related to the infection or reduced kidney function. Ask the patient to describe any vague urinary manifestations or abdominal discomfort. Inquire about any history of repeated low-grade fevers. Changes in urine color or odor may accompany bacteriuria. Chart 67-4 lists the kidney effects of chronic pyelonephritis.

Chart 67-3 Key Features

Acute Pyelonephritis

- Fever
- Chills
- Tachycardia and tachypnea
- Flank, back, or loin pain
- Tender costovertebral angle (CVA)
- Abdominal, often colicky, discomfort
- Nausea and vomiting
- General malaise or fatigue
- Burning, urgency, or frequency of urination
- Nocturia
- Recent cystitis or treatment for urinary tract infection (UTI)

Chart 67-4 Key Features

Chronic Pyelonephritis

- Hypertension
- Inability to conserve sodium
- Decreased urine-concentrating ability, resulting in nocturia
- Tendency to develop hyperkalemia and acidosis

Inspect the flanks, and gently palpate the costovertebral angle (CVA). Inspect both CVAs for enlargement, asymmetry, edema, or redness, all of which can indicate inflammation. If there is no tenderness to light palpation in either CVA, an advanced practice nurse firmly percusses each area. Tenderness or discomfort may indicate infection or inflammation.

Psychosocial Assessment.

The patient with any problem in the genitourinary area may have feelings of anxiety, embarrassment, or guilt. Listen carefully for signs of anxiety or specific fears, and prevent embarrassment during assessment. Feelings of guilt, often associated with sexual habits or practices, may be masked through delay in seeking treatment or through vague, nonspecific responses to specific or direct questions. Encourage patients to tell their own story in familiar, comfortable language.

Laboratory Assessment.

Urinalysis shows a positive leukocyte esterase and nitrite dipstick test and the presence of white blood cells and bacteria. Occasional red blood cells, white blood cell casts, and protein may be present. The urine is

cultured to determine whether gram-positive or gram-negative organisms are causing the infection. The urine sample for culture and sensitivity testing, obtained by the clean-catch method, shows the bacterial species and susceptibility or resistance of the specific organism to various antibiotics. In patients with recurrent episodes of pyelonephritis or upper UTIs, more specific testing of bacterial antigens and antibodies may help determine whether the same organism is responsible for the recurrent infections.

Blood cultures are obtained for specific organisms. Other blood tests include the C-reactive protein and erythrocyte sedimentation rate to determine the presence of inflammation.

Imaging Assessment.

An x-ray of the kidneys, ureters, and bladder (KUB) or CT is performed to visualize anatomy, inflammation, fluid accumulation, abscess formation, and defects in kidneys and the urinary tract. These tests also identify stones, tumors, or prostate enlargement. Urine reflux caused by incompetent bladder-ureter valve closure can be seen with a cystourethrogram. (See Chapter 65 for more information on imaging assessment.)

Other Diagnostic Assessment.

Other diagnostic tests include examining antibody-coated bacteria in urine, testing for certain enzymes (e.g., lactate dehydrogenase isoenzyme 5), and radionuclide renal scan. Examining urine for antibody-coated bacteria helps identify patients who may need long-term antibiotic therapy. High-molecular-weight enzymes in urine, such as lactate dehydrogenase isoenzyme 5, are present with any kidney tissue deterioration problem and give trend data. The renal scan can identify active pyelonephritis or abscesses in or around the kidney.

◆ Analysis

The priority NANDA-I nursing diagnoses and collaborative problems for patients with pyelonephritis include:

1. Acute Pain (flank and abdominal) related to inflammation and infection (NANDA-I)
2. Potential for chronic kidney disease and end-stage kidney disease related to infectious tissue destruction

◆ Planning and Implementation

Managing Pain

Planning: Expected Outcomes.

With proper intervention, the patient with pyelonephritis is expected to achieve an acceptable state of comfort. Indicators include that he or she often or consistently demonstrates these behaviors:

- Uses pharmacologic relief measures
- Uses NSAIDs appropriately
- Reports pain controlled

Interventions.

Interventions may be nonsurgical or surgical. The use of several techniques that crush stones, such as lithotripsy and percutaneous ultrasonic pyelolithotomy (see Chapter 66), has decreased the need for surgery.

Nonsurgical Management.

Interventions include the use of drug therapy, nutrition and fluid therapy, and teaching to ensure the patient's understanding of the treatment.

Drug therapy with antibiotics is prescribed to treat the infection. At first, the antibiotics are broad spectrum. After urine and blood culture and sensitivity results are known, more specific antibiotics may be prescribed. Urinary antiseptic drugs (e.g., nitrofurantoin [Macrodantin]) may also be prescribed to provide comfort.

Nutrition therapy involves ensuring that the patient's nutrition intake has adequate calories from all food groups for healing to occur. Fluid intake is recommended at 2 L/day, sufficient to result in dilute (pale yellow) urine, unless another health problem requires fluid restriction.

Surgical Management.

Surgical interventions can correct structural problems causing urine reflux or obstruction of urine outflow or can remove the source of infection.

Antibiotics are given, usually IV, to achieve adequate blood levels or sterile blood culture results. Teach the patient the nature and purpose of the proposed surgery, the expected outcome, and how he or she can participate.

The surgical procedures may be one of these: **pyelolithotomy** (stone removal from the kidney), **nephrectomy** (removal of the kidney), ureteral diversion, or reimplantation of ureter to restore proper bladder drainage.

A pyelolithotomy is needed for removal of a large stone in the kidney pelvis that blocks urine flow and causes infection. Nephrectomy is a last

resort when all other measures to clear the infection have failed. For patients with poor ureter valve closure or dilated ureters, **ureteroplasty** (ureter repair or revision) or ureteral reimplantation (through another site in the bladder wall) preserves kidney function and eliminates infections.

Preventing End-Stage Kidney Disease

Planning: Expected Outcomes.

The patient is expected to conserve existing kidney function for as long as possible and have a slow progression to end-stage kidney disease (ESKD) once the damage has occurred. Indicators include that he or she consistently demonstrates these behaviors:

- Describes the role of antibiotics and self-administration of drugs
- Explains and offers techniques to ensure adequate nutrition and hydration
- Describes the plan for post-treatment follow-up, including knowledge of recurrent manifestations
- Modifies prescribed regimen as directed by a health care professional

Interventions.

Specific antibiotics are prescribed to treat the infection. Stress the importance of completing the drug therapy as directed. Discuss with the patient and family the importance of regular follow-up examinations and completing the recommended diagnostic tests.

Blood pressure control is needed to slow the progression of kidney dysfunction. When kidney impairment decreases concentrating ability, encourage the patient to drink sufficient fluid during waking hours to prevent dehydration because dehydration could further reduce kidney function. When dietary protein is restricted, refer the patient to the dietitian as needed. Other interventions related to the progression of chronic kidney disease are covered in Chapter 68.

Community-Based Care

Pyelonephritis causes fear and anxiety in the patient and family. The severity of the acute process and its potential to develop into a chronic process are frightening. The patient and the family need reassurance that treatment and preventive measures can be successful.

Home Care Management.

If no surgery is performed, the patient may need help with self-care,

nutrition, and drug management at home. If surgery is performed, he or she may need help with incision care, self-care, and transportation for follow-up appointments.

Self-Management Education.

After assessing the patient's and family's understanding of pyelonephritis and its therapy, explain:

- Drug regimen (purpose, timing, frequency, duration, and possible side effects)
- The role of nutrition and adequate fluid intake
- The need for a balance between rest and activity, including any limitations after surgery
- The manifestations of disease recurrence
- The use of previously successful coping mechanisms

Advise the patient to complete all prescribed antibiotic regimens and to report any side effects or unusual manifestations to the health care provider rather than stopping the drugs. Refer the patient and family for nutrition counseling as needed, because many patients have special nutrition needs, such as those for diabetes or pregnancy.

Health Care Resources.

The patient may also briefly need a home health care nurse to help with drug or nutrition therapy at home. Housekeeping services may be helpful while he or she is regaining strength.

◆ Evaluation: Outcomes

Evaluate the care of the patient with pyelonephritis based on the identified priority patient problems. Expected outcomes may include that the patient will:

- Report that pain is controlled
- Be knowledgeable about the disease, its treatment, and interventions to prevent or reduce disease progression

Specific indicators for these outcomes are listed for each priority patient problem in the Planning and Implementation section (see earlier).

Immunologic Kidney Disorders

Glomerulonephritis (GN) is the third leading cause of end-stage kidney disease (ESKD) (U.S. Renal Data Systems, 2012). Whether the disease starts in the kidney or occurs as the result of other health problems, the glomeruli are usually injured (Table 67-1). For disease that starts in the kidney, a genetic basis and immune-inducing inflammation problems are common. In addition, systemic diseases and infections can have kidney effects and cause glomerular injury (Table 67-2). Conditions that lead to glomerular disease include systemic lupus erythematous and diabetic nephropathy.

TABLE 67-1

Primary Glomerular Diseases and Syndromes

- Acute glomerulonephritis
- Rapidly progressive glomerulonephritis (RPGN)
- Chronic glomerulonephritis
- Nephrotic syndrome
- Persistent, vague urinary abnormalities with few or no symptoms

TABLE 67-2

Secondary Glomerular Diseases and Syndromes

- Systemic lupus erythematosus (SLE)
- Schönlein-Henoch purpura
- Goodpasture's syndrome
- Systemic necrotizing vasculitis
- Wegener's granulomatosis
- Periarteritis nodosa (also called *polyarteritis nodosa*)
- Amyloidosis
- Diabetic glomerulopathy
- HIV-associated nephropathy
- Alport's syndrome

- Multiple myeloma
- Viral hepatitis B
- Viral hepatitis C
- Cirrhosis
- Sickle cell disease
- Nonstreptococcal postinfectious acute glomerulonephritis
- Infective endocarditis
- Hemolytic-uremic syndrome
- Thrombotic thrombocytopenic purpura

HIV, Human immune deficiency virus.

Each type of disease or syndrome has a specific pathophysiology and clinical manifestations. Their *glomerular* effects are caused by injury to the glomeruli and result in proteinuria, hematuria, decreased glomerular filtration rate (GFR), edema, and hypertension. The extent and duration of kidney injury, prognosis, and specific cause vary among these syndromes.

Immunologic changes injure the glomeruli, interstitium, or tubules, and the effects may be acute or chronic. Both antibody and cellular immune responses leading to inflammation are involved. The resultant kidney disorder can be systemic or confined to the kidneys.

Most forms of inflammation-induced glomerulonephritis (GN) occur with a collection of immune complexes in the glomeruli (Fig. 20-4 in Chapter 20). An immune complex is made up of antigens (foreign substances within the body) and antibodies. The antigen can be part of any normal kidney tissue, or it can be dissolved in a body fluid (e.g., blood). Bacteria and viruses are also antigens. Exposure to bacteria, viruses, drugs, or other toxins is believed to be the trigger for glomerular injury.

Antibody reaction with antigens can cause immune complexes to form and become deposited in glomerular tissue, leading to inflammation. These complexes trigger many inflammatory mediators, such as complement, white blood cells, and blood clotting proteins, which also damage the kidney tissue. Actions that cause tissue injury include damage to cell membranes, local edema, movement of white blood cells to the site of inflammation, and platelet activation.

Acute Glomerulonephritis

❖ Pathophysiology

An infection often occurs before the kidney manifestations of acute glomerulonephritis (GN). The onset of manifestations is about 10 days from the time of infection. Usually patients recover quickly and completely from acute GN. The term *acute nephritic syndrome* also describes this disorder.

Most causes of acute GN are infectious (Table 67-3) or are related to other systemic diseases (see Table 67-2). The incidence of acute GN is unknown. GN after a systemic streptococcal infection is more common in men.

TABLE 67-3

Infectious Causes of Acute Glomerulonephritis

- Group A beta-hemolytic *Streptococcus*
- Staphylococcal or gram-negative bacteremia or sepsis
- Pneumococcal, *Mycoplasma*, or *Klebsiella* pneumonia
- Syphilis
- Visceral abscesses
- Infective endocarditis
- Hepatitis B
- Infectious mononucleosis
- Measles
- Mumps
- Rocky Mountain spotted fever
- Cytomegalovirus infection
- Histoplasmosis
- Toxoplasmosis
- Varicella
- *Chlamydia psittaci* infection
- Coxsackievirus infection
- Any bacterial, parasitic, fungal, or viral infection (potentially)

Patient-Centered Collaborative Care

Assessment

History.

Ask about recent infection, particularly of the skin or upper respiratory tract, and about recent travel or other possible exposures to viruses, bacteria, fungi, or parasites. Recent illnesses, surgery, or other invasive procedures may suggest infections. Ask about any known systemic diseases, such as systemic lupus erythematosus (SLE), which could cause acute GN.

Physical Assessment/Clinical Manifestations.

Inspect the patient's skin for lesions or recent incisions, including body piercings. Assess the face, eyelids, hands, and other areas for edema because edema is present in most patients with acute GN. Assess for fluid overload and circulatory congestion that may accompany the fluid and sodium retention occurring with acute GN. Ask about any difficulty in breathing or shortness of breath. Assess for crackles in the lung fields, an S_3 heart sound (gallop rhythm), and neck vein distention.

Ask about changes in voiding patterns and any change in urine color, volume, clarity, or odor. Microscopic blood in the urine occurs, and patients often describe their urine as smoky, reddish brown, rusty, or cola colored. Ask about dysuria or oliguria. Weigh him or her to assess for fluid retention.

Take the patient's blood pressure, and compare it with the baseline

blood pressure. Mild to moderate hypertension occurs with acute GN as a result of fluid and sodium retention. The patient may have fatigue, a lack of energy, anorexia, nausea, and vomiting if uremia from severe kidney impairment is present.

Considerations for Older Adults

Patient-Centered Care QSEN

The less common manifestations of acute GN are more likely to occur in older adults. Circulatory congestion often is present, causing acute GN to be easily confused with congestive heart failure (CHF). Ask any older adult with CHF about voiding patterns to determine whether the problem may be related to acute GN.

Laboratory Assessment.

Urinalysis shows red blood cells *(hematuria)* and protein *(proteinuria).* An early morning specimen of urine is preferred for urinalysis because the urine is most acidic and formed elements are more intact at that time. Microscopic examination often shows red blood cell casts, as well as casts from other substances.

The glomerular filtration rate (GFR), either estimated from a single serum and urine creatinine value or measured by the 24-hour urine test for creatinine clearance, may be decreased to 50 mL/min. The older patient may have a greater decline in GFR.

A 24-hour urine collection for total protein assay is obtained. The protein excretion rate for patients with acute GN may be increased from 500 mg/24 hr to 3 g/24 hr. Serum albumin levels are decreased because of the protein lost in the urine and because of fluid retention causing dilution.

Specimens from the blood, skin, or throat are obtained for culture, if indicated. Serum creatinine and blood urea nitrogen provide information about kidney function and may be elevated, indicating impairment. Other serum tests include antistreptolysin-O titers, C3 complement levels, cryoglobulins (immunoglobulin G [IgG]), antinuclear antibodies (ANAs), and circulating immune complexes.

Antistreptolysin-O titers are increased after group A beta-hemolytic *Streptococcus* infection. Complement levels are decreased when the complement system is activated. Type III cryoglobulins may be found during acute illness. ANAs suggest an autoimmune response with inflammation, and systemic lupus erythematosus (SLE) is just one

possibility. Immune complexes containing IgG and C3 are often detected.

Other Diagnostic Assessment.

A kidney biopsy provides a precise diagnosis of the condition, assists in determining the prognosis, and helps outline treatment (see Chapter 65). The specific tissue features are determined by light microscopy, immunofluorescent stains, and electron microscopy to identify cell type, the presence of immunoglobulins, or the type of tissue deposits.

Interventions

Interventions focus on managing infection, preventing complications, and providing appropriate patient education.

Managing infection as a cause of acute GN begins with appropriate antibiotic therapy. Penicillin, erythromycin, or azithromycin is prescribed for GN caused by streptococcal infection. Check the patient's known allergies before giving any drug. To prevent infection spread, antibiotics for people in immediate close contact with the patient also may be prescribed. Stress personal hygiene and basic infection control principles (e.g., handwashing) to prevent spread of the organism. Teach patients the importance of completing the entire course of the prescribed antibiotic.

Preventing complications is an important nursing intervention. For patients with fluid overload, hypertension, and edema, diuretics and sodium and water restrictions are prescribed. The usual fluid allowance is equal to the 24-hour urine output plus 500 to 600 mL. Patients with oliguria usually have increased serum levels of potassium and blood urea nitrogen (BUN). Potassium and protein intake may be restricted to prevent hyperkalemia and uremia. Antihypertensive drugs may be needed to control hypertension (see Chapter 36).

Nausea, vomiting, or anorexia indicates that uremia is present. Dialysis is necessary if uremic manifestations or fluid volume excess cannot be controlled (see Chapter 68). **Plasmapheresis** (removal and filtering of the plasma to eliminate antibodies) also may be used (see Chapter 40).

Coordinate care to conserve patient energy. Balance activity with rest to maintain function. Relaxation techniques and participation in diversional activities can reduce emotional stress.

Preparing for self-management includes teaching the patient and family members about the purpose of prescribed drugs, the dosage and schedule, and potential adverse side effects. Ensure that they understand diet and fluid restrictions. Advise the patient to measure weight and blood pressure daily at the same time each day. Instruct him or her to notify the health care provider of any sudden increase in weight or blood

pressure.

If short-term dialysis is required to control fluid and electrolyte balance or uremic manifestations, explain peritoneal or vascular access care and dialysis schedules and routines (also see Chapter 68).

Rapidly Progressive Glomerulonephritis

Rapidly progressive glomerulonephritis (RPGN), a type of acute nephritis, is also called *crescentic glomerulonephritis* because of the presence of crescent-shaped cells in the Bowman's capsule. RPGN develops over several weeks or months and causes loss of kidney function. Patients become quite ill quickly and have manifestations of kidney impairment (hypertension, oliguria, disturbed fluid and electrolyte balance, and uremic symptoms).

The patient may have had previous infection or systemic disease, such as systemic lupus erythematosus (SLE). When associated with SLE, steroid therapy is recommended (Hahn et al., 2012). Regardless of treatment, RPGN often progresses to end-stage kidney disease (ESKD).

Chronic Glomerulonephritis

Pathophysiology

Chronic glomerulonephritis, or *chronic nephritic syndrome,* develops over 20 to 30 years or even longer. The exact onset of the disorder is rarely identified. Often the cause of the disease is not known. Mild proteinuria and hematuria, hypertension, fatigue, and occasional edema are often the only manifestations.

Although the exact cause is not known, changes in the kidney tissue result from hypertension, infection and inflammation, or poor blood flow to the kidneys. Kidney tissue atrophies, and the number of functional nephrons is greatly reduced. Biopsy in the late stages of atrophy may show glomerular changes, cell loss, protein and collagen deposits, and fibrosis of the kidney tissue. Microscopic examination shows deposits of immune complexes and inflammation.

The loss of nephrons reduces glomerular filtration. Hypertension and renal arteriolar sclerosis are often present. The glomerular damage allows proteins to enter the urine. Chronic glomerulonephritis always leads to ESKD (see Chapter 68).

Patient-Centered Collaborative Care

Assessment

History.

Ask about other health problems, including systemic diseases, kidney or urologic disorders, infectious diseases (e.g., streptococcal infections), and recent exposures to infection. Ask about overall health status and whether increasing fatigue and lethargy have occurred.

Identify the patient's voiding pattern. Ask whether the frequency of urine elimination has increased or the quantity of urine has decreased. Ask about changes in urine color, odor, or clarity and whether dysuria or incontinence has occurred. Nocturia is a common manifestation.

Assess the patient's general comfort, and ask whether new-onset dyspnea has occurred, because fluid overload can occur with decreased urine output. Ask about and observe for changes in mental functioning (e.g., irritability, an inability to read, or incapacity during job-related functions) or disturbed concentration. Changes in memory and the ability to concentrate occur as waste products collect in the blood.

Physical Assessment/Clinical Manifestations.

Assess for systemic circulatory overload. Auscultate lung fields for crackles, observe the respiratory rate and depth, and measure blood pressure and weight. Auscultate the heart for rate, rhythm, and the presence of an S_3 heart sound. Inspect the neck veins for venous engorgement, and check for edema of the feet and ankles, on the shins, and over the sacrum.

Assess for uremic manifestations, such as slurred speech, ataxia, tremors, or **asterixis** (flapping tremor of the fingers or the inability to maintain a fixed posture with the arms extended and wrists hyperextended). Inspect skin for a yellowish color, texture changes, bruises, rashes, or eruptions. Ask about itching, and document areas of dryness or any excoriation from scratching.

Diagnostic Assessment.

Urine output decreases, and urinalysis shows protein, usually less than 2 g in a 24-hour collection. The specific gravity is fixed at a constant level of dilution (around 1.010) despite variable fluid intake. Red blood cells and casts may be in the urine.

The glomerular filtration rate (GFR), measured by creatinine clearance, is low. The serum creatinine level is elevated, usually greater than 6 mg/dL but may be as high as 30 mg/dL or more. The BUN is increased, often as high as 100 to 200 mg/dL.

Decreased kidney function causes disturbed fluid and electrolyte balance. Sodium retention is common, but dilution of the plasma from excess fluid can result in a falsely normal serum sodium level (135 to 145 mEq/L) or a low sodium level (less than 135 mEq/L). When oliguria develops, potassium is not excreted and hyperkalemia occurs when levels exceed 5.4 mEq/L.

Hyperphosphatemia develops with serum levels greater than 4.7 mg/dL. Serum calcium levels are usually at the lower end of the normal range (9.0 to 10.5 mg/mL) or are slightly below normal.

Disturbances of acid-base balance with acidosis develop from hydrogen ion retention and loss of bicarbonate. However, there may be a decrease in serum carbon dioxide (CO_2) levels as patients breathe more rapidly to compensate for the acidosis. If respiratory compensation is present, the pH of arterial blood is between 7.35 and 7.45. A pH of less than 7.35 means that the patient's respiratory system is not completely compensating for the acidosis (see Chapter 12).

The kidneys are abnormally small on x-ray or CT. A kidney biopsy is important in the early stages of glomerulonephritis, when protein or blood is first present in the urine. Tissue changes include inflammation with a variety of cells infiltrating the glomerular tissue, deposits of immune complexes, and blood vessel sclerosis. In advanced disease, when the kidneys are small, biopsy is not usually performed.

Interventions

Interventions focus on slowing the progression of the disease and preventing complications. Management consists of diet changes, fluid intake sufficient to prevent reduced blood flow to the kidneys, and drug therapy to control the problems from uremia. Eventually the patient requires dialysis or transplantation to prevent death. (Care for the patient requiring dialysis or transplantation is discussed in Chapter 68.)

Nephrotic Syndrome

Pathophysiology

Nephrotic syndrome (NS) is a condition of increased glomerular permeability that allows larger molecules to pass through the membrane into the urine and then be excreted. This process causes massive loss of protein into the urine, edema formation, and decreased plasma albumin levels. Many agents and disorders are possible causes of NS.

The most common cause of glomerular membrane changes is an immune or inflammatory process. Defects in glomerular filtration can

also occur as a result of genetic defects of the glomerular filtering system, such as Fabry disease. Altered liver activity may occur with nephrotic syndrome, resulting in increased lipid production and hyperlipidemia.

Patient-Centered Collaborative Care

The main feature of nephrotic syndrome (NS) is severe proteinuria (with more than 3.5 g of protein in a 24-hour urine sample). Patients also have low serum albumin levels of less than 3 g/dL, high serum lipid levels, fats in the urine, edema, and hypertension (Chart 67-5). Renal vein thrombosis often occurs at the same time as NS, either as a cause of the problem or as an effect. NS may progress to end-stage kidney disease (ESKD), but treatment can prevent progression in most patients.

Chart 67-5 Key Features

Nephrotic Syndrome

Sudden onset of these manifestations:

- Massive proteinuria
- Hypoalbuminemia
- Edema (especially facial and periorbital)
- Lipiduria
- Hyperlipidemia
- Increased coagulation
- Reduced kidney function

Management varies depending on what process is causing the disorder (identified by kidney biopsy). Immunologic processes may improve with suppressive therapy using steroids and cytotoxic or immunosuppressive agents. Angiotensin-converting enzyme (ACE) inhibitors can decrease protein loss in the urine, and cholesterol-lowering drugs can improve blood lipid levels. Heparin may reduce vascular defects and improve kidney function. Diet changes are often prescribed. If the glomerular filtration rate (GFR) is normal, dietary intake of complete proteins is needed. If the GFR is decreased, dietary protein intake must be decreased. Mild diuretics and sodium restriction may be needed to control edema and hypertension. Assess the patient's hydration status, because vascular dehydration is common. If the plasma volume is depleted, kidney problems worsen. Acute kidney injury (AKI) may be avoided if good blood flow to the kidney is maintained.

Immunologic Interstitial and Tubulointerstitial Disorders

Problems can arise in the kidney tissues around the nephrons, as well as in the nephrons. These interstitial and tubulointerstitial disorders in the kidney are usually caused by immune problems and inflammation. The kidney changes may be acute or chronic. The acute effects often occur with drugs such as penicillins, cephalosporins, sulfonamides, or NSAIDs. Chronic interstitial nephritis has many causes, including NSAID use, complement activation, cyclosporin use, polycystic kidney disease, autoimmune disorders, inflammation, multiple myeloma, sickle cell disease, obstructive disorders, and radiation nephritis. Drug-induced problems often occur with a rash or an elevated eosinophil count. Fever is common in interstitial nephritis of unknown cause. Progression to ESKD occurs unless the cause is identified and removed.

Degenerative Disorders

Degenerative disorders that change kidney function often occur with a multisystem disorder. Many of these degenerative disorders result from changes in kidney blood vessels.

Nephrosclerosis

Pathophysiology

Nephrosclerosis is a problem of thickening in the nephron blood vessels, resulting in narrowing of the vessel lumens. This change decreases kidney blood flow, and the tissue is chronically hypoxic. Ischemia and fibrosis develop over time.

Nephrosclerosis occurs with hypertension, atherosclerosis, and diabetes mellitus. The more severe the hypertension, the greater the risk for severe kidney damage. Nephrosclerosis is rarely seen when blood pressure is consistently below 160/110 mm Hg. The changes caused by hypertension may be reversible or may progress to end-stage kidney disease (ESKD) within months or years. (Hypertension is the second leading cause of ESKD.)

Cultural Considerations

Patient-Centered Care QSEN

Hypertension is more common in African Americans and American Indians, and the risks for ESKD from hypertension are also greater for these ethnic groups (U.S. Renal Data Systems, 2012). Between 25 and 45 years of age, the ratio of African Americans to Caucasians at risk for ESKD from hypertension is nearly 20 : 1. At any health care encounter with an African-American patient or an American-Indian patient, blood pressure should always be assessed. If hypertension is present, treatment and patient education can help reduce the risk for development of ESKD.

Patient-Centered Collaborative Care

Management focuses on controlling blood pressure and reducing albuminuria to preserve kidney function. Although many antihypertensive drugs may lower blood pressure, the patient's response is important in ensuring long-term adherence to the prescribed therapy. Factors that promote adherence include once-a-day dosing, low cost, and

minimal side effects.

Lack of knowledge or misinformation about hypertension poses many challenges to health care providers working with patients who have hypertension. When kidney disease occurs, adherence to therapy is even more important for preserving health.

Many drugs can control high blood pressure (see Chapter 36), and more than one agent may be needed for best control. Angiotensin-converting enzyme (ACE) inhibitors are very useful in reducing hypertension and preserving kidney function. Diuretics can maintain fluid and electrolyte balance in the presence of kidney function insufficiency. Hyperkalemia needs to be prevented when potassium-sparing diuretics, alone or in combination with other diuretics, are used to treat hypertensive patients with known kidney disease.

Renovascular Disease

❖ Pathophysiology

Processes affecting the renal arteries may severely narrow the lumen and greatly reduce blood flow to the kidney tissues. Uncorrected renovascular disease, such as renal artery stenosis, atherosclerosis, or thrombosis, causes ischemia and atrophy of kidney tissue.

Patients with renovascular disease often have a sudden onset of hypertension, particularly in those older than 50 years. Patients with high blood pressure but with no family history of hypertension also may potentially have renal artery stenosis (RAS). RAS from atherosclerosis or blood vessel hyperplasia is the main cause of renovascular disease. Other causes include thrombosis and renal vessel aneurysms.

Atherosclerotic changes in the renal artery often occur along with sclerosis in the aorta and other vessels. Changes in the renal artery are often located where the renal artery and aorta meet. Fibrotic changes of the blood vessel wall occur throughout the length of the renal artery.

❖ Patient-Centered Collaborative Care

◆ Assessment

Key features of renovascular disease are listed in Chart 67-6. Hypertension usually first occurs after 40 to 50 years of age, and often the patient does not have a family history of hypertension. Diagnosis is made by magnetic resonance angiography (MRA), renal ultrasound, radionuclide imaging, or renal arteriography. MRA provides an excellent image of the renal vasculature and kidney anatomy. Radionuclide

imaging is a noninvasive way of evaluating kidney blood flow and excretory function. Combining radionuclide imaging with ingestion of an angiotensin-converting enzyme (ACE) inhibitor, such as captopril, improves the accuracy of the test. A renal arteriogram makes the features of the renal blood vessels visible.

Chart 67-6 Key Features

Renovascular Disease

- Significant, difficult-to-control high blood pressure
- Poorly controlled diabetes or sustained hyperglycemia
- Elevated serum creatinine
- Decreased creatinine clearance

Interventions

Identifying the type of defect, extent of narrowing, and condition of the surrounding blood vessels is critical for treatment choice. The patient's overall health and the size of the atrophied kidney also affect management decisions. Many patients with renovascular disease also have cardiovascular disease, and both conditions require treatment.

RAS may be managed by drugs to control blood pressure and by procedures to restore the blood supply to the kidney. Drugs may control high blood pressure but may not lead to long-term preservation of kidney function. In young and middle-aged adults, a lifetime of treatment with many drugs for high blood pressure makes treatment difficult and the outcomes uncertain.

Endovascular techniques are nonsurgical approaches to repair RAS. Stent placement with or without balloon angioplasty is an example of an endovascular intervention (see Chapter 36). After the procedure, the patient usually remains under close observation for 24 hours to monitor for sudden blood pressure fluctuations as the kidneys adjust to increased blood flow. Endovascular techniques are less risky and require less time for recovery than does renal artery bypass surgery (Escobar & Campbell, 2012).

Renal artery bypass surgery is a major procedure and requires 2 or more months for recovery. A bypass may be performed for either one or both renal arteries. A synthetic blood vessel graft is inserted to redirect blood flow from the abdominal aorta into the renal artery, beyond the area of narrowing. A splenorenal bypass can also restore blood flow to the kidney. The process is similar to other arterial bypass procedures (see

Chapter 38).

Diabetic Nephropathy

❖ Pathophysiology

Diabetes mellitus (DM) is the leading cause of end-stage kidney disease (ESKD) in North America (U.S. Renal Data Systems, 2012). About 36% of patients requiring dialysis or kidney transplantation have DM (U.S. Renal Data Systems, 2012). Diabetic nephropathy occurs with either type 1 or type 2 DM. Severity of diabetic kidney disease is related to the degree of hyperglycemia the patient generally experiences. With poor control of hyperglycemia, the complicating problems of atherosclerosis, hypertension, and neuropathy (which promotes loss of bladder tone, urinary stasis, and urinary tract infection) are more severe and more likely to cause kidney damage.

❖ Patient-Centered Collaborative Care

Diabetic nephropathy is a vascular complication of diabetes. Its first manifestation is microalbuminuria, and screening for small amounts of protein in the urine should begin 5 years after the diagnosis of type 1 DM and annually after type 2 DM is diagnosed. Diabetic kidney disease is progressive.

Structural and functional changes occur in the kidneys of patients with diabetes. Initially, kidney size is slightly increased and glomerular filtration rates (GFRs) are higher than normal. Any proteinuria (albuminuria) indicates the need for aggressive treatment and a thorough diagnostic workup for comorbidities. See Chapter 64 for a detailed discussion of kidney issues in patients with diabetes.

Patients with diabetes are always considered to be at risk for ESKD. If possible, nephrotoxic agents (e.g., iodinated contrast media, aminoglycosides) and dehydration are avoided. Patients with worsening kidney function may begin to have frequent hypoglycemic episodes and a reduced need for insulin or antidiabetic agents. Explain that the kidneys metabolize and excrete insulin. When kidney function is reduced, the insulin is available for a longer time and thus less of it is needed. Some patients may believe this means their diabetes is improving with reduced insulin needs, but that is not accurate. Instead, it is an indication of worsening complications.

Desired outcomes of care to prevent the development of microalbuminuria and delay the progression to ESKD in patients with

DM include:

- Achieving glycemic control (e.g., A1C <6.5%)
- Normalizing blood pressure (goal of 130/80 mm Hg or 125/75 mm Hg if proteinuria is greater than 1.0 g/24 hr and serum creatinine is greater than 1.5 mg/dL)
- Using drugs that block renin-angiotensin-aldosterone system (e.g. aldosterone)
- Treating dyslipidemia (so that the low-density lipoprotein [LDL] cholesterol is less than 100 mg/dL)

(See Chapter 64 for specific information on diabetic nephropathy.)

NCLEX Examination Challenge

Health Promotion and Maintenance

When assessing a client with diabetic nephropathy, which question about self-management should the nurse ask to determine whether the client is currently following best practices to slow the progression of this condition?

A "Have you increased your protein intake to promote healing of the damaged nephrons?"

B "Do you avoid contact sports to reduce the risk for causing trauma to your kidneys?"

C "How do you manage your diet to keep your blood glucose levels in the target range?"

D "Have you increased your fluid intake based on urine output?"

Renal Cell Carcinoma

Pathophysiology

Renal cell carcinoma (RCC) is the most common type of kidney cancer and is also known as *adenocarcinoma of the kidney.* As with other cancers, the healthy tissue of the kidney is damaged and replaced by cancer cells.

Systemic effects occurring with this cancer type are called *paraneoplastic syndromes* and include anemia, erythrocytosis, hypercalcemia, liver dysfunction with elevated liver enzymes, hormonal effects, increased sedimentation rate, and hypertension.

Anemia and erythrocytosis may seem confusing; however, most patients with this cancer have *either* anemia *or* erythrocytosis, not both at the same time. There is some blood loss from hematuria, but the small amount lost does not cause anemia. The cause of the anemia and the erythrocytosis is related to kidney cell production of erythropoietin. At times, the tumor cells produce large amounts of erythropoietin, causing erythrocytosis. At other times, the tumor cells destroy the erythropoietin-producing kidney cells and anemia results.

Parathyroid hormone produced by tumor cells can cause hypercalcemia. Other hormone changes include increased renin levels (causing hypertension) and increased human chorionic gonadotropin (hCG) levels, which decrease libido and change secondary sex features.

RCC has five distinct carcinoma cell types: clear cell, papillary cell, chromophobe cell, collecting duct carcinoma, and unclassified type (Patel et al., 2012). A few RCCs are hereditary. The most well-known genetic syndrome that includes kidney cancer is von Hippel-Lindau syndrome. These cancers are highly vascular and may occur with cancers of the pancreas, central nervous system, and adrenal glands.

Kidney tumors are classified into four stages (Table 67-4). Complications include metastasis and urinary tract obstruction. The cancer usually spreads to the adrenal gland, liver, lungs, long bones, or the other kidney. When the cancer surrounds a ureter, hydroureter and obstruction may result.

TABLE 67-4

Staging Kidney Tumors

Stage I. Tumors up to 2.5 cm are situated within the capsule of the kidney. The renal vein, perinephric fat, and adjacent lymph nodes have no tumor. **Stage II.** Tumors are larger than 2.5 cm and extend beyond the capsule but are within Gerota's fascia. The renal vein and lymph nodes are not involved. **Stage III.** Tumors extend into the renal vein, lymph nodes, or both. **Stage IV.** Tumors include invasion of adjacent organs beyond Gerota's fascia or metastasize to distant tissues.

Data from American Cancer Society. (2014). *Cancer facts and figures 2014.* Report No. 00-300M–No. 500814. Atlanta: Author.

The causes of nonhereditary RCC are unknown, but the risk is slightly higher for people who use tobacco or are exposed to cadmium and other heavy metals, asbestos, benzene, and trichloroethylene. Men are slightly more likely to acquire RCC, as are obese, African-American, or hypertensive people.

Kidney cancers account for about 64,000 new cases and 13,860 deaths annually in the United States (American Cancer Society [ACS], 2014). In Canada, 6000 new cases and 1750 deaths from kidney cancers occur each year (Canadian Cancer Society, 2014). The 5-year survival rate is 60% in the United States. Renal cell carcinoma occurs most often in patients between 55 and 60 years of age (Patel et al., 2012).

Clinical Judgment Challenge

Safety; Patient-Centered Care QSEN

The 56-year-old African-American woman is admitted for treatment of newly diagnosed renal cell carcinoma. You find her daughter in the hallway crying. She has heard that her mother has undergone genetic testing related to her cancer diagnosis and wonders if she is at increased risk for the same condition. She was with her mother during the renal scan before admission and is also worried that this exposure to a radioactive isotope will cause cancer in her.

1. Is renal cell carcinoma commonly inherited, and why is genetic testing done?
2. Do renal scan radioisotopes require radiation precautions? Why or why not?
3. What risk factors are associated with renal cell carcinoma?
4. How can you evaluate whether your information was understood by the daughter and if follow-up is needed?

Patient-Centered Collaborative Care

Assessment

History.

Ask the patient about age, known risk factors (e.g., smoking or chemical exposures), weight loss, changes in urine color, abdominal or flank discomfort, and fever. Also ask whether any other family member has ever been diagnosed with cancer of the kidney, bladder, ureter, prostate gland, uterus, ovary, or appendix.

Physical Assessment/Clinical Manifestations.

Few patients with renal cell cancer have flank pain, obvious blood in the urine, and a kidney mass that can be palpated. Ask about the nature of the flank or abdominal discomfort. Patients often describe the pain as dull and aching. The pain may be more intense if bleeding into the tumor or kidney occurs. Inspect the flank area, checking for asymmetry or an obvious bulge. An abdominal mass may be felt through *gentle* palpation. A renal bruit may be heard on auscultation.

Bloody urine is a *late* common manifestation. Blood may be visible as bright red flecks or clots, or the urine may appear smoky or cola colored. Without gross hematuria, microscopic examination may or may not reveal red blood cells.

Inspect the skin for pallor, darkening of the nipples, and, in men, breast enlargement *(gynecomastia)* caused by changing hormone levels. Other findings may include muscle wasting, weakness, poor nutrition status, and weight loss. All tend to occur late in the disease.

Diagnostic Assessment.

Urinalysis may show red blood cells. Hematologic studies show decreased hemoglobin and hematocrit values, hypercalcemia, increased erythrocyte sedimentation rate, and increased levels of adrenocorticotropic hormone (ACTH), human chorionic gonadotropin (hCG), cortisol, renin, and parathyroid hormone. Elevated serum creatinine and blood urea nitrogen (BUN) levels indicate impaired kidney function.

Kidney masses may be detected by CT scan or MRI. Ultrasound is also used to detect masses or for initial screening. Kidney biopsy may be considered to help target therapy.

Interventions

Interventions focus on controlling the cancer and preventing metastasis (ACS, 2014).

Nonsurgical Management.

Radiofrequency or cryo-ablation can slow tumor growth. It is a minimally invasive procedure carried out after MRI has precisely located the tumor. The procedure is used most commonly for patients who have only one kidney or who are not surgical candidates.

Chemotherapy has limited effectiveness against this cancer type. Use of biological response modifiers (BRMs) such as interleukin-2 (IL-2), interferon (INF), and tumor necrosis factor (TNF) has lengthened survival time (see Chapters 17 and 22). Newer targeted therapy agents, sorafenib (Nexavar) and temsirolimus (Torisel), were approved as treatment for patients with advanced renal cell carcinoma. Sorafenib, an oral drug taken daily, is a multikinase inhibitor that slows cancer cell division and inhibits blood vessel growth in the tumor. Temsirolimus is a weekly IV infusion that blocks a protein that is needed for cell division, inhibiting cell cycle progression. Other targeted drugs used to treat RCC are sunitinib (Sutent), everolimus (Afinitor), and pazopanib (Votrient) (Patel et al., 2012). These drugs have increased survival time of patients with advanced RCC.

Surgical Management.

Renal cell carcinoma is usually treated surgically by *nephrectomy* (kidney removal). Renal cell tumors are highly vascular, and blood loss during surgery is a major concern. Before surgery, the arteries supplying the kidney may be occluded (embolized) by the interventional radiologist to reduce bleeding during nephrectomy.

Preoperative Care.

Instruct the patient about surgical routines (see Chapters 14, 15, and 16). Explain the probable site of incision and the presence of dressings, drains, or other equipment after surgery. Reassure the patient about pain relief. Care before surgery may include giving blood and fluids IV to prevent shock.

Operative Procedures.

The patient is placed on his or her side with the kidney to be removed uppermost. The trunk area is flexed to increase exposure of the kidney area. Removal of the eleventh or twelfth rib may be needed to provide better access to the kidney. The surgeon removes either part or all of the kidney and all visible tumor. The renal artery, renal vein, and fascia also may be removed after tying off the ureter. A drain may be placed in the

wound before closure. The adrenal gland may be removed when the tumor is near this organ.

When a *radical* nephrectomy is performed, local and regional lymph nodes are also removed. The surgical approach may be transthoracic (as discussed in the previous paragraph), lumbar, or through the abdomen, depending on the size and location of the tumor. Radiation therapy may follow a radical nephrectomy.

Postoperative Care.

Refer to Chapter 16 for care of the patient after surgery. Nursing priorities are focused on assessing kidney function to determine effectiveness of the remaining kidney, pain management, and preventing complications.

Monitoring includes assessing for hemorrhage and adrenal insufficiency. Inspect the patient's abdomen for distention from bleeding. Check the bed linens under the patient, because blood may pool there. Hemorrhage or adrenal insufficiency causes hypotension, decreased urine output, and an altered level of consciousness.

A decrease in blood pressure is an early indication of both hemorrhage and adrenal insufficiency. With hypotension, urine output also decreases immediately. Large water and sodium losses in the urine occur in patients with adrenal insufficiency. As a result, a large urine output is followed by hypotension and oliguria (less than 400 mL/24 hr or less than 25 mL/hr). IV replacement of fluids and packed red blood cells may be needed.

The second kidney is expected to provide adequate function, but this may take days or weeks. Assess urine output hourly for the first 24 hours after surgery (urine output of 0.5 mL/kg/hr or about 30 to 50 mL/hr is acceptable). A low urine output of less than 25 to 30 mL/hr suggests decreased blood flow to the remaining kidney and potential for acute kidney injury (AKI). The hemoglobin level, hematocrit values, and white blood cell count may be measured every 6 to 12 hours for the first day or two after surgery.

Monitor the patient's temperature, pulse rate, and respiratory rate at least every 4 hours. Accurately measure and record fluid intake and output. Weigh the patient daily.

The patient may be in a special care unit for 24 to 48 hours after surgery for monitoring of bleeding and adrenal insufficiency. A drain placed near the site of incision removes residual fluid. Because of the discomfort of deep breathing, the patient is at risk for atelectasis. Fever, chills, thick sputum, or decreased breath sounds suggest pneumonia.

Managing pain after surgery usually requires opioid analgesics (e.g., hydromorphone [Dilaudid] and morphine [Statex]) given intravenously. The incision was made through major muscle groups used with breathing and movement. Liberal use of analgesics is needed for 3 to 5 days after surgery to manage pain. Oral agents may be tried when the patient can eat and drink.

Preventing complications focuses on infection and management of adrenal insufficiency. Antibiotics may be prescribed during and after surgery to prevent infection. The need for additional antibiotics is based on evidence of infection. Assess the patient at least every 8 hours for manifestations of systemic infection or local wound infection.

Adrenal insufficiency is possible as a complication of kidney and adrenal gland removal. Although only one adrenal gland may be affected, the remaining gland may not be able to secrete sufficient glucocorticoids immediately after surgery. Steroid replacements may be needed in some patients. Chapter 62 discusses the manifestations of acute adrenal insufficiency in detail along with specific nursing interventions.

Kidney Trauma

Pathophysiology

Trauma to one or both kidneys is a concern in penetrating wounds or blunt injuries to the back, flank, or abdomen. Another cause of kidney trauma is iatrogenic from urologic procedures, extracorporeal shock wave lithotripsy, kidney biopsy, or percutaneous renal procedures. Blunt trauma accounts for most kidney injuries. Kidney injury has been classified into five grades based on the severity of the injury. Grade one consists of low-grade injury in the form of kidney bruising, and grade five represents the most severe trauma associated with shattering of the kidney and tearing its blood supply. Anyone can suffer kidney trauma. Strategies to prevent trauma are reviewed in Chart 67-7.

Chart 67-7 Patient and Family Education: Preparing for Self-Management

Preventing Kidney and Genitourinary Trauma

- Wear a seat belt.
- Practice safe walking habits.
- Use caution when riding bicycles and motorcycles.
- Wear appropriate protective clothing when participating in contact sports.
- Avoid all contact sports and high-risk activities if you have only one kidney.

Patient-Centered Collaborative Care

Assessment

Obtain a history of the patient's usual health and the events involved in the trauma from the patient, a witness, or emergency personnel. Documenting the mechanism of injury can help the provider determine the severity of the injury. For example, most blunt trauma from car crashes has low severity. Critical information to acquire is a history of kidney or urologic disease, surgical intervention, or health problems such as diabetes mellitus or hypertension.

Ureteral or renal pelvic injury often causes diffuse abdominal pain. Urine outside of the urinary tract may be visible. Ask the patient about pain in the flank or abdomen. Is the pain dull? Sharp? Constant?

Intermittent? Made worse by coughing?

Patients with kidney injuries should be assessed with initial attention to the basic ABCDEs outlined in Advanced Trauma Life Support protocols. Take the patient's blood pressure, apical and peripheral pulses, respiratory rate, and temperature. Inspect both flanks for bruising, asymmetry or penetrating injuries. Also inspect the abdomen, chest, and lower back for bruising or penetrating wounds. Percuss the abdomen for distention. Inspect the urethra for blood.

Urinalysis shows hemoglobin or red blood cells from tissue damage or kidney blood vessel rupture. Microscopic examination may also show red blood cell casts, which suggest tubular damage. Hemoglobin and hematocrit values decrease with blood loss (see discussion of shock in Chapter 37).

Diagnostic procedures include ultrasound and CT. CT scan shows greater detail about blood vessel and tissue integrity. Hematomas within or through the kidney capsule can be seen, along with the integrity and patency of the urinary tract. If the patient is being taken to the operating room emergently, a one-shot high dose of ionic or nonionic IV contrast dye can be given, followed by an abdominal x-ray (KUB) to visualize the traumatic injury and any organ damage.

Interventions

Nonsurgical Management.

Drug therapy is used for bleeding prevention or control. The need for clotting factors, vitamin K, and platelets is assessed, and they are given as needed.

Fluid therapy is given to restore circulating blood volume and ensure adequate blood flow to the kidneys. Crystalloid solutions replace water and some electrolytes and include 0.9% sodium chloride (normal saline solution [NSS]), 5% dextrose in 0.45% sodium chloride, and lactated Ringer's solution. When bleeding is extensive, packed red blood cell replacement restores hemoglobin and promotes oxygenation. Fresh frozen plasma or clotting factors may help with uncontrolled bleeding. Plasma volume expanders, such as dextran or albumin, help restore plasma oncotic pressure and reduce the onset or severity of shock or fluid displacement to interstitial tissues.

During fluid restoration, give fluids at the prescribed rate and monitor the patient for indications of shock. Take vital signs as often as every 5 to 15 minutes. Measure and record urine output hourly. Output should be greater than 0.5 mL/kg/hr.

The interventional radiologist may use percutaneous or other instrumentation to drain collections of fluid or to embolize (clot) an artery or artery segment or place a stent to repair the urethra or ureters.

Nursing Safety Priority QSEN

Action Alert

If the urethral opening is bleeding, consult with the physician before attempting urinary catheterization.

Surgical Management.

Most kidney injuries are managed without surgery. Many serious injuries can be treated with minimally invasive techniques such as angiographic embolization, which accesses the arteries of the kidneys through large blood vessels in the groin, similar to a cardiac catheterization. Surgery to explore the injured kidney occurs when the patient is hemodynamically unstable and appears to be losing a lot of blood from the kidney. Patients with other significant abdominal injuries, such as injuries to the bowel, spleen, or liver, who require a laparotomy may also undergo inspection and repair of the injured kidney at the same time. The aim of surgical management is to repair the injured kidney. However, if the kidney is severely injured (usually Grade 5 injury), the surgeon performs a nephrectomy.

Community-Based Care

Teach the patient and family how to assess for infection and other complications following kidney trauma. The most common complications are urine leakage and delayed bleeding. Instruct the patient to check the pattern and frequency of urine elimination and to note whether the color, clarity, and amount appear normal. The development of an abscess surrounding the kidney also can occur. Instruct the patient to seek medical attention for worsening hematuria, a worrisome change, or pain with voiding. Chills, fever, lethargy, and cloudy, foul-smelling urine indicate a urinary tract infection or abscess formation. Traumatic kidney injury can also cause hypertension from changes in perfusion and activation of the renin-angiotensin-aldosterone system (see Chapter 65 and Fig. 65-5). Advise the patient to seek medical care promptly for all new and concerning manifestations.

Nursing Concepts and Clinical Judgment Review

What might you NOTICE if the patient is experiencing problems with urinary elimination as a result of acute pyelonephritis?

- Patient urinates frequently in small amounts.
- Patient reports pain and burning on urination.
- Patient reports back or flank pain.
- Urine is cloudy and foul-smelling
- Urine may be darker or smoky or have obvious blood in it.

What should you INTERPRET and how should you RESPOND to a patient experiencing problems with urinary elimination as a result of acute pyelonephritis?

Perform and interpret physical assessment, including:

- Asking how long manifestations have been present
- Asking about low back (midline in men) or flank pain
- Asking whether he or she has had a UTI in the past; how long ago; how it was treated; and if, antibiotics were prescribed, whether the drug course was completed
- Asking about the presence of pregnancy or any chronic health problem, especially diabetes
- Asking about any nausea or vomiting and its duration
- Determining fluid intake and output volumes
- Assessing for pain over the right and left kidneys
- Weighing the patient, and asking whether this weight is more or less than his or her usual weight
- Assessing for fever and chills
- Assessing for tachycardia
- Interpreting laboratory values:
  - Is the complete blood count with differential elevated?
  - Are the BUN and serum creatinine levels elevated?
  - Is the urinalysis positive for bacteria, leukocyte esterase, nitrate, red blood cells, white blood cells, or casts?

Respond by:

- Providing for pain control
- Teaching the patient the importance of completing the prescribed antibiotic drug regimen

On what should you REFLECT?

- Observe patient for evidence of improved urinary output (see Chapter 65).
- Think about what may have caused this infection and what steps could

be taken to prevent a similar episode.
- Think about what patient teaching focus could help reduce the risk for future pyelonephritis and its complications.

Get Ready for the NCLEX® Examination!

Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Report immediately any condition that obstructs urine flow. **Safety** QSEN
- Check the blood pressure and urine output frequently in patients who have any type of kidney problem.
- Report immediately to the health care provider any sudden decrease of urine output in a patient with kidney disease or kidney trauma. In general, adult urine output expectations are 0.5-1 mL/kg/hr. **Safety** QSEN

Health Promotion and Maintenance

- Encourage patients with diabetes to achieve tight glycemic control.
- Encourage patients with hypertension to follow their treatment regimens to maintain blood pressure within the target range.
- Teach patients at risk for urinary tract infection (UTI) to maintain a daily fluid intake of 2 L unless another health problem requires fluid restriction.
- Teach patients on antibiotic therapy for a UTI to complete the drug regimen. **Evidence-Based Practice** QSEN
- Teach all people strategies to prevent kidney trauma.

Psychosocial Integrity

- Allow the patient the opportunity to express fear or anxiety regarding the potential for chronic kidney disease and end-stage kidney disease. **Patient-Centered Care** QSEN
- Assess the patient's level of comfort in discussing issues related to elimination and the genitourinary area.
- Use language the patient is comfortable with during assessment of the kidney and urinary system. **Patient-Centered Care** QSEN
- Explain treatment procedures to patients and families.
- Refer patients with polycystic kidney disease to a geneticist or a genetic counselor.
- Refer patients to community resources, support groups, and information organizations such as the National Kidney Foundation, the Polycystic Kidney Disease Foundation, and the American

Association of Kidney Patients.

Physiological Integrity

- Instruct patients with any type of kidney problem to weigh daily and to notify their health care provider if there is a sudden weight gain. **Patient-Centered Care** QSEN
- Teach patients the expected side effects and any adverse reactions to prescribed drugs, especially as they relate to kidney function.
- Teach patients the manifestations of disease recurrence and when to seek medical help.
- Explain the genetics of autosomal dominant polycystic kidney disease.
- Use laboratory data and clinical manifestations to determine the effectiveness of therapy for pyelonephritis.
- Be aware of the clinical manifestations of hydronephrosis.
- Be aware of the relationship between hypertension and kidney disease.

CHAPTER 68

Care of Patients with Acute Kidney Injury and Chronic Kidney Disease

Chris Winkelman

PRIORITY CONCEPTS

- Elimination
- Acid-Base Balance
- Fluid and Electrolyte Balance
- Infection
- Inflammation
- Perfusion

Learning Outcomes

Safe and Effective Care Environment

1. Collaborate with members of the health care team to reduce patient risk for kidney inflammation, kidney infection, and acute kidney injury (AKI).
2. Implement interventions to protect patients with chronic kidney disease (CKD) from related systemic complications that affect elimination, fluid and electrolyte balance, and acid-base balance.
3. Implement interventions to maintain patency of hemodialysis or peritoneal access when this renal replacement therapy occurs.

Health Promotion and Maintenance

4. Assess risk for AKI in patients with hemodynamic instability.
5. Collaborate with the patient and health care team to promote adequate nutrition and fluid and electrolyte balance when AKI or CKD is diagnosed.
6. Teach transplant recipients and their families about the importance of adhering to anti-rejection therapy.

Psychosocial Integrity

7. Promote communication about patient preferences and values to plan care related to treatment for kidney failure.
8. Teach patients to use *high-quality* community resources for self-management.

Physiological Integrity

9. Compare the pathophysiology and causes of AKI with those of CKD.
10. Establish priorities in the care of patients with AKI and CKD.
11. Discuss interventions to prevent AKI.
12. Discuss the mechanisms of peritoneal dialysis (PD) and hemodialysis (HD) as renal replacement therapies.
13. Coordinate nursing care for the patient with CKD or end-stage kidney disease (ESKD).
14. Prioritize nursing care for the patient who receives a kidney transplant.

 http://evolve.elsevier.com/Iggy/

The loss of kidney function affects the ability to maintain normal processes of urinary elimination, fluid and electrolyte balance, and acid-base balance. Kidney function loss also interrupts the activity of every organ system, particularly the immune, endocrine, skeletal, and cardiovascular systems. Acute kidney injury (AKI) is most common in the acute care setting, whereas chronic kidney disease (CKD) is more likely to be seen in community settings or as a co-existing condition in acute care settings. The characteristics of AKI and CKD are described in Table 68-1.

TABLE 68-1

Characteristics of Acute Kidney Injury and Chronic Kidney Disease

CHARACTERISTIC	ACUTE KIDNEY INJURY	CHRONIC KIDNEY DISEASE
Onset	Sudden (hours to days)	Gradual (months to years)
% of nephron involvement	50%-95%	Varies by stage; generally symptomatic with 75% loss and dialysis with 90%-95% loss
Duration	May not progress; full recovery (return to baseline) possible ESKD occurs in 10%-20% with lifetime reliance on dialysis or kidney transplant	Progressive and permanent Treatment and lifestyle can slow progression and delay onset of ESKD
Prognosis	Good when kidney function is maintained or returns High mortality associated with renal replacement therapy requirements of prolonged illness	Fatal without a renal replacement therapy (dialysis or transplantation) Reduced life span and potential for complex medical regimen even with optimal treatment

ESKD, End-stage kidney disease.

Both types of kidney dysfunction can result in end-stage kidney disease (ESKD), requiring renal replacement therapy (e.g., dialysis) or kidney transplant. ESKD reduces independence, shortens life, and decreases quality of life. Many diseases and conditions are associated with the onset and severity of kidney function loss.

As described in Chapter 65, kidney functions include excretion of waste, fluid and electrolyte balance, regulation of acid-base balance, and hormone secretion. When kidney function declines gradually, it is diagnosed as CKD, also known as *chronic renal failure (CRF).* The patient may have many years of abnormal serum blood urea nitrogen and creatinine values, sometimes called *renal insufficiency,* before the uremia of ESKD develops. During this time of decreased kidney function, the patient may also experience acute kidney injury (AKI). The combination of AKI and CKD, called *acute-on-chronic kidney injury,* can accelerate loss of kidney function. Low nephron numbers from CKD contribute to the progression of kidney disease (Taal et al., 2012).

When kidney decline is sudden, the functioning nephrons are overworked and kidney failure may develop with the loss of only 50% of functioning nephrons. Acute kidney injury affects *many* body systems. Chronic kidney disease affects *every* body system. The problems that occur with kidney function loss are related to disturbances of fluid and electrolyte balance, disturbances of acid-base balance, buildup of nitrogen-based wastes, and loss of kidney hormone function.

When kidney function declines to the point that the kidneys can no longer maintain homeostasis by urine elimination, renal replacement therapy is needed to prevent death from life-threatening consequences.

Acute Kidney Injury

Pathophysiology

Acute kidney injury (AKI) has now replaced the older terminology of *acute renal failure*. AKI is a rapid reduction in kidney function resulting in a failure to maintain fluid and electrolyte balance and acid-base balance. AKI occurs over a few hours or days. Most experts described AKI as one of three classes (risk, injury, and failure or Stages 1, 2, and 3 [Table 68-2]). One expert group also describes two outcomes (loss of function and end-stage kidney disease [ESKD]) following AKI. Severity of AKI is based on increases in serum creatinine and decreased urine output. Although glomerular filtration rate (GFR) is accepted as the best overall indicator of kidney function, it is not measured during acute and critical illness (Puzantian & Townsend, 2013). GFR represents the sum filtration rate of all functional nephrons. Estimations of GFR from serum creatinine are not considered accurate during critical illness. Values from direct measurements can be altered during acute and critical illness when diuretics or IV fluids are used (Moore et al., 2012; Puzantian & Townsend, 2013). Direct measurement of GFR uses a 24-hour urinary creatinine analysis or the clearance of IV-administered markers like inulin, nonradioactive contrast agents or radioisotope compounds.

TABLE 68-2

The RIFLE and KDIGO Classification Systems for Severity and Outcomes of Acute Kidney Injury

	GLOMERULAR FILTRATION RATE (GFR)* CRITERIA	URINE OUTPUT CRITERIA
RIFLE Classification		
Risk stage	Serum creatinine increased × 1.5 or GFR decrease >25%	<0.5 mL/kg/hr for ≥6 hr
Injury stage	Serum creatinine increased × 2 or GFR decrease >50%	<0.5 mL/kg/hr for ≥12 hr
Failure stage	Serum creatinine increased × 3 or GFR decrease ≥75% or an absolute serum creatinine ≥354 µmol/L with an acute rise ≥4 µmol/L	<0.3 mL/kg/hr for ≥24 hr or anuria for ≥12 hr
Outcome: Loss	Persistent acute kidney injury (AKI), requiring renal replacement therapy for >4 wk	
Outcome: End-stage kidney disease	Requiring dialysis >3 mo	
KDIGO Classification		
Stage 1	Serum creatinine increased × 1.5-1.9 baseline or by ≥26.2 µmol/L	<0.5 mL/kg/hr for 6-12 hr
Stage 2	Serum creatinine increased × 2-2.9 baseline	<0.5 mL/kg/hr for ≥12 hr
Stage 3	Serum creatinine increased × 3 baseline or serum creatinine ≥354 µmol/L with an acute rise ≥44 µmol/L or initiation of renal replacement therapy	<0.3 mL/kg/hr for ≥24 hr or anuria for ≥12 hr

RIFLE, **R**isk, **I**njury, **F**ailure, **L**oss, **E**nd-Stage Kidney Failure; *KDIGO,* **K**idney **D**isease: **I**mproving **G**lobal **O**utcomes

*GFR must be directly measured, not estimated (Chapter 65 describes serum and urine measurement of GFR).

AKI not only affects kidney function but also causes systemic effects

and complications described in Table 68-3. These complications increase discomfort and risk for death in the patient with new AKI. Duration of oliguria or anuria is closely correlated with lack of recovery of kidney function; the longer the duration of oliguria or anuria, the less likely the patient will return to full or baseline kidney function (Davies & Leslie, 2012).

TABLE 68-3

Complications from Acute Kidney Injury

Metabolic
• Metabolic acidosis • Hyperkalemia • Hyponatremia • Hypocalcemia • Hypophosphatemia
Cardiopulmonary
• Peripheral and pulmonary edema • Heart failure • Pulmonary embolism • Pericarditis • Pericardial effusion • Hypertension • Myocardial infarction
Neurologic
• Neuromuscular irritability or weakness • Asterixis • Seizures • Mental status changes
Immune/Infectious
• Pneumonia • Sepsis
Gastrointestinal
• Nausea • Vomiting • Decreased peristalsis • Enteral nutrition intolerance • Malnutrition • Ulcer formation • Bleeding
Hematologic
• Bleeding • Thrombosis • Anemia
Renal
• Permanent kidney damage • Chronic kidney disease (CKD) • End-stage kidney disease (ESKD)
Other
• Hiccups • Elevated parathyroid hormone • Low thyroid hormone

Etiology

The causes of AKI are reduced perfusion to the kidneys, damage to kidney tissue, and obstruction. Diseases and conditions associated with reduced kidney perfusion, kidney damage, and urinary obstruction are listed in Table 68-4. (The diseases in Table 68-3 are described elsewhere in this text.) Notice that several conditions resulting in AKI are listed more than once in Table 68-4. For example, coagulopathy (disorders of bleeding and clotting; see Chapter 40) reduces perfusion, causes inflammation and direct tissue damage, and creates obstruction of urinary flow. Coagulopathy causes prerenal, intrarenal, and postrenal AKI.

TABLE 68-4

Diseases and Conditions that Contribute to Acute Kidney Injury

Perfusion Reduction (Prerenal Causes)
• Blood or fluid loss (e.g., surgery or trauma; hemorrhagic or hypovolemic shock) • Blood pressure drugs resulting in hypotension • Heart attack or heart failure resulting in low ejection fraction and low cardiac output • Infection (e.g., sepsis, septic shock) • Liver failure • Use of aspirin, ibuprofen (e.g., Advil, Motrin IB), naproxen (e.g., Aleve), or NSAIDs • Severe allergic reaction (anaphylaxis) • Severe burns • Severe dehydration • Renal artery stenosis • Bleeding or clotting in the kidney blood vessels (coagulopathy) • Atherosclerosis or cholesterol deposits that block blood flow in the kidneys
Kidney Damage (Intrinsic or Intrarenal Causes)
• Glomerulonephritis or inflammation of the glomeruli • Bleeding in the kidney • Thrombi or emboli in the kidney blood vessels • Hemolytic uremic syndrome, a condition of premature destruction of red blood cells caused by infection • Systemic infection (sepsis) • Local infection (pyelonephritis) • Lupus, an immune system disorder causing glomerulonephritis • Drugs, such as certain chemotherapy agents, antibiotics, dyes used during imaging tests (contrast-induced nephropathy), many antibiotics, and zoledronic acid (Reclast, Zometa), used to treat osteoporosis and high blood calcium levels (hypercalcemia) • Multiple myeloma, a cancer of the plasma cells • Scleroderma, a group of rare diseases affecting the skin and connective tissues • Thrombotic thrombocytopenic purpura (TTP), a rare platelet disorder that increases clotting • Ingested toxins, such as alcohol, heavy metals, and cocaine • Vasculitis, an inflammation of blood vessels • Ischemia in kidney tissue, including hypoxemia from respiratory and cardiac arrest
Urine Flow Obstruction (Postrenal Causes)
• Bladder cancer • Cervical cancer • Colon cancer • Prostate cancer • Enlarged prostate (prostate hypertrophy) • Kidney stones (nephrolithiasis and ureterolithiasis) • Nerve damage involving the nerves that control the bladder (neurogenic bladder) • Blood clots in the urinary tract

AKI is more likely to occur in hospitalized adults who are older or who have pre-existing hypertension, diabetes, peripheral vascular disease, liver disease, or chronic kidney disease (CKD). Prolonged mechanical ventilation (see Chapter 32) also is an independent risk factor for the development of AKI (Akker et al., 2013).

Traditionally, AKI caused by reduced perfusion is classed as **prerenal failure**. It is the most common cause of AKI in acute care. Damage to kidney tissue is classed as **intrarenal** or **intrinsic renal failure** and reflects injury to the glomeruli, nephrons, or tubules. Obstruction of urine flow

is also called **postrenal failure**. Although the usefulness of this classification system is a source of controversy, it does provide a framework to guide care for both prevention and treatment of AKI (Fournir, 2013). When AKI occurs in patients who already have CKD, it is called **acute-on-chronic kidney disease**. Any of these conditions can occur together such as acute prerenal and intrarenal failure occurring in someone who already has CKD. Multiple pathologies are more likely to result in end-stage kidney disease (ESKD).

With prerenal or postrenal pathology, the kidney compensates by the three responses of constricting kidney blood vessels, activating the renin-angiotensin-aldosterone pathway, and releasing antidiuretic hormone (ADH). These responses increase blood volume and improve kidney perfusion. However, these same responses reduce urine volume, resulting in **oliguria** (urine output less than 400 mL/day) and **azotemia** (the retention and buildup of nitrogenous wastes in the blood). Toxins can also cause blood vessel constriction in the kidney, leading to reduced kidney blood flow, oliguria, and azotemia.

Inflammation, infection, and damage from toxins (Table 68-5) cause intracellular changes of the tubular system in kidney tissue. Immune-mediated complexes can also damage nephrons. With extensive tubular damage, tubular cells slough and nephrons lose the ability to repair themselves. The presence of tubular debris and sediment in urine from kidney tissue damage (intrarenal failure) is sometimes termed *acute tubular necrosis.* This term is no longer favored because supportive evidence is limited for the pathologic processes and clinical diagnosis (Moore et al., 2012).

TABLE 68-5

Examples of Potentially Nephrotoxic Substances

Drugs
Antibiotics/Antimicrobials
• Amphotericin B • Colistimethate • Methicillin • Polymyxin B • Rifampin • Sulfonamides • Tetracycline hydrochloride • Vancomycin
Aminoglycoside Antibiotics
• Gentamicin • Kanamycin • Neomycin • Netilmicin sulfate • Tobramycin
Chemotherapy agents
• Cisplatin • Cyclophosphamide • Methotrexate
Nonsteroidal Anti-inflammatory Drugs (NSAIDs)
• Celecoxib • Flurbiprofen • Ibuprofen • Indomethacin • Ketorolac • Meclofenamate • Meloxicam • Nabumetone • Naproxen • Oxaprozin • Rofecoxib • Tolmetin
Other Drugs
• Acetaminophen • Captopril • Cyclosporine • Fluorinate anesthetics • Metformin • d-Penicillamine • Phenazopyridine hydrochloride • Quinine
Other Substances
Organic Solvents
• Carbon tetrachloride • Ethylene glycol
Non-drug Chemical Agents
• Radiographic contrast dye (e.g., iodinated dyes, high-osmolar dyes, and gadolinium) • Pesticides • Fungicides • Myoglobin (from breakdown of skeletal muscle)
Heavy Metals and Ions
• Arsenic • Bismuth • Copper sulfate • Gold salts • Lead • Mercuric chloride

Even with severe AKI, categorized as loss of function ("L" in *RIFLE* or stage 2 in *KDIGO* in Table 68-2), some people have return of kidney

function. It is the responsibility of all health care professionals to be alert to the possibility of AKI and implement prevention strategies when risk factors are present. *Timely implementation of interventions to remove the cause of AKI may prevent ESKD and need for lifelong renal replacement therapy or a renal transplant.*

Incidence and Prevalence

The reported prevalence of AKI from United States data ranges from 1% (community-acquired) up to 7.1% (hospital-acquired) of all hospital admissions. As many as 30% of patients admitted to an ICU experience an episode of AKI (Fournir, 2013). Transient azotemia and oliguria occur in as many as 40% of all inpatients (Uchino et al., 2010). AKI is associated with an in-hospital and 1-year mortality rate of up to 60% (Ralib et al., 2013).

Health Promotion and Maintenance

Keep in mind that severe blood volume depletion can lead to kidney injury even in people who have no known kidney problems. Urge all healthy people to avoid dehydration by drinking 2 to 3 L of water daily. This is especially important for athletes or any person who performs strenuous exercise or work and sweats heavily.

Nurses have an essential role in the prevention of AKI in hospitalized patients. Always be on the lookout for signs of impending kidney dysfunction through physical assessment and close monitoring of laboratory values. Early recognition and correction of problems causing reduced kidney blood flow often restore function before tissue damage can occur. Evaluate the patient's fluid status. Accurately measure intake and output and check body weight to identify changes in fluid balance. Note the characteristics of the urine, and report new sediment, hematuria (smoky or red color), foul odor, or other worrisome changes. It is important to immediately report to the health care provider a urine output of less than 0.5 mL/kg/hr that persists for more than 2 hours. Some experts suggest that 0.3 mL/kg/hr for more than 2 hours should be reported (Ralib et al., 2013). Waiting for 6 hours of oliguria to meet RIFLE criteria may promote kidney damage—act early!

Nursing Safety Priority QSEN

Critical Rescue

In any acute care setting, preventing volume depletion and providing intervention early when volume depletion occurs are nursing priorities. Reduced perfusion from volume depletion is a common cause of AKI. Recognize the manifestations of volume depletion (low urine output, decreased systolic blood pressure, decreased pulse pressure, orthostatic hypotension, thirst, rising blood osmolarity). Intervene early with oral fluids, or in the patient who is unable to take or tolerate oral fluid, request an increase in IV fluid rate from the health care provider to prevent permanent kidney damage.

Monitor laboratory values for any changes that reflect poor kidney function. A clinically significant increase in creatinine, especially when the increase occurs over hours or a few days, is a concern and should be reported urgently to the health care providers. Other laboratory values that help monitor kidney function include serum blood urea nitrogen (BUN); serum potassium, sodium, and osmolarity; and urine specific gravity and electrolytes.

Be aware of nephrotoxic substances that the patient may ingest or be exposed to (see Table 68-5). Question any prescription for potentially nephrotoxic drugs, and validate the dose before the patient receives the drug. Many antibiotics have nephrotoxic side effects. NSAIDs can cause or increase the risk for AKI. Combining two or more nephrotoxic drugs dramatically increases the risk for AKI. If a patient must receive a known nephrotoxic drug, closely monitor laboratory values, including BUN, creatinine, and drug peak and trough levels, for indications of reduced kidney function. When nephrotoxic agents are used, nephrons may be protected by administering a pre-treatment oral or IV bolus of fluid volume.

Patient-Centered Collaborative Care

Assessment

History.

The accurate diagnosis of AKI, including its cause, depends on a detailed history. Ask the patient about recent surgery or trauma, transfusions, or other factors that might lead to reduced kidney blood flow. Obtain a drug history, especially treatment with antibiotics and NSAIDs. Ask about recent imaging procedures requiring injection of a contrast dye. Coexisting conditions of advanced age, diabetes mellitus, long-term hypertension, systemic lupus erythematosus, major or systemic infection

(sepsis), systemic inflammation from any cause, and coagulopathy or treatment for bleeding or clotting disorders increase the risk for AKI.

To identify immune-mediated acute glomerulonephritis, ask about acute illnesses such as influenza, colds, gastroenteritis, and sore throats. Ask whether urine color is darker or appears smoky.

Anticipate AKI following any episode of hypotension, shock, burns, or heart failure exacerbation. Any problem in which the blood volume is depleted can contribute to AKI such as extensive bowel preparations, being NPO before surgery, or dehydration from exercise.

Consider whether there is a history of urinary obstructive problems. Ask the patient about any difficulty in starting the urine stream, changes in the amount or appearance of the urine, narrowing of the urine stream, nocturia, urgency, or manifestations of kidney stones. Also ask about any cancer history that may cause urinary obstruction.

Physical Assessment/Clinical Manifestations.

The manifestations of AKI are related to the buildup of nitrogenous wastes **(azotemia)**, decreased urine output **(oliguria)**, as well as to the underlying cause. As AKI progresses in severity, the patient may have manifestations of fluid overload (because in AKI, fluid is not eliminated) including pulmonary crackles, dependent and generalized edema, decreased oxygenation (low peripheral oxygenation or Spo_2), increased respiratory rate, and dyspnea. See Chapter 11 for further assessment related to fluid overload.

Laboratory Assessment.

The many changes in laboratory values in the patient with AKI are similar to those occurring in chronic kidney disease (CKD) (Chart 68-1). A rising serum creatinine is more likely to indicate prolonged or permanent kidney damage. Expect to see rising BUN levels and abnormal blood electrolytes values. Patients with AKI, however, usually do *not* have the anemia associated with CKD unless there is blood loss from another condition (e.g., surgery, trauma) or when BUN levels are high enough to break (lyse) red blood cells.

Chart 68-1 Laboratory Profile

Kidney Disease

TEST	NORMAL RANGE FOR ADULTS	VALUES IN KIDNEY DISEASE
Serum creatinine	*Male:* 0.6-1.2 mg/dL	**In Chronic Kidney Disease** May increase by 0.5-1.0 mg/dL every 1-2 yr May be as high as 15-30 mg/dL *before* manifestations of severe CKD are present **In Acute Kidney Injury** Increase of 1-2 mg/dL every 24-48 hr May increase 1-6 mg/dL in 1 wk or less
	Female: 0.5-1.1 mg/dL	
	Older adults: Decreased	
Blood urea nitrogen	10-20 mg/dL	**In Chronic Kidney Disease** May reach 180-200 mg/dL *before* manifestations develop **In Acute Kidney Injury** Often increases by 10-20 mg/dL at same pace as serum creatinine level May reach 80-100 mg/dL within 1 wk
	Older adults: May be slightly increased	
Serum sodium	136-145 mEq/L; 136-145 mmol/L (SI units)	Normal, increased, or decreased
Serum potassium	3.5-5.0 mEq/L; 3.5-5.0 mmol/L (SI units)	Increased
Serum phosphorus (phosphate)	3.0-4.5 mg/dL; 0.97-1.45 mmol/L (SI units)	Increased
	Older adults: May be slightly decreased	
Serum calcium	Total calcium: 9.0-10.5 mg/dL; 2.25-2.75 mmol/L (SI units)	Decreased
	Ionized calcium: 4.5-5.6 mg/dL; 1.05-1.3 mmol/L (SI units)	
	Older adults: Slightly decreased	
Serum magnesium	1.3-2.1 mEq/L; 0.65-1.05 mmol/L	Increased
Serum carbon dioxide combining power (bicarbonate)	23-30 mEq/L (venous); 23-30 mmol/L (SI units)	Decreased
Arterial blood pH	7.35-7.45	Decreased (in metabolic acidosis) or normal
Arterial blood bicarbonate (HCO_3^-)	21-28 mEq/L	Decreased
Arterial blood $Paco_2$	35-45 mm Hg	Decreased
Hemoglobin	*Female:* 12-16 g/dL; 7.4-9.9 mmol/L (SI units)	Decreased
	Male: 14-18 g/dL; 8.7-11.2 mmol/L (SI units)	
	Older adults: Slightly decreased	
Hematocrit	*Female:* 37%-47%	Decreased to 20%
	Male: 42%-52%	
	Older adults: May be slightly decreased	
Blood osmolarity	285-295 mOsm/kg or mmol/kg (SI)	Elevated in volume-depleted states, increasing the risk for acute kidney injury

CKD, Chronic kidney disease; *SI,* International System of Units.

Data from Pagana, K., & Pagana, T. (2014). *Mosby's manual of diagnostic and laboratory tests* (5th ed.). St. Louis: Mosby.

In early AKI, urine tests provide important information. Urine sodium levels may reflect an inability to concentrate urine. Urine may be dilute with a specific gravity near 1.000 or concentrated with a specific gravity greater than 1.030. The presence of urine sediment (e.g., red blood cells [RBCs], RBC casts, and tubular cells), myoglobin, or hemoglobin may contribute to nephron damage.

Imaging Assessment.

Ultrasonography is useful in the diagnosis of kidney and urinary tract obstruction. Dilation of the renal calyces and collecting ducts, as well as stones, can be detected. Ultrasonography can show kidney size and patency of the ureters.

CT scans without contrast dye can determine adequacy of kidney blood flow and identify obstruction or tumors. Contrast dyes are usually

avoided to prevent further kidney damage. An MRI may be used in place of CT scan at some medical centers.

X-rays of the pelvis or kidneys, ureters, and bladder (KUB) may be used to provide an initial screening view of kidneys and the urinary tract to determine the cause of AKI. Enlarged kidneys with obstruction may show hydronephrosis. X-rays can show stones obstructing the renal pelvis, ureters, or bladder. More commonly, ultrasound is used to screen for hydronephrosis.

A nuclear medicine study called *MAG3* may be used to determine the nature of the kidney failure and measure GFR. A renal scan can determine whether blood flow to the kidneys is sufficient. Cystoscopy or retrograde pyelography may be needed to identify obstructions of the lower urinary tract.

Other Diagnostic Assessments.

Kidney biopsy is performed if the cause of AKI is uncertain and manifestations persist or an immunologic disease is suspected. Prepare the patient before the test, particularly managing both hypotension and hypertension. Hypertension can contribute to intrarenal hemorrhage following needle biopsy. Provide follow-up care. Be aware of all test results, and understand how they might affect the treatment regimen. (See Chapter 65 for a detailed discussion of diagnostic tests related to the kidney.)

NCLEX Examination Challenge

Safe and Effective Care Environment

An 84-year-old male client is being admitted after surgery to remove a section of his bowel (colectomy) following a diagnosis of colon cancer. His urine output from an indwelling urinary catheter after 3 hours in the postanesthesia care unit plus the amount in the bag on admission to the medical-surgical unit totals 100 mL. The urine is cloudy and dark yellow. He also has a history of hypertension. After evaluating the patency of the collection device, what is the most appropriate action for the nurse to perform?

A Notify the health care provider of the low urine output.
B Increase the rate of IV fluids until urine output is 0.5mL/kg/hr.
C Continue to assess the client and re-evaluate urine output in 4 hours.
D Ask about his typical voiding patterns and about any previous episodes of urinary problems.

Interventions

A reduction in blood flow to the kidneys may initially not be recognized when there is no associated drop in systemic blood pressure (Davies & Leslie, 2012). Autoregulation and the renin-angiotensin-aldosterone system effectively maintain normal kidney blood flow and glomerular filtration rate. However, these mechanisms may not be working well in the critically ill patient. Thus current guidelines suggest that a mean arterial pressure (MAP) of 65 mm Hg be maintained to promote kidney perfusion. The calculation of MAP is illustrated in Table 68-6. MAP is often displayed as a component of automated blood pressure measurement devices and during intra-arterial blood pressure measurement at the ICU bedside. Observations about peripheral edema, increased daily weight, and reduced urine output can identify patients with a positive fluid balance from AKI. Blood sampling of patients at risk for AKI allows monitoring of kidney function and early recognition of elevated serum creatinine. Communicate these observations early and often to the provider so that interventions can promote kidney health and interrupt the progression of AKI when it occurs. Surviving kidney tubule cells possess a remarkable ability to regenerate and proliferate, and early identification can both stop progression of AKI and aid in recovery of kidney function.

TABLE 68-6

Calculation of Mean Arterial Pressure (MAP)

MAP = (SBP + [2 × DBP]) ÷ 3 *Abbreviations: SBP = systolic blood pressure; DBP = diastolic blood pressure*
Example:
Blood pressure 130/80; SBP = 130; DBP = 80 (130 + [2 × 80]) ÷ 3 = (130 + 160) ÷ 3 = 290 ÷ 3 = 96.666 = 97 mm Hg. **Note:** this value of 97 mm Hg is safe in relation to kidney perfusion and reduces risk for acute kidney injury (AKI) and progression of chronic kidney disease (CKD). A normal range for MAP is 70-110 mm Hg for healthy adults.

Not all patients with AKI experience oliguria. Inflammatory causes of AKI may allow proteins to enter the glomerulus, and these proteins can hold fluid in the filtrate, causing a *polyuria* (excess urine output). During AKI with high-volume urine output, hypovolemia and electrolyte *loss* are the main problems. The patient in the diuretic phase of AKI needs a plan of care that focuses on fluid and electrolyte *replacement* and monitoring. Onset of polyuria can be the start of recovery from AKI.

Base the desired outcomes of care on collaboration and communication with health care team members. Update the plan of care for either restriction or liberal administration of fluid based on timely

and accurate health care team communication.

Frequent serum monitoring, close surveillance of intake and output, drug therapy, nutrition, careful administration of fluids and minerals, and renal replacement therapy are commonly used to manage AKI.

Drug Therapy.

The health care team should consult the inpatient pharmacist for drug adjustment based on kidney function. As kidney function changes, drug dosages are changed. It is important to be knowledgeable about the site of drug metabolism and especially careful when giving drugs. Continuously monitor the patient with AKI for adverse drug events and interactions of the drugs that he or she is receiving. Diuretics may be used to increase urine output in AKI. Diuretic-induced urine output does not preserve kidney function or stop AKI, but diuretics do rid the body of retained fluid and electrolytes in the patient with AKI that has not progressed to ESKD.

Fluid challenges are often used to promote kidney perfusion. In patients without fluid overload, 500 to 1000 mL of normal saline may be infused over 1 hour. Patients with AKI often require central venous pressure (CVP) monitoring. When cardiac disease is also present and worsening, measurement of pulmonary arterial pressure by means of a pulmonary artery catheter for accurate evaluation of hemodynamic status may be needed. During fluid challenges, closely assess the response to fluid and slow the infusion if indications of fluid overload, particularly respiratory distress, occur.

Calcium channel blockers may be used to treat AKI resulting from nephrotoxins. These drugs prevent the movement of calcium into the kidney cells, maintain kidney cell integrity, and improve kidney blood flow. If they do not improve GFR as estimated by serum creatinine (described in Chapter 65), calcium channel blockers are stopped.

Investigation is ongoing to identify biomarkers that can indicate kidney injury early. Neutrophil gelatinase-associated lipocalin (NGAL) and kidney injury molecule-1 (KIM-1) are promising new biomarkers to identify AKI and guide treatment (Obermüller et al., 2014; Vanmassenhove et al., 2013).

Nutrition Therapy.

Patients who have AKI often have a high rate of *catabolism* (protein breakdown). Increases in metabolism and protein breakdown may be related to the stress of illness and the increase in blood levels of catecholamines, cortisol, and glucagon. The rate of protein breakdown

correlates with the severity of uremia and azotemia. Catabolism causes the breakdown of muscle for protein and increases azotemia.

A registered dietitian will calculate the patient's protein and caloric needs. Whereas this occurs for all patients admitted to an ICU, a consult may need to be requested for inpatients outside of the ICU or for those in the community settings. Work with the dietitian to establish a diet with specified amounts of protein, sodium, and fluids. For the patient who does not require dialysis, 0.6 g/kg of body weight or 40 g/day of protein is usually prescribed. For patients who do require dialysis, the protein level needed will range from 1 to 1.5 g/kg. The amount of dietary sodium ranges from 60 to 90 mEq/kg. If high blood potassium levels are present, dietary potassium is restricted to 60 to 70 mEq/kg. The daily amount of fluid permitted is calculated to be equal to the urine volume plus 500 mL. Assess food intake every shift to ensure that caloric intake is adequate.

Many patients with AKI are too ill or their appetite is too poor to meet caloric goals. For these patients, nutrition support is needed. Nutrition support can include oral supplements, enteral nutrition, or parenteral nutrition (hyperalimentation). The purposes of nutrition support in AKI are to provide sufficient nutrients to maintain or improve nutrition status, to preserve lean body mass, to restore or maintain fluid balance, and to preserve kidney function.

There are several kidney-specific formulations of oral supplements and enteral solutions (e.g., Nepro, Suplena Renalcal, and NovaSource Renal). As a rule, specialty tube feedings for kidney patients are lower in sodium, potassium, and phosphorus and higher in calories than are standard feedings. Enteral nutrition, delivered with a nasogastric or nasojejunal tube (these tubes can also be placed orally), is an effective route to deliver nutrition support. If TPN is used, the IV solutions are mixed to meet the patient's specific needs. Because kidney function is unstable in AKI, continuously monitor fluid balance (intake and output) and serum electrolyte levels to indicate how the supplementation affects fluid and electrolyte balance. IV fat emulsion (Intralipid) infusions can provide a nonprotein source of calories. In uremic patients, fat emulsions are used in place of glucose to avoid the problems of excessive sugars.

Renal Replacement Therapy.

Renal replacement therapy (RRT), also called *dialysis,* is used for patients with loss of kidney function. Indications for dialysis use include symptomatic uremia (pericarditis, neuropathy, or unexplained decline in cognition), persistent or rapidly rising high potassium levels (i.e., greater

than 6.5 mEq/L), severe metabolic acidosis (pH less than 7.1), or fluid overload that compromises tissue perfusion. When AKI is associated with drug or alcohol intoxication, RRT also can remove toxins.

Immediate vascular access for RRT in patients with AKI is made by placement of a catheter specific for dialysis (Fig. 68-1). The catheter is placed in a central vein using best practices to avoid catheter-associated bloodstream infections (see Chapter 13, pp. 193-196). Placement of a dialysis catheter requires informed consent and a "time-out" similar to other surgical procedures (see Chapter 14, Care of Preoperative Patients). The catheter is not used to acquire blood samples, give drugs or fluid, or monitor central venous pressure. Provide site care in accordance with institutional policy and best practices to avoid catheter-related bloodstream infection (CR-BSI).

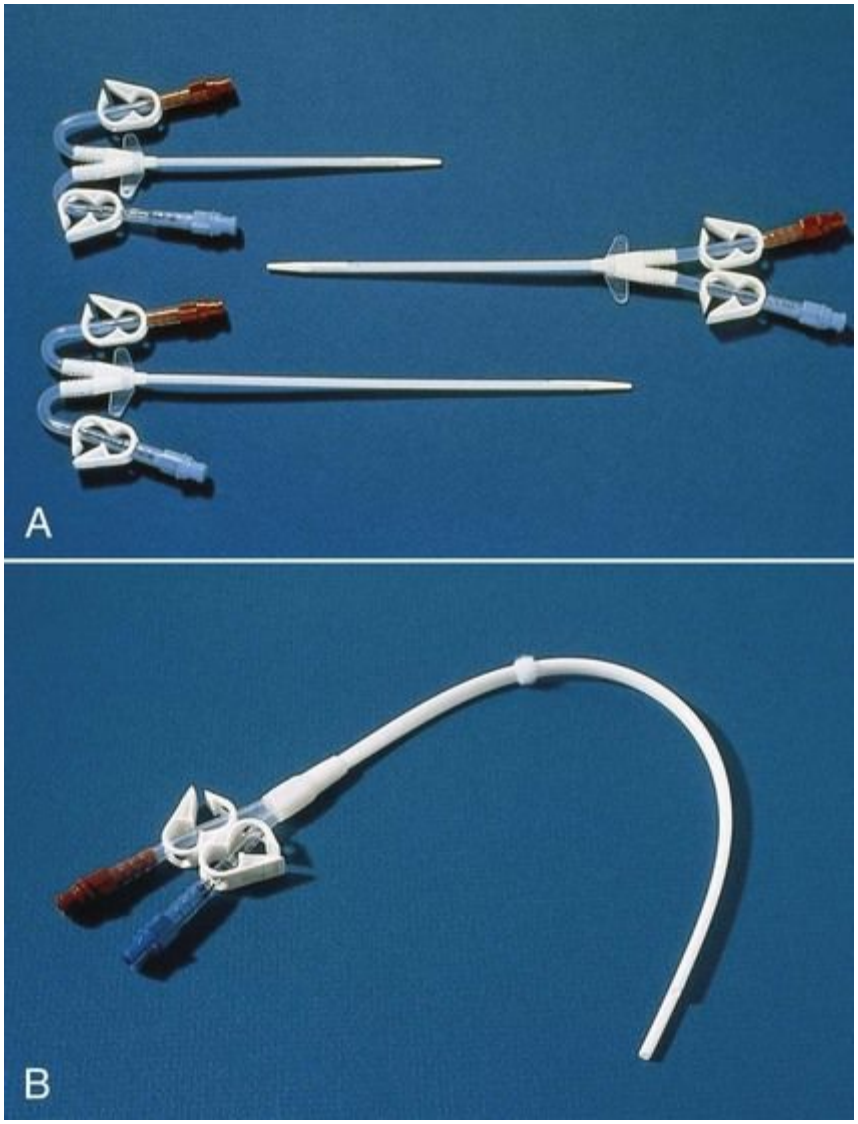

FIG. 68-1 Subclavian dialysis catheters. These catheters are radiopaque tubes that can be used for hemodialysis access. The Y-shaped tubing allows arterial outflow and venous return through a single catheter. **A,** Mahurkar catheters, made of polyurethane and used for short-term access. **B,** A PermCath catheter, made of silicone and used for long-term access.

A long-term dialysis catheter may be placed in the radiology department using a tunneling technique. The patient receives moderate sedation. Under ultrasound or fluoroscopic guidance, the physician makes a small incision where the internal jugular vein passes behind the clavicle. A 6- to 8-cm tunnel is created away from the site of the incision. A long-term hemodialysis catheter is inserted through the tunnel and into the jugular vein. Keeping a segment of the catheter within the subcutaneous tissues before entering the jugular vein reduces the risk for infection. These centrally placed catheters are dedicated to dialysis alone and require aseptic dressing changes as for all central venous catheters.

Dialysis catheters have two lumens—one for outflow and one for inflow. This allows the patient's blood to flow out and, once dialyzed, to be returned through the inflow lumen. Some catheters have a third lumen for the dialysis nurse to sample venous blood or give drugs and fluid during dialysis.

Intermittent Versus Continuous Renal Replacement Therapy.

Renal replacement therapy (RRT) is a supportive strategy to purify blood, substituting for the normal function of the kidney. Particles are separated from blood based on the different ability of particles to pass through (diffuse) a membrane. RRT can be delivered intermittently, continuously, or as a hybrid of these treatment approaches to hospitalized patients. There is no difference in the number of patients who go on to recover kidney function based on the type of RRT administered during AKI. Mortality is significant, regardless of modality, among patients with AKI who require RRT, and this mortality is around 50% while in the hospital (Elseviers et al., 2010).

Intermittent RRT, sometimes called *hemodialysis,* is delivered over 3 to 6 hours. Generally a technician or nurse with specialized training brings the dialysis machine to the bedside of a critically ill patient. Patients who do not need intensive care may be transported to an inpatient dialysis unit for the duration of the RRT treatment.

Intermittent RRT uses a dialysis machine to mix and monitor the dialysate. Dialysate is the fluid that helps remove the unwanted particles and waste products from blood. Dialysate is prescribed by the health care provider as an admixture to restore electrolytes and minerals to normal levels in the blood. The machine also monitors the flow of blood while it is outside of the body. Alarms are set and monitored by the dialysis technician or nurse to ensure safe and effective flow. This type of RRT has a long history of safety and effectiveness in ESKD. It is usually delivered 3 or 4 times weekly and may require anticoagulation in the dialysis circuit. However, this high-intensity treatment creates shifts of fluid and electrolytes that may not be tolerated in acutely and critically ill patients.

Continuous renal replacement therapies (RRTs), also known as *hemofiltration,* are alternative methods for removing wastes and restoring fluid and electrolyte balance in hospitalized adults with AKI who are too unstable to tolerate the changes in blood pressure that occur with intermittent conventional hemodialysis. In all hemodialysis, blood is passed through a filter to remove waste and undesired particles. Unlike intermittent hemodialysis, continuous RRT removes and returns blood over 12 to 24 hours each day. Another difference between continuous

RRT and intermittent hemodialysis is the approach used to remove particles from blood. Hemofiltration uses ultrafiltration, whereas diffusion is used in intermittent dialysis to remove toxins and other particles. *Ultrafiltration* is the separation of particles from a suspension by passage through a filter with very fine pores. In ultrafiltration, the separation is performed by convective transport. During intermittent hemodialysis, separation depends on differential diffusion. Some approaches to continuous RRT combine ultrafiltration with diffusion (combined hemofiltration and hemodialysis).

Continuous RRT occurs only in the ICU because of (1) the need for frequent monitoring and specialized skill set to maintain safety during *extracorporeal circulation* (blood flow outside the body) and (2) the need for ongoing replacement of fluid and electrolytes. Many agencies require nurses who deliver continuous RRT to attend classes and demonstrate competency in care annually. The American Nephrology Nurses Association provides resources for RRT policies and procedures.

There are several strategies to provide hemofiltration to critically ill patients. Continuous venovenous hemofiltration (CVVH) is more commonly used. CVVH is powered by a pump that drives blood from the patient catheter into the dialyzer (filter). The ultrafiltrate fluid is then collected into a bag for disposal. There may be a second pump that acts on the ultrafiltrate tubing to create negative pressure and increase fluid removal. Replacement fluid is infused via the inflow circuit in some systems. The pump increases the risk for an air embolus, but RRT systems should have alarms that detect air. These systems may also use anticoagulants but at lower doses than needed for systems using arterial access. CVVH can also be combined with dialysis (continuous venovenous hemofiltration and dialysis [CVVHD]). CVVHD is similar to intermittent RRT except that the rates of blood circulation and waste formation are much slower with CVVHD, thus the need for continuous therapy (Golestaneh et al., 2012).

Another modality for RRT is a hybrid of continuous and intermittent approaches. Slow continuous ultrafiltration (SCUF) provides slow removal of fluid over 12 to 24 hours. It can be useful when azotemia or uremia is not a concern (Streets & Vickers, 2012). Sustained low-efficiency dialysis (SLED) uses the dialysis machine to deliver prolonged dialysis for 12 to 24 hours. Lower blood flow and dialysate flow rates remove both particles and water and may be better tolerated by the unstable or critically ill patient, with fewer episodes of hypotension.

Continuous RRT is expensive and resource intensive (Allegretti et al., 2013; Golestaneh et al., 2012). It requires consultation and collaboration

with the nephrologist and, often, with nurses specialized in dialysis delivery. Clear evidence about when to start or stop RRT when AKI occurs does not yet exist. Conservative management of fluid and electrolyte balance, acid-base balance, and drug therapy is an acceptable and reasonable approach to manage AKI. This approach may be associated with less mortality up to 2 years following RRT for AKI.

Posthospital Care.

The care for a patient with AKI after discharge from the hospital varies, depending on the status of the kidney function when the patient is discharged. The course of AKI varies, with recovery lasting up to several months. If the kidney injury is resolving, follow-up care may be provided by a nephrologist or by the family physician in consultation with the nephrologist. Frequent medical visits are necessary, as are scheduled laboratory blood and urine tests to monitor kidney function. A dietitian can plan modifications to the patient's diet according to the degree of kidney function and ongoing nutrition needs. Fluid restrictions and daily weights may be advised to avoid fluid overload while kidneys are recovering.

About 10% of patients who receive RRT for AKI in the hospital experience ESKD and require chronic intermittent dialysis or renal transplantation (Allegretti et al., 2013). In patients who require dialysis at discharge following AKI, follow-up care is similar to that needed for patients with ESKD from CKD (see Community-Based Care, pp. 1444-1446). Depending on their level of independence and family support, patients may also need home care nursing or social work assistance.

NCLEX Examination Challenge

Physiological Integrity

The nurse is completing documentation for a client with acute kidney injury who is being discharged today. The nurse notices that the client has a serum potassium level of 5.8 mEq/L. Which is the priority nursing action?

A Asking the client to drink an extra 500 mL of water to dilute the electrolyte concentration and then re-checking the serum potassium level.

B Encouraging the client to eat potassium-binding foods and to contact his or her primary care provider within 24 hours.

C Checking the remaining values on the electrolyte panel and informing

the primary care provider of all results before the client is discharged.

D Applying a cardiac monitor and evaluating the client's muscle strength and muscle irritability.

Chronic Kidney Disease

❖ Pathophysiology

Unlike acute kidney injury (AKI), **chronic kidney disease (CKD)** is a progressive, irreversible disorder and kidney function does *not* recover (Taal et al., 2012). When kidney function is too poor to sustain life, CKD becomes **end-stage kidney disease (ESKD)**. Terms used with CKD include **azotemia** (buildup of nitrogen-based wastes in the blood), **uremia** (azotemia with clinical manifestations [Chart 68-2]), and **uremic syndrome**. See Table 68-1 for a comparison of AKI and CKD.

Chart 68-2 Key Features

Uremia

- Metallic taste in the mouth
- Anorexia
- Nausea
- Vomiting
- Muscle cramps
- Uremic "frost" on skin
- Itching
- Fatigue and lethargy
- Hiccups
- Edema
- Dyspnea
- Paresthesias

Stages of Chronic Kidney Disease

The kidneys fail in an organized fashion involving five stages based on estimated glomerular filtration rate (GFR). Direct measurement (described in Chapter 65, using a 3-hour or 24-hour urine collection) is advised for the most accurate estimation of GFR. The five stages of CKD are described in Table 68-7. CKD starts with a normal GFR but increased risk for kidney damage. In the first stage, the person may have a normal GFR (greater than 90 mL/min) but urine findings or structural abnormalities or genetic trait point to kidney disease. The patient is at increased risk for kidney damage from infection, inflammation, pregnancy, dehydration, and hypotension or hypertension. Careful management of conditions like diabetes, hypertension, and heart failure can slow the progression of CKD even before GFR changes and manifestations of CKD

occur (Wynne et al., 2012).

TABLE 68-7

Stages of Chronic Kidney Disease

Stage	Estimated Glomerular Filtration Rate	Intervention
Stage 1 At risk; normal kidney function but urine findings or structural abnormalities or genetic trait point to kidney disease	>90 mL/min	Screen for risk factors and manage care to reduce risk: • Uncontrolled hypertension • Diabetes mellitus • Chronic kidney or urinary tract infection • Family history of genetic kidney diseases • Exposure to nephrotoxic substances
Stage 2 Mild chronic kidney disease (CKD); reduced kidney function; laboratory values and other findings (e.g. structural changes) point to kidney disease	60-89 mL/min	Focus on reduction of risk factors
Stage 3 Moderate CKD	30-59 mL/min	Implement strategies to slow disease progression
Stage 4 Severe CKD	15-29 mL/min	Manage complications Discuss patient preferences and values Educate about options and prepare for renal replacement therapy
Stage 5 End-stage kidney disease (ESKD)	<15 mL/min	Implement renal replacement therapy or kidney transplantation

In the next stage, *mild CKD*, GFR is reduced, ranging between 60 and 89 mL/min. Kidney nephron damage has occurred, and there may be slight elevations of metabolic wastes in the blood because of nephron loss. Levels of blood urea nitrogen (BUN), serum creatinine, uric acid, and phosphorus are not sensitive enough to define this stage. Increased output of dilute urine may occur at this stage of CKD and contribute to severe dehydration.

Nursing Safety Priority QSEN

Action Alert

Teach patients with mild CKD that carefully managing fluid volume, blood pressure, electrolytes, and other kidney-damaging diseases by following prescribed drug and nutrition therapies can prevent damage and slow the progression to ESKD.

In *moderate CKD*, GRF reduction continues and ranges between 30 and 59 mL/min. Nephron damage is greater, and azotemia is present. Ongoing management of the underlying conditions that cause nephron damage is essential, especially glycemic and blood pressure control. Restriction of fluids, proteins, and electrolytes is needed.

Over time, patients progress to *severe CKD* (the fourth stage) and *end-stage kidney disease* (ESKD) (the fifth stage). Excessive amounts of urea

and creatinine build up in the blood, and the kidneys cannot maintain homeostasis. Severe impairments of fluid and electrolyte balance and acid-base balance occur. Without renal replacement therapy, death results from ESKD.

Kidney Changes

CKD with greatly reduced GFR causes many problems, including abnormal urine production, severe disruption of fluid and electrolyte balance, and metabolic abnormalities. Because healthy nephrons become larger and work harder, urine production and water elimination are sufficient to maintain essential homeostasis until about three fourths of kidney function is lost. As the disease progresses, the ability to produce diluted urine is reduced, resulting in urine with a fixed osmolarity *(isosthenuria).* As kidney function continues to decline, the BUN increases and urine output decreases. At this point, the patient is at risk for fluid overload.

Metabolic Changes

Urea and creatinine excretion are disrupted by CKD. Creatinine comes from proteins present in skeletal muscle. The rate of creatinine excretion depends on muscle mass, physical activity, and diet. Without major changes in diet or physical activity, the serum creatinine level is constant. Creatinine is partially excreted by the kidney tubules, and a decrease in kidney function leads to a buildup of serum creatinine. Urea is made from protein metabolism and is excreted by the kidneys. The BUN level normally varies directly with protein intake.

Sodium excretion changes are common. Early in CKD, the patient is at risk for *hyponatremia* (sodium depletion) because there are fewer healthy nephrons to reabsorb sodium. Thus sodium is lost in the urine. Polyuria of mild to moderate CKD also causes sodium loss.

In the later stages of CKD, kidney excretion of sodium is reduced as urine production decreases. Then sodium retention and high serum sodium levels *(hypernatremia)* can occur with only modest increases in dietary sodium intake. This problem leads to severe disruption of fluid and electrolyte balance (see Chapter 11). Sodium retention causes hypertension and edema.

Even with sodium retention, the serum sodium level may appear normal because plasma water is retained at the same time. If fluid retention occurs at a greater rate than sodium retention, the serum sodium level is falsely low because of dilution (see Chart 68-1).

Potassium excretion occurs mainly through the kidney. Any increase in

potassium load during the later stages of CKD can lead to **hyperkalemia** (high serum potassium levels). Normal serum potassium levels of 3.5 to 5 mEq/L are maintained until the 24-hour urine output falls below 500 mL. High potassium levels then develop quickly, reaching 7 to 8 mEq/L or greater. Life-threatening changes in cardiac rate and rhythm result from this elevation due to abnormal depolarization and repolarization. Other factors contribute to high potassium levels in CKD, including the ingestion of potassium in drugs, failure to restrict dietary potassium, tissue breakdown, blood transfusions, and bleeding or hemorrhage. (See Chapter 11 for discussion of potassium problems.)

Acid-base balance is affected by CKD. In the early stages, blood pH changes little because the remaining healthy nephrons increase their rate of acid excretion. As more nephrons are lost, acid excretion is reduced and metabolic acidosis results (see Chapter 12).

Many factors lead to acidosis in CKD. First, the kidneys cannot excrete excessive hydrogen ions (acids). Normally, tubular cells move hydrogen ions into the urine for excretion, but ammonium and bicarbonate are needed for this movement to occur. In patients with CKD, ammonium production is decreased and reabsorption of bicarbonate does not occur. This process leads to a buildup of hydrogen ions and reduced levels of bicarbonate *(base deficit).* High potassium levels further reduce kidney ammonium production and excretion.

As CKD worsens and acid retention increases, increased respiratory action is needed to keep blood pH normal. The respiratory system adjusts or compensates for the increased blood hydrogen ion levels (acidosis or decreased pH) by increasing the rate and depth of breathing to excrete carbon dioxide through the lungs. This breathing pattern, called **Kussmaul respiration**, increases with worsening kidney disease. Serum bicarbonate measures the extent of metabolic acidosis (bicarbonate deficit). Patients with CKD usually need alkali replacement to counteract acidosis.

Calcium and phosphorus balance is disrupted by CKD. A complex, balanced normal reciprocal relationship exists between calcium and phosphorus (used interchangeably with phosphate) and is influenced by vitamin D (see Chapter 11). The kidney produces a hormone needed to activate vitamin D, which then enhances intestinal absorption of calcium.

Normally, excess dietary phosphorus is excreted by the kidneys in the urine. In CKD, phosphorus overload leads to secretion of a phosphaturic hormone from bone (Fukagawa et al., 2013). This hormone, fibroblast growth factor 3 (GG3), contributes to mineral imbalance.

Parathyroid hormone (PTH) controls the amount of phosphorus in the

blood by causing tubular excretion of phosphorus when there is an excess. An early effect of CKD is reduced phosphorus excretion (Fig. 68-2). As plasma phosphorus levels increase *(hyperphosphatemia),* calcium levels decrease *(hypocalcemia).* Chronic low blood calcium levels stimulate the parathyroid glands to release more PTH. Under the influence of additional PTH, calcium is released from storage areas in bones *(bone resorption),* which results in bone density loss. The extra calcium from the bone is needed to balance the excess plasma phosphorus level. The problem of low blood calcium levels is made worse with severe CKD because kidney cell damage also reduces production of active vitamin D. Thus less calcium is absorbed through the intestinal tract in the absence of sufficient vitamin D.

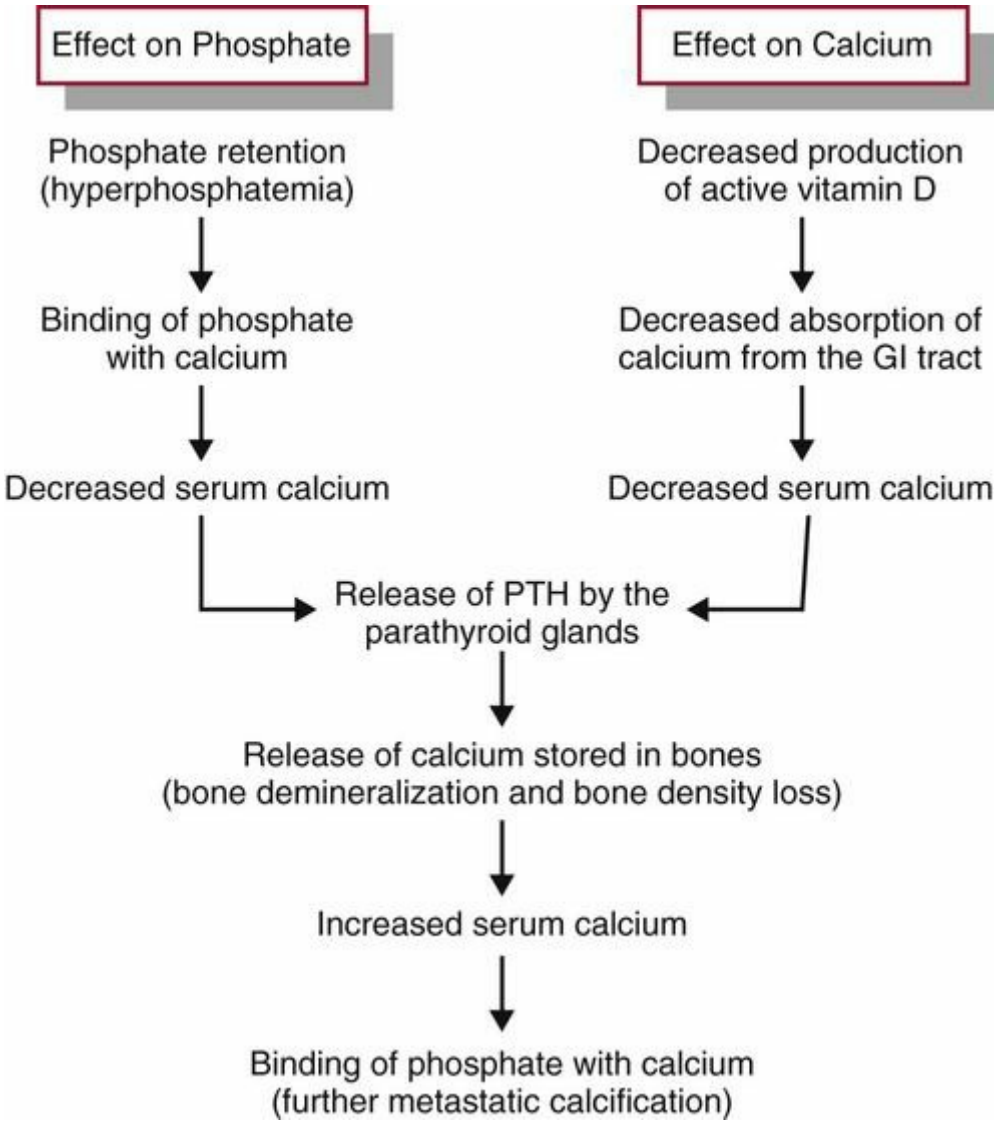

FIG. 68-2 The effects of kidney dysfunction on phosphorus and calcium balance. *PTH,* Parathyroid hormone.

The problems in bone metabolism and structure caused by CKD-

induced low calcium levels and high phosphorus levels are called **renal osteodystrophy**. Bone mineral loss causes bone pain, spinal sclerosis, fractures, bone density loss, osteomalacia, and tooth calcium loss.

Crystals formed from excessive calcium phosphorus are called *metastatic calcifications* and may precipitate in many body areas. When the plasma level of the calcium-phosphorus product (serum calcium level multiplied by the serum phosphorus level) exceeds 70 mg/dL, the crystals may lodge in the kidneys, heart, lungs, major blood vessels, joints, eyes (causing conjunctivitis), and brain. Skin itching increases with calcium-phosphorus imbalances.

Calcium is also deposited in atherosclerotic plaques and in the intima of blood vessels. Vascular calcium deposits are a marker of significant risk for cardiovascular disease.

Cardiac Changes

Hypertension is common in most patients with CKD. This problem may be either the cause or the result of CKD. In patients who have other causes of hypertension such as atherosclerosis, the increased blood pressure damages the glomerular capillaries and eventually ESKD results.

CKD itself elevates blood pressure by causing fluid and sodium overload and dysfunction of the renin-angiotensin-aldosterone system. Hypertension alone can damage kidney arterioles, reducing perfusion. A decrease in kidney blood flow results in the production and release of a number of signaling chemicals, including renin, to improve blood flow to the kidney. The release of renin triggers the production of angiotensin and aldosterone. Angiotensin causes blood vessel constriction and increases blood pressure. Aldosterone, a hormone released by the adrenal glands, stimulates kidney tubules to reabsorb sodium and water. These actions increase plasma volume and raise blood pressure. However, in the presence of CKD, an increase in blood pressure may not result in increased blood flow, and the production of renin continues, which creates a cycle of vasoconstriction in kidney arterioles and peripheral arterioles. The result is severe hypertension that worsens kidney function. Hypertension with CKD is difficult to manage. Many patients with CKD have heart damage and heart enlargement from the long-term hypertension that results in coronary artery damage and poor coronary artery perfusion.

Hyperlipidemia occurs in CKD from changes in fat metabolism that increase triglyceride, total cholesterol, and low-density lipoprotein (LDL)

levels. These changes increase the patient's risk for coronary artery disease and acute cardiac events. Problems with lipids and atherosclerosis are significantly increased for the patient with both CKD and diabetes.

Heart failure may occur in CKD because it increases the workload on the heart as a result of anemia, hypertension, and fluid overload. Left ventricular enlargement and heart failure are common in ESKD. Uremia may cause *uremic cardiomyopathy,* the uremic toxin effect on the myocardium. Heart failure also may occur in these patients because of hypertension and coronary artery disease. Cardiac disease is a leading cause of death in patients with ESKD.

Pericarditis also occurs in patients with CKD. The pericardial sac becomes inflamed by uremic toxins or infection. If it is not treated, this problem leads to pericardial effusion, cardiac tamponade, and death. Manifestations include shortness of breath from low cardiac output, severe chest pain, tachycardia, narrow *pulse pressure* (close values for systolic and diastolic blood pressure), low-grade fever, and a pericardial friction rub that can be heard with a stethoscope placed over the left sternal border. Dysrhythmias may occur with uremia and uremic pericarditis. Treatment of tamponade requires removal of pericardial fluid by placement of a needle, catheter, or drainage tube into the pericardium.

Hematologic Changes

Anemia is a common problem in patients in the later stages of CKD, and it worsens the CKD manifestations. The causes of anemia include a decreased erythropoietin level that decreases red blood cell (RBC) production, decreased RBC survival time resulting from uremia, iron and folic acid deficiencies, and increased bleeding as a result of impaired platelet function.

Gastrointestinal Changes

Uremia affects the entire GI system. The flora of the mouth change with uremia. The mouth contains the enzyme *urease,* which breaks down urea into ammonia. The ammonia generated then causes *halitosis* (bad breath) and *stomatitis* (mouth inflammation).

Anorexia, nausea, vomiting, and hiccups are common in patients with uremia. The specific cause of these problems is unknown but may be related to high BUN and creatinine levels as well as acidosis.

Peptic ulcer disease is common in patients with uremia, but the exact

cause is unclear. Uremic colitis with watery diarrhea or constipation may also be present with uremia. Ulcers may occur in the stomach or intestine, causing erosion of blood vessels. The blood loss caused by these erosions may lead to hemorrhagic shock from severe GI bleeding.

Etiology and Genetic Risk

The causes of CKD are complex (Table 68-8). More than 100 different disease processes can result in progressive loss of kidney function (see also Chapter 67). Two main causes of CKD leading to dialysis are hypertension and diabetes mellitus. African-American patients are much more likely to develop ESKD and to have hypertensive ESKD.

TABLE 68-8

Selected Causes of Chronic Kidney Disease

Glomerular Disease
• Glomerulonephritis • Basement membrane disease • Goodpasture's syndrome • Intercapillary glomerulosclerosis
Tubular Disease
• Chronic hypercalcemia • Chronic potassium depletion • Fanconi's syndrome • Heavy metal (lead) poisoning
Vascular Disease of the Kidney
• Ischemic disease of the kidney • Bilateral renal artery stenosis • Nephrosclerosis • Hyperparathyroidism
Inherited or Genetic Conditions
• Hypoplastic kidneys • Medullary cystic disease • Polycystic kidney disease
Infection
• Pyelonephritis • Tuberculosis
Systemic Vascular Disease
• Intrarenal renovascular hypertension • Extrarenal renovascular hypertension
Metabolic Kidney Disease
• Diabetes • Amyloidosis • Gout (hyperuricemic nephropathy) • Milk-alkali syndrome • Sarcoidosis
Connective Tissue Disease
• Progressive systemic sclerosis • Systemic lupus erythematosus • Polyarteritis
Urinary Tract Disease
• Obstructive uropathy

Note: List is not all-inclusive.

Incidence and Prevalence

The number of patients being treated for CKD is increasing, particularly among people older than 65 years. Over 871,000 people in the United States are being treated for ESKD (U.S. Renal Data Systems [USRDS], 2014). As many as 25% of patients receiving treatment for ESKD die in the first year of dialysis. Chart 68-3 addresses the prevention of kidney and urinary problems.

Chart 68-3 Patient and Family Education: Preparing for Self-Management

Prevention of Kidney and Urinary Problems

- Be alert to the general appearance of your urine. Note any changes in its color, clarity, or odor.
- Changes in the frequency or volume of urine passage occur with changes in fluid intake. More frequent or infrequent voiding not associated with changes in fluid intake may signal health problems.
- Any discomfort or distress with the passage of urine is not normal. Pain, burning, urgency, aching, or difficulty with initiating urine flow or complete bladder emptying is of some concern.
- The kidneys need 1 to 2 liters of fluid a day to flush out your body wastes. Water is the ideal flushing agent.
- Avoid sugary, high-calorie drinks; they provide low-quality calories that contribute to weight gain and hyperglycemia-induced diuresis.
- Changes in kidney function are often silent for many years. Periodically ask your health care provider to measure your kidney function with a blood test (serum creatinine) and a urinalysis.
- If you have a history of kidney disease, diabetes mellitus, hypertension (high blood pressure), or a family history of kidney disease, you should know your serum creatinine level and your glomerular filtration rate (either estimated from serum creatinine or measured with a 24-hour creatinine urine collection). At least one checkup per year that includes laboratory blood and urine testing of kidney function is recommended.
- If you are identified as having decreased kidney function, ask about whether any prescribed drug, diagnostic test, or therapeutic procedure will present a risk to your current kidney function. Evaluate the contribution of diet to risk for kidney disease with your health care provider or a dietitian. Check out all nonprescription drugs with your physician or pharmacist before using them.

Health Promotion and Maintenance

The health-promotion activities to prevent or delay the onset of CKD focus on controlling the diseases that lead to its development, such as diabetes mellitus and hypertension. Educating and encouraging the patient to accept lifestyle modifications and how to implement them are incorporated into the plan of care in an ongoing manner. Diet adjustments (e.g., sodium, protein, and cholesterol restriction), weight maintenance (i.e., achieve body mass index of 22-25 kg/m^2), cessation of smoking, participation in 30 to 60 minutes of moderate-intensity exercise daily, and limitation of alcohol to 1 or 2 drinks daily are examples of lifestyle recommendations for the patient with CKD (Saccomano & DeLuca, 2012). Identifying patients who have diabetes or hypertension at an early stage is critical to CKD prevention. Teach patients to adhere to drug and diet regimens and to engage in regular physical activity to prevent the blood vessel changes and cascade of kidney cell damage that lead to CKD. Instruct patients with diabetes to keep their blood glucose levels within the prescribed range. Teach patients with hypertension that drug therapy reduces vessel damage. Lifestyle changes in diet and activity promote health and healthy kidneys. Urge patients with diabetes or hypertension to have yearly testing for microalbuminuria along with serum creatinine and BUN.

Teach everyone treated for an infection anywhere in the kidney/urinary system to take all antibiotics as prescribed. Urge everyone to drink at least 2 L of water daily unless a health problem requires fluid restriction. Caution people who use NSAIDs to use the lowest dose for the briefest time period because these drugs interfere with blood flow to the kidney. High-dose and long-term NSAID use reduces kidney function.

Patient-Centered Collaborative Care

Assessment

History.

When taking a history from a patient with risk for or actual chronic kidney disease (CKD), document the patient's age and gender. Accurately measure weight and height, and ask about usual weight and recent weight gain or loss. Weight gain may indicate fluid retention from poor kidney function. Weight loss may be the result of anorexia from high blood urea levels.

Obtain a complete history of kidney and urologic disorders, long-term health problems, and drug use. Long-term health problems such as hypertension, diabetes, systemic lupus erythematosus, arthritis, cancer, and tuberculosis can cause decreased kidney function. Ask the patient about family members' kidney disease that might indicate a genetic problem.

Document the use of current and past prescription and over-the-counter drugs because many drugs are nephrotoxic and can cause kidney damage (see Table 68-5). Inquire about contrast-induced nephropathy by asking if the patient has had x-rays or CT scan with dye.

Examine the patient's dietary habits, and discuss any present GI problems. A change in the taste of foods often occurs with CKD. Patients may report that sweet foods are not as appealing or that meats have a metallic taste. Ask about the presence of nausea, vomiting, anorexia, hiccups, diarrhea, or constipation. These manifestations may be the result of excess wastes that the body cannot excrete because of kidney disease.

Ask about the patient's energy level and any recent injuries or bleeding. Explore changes in his or her daily routine as a possible *result* of fatigue. Fatigue is a common and often profound problem among patients with CKD, particularly among patients receiving dialysis (Horigan et al., 2012). Weakness, drowsiness, and shortness of breath suggest impending pulmonary edema or neurologic degeneration. Ask about bruising or bleeding, which can be caused by hematologic changes from uremia.

Discuss urine elimination in detail, including frequency of urination, appearance of the urine, and any difficulty starting or controlling urination. These data can help identify urologic problems that may influence existing kidney function.

NCLEX Examination Challenge

Health Promotion and Maintenance

A 60-year-old African-American client is newly diagnosed with mild chronic kidney disease (stage 2 CKD). She has a history of diabetes, and her current A1C is 8.0%. She asks the nurse whether any of the following factors could have caused this problem. Which factor should the nurse indicate may have influenced the development of CKD?

A She heavily salted her food as a child and teenager but added no extra salt to her food as an adult.

B Her chronic hyperglycemia causes blood vessel changes in the kidney that can damage kidney tissue.
C Her paternal grandparents had type 2 diabetes and hypertension.
D She drinks 2 cups of coffee with cream daily.

Physical Assessment/Clinical Manifestations.

CKD causes changes in all body systems (Chart 68-4). Most manifestations are related to changes in fluid and electrolyte balance, acid-base balance, and buildup of nitrogenous wastes.

Chart 68-4 Key Features

Severe Chronic and End-Stage Kidney Disease

Neurologic Manifestations

- Lethargy and daytime drowsiness
- Inability to concentrate or decreased attention span
- Seizures
- Coma
- Slurred speech
- Asterixis (jerky movements or "flapping" of the hands)
- Tremors, twitching, or jerky movements
- Myoclonus
- Ataxia (alteration in gait)
- Paresthesias

Cardiovascular Manifestations

- Cardiomyopathy
- Hypertension
- Peripheral edema
- Heart failure
- Uremic pericarditis
- Pericardial effusion
- Pericardial friction rub
- Cardiac tamponade
- Cardiorenal syndrome

Respiratory Manifestations

- Uremic halitosis
- Tachypnea
- Deep sighing, yawning

- Kussmaul respirations
- Uremic pneumonitis
- Shortness of breath
- Pulmonary edema
- Pleural effusion
- Depressed cough reflex
- Crackles

Hematologic Manifestations

- Anemia
- Abnormal bleeding and bruising

Gastrointestinal Manifestations

- Anorexia
- Nausea
- Vomiting
- Metallic taste in the mouth
- Changes in taste acuity and sensation
- Uremic colitis (diarrhea)
- Constipation
- Uremic gastritis (possible GI bleeding)
- Uremic fetor (breath odor)
- Stomatitis

Urinary Manifestations

- Polyuria, nocturia (early)
- Oliguria, anuria (later)
- Proteinuria
- Hematuria
- Diluted, straw-colored urine appearance (early)
- Concentrated and cloudy urine appearance (later)

Integumentary Manifestations

- Decreased skin turgor
- Yellow-gray pallor
- Dry skin
- Pruritus
- Ecchymosis
- Purpura
- Soft-tissue calcifications
- Uremic frost (late, premorbid)

Musculoskeletal Manifestations

- Muscle weakness and cramping
- Bone pain
- Fractures
- Renal osteodystrophy

Reproductive Manifestations

- Decreased fertility
- Infrequent or absent menses
- Decreased libido
- Impotence
- Sexual dysfunction

Neurologic manifestations of CKD and uremic syndrome vary (see Chart 68-4). Observe for problems ranging from lethargy to seizures or coma, which may indicate uremic encephalopathy. Assess for sensory changes that appear in a glove-and-stocking pattern over the hands and feet (peripheral neuropathy). Check for weakness in the upper and lower extremities (e.g., uremic neuropathy).

If untreated, encephalopathy can lead to seizures and coma. Dialysis is used for CKD when neurologic problems result. The manifestations of encephalopathy may resolve with dialysis. However, improvement in neuropathy is limited if it is severe and motor function is impaired.

Cardiovascular manifestations of CKD and uremia result from fluid overload, hypertension, heart failure (HF), pericarditis, potassium-induced dysrhythmias, and cholesterol/calcium (plaque) deposits in blood vessels. Assess for manifestations of reduced sodium and water excretion. Circulatory overload, if untreated, leads to hypertension, pulmonary edema, peripheral edema, and HF.

Assess heart rate and rhythm, listening for extra sounds (particularly an S_3), irregular patterns, or a pericardial friction rub. Unless a dialysis vascular access has been created, measure blood pressure in each arm. Assess the jugular veins for distention, and assess for edema of the feet, shins, and sacrum and around the eyes. Crackles during lung auscultation and shortness of breath with exertion and at night suggest fluid overload.

Respiratory manifestations of CKD also vary (e.g., breath that smells like urine [*uremic fetor* or uremic halitosis], deep sighing, yawning, shortness of breath). Observe the rhythm, rate, and depth of breathing. Tachypnea and **hyperpnea** (increased depth of breathing) occur with metabolic

acidosis.

With severe metabolic acidosis, extreme increases in rate and depth of ventilation (Kussmaul respirations) occur. A few patients have pneumonitis, or *uremic lung.* In these patients, assess for thick sputum, reduced coughing, tachypnea, and fever. A pleural friction rub may be heard with a stethoscope. Patients often have pleuritic pain with breathing. Auscultate the lungs for crackles, which indicate fluid overload.

Hematologic manifestations of CKD include anemia and abnormal bleeding. Check for indicators of anemia (e.g., fatigue, pallor, lethargy, weakness, shortness of breath, dizziness). Check for abnormal bleeding by observing for bruising, petechiae, purpura, mucous membrane bleeding in the nose or gums, or intestinal bleeding (black, tarry stools **[melena]**).

GI manifestations of CKD include foul breath and mouth inflammation or ulceration. Document any abdominal pain, cramping, or vomiting. Test all stools for occult blood.

Skeletal manifestations of CKD are related to osteodystrophy from poor absorption of calcium and continuous bone calcium loss. Adults with osteodystrophy have thin, fragile bones that are at risk for pathologic fractures with even slight trauma. Vertebrae become more compact and may bend forward, leading to an overall loss of height. Ask about changes in height and any unexplained bone pain. Observe for spinal curvatures and any unusual bumps or protrusions in bone areas that may indicate fractures. Handle the patient carefully during examination and care.

Urine manifestations in CKD reflect the kidneys' decreasing function. At first, urine amount, frequency, and appearance change. Protein, sediment, or blood may be in the urine.

The amount and composition of the urine change as kidney function decreases. With the onset of mild to moderate CKD, the urine may be more dilute and clearer because tubular reabsorption of water is reduced. The actual urine output in a patient with CKD varies with the amount of remaining kidney function. The patient with severe CKD or ESKD usually has oliguria, but some patients continue to produce 1 L or more daily. Daily urine volume usually changes again after dialysis is started. A long duration of oliguria is an indication that recovery of kidney function is not to be expected.

Skin manifestations of CKD occur as a result of uremia. Pigment is deposited in the skin, causing a yellowish coloration, or darkening when skin is brown or bronze. The anemia of CKD causes a sallowness,

appearing as a faded suntan on lighter-skinned patients.

Skin oils and turgor are decreased in patients with uremia. A distressing problem of uremia is severe *pruritus* (itching). **Uremic frost**, a layer of urea crystals from evaporated sweat, may appear on the face, eyebrows, axillae, and groin in patients with advanced uremic syndrome. Assess for bruises *(ecchymosis)*, purple patches *(purpura)*, and rashes.

Psychosocial Assessment.

Chronic kidney disease (CKD) and its treatment disrupt many aspects of a patient's life. Psychosocial assessment and support are part of the nurse's role from the time that CKD is first diagnosed. Ask about the patient's understanding of the diagnosis and what the treatment regimen means to him or her (e.g., diet, drugs, dialysis). Assess for anxiety and for the coping styles used by the patient or family members. Issues affected by CKD include family relations, social activity, work patterns, body image, and sexual activity. The long-term nature of severe CKD and ESKD, the many treatment options, and the uncertainties about the course of the disease and its treatment require ongoing psychosocial assessment.

Laboratory Assessment.

CKD causes extreme changes in many laboratory values (see Chart 68-1). Monitor these blood values: creatinine, blood urea nitrogen (BUN), sodium, potassium, calcium, phosphorus, bicarbonate, hemoglobin, and hematocrit. Also monitor GFR for trends.

A urinalysis is performed. In the early stages of CKD, urinalysis may show excessive protein, glucose, red blood cells (RBCs) and white blood cells (WBCs), and decreased or fixed specific gravity. Urine osmolarity is usually decreased. As CKD progresses, urine output decreases dramatically and osmolarity increases.

Glomerular filtration rate (GFR) can be estimated from serum creatinine levels, age, gender, race, and body size. But this type of estimation is generally considered for screening rather than for staging of CKD. Estimation of GFR based on serum creatinine is also useful to calculate drug dose or drug frequency when reduced renal function is a concern. However, to determine stage of CKD, a urine collection of 3 hours to 24 hours is usually done.

In severe CKD, measurements of the serum creatinine and BUN levels may be used to determine the presence and degree of uremia. Serum creatinine levels may increase gradually over a period of years, reaching levels of 15 to 30 mg/dL or more, depending on the patient's muscle

mass. BUN levels are directly related to dietary protein intake. Without protein restriction, BUN levels may rise to 10 to 20 times the value of the serum creatinine level. With dietary protein restriction, BUN levels are elevated but less than those of non–protein-restricted patients. Fluid balance also affects BUN.

Imaging Assessment.

Few x-ray findings are abnormal with CKD. Bone x-rays of the hand can show renal osteodystrophy. With long-term ESKD, the kidneys shrink (except for ESKD caused by polycystic kidney disease) and may be 8 to 9 cm or smaller. This small size results from atrophy and fibrosis. If CKD progresses suddenly, a kidney ultrasound or CT scan without contrast medium may be used to rule out an obstruction. (See Chapter 65 for a complete description of diagnostic tests for kidney function.)

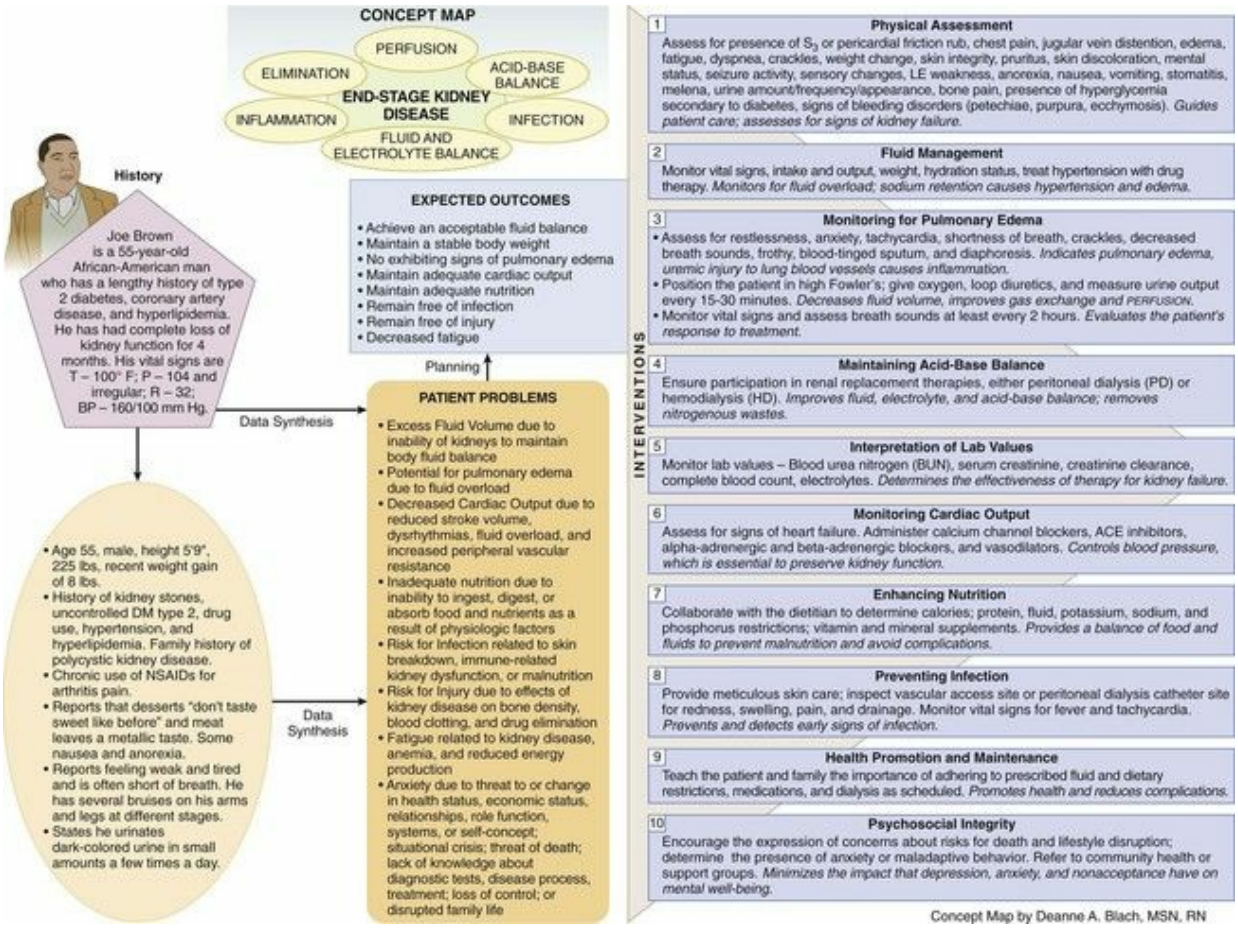
Analysis

The patient with CKD usually has had a progressive reduction of kidney function and is often hospitalized for adjustment of the treatment plan. The focus of care is to manage problems and prevent complications. The priority NANDA-I nursing diagnoses and collaborative problems for patients with CKD include:

1. Excess Fluid Volume related to the inability of diseased kidneys to maintain body fluid balance (NANDA-I)
2. Potential for pulmonary edema related to fluid overload
3. Decreased Cardiac Output related to reduced stroke volume, dysrhythmias, fluid overload, and increased peripheral vascular resistance (NANDA-I)
4. Inadequate nutrition related to inability to ingest, digest, or absorb food and nutrients as a result of physiologic factors
5. Risk for Infection related to skin breakdown, immune-related kidney dysfunction, or malnutrition (NANDA-I)
6. Risk for Injury related to effects of kidney disease on bone density, blood clotting, and drug elimination (NANDA-I)
7. Fatigue related to kidney disease, anemia, and reduced energy production (NANDA-I)
8. Anxiety related to threat to or change in health status, economic status, relationships, role function, systems, or self-concept; situational crisis; threat of death; lack of knowledge about diagnostic tests, disease process, treatment; loss of control; or disrupted family life (NANDA-I)

Planning and Implementation

The Concept Map on p. 1425 discusses nursing care issues related to patients who have end-stage kidney disease (ESKD).



Managing Fluid Volume

Planning: Expected Outcomes.

The patient with CKD is expected to achieve and maintain an acceptable fluid and electrolyte balance. Indicators include that blood pressure, central venous pressure, and electrolytes are normal or nearly normal. Body weight is stable (±2 lbs overnight and 5 lbs weekly) and does not increase more than 3 pounds between dialysis sessions.

Interventions.

Management of the patient with CKD includes drug therapy, nutrition therapy, fluid restriction, and dialysis. Dialysis using extracorporeal blood circulation (hemodialysis) is done intermittently for 3 to 4 hours, typically 3 days per week. Alternatively, some patients with ESKD receive

peritoneal dialysis. PD uses the peritoneum as the dialyzing membrane. The dialysate is infused through a catheter implanted in the peritoneum. Dialysis for ESKD is described on pp. 1431-1437 in this chapter.

The purpose of fluid management is to attain fluid balance and prevent complications of fluid overload (Chart 68-5). Monitor the patient's intake and output and hydration status. Assess for manifestations of fluid overload (e.g., lung crackles, edema, distended neck veins).

Chart 68-5 Best Practice for Patient Safety & Quality Care QSEN

Managing Fluid Volume

- Weigh the patient daily at the same time each day, using the same scale, with the patient wearing the same amount and type of clothing, and graph the results.
- Observe the weight graph for trends (1 L of water weighs 1 kg).
- Accurately measure all fluid intake and output.
- Teach the patient and family about the need to keep fluid intake within prescribed restricted amounts and to ensure that the prescribed daily amount is evenly distributed throughout the 24 hours.
- Monitor for these manifestations of fluid overload at least every 4 hours:
  - Decreased urine output
  - Rapid, bounding pulse
  - Rapid, shallow respirations
  - Presence of dependent edema
  - Auscultation of crackles or wheezes
  - Presence of distended neck veins in a sitting position
  - Decreased oxygen saturation
  - Elevated blood pressure
  - Narrowed pulse pressure
- Assess level of consciousness and degree of cognition.
- Ask about the presence of headache or blurred vision.

Drug therapy with diuretics is prescribed for patients with mild to severe CKD to increase urinary elimination of fluid. The increased urine output produced from these drugs helps reduce fluid overload and hypertension in patients who still have some urine output. Diuretics are seldom used in ESKD after dialysis is started because, as kidney function

is reduced, these drugs can have harmful side effects on the remaining kidney cells and on a patient's hearing.

Assess fluid status by obtaining daily weights and reviewing intake and output. Daily weight gain in these patients indicates fluid retention rather than true body weight gain. Estimate the amount of fluid retained: 1 kg of weight equals about 1 L of fluid retained. Weigh the patient daily at the same time each day, on the same scale, wearing the same amount of clothing, and after voiding (if the patient is not anuric). Monitor weight for changes before and after dialysis.

Fluid restriction is often needed. Consider all forms of fluid intake, including oral, IV, and enteral sources, when calculating fluid intake. Assist the patient in spreading oral fluid intake over a 24-hour period. Monitor his or her response to fluid restriction, and notify the health care provider if manifestations of fluid overload persist or worsen.

Preventing Pulmonary Edema

Planning: Expected Outcomes.

The patient with CKD is expected to remain free of pulmonary edema by maintaining optimal fluid balance. Indicators include that the patient has no breathing difficulty and no adventitious lung sounds (e.g., crackles, wheezes) with auscultation and that oxygen saturation remains greater than 92%.

Interventions.

In the patient with CKD, pulmonary edema can result from left-sided heart failure related to fluid overload or from blood vessel injury. In left-sided heart failure, the heart is unable to eject blood adequately from the left ventricle, leading to an increased pressure in the left atrium and in the pulmonary blood vessels. The increased pressure causes fluid to cross the capillaries into the pulmonary tissue, forming edema (McCance et al., 2014). Pulmonary edema can also occur from injury to the lung blood vessels as a result of uremia. This condition causes inflammation and capillary leak. Fluid then leaks from pulmonary circulation into the lung tissue and the alveoli. It may also leak into the pleural space, causing a *pleural effusion*.

Assess the patient for early indicators of pulmonary edema, such as restlessness, anxiety, rapid heart rate, shortness of breath, and crackles that begin at the base of the lungs. As pulmonary edema worsens, the level of fluid in the lungs rises. Auscultation reveals increased crackles and decreased breath sounds. The patient may have frothy, blood-tinged

sputum. As cardiac and pulmonary function decrease further, the patient becomes diaphoretic and cyanotic.

The patient with pulmonary edema usually is admitted to the hospital for aggressive treatment and continuous cardiac monitoring. Place the patient in a high-Fowler's position and give oxygen to improve gas exchange. Drug therapy with kidney failure and pulmonary edema is difficult because of potential adverse drug effects on the kidneys. Loop diuretics such as IV furosemide (Lasix) are used to manage pulmonary edema. Kidney impairment increases the risk for *ototoxicity* (ear damage with hearing loss) with furosemide; thus IV doses are given cautiously. Diuresis usually begins within 5 minutes of giving IV furosemide. Measure urine output every 15 to 30 minutes during the acute episode and every hour thereafter until the patient is stabilized. Monitor vital signs and assess breath sounds at least every 2 hours to evaluate the patient's response to this treatment.

IV morphine sulfate (1 to 2 mg) can be prescribed to reduce myocardial oxygen demand by triggering blood vessel dilation and to provide sedation. Dosage adjustments are needed to achieve the desired response and avoid respiratory depression. Monitor the patient's respiratory rate, oxygen saturation, and blood pressure hourly during this therapy. Other drugs that dilate blood vessels, such as nitroglycerin, may be given as a continuous infusion to reduce pulmonary pressure from left heart failure. Monitor vital signs at least hourly because this drug combination may cause severe hypotension.

Monitor serum electrolyte levels daily, and report abnormalities to the health care provider so that imbalances can be corrected quickly. If using electrocardiogram (ECG) monitoring, identify dysrhythmias as they occur and report changes in rhythm that affect consciousness or blood pressure immediately to the health care provider. Monitor oxygen saturation levels by pulse oximetry, and consult with the respiratory therapist for the optimal method to deliver oxygen (e.g., facemask, nasal cannula, or noninvasive mechanical support [see Chapter 28]). Monitor the patient for worsening of the condition, manifested as increasing hypoxemia. He or she may require temporary intubation and mechanical ventilation if respiratory failure occurs.

Patients with CKD who have existing cardiac problems, high blood pressure, or chronic fluid retention are at increased risk for developing pulmonary edema. They are less likely to respond quickly to treatment and are more likely to develop problems related to drug therapy. Ultrafiltration may be used with these patients to reduce fluid volume.

Increasing Cardiac Output

Planning: Expected Outcomes.

The patient with CKD is expected to attain and maintain adequate cardiac output. Indicators include that systolic and diastolic blood pressures, ejection fraction, peripheral pulses, and cognitive status are either normal or nearly normal.

Interventions.

Many patients with long-standing hypertension are at risk for CKD and accelerated progression of kidney failure once CKD occurs. *Therefore blood pressure control is essential in preserving kidney function.* To control blood pressure, calcium channel blockers, angiotensin-converting enzyme (ACE) inhibitors, alpha-adrenergic and beta-adrenergic blockers, and vasodilators may be prescribed. ACE inhibitors are the most effective drugs to slow the progression of CKD in patients with hypertension. Calcium channel blockers can improve the GFR and blood flow within the kidney.

More information on the specific drugs for blood pressure control can be found in Chapter 36. Indications vary depending on the patient, and these drugs are used carefully to avoid complications. Different dosages and combinations may be tried until blood pressure control is adequate and side effects are minimized.

Teach the patient and family to measure blood pressure daily. Evaluate their ability to measure and record blood pressure accurately using their own equipment. Re-check measurement accuracy on a regular basis. Teach the patient and family about the relationship of blood pressure control to diet and drug therapy. Instruct the patient to weigh daily and to bring records of blood pressure measurements, drug administration times, and weights for discussion with the physician, nurse, or registered dietitian.

Assess the patient on an ongoing basis for manifestations of reduced cardiac output, heart failure, and dysrhythmias. These topics are discussed in Chapters 35 through 38.

Enhancing Nutrition

Planning: Expected Outcomes.

The patient with CKD is expected to maintain adequate nutrition. The patient should have a protein-caloric intake appropriate for his or her weight-to-height ratio, muscle tone, and laboratory values (serum

albumin, hematocrit, hemoglobin).

Interventions.

The nutrition needs and diet restrictions for the patient with CKD vary according to the degree of kidney function and the type of renal replacement therapy used (Table 68-9). The purpose of nutrition therapy is to provide the food and fluids needed to prevent malnutrition and avoid complications from CKD.

TABLE 68-9

Dietary Restrictions Needed for Severe Kidney Disease

DIETARY COMPONENT	WITH CHRONIC UREMIA	WITH HEMODIALYSIS	WITH PERITONEAL DIALYSIS
Protein	0.55-0.60 g/kg/day	1.0-1.5 g/kg/day	1.2-1.5 g/kg/day
Fluid	Depends on urine output but may be as high as 1500-3000 mL/day	500-700 mL/day plus amount of urine output	Restriction based on fluid weight gain and blood pressure
Potassium	60-70 mEq/day	70 mEq/day	Usually no restriction
Sodium	1-3 g/day	2-4 g/day	Restriction based on fluid weight gain and blood pressure
Phosphorus	700 mg/day	700 mg/day	800 mg/day

The patient is referred to a dietitian for dietary teaching and planning. Work with the dietitian to teach the patient about diet changes that are needed as a result of CKD. Common changes include control of protein intake; fluid intake limitation; restriction of potassium, sodium, and phosphorus intake; taking vitamin and mineral supplements; and eating enough calories to meet metabolic need.

Protein restriction early in the course of the disease prevents some of the problems of CKD and may preserve kidney function. Protein is restricted on the basis of the degree of kidney impairment (reduced GFR) and the severity of the manifestations. Buildup of waste products from protein breakdown is the main cause of uremia.

The glomerular filtration rate (GFR) and treatment of CKD is used to guide safe levels of protein intake. A patient with a severely reduced GFR who is *not* undergoing dialysis is usually permitted 0.55 to 0.60 g of protein per kilogram of body weight (e.g., 40 g of protein daily for a 150-lb [70-kg] adult). If protein is lost in the urine, protein is added to the diet in amounts equal to that lost in the urine. Protein requirements are calculated based on actual body weight (corrected for edema), not ideal body weight.

The patient with ESKD receiving dialysis needs more protein because some protein is lost through dialysis. Protein requirements are tailored according to the patient's post-dialysis, or “dry,” weight. Generally,

patients receiving dialysis are allowed about 1 to 1.5 g of protein/kg/day. Peritoneal dialysis (PD) patients are allowed 1.2 to 1.5 g of protein/kg/day because protein is lost with each exchange. Suggested protein-containing foods are milk, meat, or eggs. If protein intake is not adequate, significant muscle wasting can occur. BUN and serum prealbumin and albumin levels are used to monitor the adequacy of protein intake. Decreased serum prealbumin or albumin levels indicate poor protein intake.

Sodium restriction is needed in patients with little or no urine output. Both fluid and sodium retention cause edema, hypertension, and heart failure (HF). Most patients with CKD retain sodium; a few cannot conserve sodium.

Estimate fluid and sodium retention status by monitoring the patient's body weight and blood pressure. In uremic patients not receiving dialysis, sodium is limited to 1 to 3 g daily and fluid intake depends on urine output. In patients receiving dialysis, the sodium restriction is 2 to 4 g daily and fluid intake is limited to 500 to 700 mL plus the amount of any urine output. Instruct the patient not to add salt at the table or during cooking. Many foods are significant sources of sodium (e.g., processed foods, fast foods, potato chips, pretzels, pickles, ham, bacon, sausage) and difficult to moderate or remove from one's diet. Inattention to sodium intake can increase the duration or number of dialysis treatments and contribute to *disequilibrium syndrome* (feeling "zonked") following dialysis.

Potassium restriction may be needed because high blood potassium levels can cause dangerous cardiac dysrhythmias. Monitor the ECG for tall, peaked T waves caused by hyperkalemia. Document serum potassium levels. Instruct the patient with ESKD to limit potassium intake to 60 to 70 mEq/day. Teach him or her to read labels of seasoning agents carefully for sodium and potassium content. Chart 11-6 in Chapter 11 lists common foods that are low in potassium and are permitted, along with foods that are high in potassium and should be avoided. Instruct patients to avoid salt substitutes composed of potassium chloride. Those receiving peritoneal dialysis or who are producing urine may not need potassium restriction.

Phosphorus restriction for control of phosphorus levels is started early in CKD to avoid renal osteodystrophy (bone defects). Monitor serum phosphorus levels. Dietary phosphorus restrictions and drugs to assist with phosphorus control may be prescribed. Phosphate binders must be taken at mealtimes. Most patients with CKD already restrict their protein intake, and because high-protein foods are also high in phosphorus, this

reduces phosphorus intake. Chapter 11 lists foods high in potassium, sodium, and phosphorus. Cinacalcet (Sensipar), a drug to control parathyroid hormone excess, is also used to manage hyperphosphatemia and hypocalcemia.

Vitamin and mineral supplementation is needed daily for most patients with CKD. Low-protein diets are also low in vitamins, and water-soluble vitamins are removed from the blood during dialysis. Anemia also is a problem in patients with CKD because of the limited iron content of low-protein diets and decreased kidney production of erythropoietin. Thus supplemental iron is needed. Calcium and vitamin D supplements may be needed, depending on the patient's serum calcium levels and bone status.

Nutrition needs for patients undergoing peritoneal dialysis (PD) are slightly different from those for patients undergoing dialysis. Because protein is lost with the dialysate in PD, replacing lost protein is needed. Often 1.2 to 1.5 g of protein per kilogram of body weight per day is recommended. Patients may have anorexia and have difficulty eating enough protein. High-calorie oral supplements may also be needed (e.g., Magnacal Renal, Ensure Plus). Sodium restriction varies with fluid weight gain and blood pressure. Usually dietary potassium does not need to be restricted because the dialysate is potassium-free. Any potassium restriction is determined by serum potassium levels.

Collaborate with the dietitian to assess each patient's nutrition needs. Teach the patient the dietary regimen, and evaluate his or her understanding of and adherence to it. Give the patient and family written examples of the diet to promote adherence. Help patients adapt diet restrictions to their budget, ethnic background, and food preferences.

Preventing Infection

Planning: Expected Outcomes.

The patient with CKD is expected to remain free of infection. Indicators include that the patient will have only mild or no fever, no lymph node enlargement, negative urine culture, negative dialysis access site culture, and white blood cell count either within the normal range or only slightly elevated.

Interventions.

Provide meticulous care to any areas where skin is not intact (e.g., incisions, site of drains, puncture sites, cracked or excoriated skin, pressure ulcers), and provide preventive skin care to intact areas. For

patients with ESKD undergoing dialysis, inspect the vascular access site or peritoneal dialysis catheter insertion site every shift for redness, swelling, pain, and drainage. Monitor vital signs for manifestations of infection (e.g., fever, tachycardia).

Preventing Injury

Planning: Expected Outcomes.

The patient with CKD is expected to remain free of injury. Indicators include that the patient should not have any of these problems:

- Pathologic fractures
- Toxic side effects from drug therapy
- Bleeding

Interventions.

Injury prevention strategies are needed because the patient with long-standing CKD may have brittle, fragile bones that fracture easily and cause little pain. When lifting or moving a patient with fragile bones, use a lift sheet rather than pulling the patient. Teach unlicensed assistive personnel (UAP) the correct use of lift sheets. Observe for normal range of joint motion and for any unusual surface bumps or depressions over bony areas.

Managing drug therapy in patients with CKD is a complex clinical problem. Many over-the-counter drugs contain agents that alter kidney function. Therefore it is important to obtain a detailed drug history. Know the use of each drug, its side effects, and its site of metabolism.

Certain drugs must be avoided, and the dosages of others must be adjusted according to the degree of remaining kidney function. As the patient's kidney function decreases, repeated dosage adjustments are necessary. Assess for side effects and indications of drug toxicity, and notify the prescriber as appropriate.

Nursing Safety Priority QSEN

Drug Alert

Monitor the patient with severe CKD or ESKD closely for drug-related complications, and ensure that dosages are adjusted as needed. Consult with the pharmacist to determine safe effective doses.

Many drugs are routinely given to patients with CKD, and some of the

common drugs are detailed in Chart 68-6. Know the rationale for these drugs and the indicated nursing interventions. Many patients also have cardiac disease and may require cardiac drugs such as digoxin. Patients with severe CKD and ESKD are particularly at risk for digoxin toxicity because the drug is excreted by the kidneys. When caring for patients with CKD who are receiving digoxin, monitor for indications of toxicity, such as nausea, vomiting, anorexia, visual changes, restlessness, headache, fatigue, confusion, bradycardia, and tachycardia. Monitor the serum drug levels to be certain they are in the therapeutic range (0.8-2 ng/mL). Also closely monitor the serum potassium levels of any patient receiving digoxin.

Chart 68-6 Common Examples of Drug Therapy

Chronic Kidney Disease

DRUG/DOSAGE	ACTION/PURPOSE	NURSING INTERVENTIONS	RATIONALES
Loop Diuretics			
Furosemide (Lasix) Bumetanide (Bumex, Burinex) Dose varies with severity of kidney damage; not effective in ESKD	Manage volume overload when urinary elimination is still present.	Monitor intake and output.	Generally the expected outcome is for output to be greater than intake by 500-1000 mL per 24 hr.
		Monitor electrolytes.	Loop diuretics result in loss of potassium; this can be a desired effect in patients with hyperkalemia
Vitamins and Minerals			
Phosphate Binders: Calcium acetate (PhosLo) 2-4 capsules with each meal Calcium carbonate (Caltrate, Oystercal, others) 2-4 capsules with each meal Lanthanum carbonate (Fosrenol) 500-1000 mg tablets Sevelamer (Renagel, Renvela) 400-800 mg Taken just before or with meals	High blood phosphorus levels cause hypocalcemia and osteodystrophy. These drugs bind to dietary phosphorous and phosphate, typically by using calcium to form an insoluble calcium phosphate such that neither mineral is absorbed from the gastrointestinal tract. These are non-calcium, non-aluminum phosphate binders.	Teach patients to take drugs with meals. Teach patients not to take these drugs within 2 hours of other schedule drugs. Teach patients to separate administration of phosphate binders from other scheduled drugs by 2 or more hours. Monitor both serum phosphorus and calcium levels. Monitor for constipation.	Oral phosphate binders reduce hyperphosphatemia common in severe CKD and ESKD. Many of these drugs can bind with other oral drugs—notably cardiovascular drugs and antibiotics. Drugs that use calcium to bind phosphorus can cause hypercalcemia. Bound phosphorus is excreted in feces. These drugs can cause significant constipation leading to fecal impaction or ileus. Manage constipation with stool softeners like docusate or bowel stimulants such as senna.
		Teach patients to report muscle weakness, slow or irregular pulse, or confusion to the prescriber.	These are manifestations of hypophosphatemia, which require dosage adjustment.
Multivitamins and vitamin B supplements: Folic acid (vitamin B_9, Folvite, Novo-Folacid) 1 mg orally daily	When the patient is receiving dialysis, many essential vitamins and minerals are removed from the blood. Replacement is needed to prevent severe deficiencies.	Teach patients to take the drugs after dialysis.	Dialysis removes the drug from the blood.
		Teach patients to take iron supplements (ferrous sulfate) with meals.	Food reduces nausea and abdominal discomfort.
Iron Salts: Ferrous sulfate (Feosol, Novoferrosulfa) 325 mg orally three or four times daily Iron sucrose (Venofer) 20 mg/mL; 100 mg per dialysis session		Teach patients to take stool softeners daily while taking iron supplements.	Oral iron preparations cause constipation, and most patients with kidney disease must reduce their fluid intake, further increasing the risk for constipation.
		Remind patients that iron supplements change the color of the stool.	Knowing the expected side effects decreases anxiety when they appear.
Vitamin D: Calcitriol (Rocaltrol, Calcijex, Vectical) 0.25-0.5 mcg capsules or 1 mcg/mL solution Paricalcitol (Zemplar) 1-4 mcg capsules or injectable solution	This is the active form of vitamin D. It is used to suppress parathyroid production and secretion and to treat hypocalcemia.	Monitor serum levels of vitamin D and calcium.	Monitor for hypocalcemia or evidence of vitamin D toxicity.
Doxercalciferol (Hectorol) 0.25-2.5 mg, given 3 times/weekly at dialysis	This is a vitamin D analog that does not require activation by the kidneys.		
	Erythropoietin-Stimulating Agents (ESAs)		
Epoetin alfa (Epogen, Procrit, generic) 50-100 units/kg subcutaneously or IV three times a week for patients on dialysis Darbepoetin alfa (Aranesp) 0.45 mcg/kg subcutaneously or IV once weekly for patients on dialysis	Drug prevents anemia by stimulating red blood cell growth and maturation in the bone marrow.	Monitor hemoglobin values. Start when hemoglobin is less than 10 g/dL and the rate of decline indicates the likelihood of requiring a red blood cell transfusion. Once the hemoglobin level is greater than 11 g/dL, reduce or interrupt dose. Teach patients to report any of these side effects to the prescriber as soon as possible: chest pain, difficulty breathing, high blood pressure, rapid weight gain, seizures, skin rash or hives, swelling of feet or ankles.	Drug can induce serious cardiovascular problems, such as myocardial infarction (MI).
Parathyroid Hormone Modulator			
Cinacalcet (Sensipar) 30-180 mg daily	Reduce parathyroid hormone levels. This drug increases the sensitivity to calcium on the chief cell receptors in the parathyroid gland.	Monitor levels of serum calcium. Teach the patient to monitor for diarrhea and muscle pain (myalgia).	This drug should not be used in severe hypocalcemia (levels less than 8.4 mg/dL).

CKD, Chronic kidney disease; *ESKD,* end-stage kidney disease.

Drug Alert

Doses of digoxin are much lower than for most drugs. When digoxin is administered to older adults with kidney disease, the prescribed daily dose may be even lower (0.0625 mg). Check and recheck the dosage before administering digoxin to a patient with kidney disease.

Drugs to control an excessively high phosphorus level include phosphate-binding agents. Non-calcium binders may be preferred to reduce the risk for extraskeletal deposition of calcium and subsequent vessel disease or stone formation (Lewis, 2012). These drugs help prevent renal osteodystrophy and related injuries. Stress the importance of taking these agents and all prescribed drugs.

Hypophosphatemia (low serum phosphorus levels) is a complication of phosphate binding, especially in patients who are not eating adequately but who are continuing to take phosphate-binding drugs. *Hypercalcemia* (high serum calcium levels) also is a possible complication for patients taking calcium-containing compounds to control phosphorus excess. In patients taking aluminum-based phosphate binders for prolonged periods, aluminum deposits may cause bone disease or permanent neurologic problems. Monitor the patient for muscle weakness, anorexia, malaise, tremors, and bone pain.

Teach patients with kidney disease to avoid antacids containing magnesium. These patients cannot excrete magnesium and thus should avoid additional intake.

Some drugs, in addition to those used to treat kidney failure, require special attention. These drugs include antibiotics, opioids, antihypertensives, diuretics, insulin, and heparin.

Many antibiotics are safe for patients with CKD, but those excreted by the kidney require dose adjustment. To prevent complications of bloodstream infection from mouth bacteria, prophylactic antibiotic treatment is given to patients with CKD before any dental procedures. The antibiotic used varies with the patient's needs and the health care provider's preference.

Give opioid analgesics cautiously in patients with severe CKD or ESKD because the effects often last longer. Patients with uremia are sensitive to the respiratory depressant effects of these drugs. Because opioids are broken down by the liver and not the kidneys, the dosages are often the same regardless of the level of kidney function. Monitor the patient's reactions closely after opioids are given to determine whether adjustments are needed.

As CKD progresses, the patient with diabetes often requires reduced doses of insulin or antidiabetic drugs because the failing kidneys do not excrete or metabolize these drugs well. Thus the drugs are effective longer, increasing the risk for hypoglycemia. Monitor blood glucose levels at least 4 times daily to assess whether a dosage change is needed.

Poor platelet function and capillary fragility in CKD make anticoagulant therapy risky. Monitor patients receiving heparin, warfarin, or any anticoagulant every shift for bleeding. See Chapter 40 for more information on caring for patients at increased risk for bleeding.

Minimizing Fatigue

Planning: Expected Outcomes.

The patient with chronic kidney disease (CKD) is expected to conserve energy by balancing activity and rest. Indicators include that the patient will be able to participate in self-care activities, have interest in surroundings, and demonstrate mental concentration.

Interventions.

Some causes of fatigue in the patient with CKD include vitamin deficiency, anemia, and buildup of urea. All patients are given vitamin and mineral supplements because of diet restrictions and vitamin losses from dialysis. Avoid giving these supplements before hemodialysis (HD) treatment because they will be dialyzed out of the body and the patient will receive no benefit.

The anemic patient with CKD is treated with agents to stimulate red blood cell production (Dutka, 2012). The outcome of this therapy is to maintain a hemoglobin level around 10 g/dL. This therapy is effective in triggering bone marrow production of red blood cells if the patient has adequate iron stores. Iron supplements may be needed if patients are iron deficient. Many who receive these drugs report improved appetite and sexual function along with decreased fatigue. The increased production of all blood cells from this therapy may increase blood pressure. The improved appetite challenges patients in their attempts to maintain protein, potassium, and fluid restrictions and requires additional education.

Reducing Anxiety

Planning: Expected Outcomes.

The patient with CKD is expected to have reduced tension and

apprehension. Indicators include that the patient consistently demonstrates these behaviors:
• Seeks information to reduce anxiety
• Uses effective coping strategies
• Reports an absence of anxiety manifestations

Interventions.

The nurse coordinates a team of health care professionals to support and counsel the patient and family, often over many years of treatment. The nurse has the most contact with the patient when he or she is hospitalized or undergoing in-center dialysis treatments. Perform an ongoing assessment of the patient's anxiety level. Observe behavior for cues indicating anxiety (e.g., anxious facial expressions, clenching of hands, tapping of feet, withdrawn posture, absence of eye contact, an increased pulse rate). Evaluate the support systems, such as the involvement of family and friends with the patient's care.

Unfamiliar settings and lack of knowledge about treatments and tests can increase the patient's anxiety level. Explain all procedures, tests, and treatments. Identify the patient's knowledge needs about kidney disease. Provide instruction at a level he or she can understand using a variety of written and visual materials.

Provide continuity of care, whenever possible, by using a consistent nurse-patient relationship to decrease anxiety and promote discussions of concerns. As you develop the nurse-patient relationship, encourage the patient to discuss current problems or concerns.

Encourage the patient to ask questions and discuss fears about the diagnosis. An open atmosphere that allows for discussion can decrease anxiety. Facilitate discussions with family members about the prognosis and the impact on lifestyle.

Renal Replacement Therapies

Renal replacement therapy (RRT) is needed when the pathologic changes of stage 4 and stage 5 CKD are life threatening or pose continuing discomfort. When the patient can no longer be managed with conservative therapies, such as diet, drugs, and fluid restriction, dialysis is indicated. Transplantation may be discussed at any time.

Hemodialysis

Intermittent hemodialysis (HD) is the most common RRT used with ESKD (Table 68-10). Dialysis removes excess fluids and waste products

and restores chemical and electrolyte balance. HD involves passing the patient's blood through an artificial semipermeable membrane to perform the filtering and excretion functions of the kidney. This therapy usually requires technicians to provide meticulous care to the machines delivering HD and nurses to implement and supervise direct care. Such measures are essential to safe HD. Technical or human error can lead to avoidable complications (e.g., hemolysis, air embolism, dialysate error, contamination).

TABLE 68-10

Comparison of Hemodialysis and Peritoneal Dialysis

HEMODIALYSIS	PERITONEAL DIALYSIS
Advantages	
More efficient clearance of wastes Short time needed for treatment	Flexible schedule for exchanges Few hemodynamic changes during and following exchanges Less dietary and fluid restrictions
Complications	
Disequilibrium syndrome Muscle cramps and back pain Headache Itching Hemodynamic and cardiac adverse events (hypotension, cell lysis contributing to anemia, cardiac dysrhythmias) Infection Increased risk for subdural and intracranial hemorrhage from anticoagulation and changes in blood pressure during dialysis	Protein loss Peritonitis Hyperglycemia from dialysate Respiratory distress Bowel perforation Infection Weight gain; discomfort from "carrying" 1-2 liters in abdomen during dwell time; potential for back pain or development of hernia
Contraindications	
Hemodynamic instability or severe cardiac disease Severe vascular disease that prevents vascular access Serious bleeding disorders Uncontrolled diabetes	Extensive peritoneal adhesions, fibrosis, or active inflammatory gastrointestinal disease (e.g., diverticulitis, inflammatory bowel conditions) Ascites or massive central obesity Recent abdominal surgery
Access	
Vascular access route	Intra-abdominal catheter
Procedure	
Complex; requires a second person trained in the technique whether completed at home or at a dialysis unit/center Special training for center personnel and in-home use; requires at least two people to manage process	Simple, easier to complete at home compared with at-home hemodialysis Less complex training; typically managed by patient; can be managed by one person

Patient Selection.

Any patient may be considered for intermittent HD therapy. Starting HD depends on manifestations from disruptions of fluid and electrolyte balance and waste and toxin accumulation, not the GFR alone (Yeun et al., 2012). Dialysis is started immediately for patients who have:

- Fluid overload that does not respond to diuretics (including fluid overload with **pericarditis**)
- Symptomatic **hyperkalemia**
- **Calciphylaxis** (a condition of thrombosis and skin necrosis that can occur in stage 5 CKD)
- Symptomatic toxin ingestion such as drug overdose or poisoning that is

dialyzable (see Table 68-13)

Most commonly, hemodialysis for CKD is started when uremic manifestations (e.g., nausea and vomiting, decreased attention span, decreased cognition, and pruritus) are present.

Many patients survive for years with HD therapy, and others may live only a few months. How long the patient survives using HD therapy depends on his or her age, the cause of CKD, and the presence of other diseases, such as cardiovascular disease or diabetes. General patient selection criteria are:

- Irreversible kidney failure when other therapies are unacceptable or ineffective
- No disorders that would seriously complicate HD
- Patient values and preferences
- Expected ability to continue or resume roles at home, work, or school

Dialysis Settings.

Patients with CKD may receive HD treatments in many settings, depending on specific needs. Regardless of the setting for therapy, they need ongoing nursing support to maintain this complex and lifesaving treatment.

Patients may be dialyzed in a hospital-based center if they have recently started treatment or have complicated conditions that require close supervision. Stable patients not requiring intense supervision may be dialyzed in a community or freestanding dialysis center. Selected patients may participate in complete or partial self-care in an ambulatory care center or with in-home HD.

In-home HD is the least disruptive and allows the patient to adapt the regimen to his or her lifestyle. Many cannot participate in in-home dialysis because they lack a skilled partner to assist with the therapy and manage the dialysis machine. Some patients and partners find the use of in-home dialysis to be too stressful. In addition, a water treatment system must be installed in the home to provide a safe, clean water supply for the dialysis process. More compact and more easily managed systems have contributed to the growth of in-home HD (Yeun et al., 2012).

Procedure.

Dialysis works using the passive transfer of toxins by diffusion. **Diffusion** is the movement of molecules from an area of higher concentration to an area of lower concentration. The rate of diffusion during dialysis is most dependent on the difference in the solute

concentrations between the patient's blood and the dialysate. Large molecules, such as RBCs and most plasma proteins, cannot pass through the membrane.

When HD is started, blood and **dialysate** (dialyzing solution) flow in opposite directions across an enclosed semipermeable membrane. The dialysate contains a balanced mix of electrolytes and water that closely resembles human plasma. On the other side of the membrane is the patient's blood, which contains nitrogen waste products, excess water, and excess electrolytes. During HD, the waste products move from the blood into the dialysate because of the difference in their concentrations (diffusion). Some water is also removed from the blood into the dialysate by *osmosis*. Electrolytes can move in either direction, as needed, and take some fluid with them. Potassium and sodium typically move out of the plasma into the dialysate. Bicarbonate and calcium generally move from the dialysate into the plasma. This circulating process continues for a preset length of time, removing nitrogenous wastes and reestablishing fluid and electrolyte balance, as well as restoring acid-base balance. Water volume may be removed from the plasma by applying positive or negative pressure to the system.

The HD system includes a dialyzer, dialysate, vascular access routes, and an HD machine. The artificial kidney, or **dialyzer** (Fig. 68-3), has four parts: a blood compartment, a dialysate compartment, a semipermeable membrane, and an enclosed support structure.

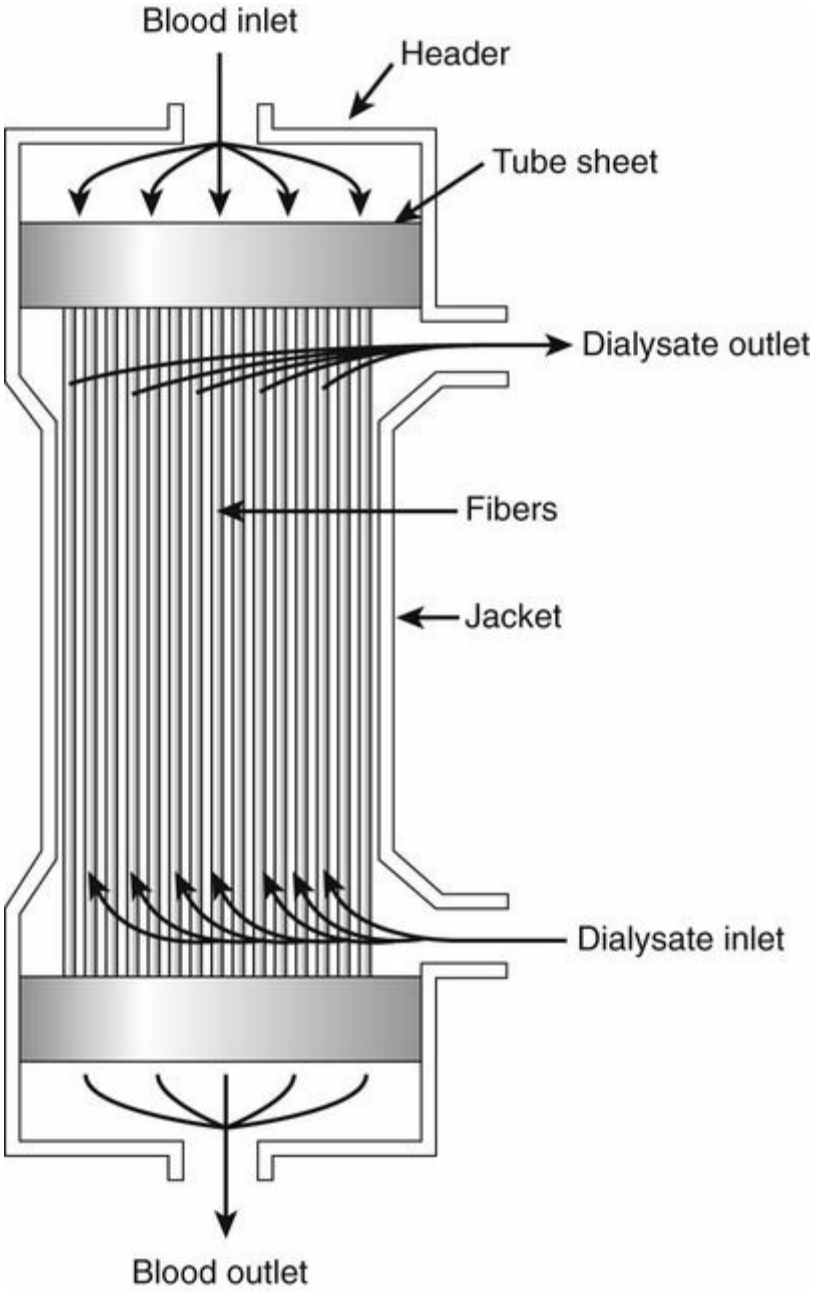


FIG. 68-3 Hollow fiber dialyzer (artificial kidney) used in hemodialysis.

Dialysate is made from water and chemicals and is free of any waste products or drugs. Often dialysate is made in the pharmacy in an acute care setting. It may be made by technicians in dialysis centers. Because bacteria and other organisms are too large to pass through the membrane, dialysate is not sterile. The water used in dialysate must meet specific standards and usually requires special treatment before mixing the dialysate. The dialysate composition may be altered according to the patient's needs for management of electrolyte imbalances. During HD, the dialysate is warmed to 100° F (37.8° C) to increase the diffusion rate and to prevent hypothermia.

The HD machine has built-in safety features such as the ability to

record patient vital signs, blood and dialysate flows, arterial and venous pressures, delivered dialysis dose, plasma volume changes and thermal changes. If any of these problems are detected, an alarm sounds to protect the patient from life-threatening complications.

All dialyzers function in a similar manner. Fig. 68-4 shows a comparison of fluid and particle movement across the dialyzer membranes, comparing intermittent HD with continuous renal replacement circuits. For intermittent HD, the number and length of treatments depend on the amount of wastes and fluid to be removed, the clearance capacity of the dialyzer, and the blood flow rate to and from the machine. Fig. 68-5 shows a typical intermittent dialysis machine. Most patients receive three 4-hour treatments over the course of a week. For those with some ongoing urine production, two 5- to 6-hour treatments a week may be adequate. If the patient gains large amounts of fluid, a longer HD treatment time may be needed to remove the fluid without hypotension or severe side effects.

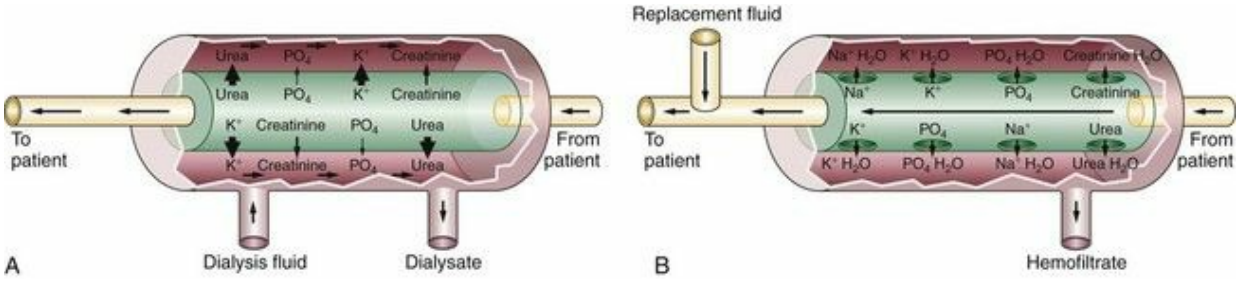

FIG. 68-4 Comparison of hemodialysis and hemofiltration fluid and solute movements across the membrane. Demonstrates this movement in hemodialysis **(A)** and in hemofiltration **(B)**. The *arrows* that cross the membrane indicate the predominant direction of movement of each solute through the membrane; the relative size of the *arrows* indicates the net amounts of the solute transferred. Other *arrows* indicate the direction of flow.

FIG. 68-5 Renal replacement therapy with an intermittent hemodialysis machine.

Anticoagulation.

Blood clotting can occur during dialysis. Anticoagulation, usually with heparin, is most often delivered into the blood circuit via a pump. In patients with high risk for bleeding, a reduced dose, regional anticoagulation (using citrate rather than heparin for anticoagulation or reversing heparin actions by administering protamine before returning blood to the patient), or no anticoagulation may be used. Patient response to heparin varies, and the dose is adjusted on the basis of each patient's need.

Heparin remains active in the body for 4 to 6 hours after dialysis, increasing the patient's risk for hemorrhage during and immediately after HD treatments. Invasive procedures must be avoided during that time. Monitor him or her closely for any manifestations of bleeding or hemorrhage. Protamine sulfate is an antidote to heparin and always should be available in the dialysis setting.

Vascular Access.

Vascular access is required for hemodialysis (Table 68-11 and Fig. 68-6). The procedure requires the easy availability of a large amount of blood flow: at least 250 to 300 mL/min, usually for a period of 3 to 4 hours. Normal venous cannulation does not provide this high rate of blood flow.

TABLE 68-11

Types of Vascular Access for Hemodialysis

ACCESS TYPE	DESCRIPTION	LOCATION	TIME TO INITIAL USE
Permanent			
AV fistula	An internal anastomosis of an artery to a vein	Forearm	2-4 mo or longer
		Upper arm	
AV graft	Synthetic vessel tubing tunneled beneath the skin, connecting an artery and a vein	Forearm	1-2 wk
		Upper arm	
		Inner thigh	
Temporary			
Dialysis catheter	A specially designed catheter with separate lumens for blood outflow and inflow	Subclavian, internal jugular, or femoral vein	Immediately after insertion and x-ray confirmation of placement
Subcutaneous device	An internal device with two metallic access ports and two catheters inserted into large central veins	Subclavian	

AV, Arteriovenous.

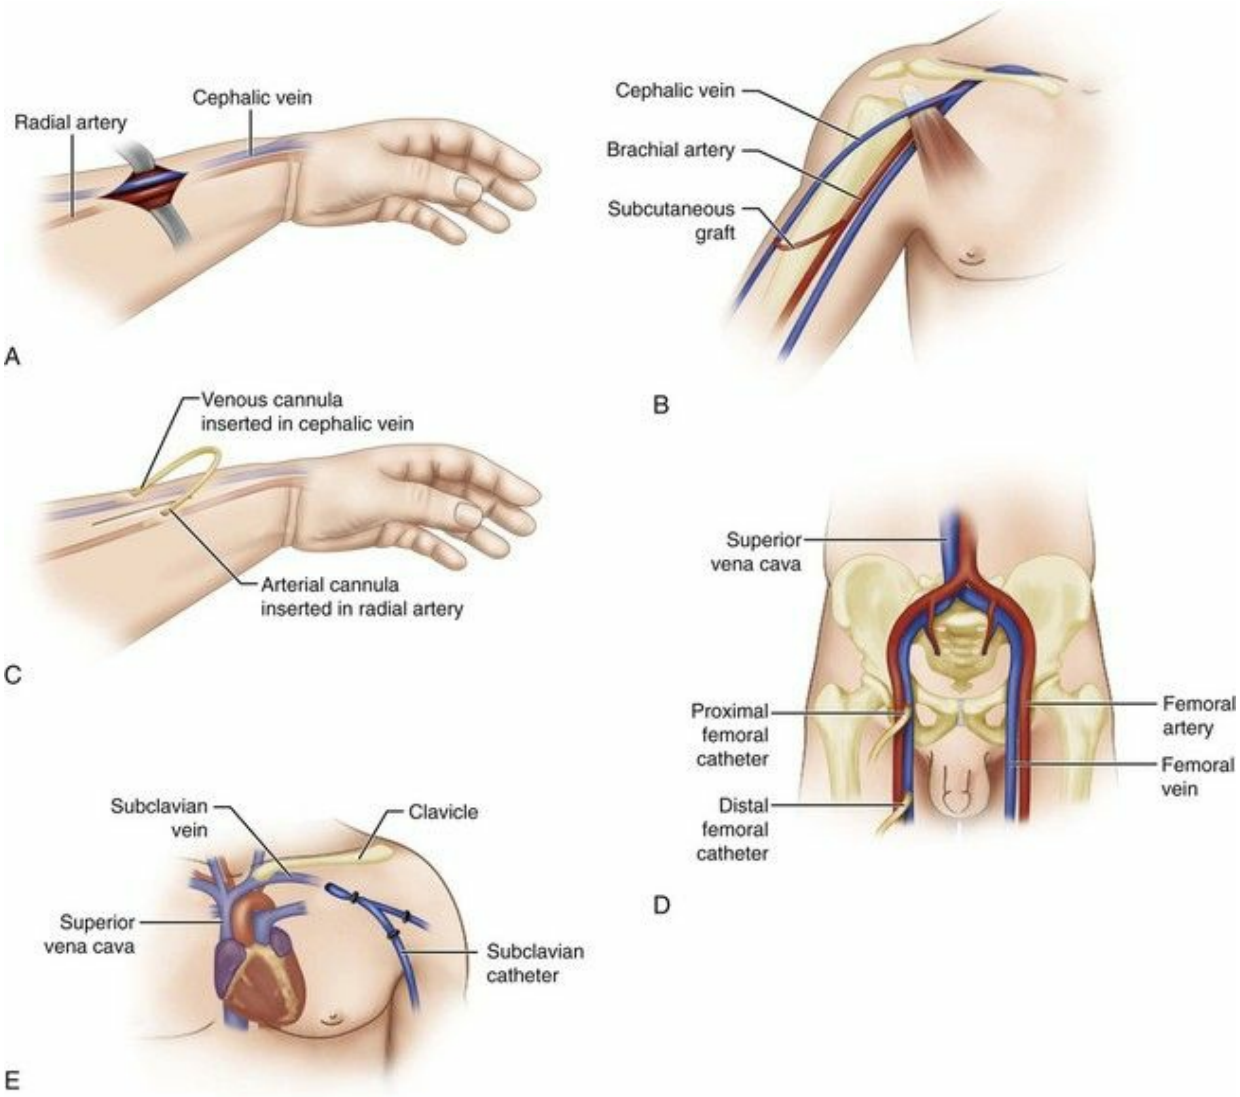

FIG. 68-6 Frequently used means for gaining vascular access for hemodialysis include arteriovenous fistula **(A),** arteriovenous graft **(B),** external arteriovenous shunt **(C),** femoral vein catheterization **(D),** and subclavian vein catheterization **(E)**. **A** and **B** are options for long-term vascular access for hemodialysis. **C, D,** and **E** are used for short-term access for intermittent hemodialysis or for continuous renal replacement therapy in acute care.

Long-term vascular access is internal for most patients having long-term HD (see Table 68-11). The two common choices are an internal arteriovenous (AV) fistula or an AV graft (see Fig. 68-6 *A, B,* and *C*). *AV fistulas* are formed by surgically connecting an artery to a vein. The vessels used most often are the radial or brachial artery and the cephalic vein of the nondominant arm. Fistulas increase venous blood flow to 250 to 400 mL/min, the amount needed for effective dialysis.

Time is needed after anastomosis for the AV fistula to develop. As the AV fistula "matures," the increased pressure of the arterial blood flow into the vein causes the vessel walls to thicken. This thickening increases

their strength and durability for repeated cannulation. Patients differ in the amount of time needed for the fistula to mature. Some fistulas may not be ready for use for as long as 4 months after the surgery, and a temporary vascular access (AV shunt or HD catheter) is used during this time. Fig. 68-7 shows a mature fistula.

FIG. 68-7 A mature fistula for hemodialysis access. The increased pressure from the anastomosed artery forced blood into the vein. This process caused the vein to dilate enough for fistula needles to be placed for hemodialysis. When the vein is sufficiently dilated, a process that takes 8 to 12 weeks, the fistula is said to be "developed" or "mature."

To access a fistula, cannulate it by inserting two needles—one toward the venous blood flow and one toward the arterial blood flow. This procedure allows the HD machine to draw the blood out through the arterial needle and return it through the venous needle.

Arteriovenous grafts are used when the AV fistula does not develop or when complications limit its use. The polytetrafluoroethylene (PTFE) graft is a synthetic material (GORE-TEX). This type of graft is commonly used for older patients using HD. Figs. 68-6, *A*, and 68-7 show a patient's fistula.

Precautions.

Some precautions are needed to ensure the functioning of an internal AV fistula or AV graft. First assess for adequate circulation in the fistula or graft as well as in the lower portion of the arm. Check distal pulses and capillary refill in the arm with the fistula or graft. Then check for a bruit or a thrill by auscultation or palpation over the access site. Chart 68-7 lists best practices for care of the patient with an HD access.

Chart 68-7 Best Practice for Patient Safety & Quality Care QSEN

Caring for the Patient with an Arteriovenous Fistula or Arteriovenous Graft

- Do not take blood pressure readings using the extremity in which the vascular access is placed.
- Do not perform venipunctures or start an IV line in the extremity in which the vascular access is placed.
- Palpate for thrills and auscultate for bruits over the vascular access site every 4 hours while the patient is awake.
- Assess the patient's distal pulses and circulation in the arm with the access.
- Elevate the affected extremity postoperatively.
- Encourage routine range-of-motion exercises.
- Check for bleeding at needle insertion sites.
- Assess for manifestations of infection at needle sites.
- Instruct the patient not to carry heavy objects or anything that compresses the extremity in which the vascular access is placed.
- Instruct the patient not to sleep with his or her body weight on top of the extremity in which the vascular access is placed.

AV, Arteriovenous.

Nursing Safety Priority QSEN

Action Alert

Because repeated compression can result in the loss of the vascular access, avoid taking the blood pressure or performing venipunctures in the arm with the vascular access. Do not use an AV fistula or graft for delivery of IV fluids.

Complications.

Complications can occur with any type of access. The most common problems are thrombosis or stenosis, infection, aneurysm formation, ischemia, and heart failure. Table 68-12 lists strategies to prevent access complications.

TABLE 68-12

Interventions for Preventing Complications in Hemodialysis Vascular Access

ACCESS TYPE	BLEEDING	INFECTION	CLOTTING
AV fistula or AV graft	Apply pressure to the needle puncture sites.	Prepare skin using best practices before cannulation. Typically 2% chlorhexidine is used, similar to central line skin preparation. Between hemodialysis sessions, the patient should wash the area with antibacterial soap and rinse with water.	Avoid constrictive devices.
			Rotate needle insertion sites with each hemodialysis treatment.
			Assess for thrill and bruit.
Hemodialysis catheters (temporary and permanent)	Monitor the access site.	Use aseptic technique to dress site and access catheter.	Place a heparin or heparin/saline dwell solution after hemodialysis treatment.
			Do not use access except for dialysis treatments.

AV, Arteriovenous.

Thrombosis, or clotting of the AV access, is the most frequent complication. Most grafts fail because of high-pressure arterial flow entering the venous system. The muscle layers of the veins react to this increased pressure by thickening. The venous thickening reduces or occludes blood flow. An interventional radiologist can re-open failing grafts with the injection of a thrombolytic drug (e.g., tPA) to dissolve the clot. The clot usually dissolves within minutes, and often a stricture is revealed at the point where the graft and the vein connect. The stricture can be corrected by balloon angioplasty.

Most infections of the vascular access are caused by *Staphylococcus aureus* introduced during cannulation. Prepare the skin with an antibacterial agent according to agency policy before cannulation to prevent infection.

Aneurysms can form in the fistula and are caused by repeated needle punctures at the same site. Large aneurysms may cause loss of the fistula's function and require surgical repair.

Ischemia occurs in a few patients with vascular access when the fistula decreases arterial blood flow to areas below the fistula *(steal syndrome).* Manifestations vary from cold or numb fingers to gangrene. If the collateral circulation is poor, the fistula may need to be surgically tied off and a new one created in another area to preserve extremity circulation.

Shunting of blood directly from the arterial system to the venous system, through the fistula, can cause heart failure in patients with

limited cardiac function. This complication is rare, but if it does occur, the fistula may need to be revised to reduce arterial blood flow.

Temporary Vascular Access.

Temporary access with special catheters can be used for patients requiring immediate HD. A catheter designed for HD may be inserted into the subclavian, internal jugular, or femoral vein. The lumens of these devices are much smaller than the permanent accesses, and more time (4 to 8 hours) is required to complete a dialysis session.

Subcutaneous devices may also be surgically inserted to provide temporary access for HD. Implanted beneath the skin, these devices are composed of two small metallic ports with attached catheters that are inserted into large central veins. The ports of subcutaneous devices have internal mechanisms that open when needles are inserted and close when needles are removed. Blood from one port flows from the body to the HD machine and returns to the body via the other port. These devices may be ideal for patients waiting for permanent access placement or a kidney transplant.

Clinical Judgment Challenge

Evidence-Based Practice; Patient-Centered Care QSEN

The patient just completed a vascular "mapping" procedure with an angiogram to plan the site of an AV fistula for hemodialysis. You are considering the care priorities for the patient's return when the AV fistula is formed.

1. What are important teaching points for the period immediately following AV fistula formation?
2. The patient asks if there is anything she can do to make this AV fistula last a long time. How should you respond to promote best practices in AV fistula self-management?
3. What else should this patient know about AV fistula care?

Hemodialysis Nursing Care.

Many drugs are dialyzable (i.e., can be partially removed from the blood during dialysis). Coordinate with the health care provider to assess the patient's drug regimen and determine which drugs should be held until after HD treatment. Table 68-13 lists common dialyzable drugs that should be given *after* rather than before HD. Consult the dialysis nurse or nephrologists to determine if antihypertensive drugs should be given

before a scheduled dialysis treatment; some short-acting antihypertensives can contribute to hypotension during dialysis (Ryan, 2012).

TABLE 68-13
Examples of Dialyzable Drugs

Consult the pharmacist, nephrologist, or dialysis nurse to plan the best time to administer a drug based on the dialysis schedule.
Aminoglycosides
• Amikacin • Gentamicin • Tobramycin
Antituberculosis Agents
• Ethambutol • Isoniazid
Antiviral and Antifungal Agents
• Acyclovir • Ganciclovir • Fluconazole
Cephalosporins
• Cefaclor • Cefazolin • Cefoxitin • Ceftizoxime • Ceftriaxone • Cefuroxime • Cefepime
Anticonvulsants
• Ethosuximide • Gabapentin • Phenobarbital
Penicillins
• Amoxicillin • Ampicillin • Cloxacillin • Dicloxacillin • Mezlocillin • Penicillin G • Ticarcillin
Miscellaneous
• Aztreonam • Cimetidine • Vitamins • Clavulanic acid • Allopurinol • Enalapril • Aspirin

The time required to complete an HD treatment usually is at least 4 hours. During this time patients may use various distraction techniques to prevent boredom. This time can be used also for brief health teaching opportunities (see the Quality Improvement box).

Quality Improvement QSEN

Using Hemodialysis Time as a Teachable Moment

Wilson, B., & Lawrence, J. (2013). Implementation of a foot assessment program in a regional satellite hemodialysis setting. *Canadian Association of Nephrology Nurses and Technologists Journal, 23*(2), 41-47.

Because many patients receiving hemodialysis (HD) also have diabetes, the authors designed a quality improvement project to implement guidelines for foot care among their patients in an ambulatory care HD setting. The program included a one-time full assessment of risk for all patients followed by a monthly foot check for all patients with diabetes. Results included early identification of patients with a foot problem, timelier referral for treatment of foot problems, and a high degree of staff and patient satisfaction with the program.

Commentary: Implications for Practice and Research

This is an example of translating guidelines into practice and using guidelines in an uncommon setting to provide consistent assessment for diabetic patients at high risk for impaired self-management. Although the guidelines were Canadian and the implementation occurred in a single site, the steps to translating a guideline into practice and evaluating adherence to practice can be followed by other sites interested in delivering high-quality care to high-risk patients who receive hemodialysis.

Post-Dialysis Care.

Closely monitor the patient immediately and for several hours after dialysis for any side effects from the treatment. Common problems include hypotension, headache, nausea, vomiting, dizziness, and muscle cramps.

Obtain vital signs and weight for comparison with pre-dialysis measurements. Blood pressure and weight are expected to be reduced as a result of fluid removal. Hypotension may require rehydration with IV fluids, such as normal saline. The patient's temperature may also be elevated because the dialysis machine warms the blood slightly. If he or she has a fever, sepsis may be present and a blood sample is needed for culture and sensitivity.

The heparin required during HD increases the risk for excessive bleeding. All invasive procedures must be avoided for 4 to 6 hours after dialysis. Continually monitor the patient for hemorrhage during and for at least 1 hour after dialysis (Chart 68-8).

Chart 68-8 Best Practice for Patient Safety & Quality Care QSEN

Caring for the Patient Undergoing Hemodialysis

- Weigh the patient before and after dialysis.
- Know the patient's dry weight.
- Discuss with the health care provider whether any of the patient's drugs should be withheld until after dialysis.
- Be aware of events that occurred during previous dialysis treatments.
- Measure blood pressure, pulse, respirations, and temperature.
- Assess for manifestations of orthostatic hypotension.
- Assess the vascular access site.
- Observe for bleeding.
- Assess the patient's level of consciousness.
- Assess for headache, nausea, and vomiting.

Complications of Hemodialysis.

Few adverse events occur during a 3- to 4-hour HD treatment under current practice protocols. Improved water treatment, more physiologic solutions, and improvements in HD equipment and procedures have significantly improved safe care for patients receiving this treatment. Complications during HD include hypotension, dialysis disequilibrium syndrome, cardiac events, and reactions to dialyzers.

Nursing Safety Priority QSEN

Critical Rescue

Hypotension can occur in up to 50% of HD treatments (Yeun et al., 2012). Heat transfer from warmed solutions can result in vasodilation and a drop in blood pressure. When this occurs, consider reducing the temperature of the dialysate to 35° C (95° F). A shift of fluid from the intravascular to extravascular space related to the difference in electrolytes concentrations between HD solutions and blood also contributes to low blood pressure. Whereas modest declines in blood pressure can be addressed by adjusting the rate of extracorporeal blood flow and placing the patient in a legs-up (Trendelenburg) position, sustained or symptomatic hypotension is treated with a fluid bolus of 100 to 250 mL of normal saline or sometimes albumin or mannitol. A second bolus may be needed. If hypotension persists, consider that new-

onset myocardial injury or pericardial disease may be a contributing factor and administer oxygen, reduce the blood flow, and notify the health care provider urgently. Discontinue HD when hypotension continues despite cooling dialysate or providing up to two bolus infusions.

Dialysis disequilibrium syndrome may develop during HD or after HD has been completed. It is characterized by mental status changes and can include seizures or coma; it is uncommon to observe this severity of disequilibrium syndrome with today's HD practice. A mild form of disequilibrium syndrome includes manifestations of nausea, vomiting, headaches, fatigue, and restlessness. It is thought to be the result of a rapid reduction in electrolytes and other particles (**solutes**) in a short time frame. Maintaining a low blood flow or reducing blood flow with the onset of manifestations can prevent this syndrome.

Cardiac events during HD are associated with underlying cardiovascular disease, especially left ventricular hypertrophy, coronary vascular disease, and a history of cardiac dysrhythmias. These conditions are described in Chapters 35, 36, and 38. Cardiac events leading to a full cardiac arrest are most concerning in an ambulatory care or in-home HD setting. Although cardiac arrest is a rare event, the setting should be equipped with an automatic defibrillator and staff or family trained in cardiopulmonary resuscitation. Often cardiac arrest is related to new-onset cardiac ischemia. The patient then needs to be managed in an acute care setting in which the presence of myocardial disease can be evaluated and cardiac treatment optimized.

Pericardial disease is a complication of patients with ESKD. Assess the patient's heart sounds for the presence of a pericardial rub prior to dialysis. Intensification of dialysis may be used to treat this complication. Other treatment might include NSAID use or surgery as described on p. 1421.

Reactions to dialyzers still occur, although more biocompatible membranes and careful attention to rinsing the dialyzer before use (to eliminate sterilizing agents) have reduced this type of adverse event during HD. Reactions occur during a “first-time” use of the filter and resemble an anaphylactic episode early during HD, with profound hypotension (Chapter 20 describes anaphylactic reactions). With suspected dialyzer reactions, the nurse does not return the blood to the patient and discontinues HD. Corticosteroids may be used to treat the immune reaction.

Other potential complications of recurrent HD require the nurse to

monitor the level of consciousness and vital signs frequently during treatment and to slow or stop HD when manifestations occur. Hypoglycemia is a rare adverse HD event and more likely to occur when the patient has diabetes. Hypoglycemia is managed by providing glucose and increasing dialysis glucose concentration in subsequent treatments. Hemorrhage can occur when needle dislodgement or circuit connections become loose and is amplified by the anticoagulation treatment to maintain circuit patency. Some hemolysis will occur because of mechanical trauma to red blood cells, contributing to the anemia of CKD and, perhaps, sensations of dyspnea or chest tightness.

Infectious diseases transmitted by blood transfusion are a serious complication of long-term HD. Two of the most serious blood-transmitted infections are hepatitis and human immune deficiency virus (HIV) infection. *Hepatitis B infection* and *hepatitis C infection* in patients with CKD have decreased because the use of erythropoietin-stimulating agents (ESAs) has reduced the need for blood transfusions to maintain red blood cell counts. Hepatitis is a problem because of the blood access and the risk for contamination during HD. The viruses can be transmitted through the use of contaminated needles or instruments, by entry of contaminated blood through open wounds in the skin or mucous membranes, or through transfusions with contaminated blood. Monitor all patients receiving HD for manifestations of hepatitis (see Chapter 58).

HIV is a bloodborne virus that poses some risk for patients undergoing HD. Fortunately, the risks for HIV transmission are reduced by the consistent practice of Standard Precautions, routine screening of donated blood for HIV, and decreased need for blood transfusions with CKD and ESKD. Patients who have been undergoing HD or who received frequent transfusions during the early to middle 1980s are at risk for acquired immune deficiency syndrome (AIDS) (see Chapter 19).

Considerations for Older Adults

Patient-Centered Care QSEN

Between the years 2000 and 2010, a threefold increase in the number of older adults diagnosed with CKD occurred (Elliott, 2012). In 2010, the number of patients ages 60 years and older increased to more than 25% of patients beginning ESKD therapy (USRDS, 2014). The overall mean age for new patients requiring dialysis is 64.6. Patients older than 65 years who are receiving HD are more at risk for dialysis-induced hypotension. These patients require more frequent monitoring during and after dialysis.

Peritoneal Dialysis

Peritoneal dialysis (PD) allows exchanges of wastes, fluid, and electrolytes to occur in the peritoneal cavity. PD is slower than hemodialysis (HD), however, and more time is needed to achieve the same effect. Other disadvantages of PD are the protein loss in outflow fluid, risk for peritoneal injury, and potential discomfort from indwelling fluid. Advantages and complications are listed in Table 68-10. The use of PD has deceased and currently accounts for less than 10% of dialysis (USRDS, 2014).

Patient Selection.

Most patients with CKD can select either HD or PD. For those who are unstable and those who cannot tolerate anticoagulation, PD is less hazardous than HD. For some patients, vascular access problems may eliminate HD as an option. At times a patient may use PD until a new arteriovenous (AV) fistula matures. PD is often the treatment of choice for older adults because it offers more flexibility if his or her status changes frequently.

Peritoneal dialysis *cannot* be performed if peritoneal adhesions are present or if extensive intra-abdominal surgery has been performed. In these cases, the surface area of the peritoneal membrane is not sufficient for adequate dialysis exchange. Peritoneal membrane fibrosis may occur after repeated infection, which decreases membrane permeability.

Procedure.

A siliconized rubber (Silastic) catheter is surgically placed into the abdominal cavity for infusion of dialysate (Fig. 68-8). Usually 1 to 2 L of dialysate is infused by gravity *(fill)* into the peritoneal space over a 10- to 20-minute period, according to the patient's tolerance. The fluid stays *(dwells)* in the cavity for a specified time prescribed by the physician. The fluid then flows out of the body *(drains)* by gravity into a drainage bag. The peritoneal outflow contains the dialysate and the excess water, electrolytes, and nitrogen-based waste products. The dialyzing fluid is called peritoneal *effluent* on outflow. The three phases of the process (infusion, or "fill"; dwell; and outflow, or drain) make up one PD exchange. The number and frequency of PD exchanges are prescribed by the physician, depending on manifestations and laboratory data.

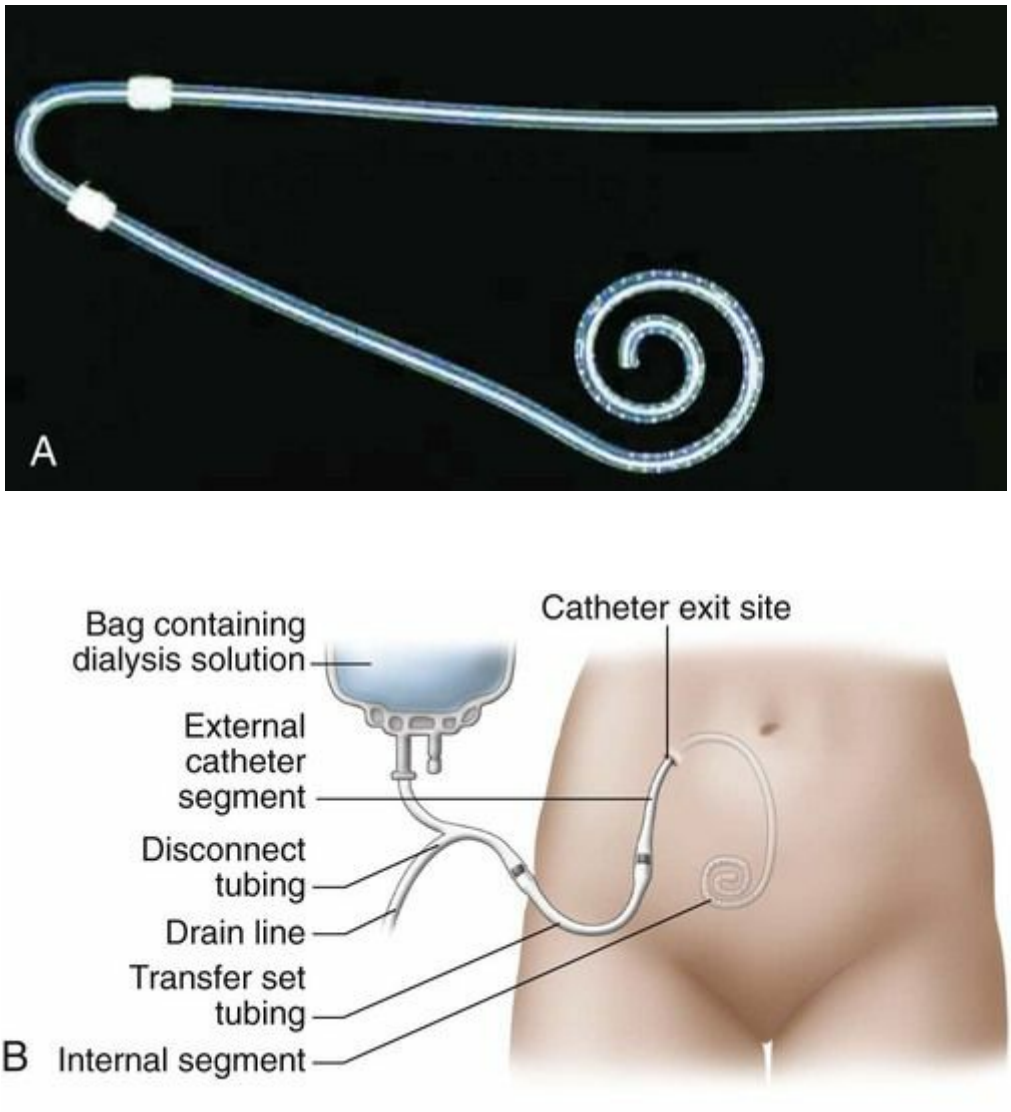

FIG. 68-8 Peritoneal dialysis catheter. **A,** The actual Silastic peritoneal dialysis catheter. **B,** Positioning of the Silastic catheter within the abdominal cavity.

Process.

Peritoneal dialysis occurs through diffusion and osmosis across the semipermeable peritoneal membrane and capillaries. The peritoneal membrane is large and porous. It allows solutes (particles) and water to move from an area of higher concentration in the blood to an area of lower concentration in the dialyzing fluid (diffusion).

The peritoneal cavity is rich in capillaries and is a ready access to the blood supply. The fluid and waste products dialyzed from the patient move through the blood vessel walls, the interstitial tissues, and the peritoneal membrane and are removed when the dialyzing fluid is drained from the body.

PD efficiency is affected by many factors. Infection can cause scarring and reduce capillary blood flow. Vascular disease and decreased perfusion

of the peritoneum reduce PD diffusion. For PD, water removal depends on the concentration of the dialysate. PD efficiency can be altered by the *tonicity* (i.e., number of particles per liter of fluid) of the dialysate. Increasing the dialysate glucose concentration makes the solution more hypertonic. The more hypertonic the solution, the greater the osmotic pressure for water filtration and fluid removal from the patient during an exchange. The dialysate concentration is prescribed on the basis of the patient's fluid status.

Dialysate Additives.

Heparin may be added to the dialysate to prevent clotting of the catheter or tubing. Usually intraperitoneal (IP) heparin is needed only after new catheter placement or if peritonitis occurs. IP heparin is not absorbed systemically and does not affect blood clotting.

Other agents that may be given in the dialysate include potassium and antibiotics. Commercially prepared dialysate does not contain potassium. Some patients need potassium added to the dialysate to prevent hypokalemia. Antibiotics may be given by the IP route when peritonitis is present or suspected. Potassium and antibiotics are not mixed in the same dialysate bag because interactions may reduce the antibiotic effect.

Types of Peritoneal Dialysis.

Many types of PD are available, including continuous ambulatory PD, multiple-bag continuous ambulatory PD, automated PD, intermittent PD, and continuous-cycle PD. The type selected depends on the patient's ability and lifestyle. The two most commonly used types of PD are continuous ambulatory peritoneal dialysis and continuous cycling peritoneal dialysis.

Continuous ambulatory peritoneal dialysis (CAPD) is performed by the patient with the infusion of four 2-L exchanges of dialysate into the peritoneal cavity. Each time, the dialysate remains for 4 to 8 hours, and these exchanges occur 7 days a week (Figs. 68-9 through 68-11). During the dwell period, the patient can use a continuous connect system or disconnect and reconnect at a later time. Most long-term patients with PD prefer to complete exchanges overnight with an automated cycler (automatic peritoneal dialysis [APD], described below).

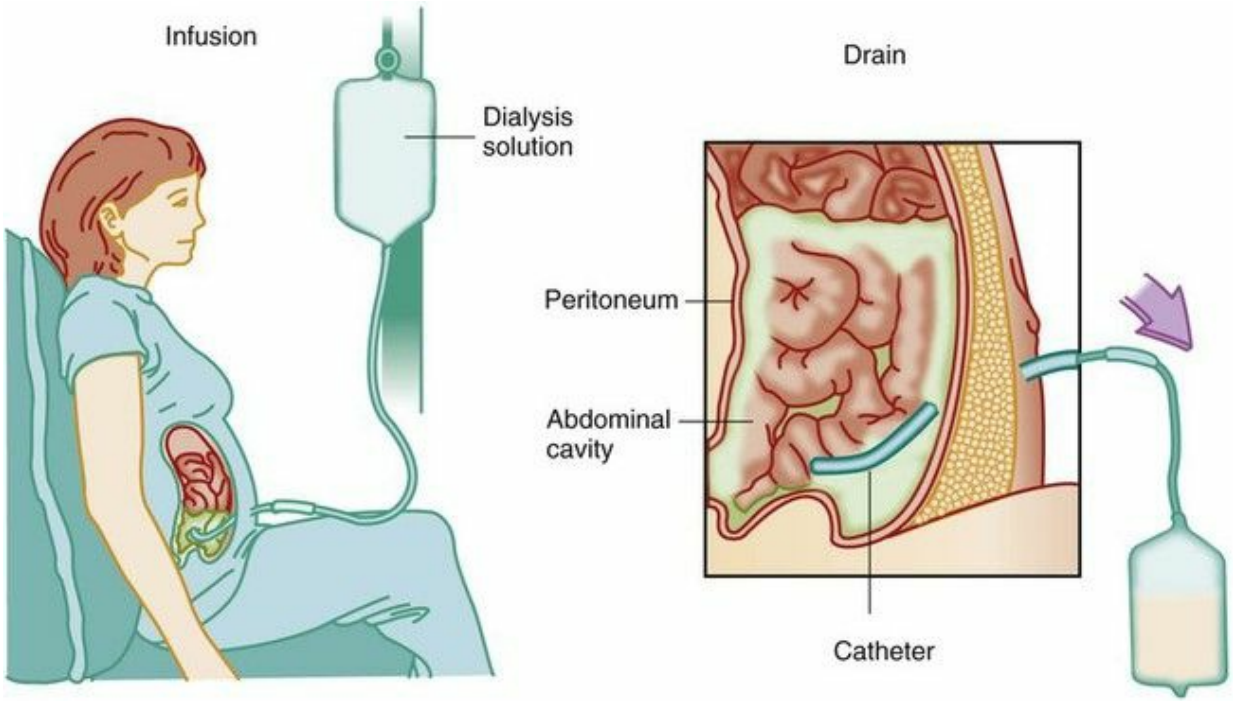

FIG. 68-9 Peritoneal dialysis exchange for control of fluids, electrolytes, nitrogenous wastes, blood pressure, and acid-base balance. The peritoneal membrane acts as the dialyzing membrane.

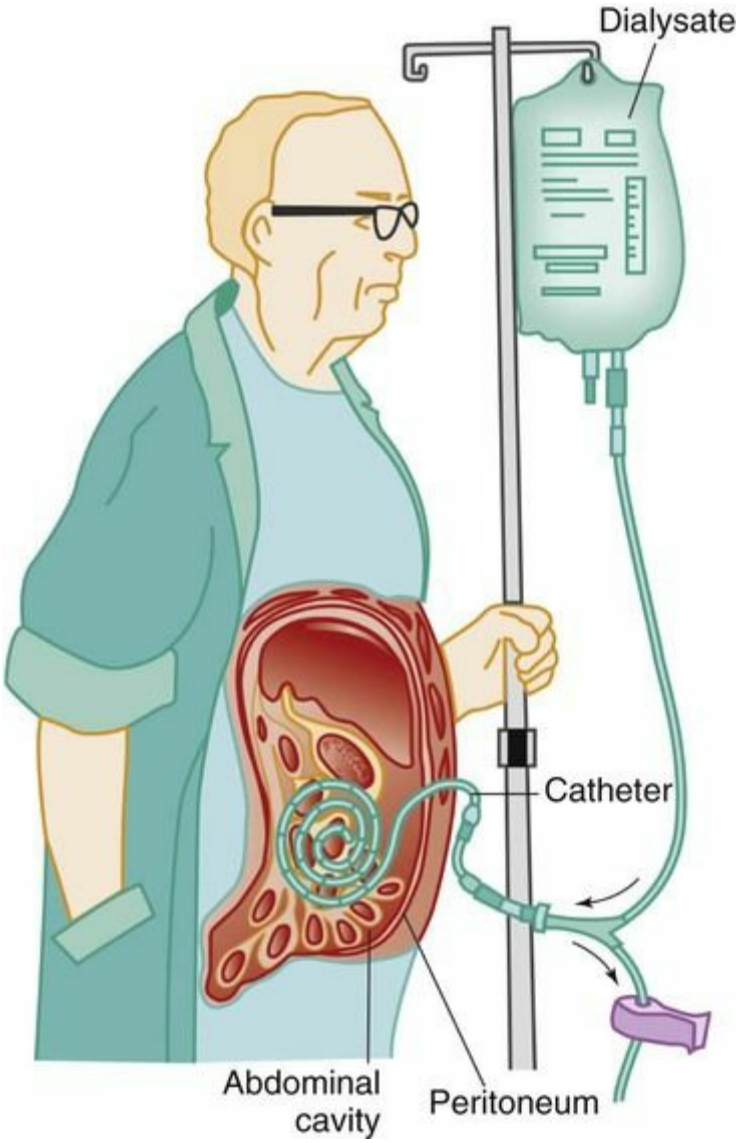

FIG. 68-10 A patient performing continuous ambulatory peritoneal dialysis (CAPD). Note that the patient can walk with this setup.

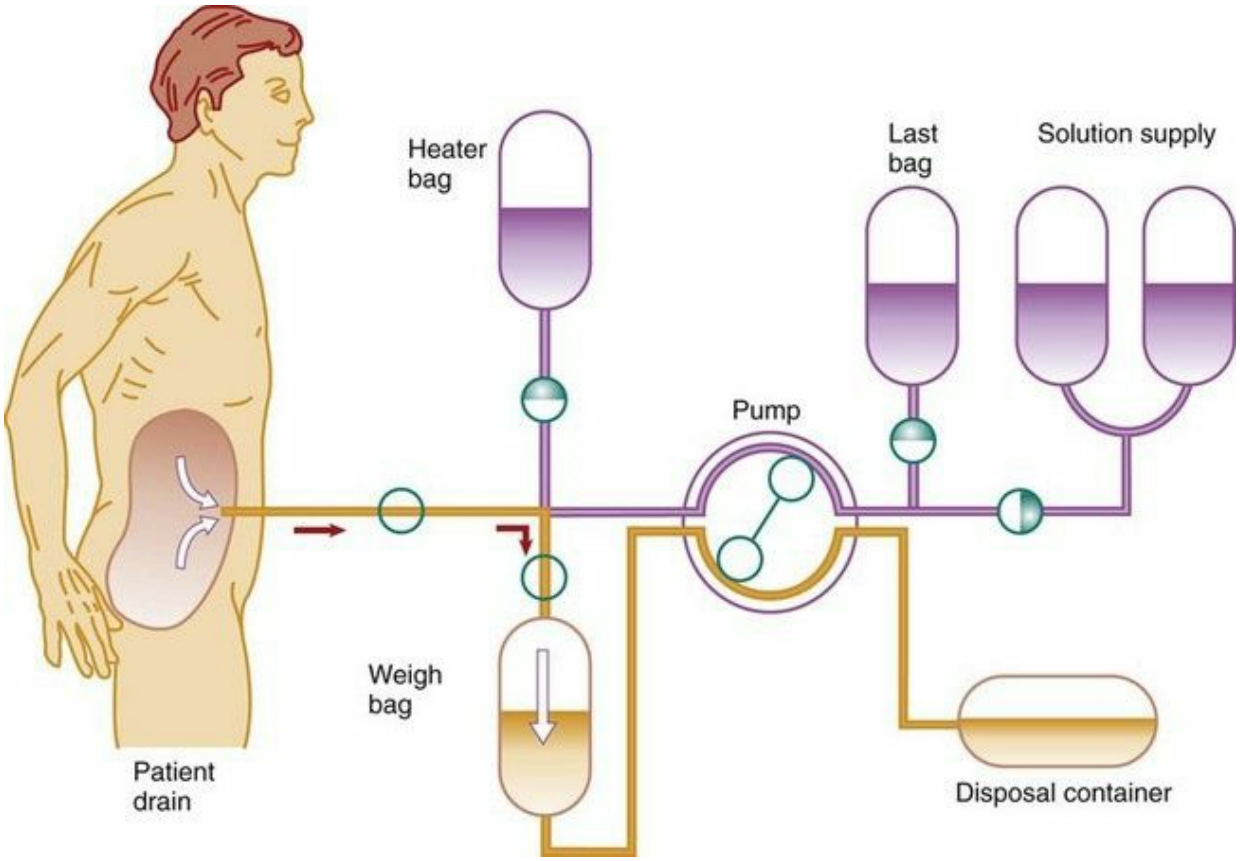

FIG. 68-11 Peritoneal dialysis machine circuit in automated peritoneal dialysis (APD).

With the continuous *connect* system (straight transfer set), the dialysate bag is attached to the catheter by 48-inch tubing. The empty bag and tubing are folded and worn beneath the clothing until they are used for outflow. After draining, the patient removes the bag and connects a new bag to repeat the process.

With the *disconnect system* (Y - transfer set), the patient removes the connecting tubing and empties the dialysate bag after inflow and attaches a cap to the PD catheter. The disconnect system eliminates the need to wear the tubing and bag but requires opening the system 2 extra times with each exchange. The extra opening of the system increases the risk for infection.

With CAPD, no machine is necessary and no partner is required. However, it is best for a partner also trained in CAPD to be available as a support for the patient if illness occurs. Devices to assist in the safe, sterile connection of the tubing spike into the dialysate bag are available. These are useful for patients with poor vision, limited manual dexterity, or reduced hand and arm strength. CAPD allows constant removal of fluid and wastes and more closely resembles kidney action than HD. Some patients even perform their own exchanges while hospitalized.

Continuous-cycle peritoneal dialysis (CCPD) is a form of automated

dialysis that uses an automated cycling machine. Exchanges occur at night while the patient sleeps. The final exchange of the night is left to dwell through the day and is drained the next evening as the process is repeated. CCPD offers the advantage of 24-hour dialysis, as in CAPD, but the sterile catheter system is opened less often.

Automated peritoneal dialysis (APD) may be used in the acute care setting, the ambulatory care dialysis center, or the patient's home. APD uses a cycling machine for dialysate inflow, dwell, and outflow according to preset times and volumes. A warming chamber for dialysate is part of the machine (Fig. 68-12). The functions are programmed for the patient's specific needs. A typical prescription calls for 30-minute exchanges (10/10/10 for inflow, dwell, and outflow) for a period of 8 to 10 hours. The machines have many safety monitors and alarms and are relatively simple to learn to use.

FIG. 68-12 A cycler machine for automated peritoneal dialysis at home.

Automated peritoneal dialysis has several advantages. It permits in-home dialysis while the patient sleeps, allowing him or her to be dialysis-free during waking hours. The incidence of peritonitis is reduced with APD because fewer connections and disconnections are needed. Also, APD can be used to deliver larger volumes of dialysis solution for patients who need higher clearances.

Intermittent peritoneal dialysis (IPD) combines osmotic pressure gradients with true dialysis. The patient usually requires exchanges of 2 L of dialysate at 30- to 60-minute intervals, allowing 15 to 20 minutes of

drain time. For most patients, 30 to 40 exchanges of 2 L three times weekly are needed. IPD treatments can be automated or manual.

Complications.

Complications are possible with PD, but many can be prevented with meticulous care and appropriate patient education for self-management. Problems and complications are more common when evidence-based guidelines for catheter care are not followed (see the Quality Improvement box regarding PD catheters).

Quality Improvement QSEN

Follow PD Catheter Guidelines to Reduce Complications

Wong, L.P., Yamamoto, K.T., Reddy, V., Cobb, D., Chamberlin, A., Pham, H., et al. (2014). Patient education and care for peritoneal dialysis catheter placement: A quality improvement study. *Peritoneal Dialysis International, 34*(1), 12-23.

Although there are practice guidelines for placement of a peritoneal dialysis (PD) catheter, it is unknown if these recommendations are followed. The authors observed the care of 46 new patients at a single site—a regional PD center in the United States Northwest. Patients completed a questionnaire derived from the International Society for Peritoneal Dialysis (ISPD) catheter guidelines and were followed for early complications.

Results indicated that there were many and serious deviations from the ISPD catheter guidelines and that these deviations were linked to adverse outcomes. For example, after insertion, 20% of patients reported not being given instructions for follow-up care and 46% reported not being taught the warning signs of PD catheter infection. In 41% of patients, a complication developed, with 30% of patients experiencing a catheter or exit-site problem and 11% developing infection. Improving patient education and care coordination for PD catheter placement were identified as the next steps in the quality improvement (QI) cycle.

Commentary: Implications for Practice and Research

This study shows the initial steps of gathering information in a Plan-Do-Study-Act cycle of QI. First the guidelines for care were identified, and then they were operationalized as a patient questionnaire with a focus on education and as a provider checklist to observe components of high-quality care. The data were then linked to patient outcomes. The association of less-than-optimal education and care to serious and

recurrent adverse patient outcomes is a powerful approach to develop essential interventions with the next cycle in order to provide safe, effective care.

Peritonitis is the major complication of PD, most commonly caused by connection site contamination. To prevent peritonitis, use meticulous sterile technique when caring for the PD catheter and when hooking up or clamping off dialysate bags (Chart 68-9).

Chart 68-9 Best Practice for Patient Safety & Quality Care QSEN

Caring for the Patient with a Peritoneal Dialysis Catheter

- Mask yourself and your patient. Wash your hands.
- Put on sterile gloves. Remove the old dressing. Remove the contaminated gloves.
- Assess the area for signs of infection, such as swelling, redness, or discharge around the catheter site.
- Use aseptic technique:
  - Open the sterile field on a flat surface, and place two precut 4 × 4–inch gauze pads on the field.
  - Place three cotton swabs soaked in povidone-iodine or other solution prescribed by your health care provider on the field. Put on sterile gloves.
- Use cotton swabs to clean around the catheter site. Use a circular motion starting from the insertion site and moving away toward the abdomen. Repeat with all three swabs.
- As an alternative (if recommended by your health care provider or clinic), cleanse the area with sterile gauze pads using soap and water. Use a circular motion starting from the insertion site and moving away toward the abdomen. Rinse thoroughly.
- Apply precut gauze pads over the catheter site. Tape only the edges of the gauze pads.

Manifestations of peritonitis include cloudy dialysate outflow (effluent), fever, abdominal tenderness, abdominal pain, general malaise, nausea, and vomiting. *Cloudy or opaque effluent is the earliest indication of peritonitis.* Examine all effluent for color and clarity to detect peritonitis early. When peritonitis is suspected, send a specimen of the dialysate outflow for culture and sensitivity study, Gram stain, and cell count to

identify the infecting organism.

Pain during the inflow of dialysate is common when patients are first started on PD therapy. Usually this pain no longer occurs after a week or two of PD. Cold dialysate increases discomfort. Warm the dialysate bags before instillation by using a heating pad to wrap the bag or by using the warming chamber of the automated cycling machine. *Microwave ovens are* ***not*** *recommended for the warming of dialysate.*

Exit site and tunnel infections are serious complications. The exit site from a PD catheter should be clean, dry, and without pain or inflammation. Exit-site infections (ESIs) can occur with any type of PD catheter. These infections are difficult to treat and can become chronic. They can lead to peritonitis, catheter failure, and hospitalization. Dialysate leakage and pulling or twisting of the catheter increase the risk for ESIs. A Gram stain and culture should be performed when exit sites have purulent drainage.

Tunnel infections occur in the path of the catheter from the skin to the cuff. Manifestations include redness, tenderness, and pain. ESIs are treated with antimicrobials. Deep cuff infections may require catheter removal.

Poor dialysate flow is usually related to constipation. To prevent constipation, a bowel preparation is prescribed before placement of the PD. An enema before starting PD may also prevent flow problems. Teach patients to eat a high-fiber diet and to use stool softeners to prevent constipation. Other causes of flow difficulty include kinked or clamped connection tubing, the patient's position, fibrin clot formation, and catheter displacement.

Ensure that the drainage bag is lower than the patient's abdomen to enhance gravity drainage. Inspect the connection tubing and PD system for kinking or twisting. Ensure that clamps are open. If inflow or outflow drainage is still inadequate, reposition the patient to stimulate inflow or outflow. Turning the patient to the other side or ensuring that he or she is in good body alignment may help. Having the patient in a supine low-Fowler's position reduces abdominal pressure. Increased abdominal pressure from sitting or standing or from coughing contributes to leakage at the PD catheter site.

Fibrin clot formation may occur after PD catheter placement or with peritonitis. Milking the tubing may dislodge the fibrin clot and improve flow. An x-ray is needed to identify PD catheter placement. If displacement has occurred, the physician repositions the PD catheter.

Dialysate leakage is seen as clear fluid coming from the catheter exit site. When dialysis is first started, small volumes of dialysate are used. It may take patients 1 to 2 weeks to tolerate a full 2-L exchange without

leakage around the catheter site. Leakage occurs more often in obese patients, those with diabetes, older adults, and those on long-term steroid therapy. During periods of catheter leak, patients may require hemodialysis (HD) support.

Other complications of PD include bleeding, which is expected when the catheter is first placed, and bowel perforation, which is serious. When PD is first started, the outflow may be bloody or blood tinged. This condition normally clears within a week or two. After PD is well-established, the effluent should be clear and light yellow. Observe for and document any change in the color of the outflow. Brown-colored effluent occurs with a bowel perforation. If the outflow is the same color as urine and has the same glucose level, a bladder perforation is probable. Cloudy or opaque effluent indicates infection.

Nursing Care During Peritoneal Dialysis.

In the hospital setting, PD is routinely started and monitored by the nurse. Before the treatment, assess baseline vital signs, including blood pressure, apical and radial pulse rates, temperature, quality of respirations, and breath sounds. Weigh the patient, always on the same scale, before the procedure and at least every 24 hours while receiving treatment. Weight should be checked after a drain and before the next fill to monitor the patient's "dry weight." Baseline laboratory tests, such as electrolyte and glucose levels, are obtained before starting PD and are repeated at least daily during the PD treatment.

Continually monitor the patient during PD. Take and record vital signs every 15 to 30 minutes. Assess for respiratory distress, pain, or discomfort. Check the dressing around the catheter exit site every 30 minutes for wetness during the procedure. Monitor the prescribed dwell time, and initiate outflow. Assess blood glucose levels in patients who absorb glucose.

Observe the outflow pattern (outflow should be a continuous stream after the clamp is completely open). Measure and record the total amount of outflow after each exchange. Maintain accurate inflow and outflow records when hourly PD exchanges are performed. When outflow is less than inflow, the difference is retained by the patient during dialysis and is counted as fluid intake. Weigh the patient daily to monitor fluid status.

Kidney Transplantation

Dialysis and kidney transplant are life-sustaining *treatments* for end-stage

kidney disease (ESKD). Kidney transplant is not considered a "cure." Each patient, in consultation with a nephrologist, determines which type of therapy is best suited to his or her physical condition and lifestyle. About 17,000 to 18,000 kidney transplants are performed yearly in the United States. Currently about 159,000 people are awaiting kidney transplant in North America. The median time on the waiting list is 678 days (USRDS, 2014).

Candidate Selection Criteria.

Candidates for transplantation must be free of medical problems that might increase the risks from the procedure. The usual age-range for kidney transplant is 2 to 70 years. Patients older than 70 years are considered for transplant on an individual basis because complications are more common in the older adult.

The patient is thoroughly assessed before he or she is considered for a kidney transplant. Patients who have advanced, uncorrectable cardiac disease are excluded from the procedure because these problems are made worse by transplantation. Other conditions that preclude kidney transplant include metastatic cancer, chronic infection, and severe psychosocial problems such as alcoholism or chemical dependency. Long-standing pulmonary disease increases the risk for complications and death from respiratory infection. Patients with diseases of the GI system, such as peptic ulcers and diverticulosis, require treatment before consideration for transplantation because some diseases are made worse by the large doses of steroids used after surgery.

The urinary system is completely evaluated to ensure normal urine flow. Many patients with ESKD have not used their lower urinary tract for years, and ureteral or bladder problems may require surgical correction before a kidney is transplanted.

Patients with a recent history of cancer are treated with dialysis because of the shortage of donor organs and the uncertain life expectancy of these patients. In addition, the drugs used after the procedure increase the risk for cancer recurrence. If more than 2 to 5 years have passed since cancer eradication, the patient can be considered for a transplant.

Diabetes mellitus and other endocrine problems cause great risks. Patients with these problems can have a kidney transplant but require intense observation and management to limit complications. Other pre-existing conditions are considered on an individual basis, depending on the patient's health status. Kidney transplantation is considered for most patients with ESKD and is the optimal therapy for many people.

Donors.

Kidney donors may be living donors (related or unrelated to the patient), non-heart-beating donors (NHBDs), and cadaveric donors. The available kidneys are matched on the basis of tissue type similarity between the donor and the recipient. NHBDs are persons declared dead by cardiopulmonary criteria. Kidneys from NHBDs are removed (harvested) immediately after death in cases in which patients have previously given consent for organ donation. If immediate removal must be delayed, the organ is preserved by infusing a cool preservation solution into the abdominal aorta after death is declared and until surgery can be performed. Cadaveric donors are usually people who suffered irreversible brain injury, most often as a result of trauma. These donors are maintained with mechanical ventilation and must have sufficient perfusion for the kidneys to remain viable.

The size of the kidney is seldom a problem in adults. Kidneys transplanted from children become larger to meet adult needs within a few months.

Organs from living *related* donors (LRDs) have the highest rates of kidney graft survival (90%). A living donor is one who is medically compatible with the recipient (Ficorelli et al., 2013). LRDs are usually at least 18 years old and are seldom older than 65 years, although there are reports of donors age 70 years with good outcomes for both the donor and recipient (Berger et al., 2011). Physical criteria for donors include:

- Absence of systemic disease and infection
- No history of cancer
- No hypertension or kidney disease
- Adequate kidney function as determined by diagnostic studies

LRDs must express a clear understanding of the surgery and a willingness to give up a kidney. Some transplant centers require a psychiatric evaluation to assess the donor's motivation.

A paired or chain exchange donation can be done when two kidney donor/recipient pairs have blood types that are not compatible (Gentry et al., 2011). The recipients trade donors so that each recipient can receive a kidney with a compatible blood type and tissue type (Fig. 68-13). Once the evaluations of all donors and recipients are completed, the series of kidney transplant operations are scheduled to occur consecutively (www.paireddonaton.org).

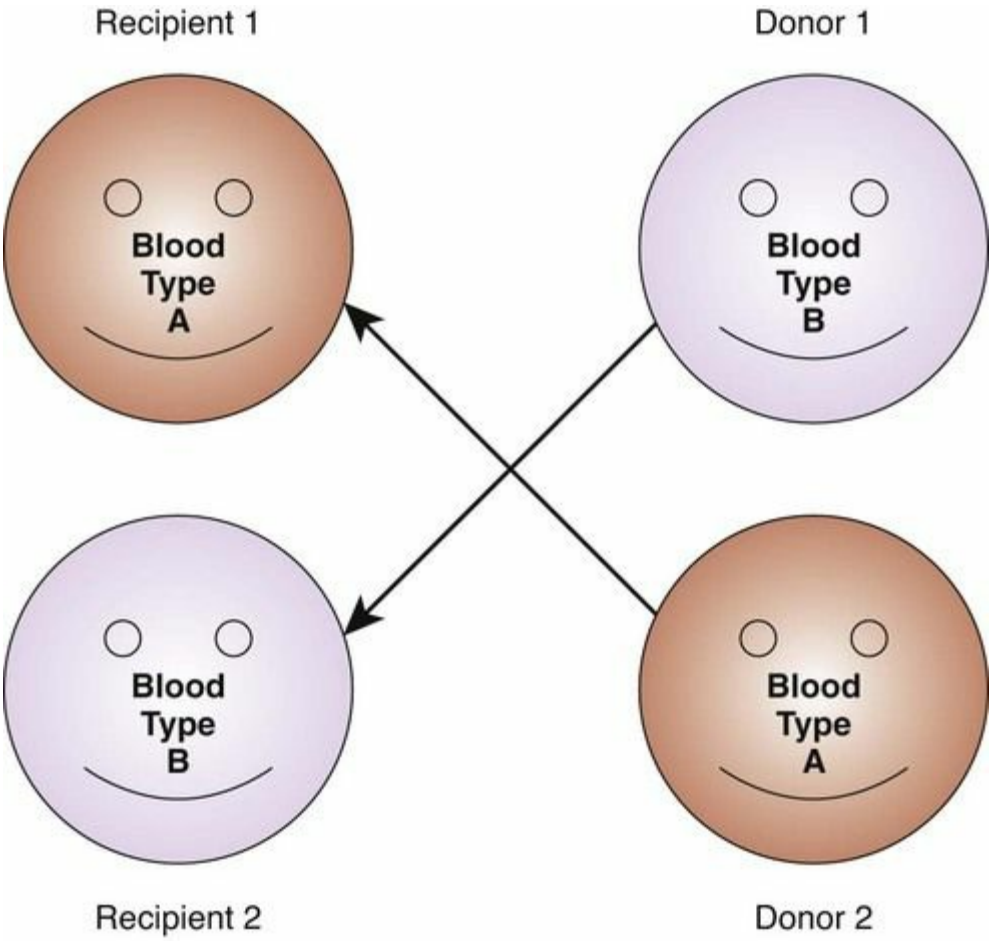

FIG. 68-13 An example of a paired exchange kidney donation. *Donor 1* is related to or acquainted with *recipient 1* and has agreed to donate a kidney but is not a blood type or tissue type match with *recipient 1. Donor 1* is compatible with *recipient 2* and agrees to donate a kidney to *recipient 2* if *donor 2* agrees to donate a kidney to *recipient 1 with confirmed compatibility to recipient 1.*

Because of advances in immunosuppressant therapy and medical management, the United Network for Organ Sharing (UNOS) reported 1-year kidney transplant graft survival to be almost 95% for all centers in the United States during 2012 (UNOS, 2014).

Preoperative Care.

Many issues related to patient health and the actual transplant procedure must be addressed before surgery. The *Clinical Pathway* on the *Evolve* website highlights care needs for the patient undergoing kidney transplantation.

Immunologic studies are needed because the major barrier to transplant success after a suitable donor kidney is available is the body's ability to reject "foreign" tissue. This immunologic process can attack the transplanted kidney and destroy it. For immunologic problems to be

overcome, tissue typing is performed on all candidates. These studies include simple blood typing and human leukocyte antigen (HLA) studies, as well as other tests. A donated kidney *must* come from a donor who is the same blood type as the recipient. The HLAs are the main immunologic feature used to match transplant recipients with compatible donors. The more similar the antigens of the donor are to those of the recipient, the more likely the transplant will be successful and rejection will be avoided (see Chapter 17).

Nursing actions before surgery include teaching about the procedure and care after surgery, in-depth patient assessment, coordination of diagnostic tests, and development of treatment plans. See Chapter 14 for more discussion of standard preoperative nursing care.

The patient usually requires dialysis within 24 hours of the surgery and often receives a blood transfusion before surgery. Usually blood from the kidney donor is transfused into the recipient. This procedure increases graft survival of organs from living related donors (LRDs).

Operative Procedures.

The donor nephrectomy procedure varies depending on whether the donor is a non-heart-beating donor (NHBD), cadaveric donor, or living donor (Beach et al., 2011). The NHBD or cadaveric donor nephrectomy is a sterile autopsy procedure performed in the operating room. All arterial and venous vessels and a long piece of ureter are preserved. After removal, the kidneys are preserved until time for implantation into the recipient. The technique for kidney removal from living donors is a laparoscopic procedure. Donors need postoperative nursing care and support for the psychological adjustment to loss of a body part.

Transplantation surgery usually takes several hours. The new kidney is usually placed in the right or left anterior iliac fossa (Fig. 68-14) instead of the usual kidney position. This placement allows easier connection of the ureter and the renal artery and vein. It also allows for easier kidney palpation. The recipient's own failed kidneys are not removed unless chronic kidney infection is present or, as in the case of polycystic kidney disease, the nonfunctioning, enlarged kidneys cause pain. After surgery, the patient is taken to the postanesthesia care unit and then, when stable, to a designated unit in the transplant center or to a critical care unit.

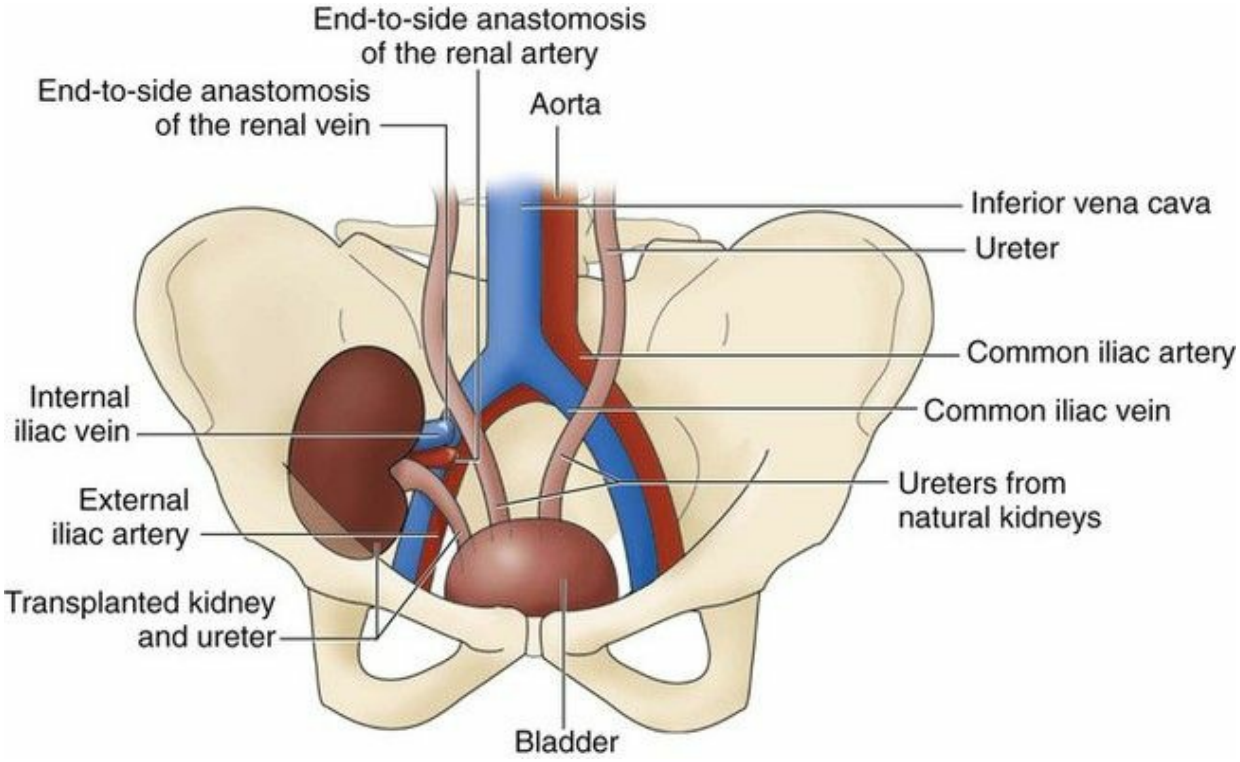

FIG. 68-14 Placement of a transplanted kidney in the right iliac fossa.

Postoperative Care.

Care of the recipient after surgery requires that nurses be knowledgeable about the expected clinical findings and potential complications. Nursing care includes ongoing physical assessment, especially evaluation of kidney function. The most common complications occurring in patients after renal transplant are rejection and infection. Immunosuppressive drug therapy used to prevent tissue rejection impairs healing and increases the risk for infection.

Urologic management is essential to graft success. A urinary catheter is placed for accurate measurements of urine output and decompression of the bladder. Decompression prevents stretch on sutures and ureter attachment sites on the bladder.

Assess urine output at least hourly during the first 48 hours. An abrupt decrease in urine output may indicate complications such as rejection, acute kidney injury (AKI), thrombosis, or obstruction. Examine the urine color. The urine is pink and bloody right after surgery and gradually returns to normal over several days to several weeks, depending on kidney function. Obtain daily urine specimens for urinalysis, glucose measurement, the presence of acetone, specific gravity measurement, and culture (if needed).

Occasionally, continuous bladder irrigation is prescribed to decrease

blood clot formation, which could increase pressure in the bladder and endanger the graft. Perform routine catheter care, according to agency policy, to reduce catheter-associated urinary tract infection (CAUTI). The catheter is removed as soon as possible to avoid infection—usually 3 to 5 days after surgery. After surgery, the function of the transplanted kidney (graft) can result in either oliguria or diuresis. Oliguria may occur as a result of ischemia and AKI, rejection, or other complications. To increase urine output, the health care provider may prescribe diuretics and osmotic agents. Closely monitor the patient's fluid status because fluid overload can cause hypertension, heart failure, and pulmonary edema. Evaluate his or her fluid status by weighing daily, measuring blood pressure every 2 to 4 hours, and measuring intake and output.

Instead of oliguria, the patient may have diuresis, especially with a kidney from a living related donor (LRD). Monitor intake and output, and observe for disruptions of fluid and electrolyte balance, such as low potassium and sodium levels. Excessive diuresis may cause hypotension.

Nursing Safety Priority QSEN

Critical Rescue

Notify the physician immediately about hypotension or excessive diuresis (e.g., unanticipated urine output 500-1000 mL greater than intake over 12-24 hours or other goal for intake and output [I&O]) because hypotension reduces blood flow and oxygen to the new kidney, threatening graft survival.

Complications.

Many complications are possible after kidney transplantation. Early detection and intervention improve the chances for graft survival.

Rejection is the most serious complication of transplantation and is the leading cause of graft loss. A reaction occurs between the tissues of the transplanted kidney and the antibodies and cytotoxic T-cells in the recipient's blood. These substances treat the new kidney as a foreign invader and cause tissue destruction, thrombosis, and eventual kidney necrosis.

The three types of rejection are hyperacute, acute, and chronic. Acute rejection is the most common type with kidney transplants. It is treated with increased immunosuppressive therapy and often can be reversed. Rejection is diagnosed by manifestations, a CT or renal scan, and kidney biopsy. Table 68-14 lists the features of the three types of rejection.

Chapter 17 discusses their causes and treatment.

TABLE 68-14

Comparison of Hyperacute, Acute, and Chronic Post-Transplant Rejection

HYPERACUTE REJECTION	ACUTE REJECTION	CHRONIC REJECTION
Onset		
Within 48 hours after surgery	1 week to any time postoperatively; occurs over days to weeks	Occurs gradually during a period of months to years
Clinical Manifestations		
Increased temperature	Oliguria or anuria	Gradual increase in BUN and serum creatinine levels
Increased blood pressure	Temperature over 100° F (37.8° C)	
Pain at transplant site	Increased blood pressure	Fluid retention
	Enlarged, tender kidney Lethargy Elevated serum creatinine, BUN, potassium levels Fluid retention	Changes in serum electrolyte levels Fatigue
Treatment		
Immediate removal of the transplanted kidney	Increased doses of immunosuppressive drugs	Conservative management until dialysis is required

BUN, Blood urea nitrogen.

Ischemia from delayed transplantation following harvesting can contribute to AKI. Newly transplanted patients with AKI may need dialysis until adequate urine output returns and the blood urea nitrogen (BUN) and creatinine levels normalize. Biopsy can be used to determine if oliguria is the result of AKI or rejection.

Thrombosis of the major renal blood vessels may occur during the first 2 to 3 days after the transplant. A sudden decrease in urine output may signal impaired perfusion resulting from thrombosis. Ultrasound of the kidney may show decreased or absent blood supply. Emergency surgery is required to prevent ischemic damage or graft loss.

Renal artery stenosis may result in hypertension. Other manifestations include a bruit over the artery anastomosis site and decreased kidney function. A CT or renal scan can quantify the blood flow to the kidney. The involved artery may be repaired surgically or by balloon angioplasty in the radiology department. The decision to perform a balloon repair is determined by the amount of healing time after the surgery.

Other vascular problems include vascular leakage or thrombosis, both of which require an emergency transplant nephrectomy.

Other complications may involve the surgical wound or urinary tract. Wound problems, such as hematomas, abscesses, and lymphoceles (cysts containing lymph fluid), increase the risk for infection and exert pressure on the new kidney. Infection is a major cause of death in the transplant recipient. Prevention of infection is essential. Strict aseptic technique and handwashing must be rigorously enforced. Transplant recipients may not have the usual manifestations of infection because of the

immunosuppressive therapy. Low-grade fevers, mental status changes, and vague reports of discomfort may be the only manifestations before sepsis. Always consider the possibility of infection with any patient after a kidney transplant. Urinary tract complications include ureteral leakage, fistula, or obstruction; stone formation; bladder neck contracture; and graft rupture. Surgical intervention may be required.

Immunosuppressive Drug Therapy.

The success of kidney transplantation depends on changing the patient's immunologic response so that the new kidney is not rejected as a foreign organ. Immunosuppressive drugs protect the transplanted organ. These drugs include corticosteroids, inhibitors of T-cell proliferation and activity (azathioprine, mycophenolic acid, cyclosporine, and tacrolimus), mTOR inhibitors (to disrupt stimulatory T-cell signals), and monoclonal antibodies. Chapter 17 discusses the mechanisms of action for these agents and the associated patient responses. Patients taking these drugs are at an increased risk for death from infection.

Some patients do not follow the regimen correctly and are at high risk for losing the transplanted kidney. Work with the patient to ensure adherence to the drug regimen.

Despite the complexity of drug regimens following kidney transplantation, 85.5% of patients are living 5 years after transplantation compared with 35.8% of patients who receive dialysis for 5 years. The costs of HD are 3 times the cost of kidney transplantation over the same 5 years (USRDS, 2014).

Nursing Safety Priority QSEN

Action Alert

Teach patients and families about the importance of adhering to the anti-rejection drug regimen to prevent transplant rejection.

Clinical Judgment Challenge

Patient-Centered Care QSEN

The patient is a 64-year-old man with ESKD who has been on hemodialysis for 3 years while waiting for a kidney transplant. He expresses frustration with the wait from time to time and has told you that he fears that he will be considered too old to receive a kidney if much more time goes by. He states that he feels “chained” to the dialysis

center.

1. How should you respond to his concern about age possibly affecting his ability to be a transplant recipient?
2. How do you respond to his feeling about being chained to the dialysis center?
3. What other resources can you offer to help him be informed and deal with the emotional aspects of dialysis?

Community-Based Care

Home Care Management.

Because of the complex nature of CKD, its progressive course, and many treatment options, a case manager is helpful in planning, coordinating, and evaluating care. As kidney disease progresses, the patient is seen by a physician or nurse practitioner regularly. Together with the dietitian and social worker, evaluate the home environment and determine equipment needs before discharge. Once the patient is discharged, home care nurses direct care and monitor progress.

Provide health teaching about the diet in kidney disease and the progression of disease. As CKD approaches end-stage kidney disease (ESKD), one of these treatment methods is chosen: hemodialysis (HD), peritoneal dialysis (PD), or transplantation. For each form of treatment, the patient and partner must learn about the procedures and consider his or her personal lifestyle, support systems, and methods of coping. Decision making about treatment type or even whether to pursue treatment is difficult for patients and families. Provide information and emotional support to assist patients with these decisions.

Teach patients who select hemodialysis (HD) about the machine and vascular access care. If in-home HD is selected, preparations are needed for the appropriate equipment, including a water treatment system. Referral to a home health care agency is essential for a successful transition to at-home HD. A home care visit occurs before discharge to coordinate equipment setup. Family members or agency staff must be available to respond to alarms during treatment. Because nocturnal HD is a growing modality, additional safety considerations must be addressed, including a plan for treatment discontinuation or generator backup during power outages. Regardless of whether the treatment occurs at home or in a center, promote independence through teaching and best practices in self-management.

The patient receiving PD needs extensive training in the procedure. He or she also needs help in obtaining equipment and the many supplies

needed. Home care nurses assess patients, monitor vital signs, assess adherence with drug and diet regimens, and monitor for manifestations of peritonitis.

The nurse plays a vital role in the long-term care of the patient with a kidney transplant. Facilitate acceptance and understanding of the anti-rejection drug regimen as a part of daily life. Carefully monitor for indications of graft rejection and for complications, such as infection. Chart 68-10 describes the focused assessment for the patient following kidney transplant.

Chart 68-10 Focused Assessment

The Patient Following Kidney Transplant

Assess cardiovascular and respiratory status, including:

- Vital signs, with special attention to blood pressure
- Presence of S_3 or pericardial friction rub
- Presence of chest pain
- Presence of edema (periorbital, pretibial, sacral)
- Jugular vein distention
- Presence of dyspnea
- Presence of crackles, beginning at the lung bases and extending upward

Assess nutritional status, including:

- Weight gain or loss
- Presence of anorexia, nausea, or vomiting

Assess kidney status, including:

- Amount, frequency, and appearance of urine (in non-anuric patients)
- Presence of bone pain
- Presence of hyperglycemia secondary to diabetes

Assess hematologic status, including:

- Presence of petechiae, purpura, ecchymoses
- Presence of fatigue or shortness of breath

Assess gastrointestinal status, including:

- Presence of stomatitis
- Presence of melena

Assess integumentary status, including:

- Skin integrity
- Presence of pruritus
- Presence of skin discoloration

Assess neurologic status, including:

- Changes in mental status
- Presence of seizure activity
- Presence of sensory changes
- Presence of lower extremity weakness

Assess laboratory data, including:

- BUN
- Serum creatinine
- Creatinine clearance
- CBC
- Electrolytes

Assess psychosocial status, including:

- Presence of anxiety
- Presence of maladaptive behavior

BUN, Blood urea nitrogen; *CBC,* complete blood count.

Self-Management Education.

Instruct patients and family members in all aspects of nutrition therapy, drug therapy, and complications. Teach them to report complications, such as fluid overload and infection. When a patient has a specific form of therapy, such as dialysis or transplantation, focus teaching on the chosen type of intervention. Assess the need for immunizations, and request a prescription to administer needed ones before transplantation.

Hemodialysis (HD) is the most complex form of therapy for the patient and family to understand. Even if patients receive HD in a dialysis center instead of at home, they are expected to have some knowledge of the process. Teach the patient or a family member to care for the vascular access and to report signs of infection and stenosis. Those who plan to have in-home HD will need a partner. Both the patient and the partner must be taught the entire process of HD and must be able to perform it independently before the patient is discharged.

Peritoneal dialysis (PD) involves extensive health teaching for the patient and family. Emphasize sterile technique because peritonitis is the most common complication of PD. Instruct patients to report any manifestation of peritonitis, especially cloudy effluent and abdominal pain. If peritonitis develops, teach patients how to give themselves antibiotics by the intraperitoneal (IP) route. Stress the importance of completing the antibiotic regimen. Remind patients that repeated episodes of peritonitis can reduce the effectiveness of PD, which may require the transfer to HD.

The patient receiving a kidney transplant also needs extensive health teaching. Provide instruction about drug regimens, home monitoring,

immunosuppression, manifestations of rejection, infection, and prescribed changes in the diet and activity level.

Psychosocial Preparation.

Provide psychological support for the patient and family. Help the patient adjust to the diagnosis of kidney failure and eventually accept the treatment regimens.

Many patients view dialysis as a cure instead of lifelong management. For many patients, reduction of uremic manifestations in the first weeks after starting dialysis treatment creates a sense of well-being (the "honeymoon" period). They feel better physically, and their mood may be happy and hopeful. At this time they tend to overlook the discomfort and inconvenience of dialysis. Use this time to begin health teaching. Stress that although manifestations are reduced, not to expect a complete return to the previous state of well-being before ESKD.

Many patients become discouraged during the first year of treatment. This mood state may last a few months to a year or longer. The difficulties of incorporating dialysis into daily life are staggering, and patients may become depressed as problems occur. They may struggle with the idea of having to be permanently dependent on a disruptive therapy. Patients may feel helpless and dependent. Some people may deny the need for dialysis or may not adhere to drug therapy and diet restrictions. Monitor any behaviors that may contribute to nonadherence, and suggest psychiatric referrals. Help the patient and family focus on the positive aspects of the treatments. Continue health education with patients as active participants and decision makers.

Most patients with CKD eventually enter a phase of acceptance or resignation. Each person reacts differently. To make this long-term adaptation, the patient must adjust to continuous change. Concerns depend on the patient's health and specific treatment method.

After patients have accepted or become resigned to the chronic aspect of their disease, they usually attempt to return to their previous activities. Resuming the previous level of activity, however, may not be possible. Help patients develop realistic expectations that allow them to lead active, productive lives.

Health Care Resources.

Professionals from many disciplines are resources for the patient with ESKD. Home care nurses monitor the patient's status and evaluate maintenance of the prescribed treatment regimen (HD or PD). Social services are often involved because of the complex process of applying

for financial aid to pay for the required medical care. A physical therapist may be beneficial in helping to improve the patient's functional health. A dietitian can assist the patient and family members in understanding special dietary needs. A psychiatric evaluation may be needed if depressive symptoms are present. Pharmacists provide invaluable insight and teaching about drug therapy and adjustments to meet outcomes. Clergy and pastoral care specialists offer spiritual support.

Patients with CKD are routinely followed by a physician, usually a nephrologist. Organizations such as the National Kidney Foundation (NKF), the American Kidney Fund, and the National Association of Patients on Hemodialysis and Transplantation (NAPHT) may be helpful to patients and families.

Evaluation: Outcomes

Evaluate the care of the patient with CKD based on the identified priority problems. The expected outcomes are that with appropriate management the patient should:

- Achieve and maintain appropriate fluid and electrolyte balance
- Maintain an adequate nutrition status
- Avoid infection at the vascular access site
- Use effective coping strategies
- Report an absence of physical manifestations of anxiety
- Prevent or slow systemic complications of CKD, including osteodystrophy

Specific indicators for these outcomes are listed for each priority problem under the Planning and Implementation section (see earlier).

Nursing Concepts and Clinical Judgment Review

What might you NOTICE if the patient is experiencing reduced perfusion and altered urinary elimination related to acute kidney injury?

- Hemodynamic instability, especially hypotension and tachycardia that persist or recur
- Urine output (elimination) of less than 0.5 mL/kg/hr for more than 2 hours; some experts suggest reporting urine output of less than 0.3 mL/kg/hr for more than 2 hours.
- Serum creatinine increased above baseline or admission values
- Patient reports of back or flank pain
- Urine that has sediment or is dark or smoky or has obvious blood in it
- Signs of abnormalities in fluid and electrolytes including dehydration

and abnormal serum and urine potassium and sodium values

How should you INTERPRET and how should you RESPOND to a patient experiencing complications from infection, inflammation, disturbances in fluid and electrolyte balance, and altered acid-base balance as a result of chronic kidney disease?

Perform and interpret physical assessment, including:

- Asking how long manifestations have been present
- Determining fluid intake and output volumes
- Weighing the patient, and asking whether this weight is more or less than the usual weight
- Assessing for tachycardia, hypertension, and hypotension
- Assessing for pulmonary congestion
- Assessing for skin tissue integrity related to risk for injury from uremia and edema
- Interpreting laboratory values:
  - BUN and serum creatinine levels elevated with altered cognition
  - Serum potassium level elevated with potential for cardiac dysrhythmias
  - Low serum calcium indicating risk for renal osteodystrophy
  - Arterial pH or venous base deficit

Respond by:

- Ensuring hemodynamic stability
- Monitoring urine output
- Monitoring for fluid overload and, after dialysis, dehydration
- Evaluating laboratory results regularly with physical assessment
- Evaluating patient risk for falls or other unsafe situations
- Promoting best practices related to care of the patient with vascular access for hemodialysis
- Providing education about drugs used to manage CKD and kidney transplant

On what should you REFLECT?

- Observe patient for evidence of improved urine output after implementing the plan of care for AKI.
- Plan care to avoid periods of inadequate kidney perfusion from hypotension and dehydration.
- Identify and evaluate the effect of interventions to minimize the risk for infection, including appropriate administration of immunizations, particularly in patients with CKD and altered immunity from kidney

transplant.
- Think about topics for patient teaching that could help prevent complications from AKI or progressive CKD.
- Explore how patient preferences and values affect patient decisions about self-management in CKD.
- Explain how immunosuppression in kidney transplant patients and patients with ESKD alters immune responses, including inflammation.
- Consider how timeliness (routine versus urgent versus immediate) and accuracy (e.g., isolated versus trend, and complete versus focused data) of communication to the health care provider or other health care team members can avoid or reduce complications, worsening CKD, transplant rejection, and severity of AKI.
- Inform health care providers about signs of local or systemic infection, vital signs that are not within normal ranges or ranges that are not acceptable for the patient, abnormal laboratory results, or other changes in patient status that require urgent assessment and intervention.

Get Ready for the NCLEX® Examination!

Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Use sterile technique when initiating and providing renal replacement therapy. **Safety** QSEN
- Implement fall precautions and consider physical therapy referral for patients with CKD osteodystrophy to prevent fractures. **Safety** QSEN
- Use skin protective measures to reduce injury and pressure ulcer formation in patients with CKD. **Safety** QSEN
- Communicate to health care providers patient assessments that indicate dehydration or hypovolemia to avoid inadequate kidney perfusion. **Teamwork and Collaboration** QSEN
- Avoid taking blood pressure measurements or drawing blood from an arm with a vascular access (AV fistula or graft). **Safety** QSEN
- Do not use a renal replacement vascular access device (the AV fistula or graft site) to give IV fluids. **Safety** QSEN

Health Promotion and Maintenance

- Encourage patients with AKI, CKD, or end-stage kidney disease (ESKD) to follow fluid and dietary restrictions regarding sodium, potassium, and protein.
- Teach patients the expected side effects, any adverse reactions to prescribed drugs, and when to contact the prescriber. **Safety** QSEN
- Teach patients using peritoneal dialysis the manifestations of peritonitis. **Patient-Centered Care** QSEN
- Teach patients receiving immunosuppressive therapy for kidney transplantation to assess themselves daily for fever, general malaise, and nausea or vomiting, as well as weight gain, indicating new fluid retention. **Patient-Centered Care** QSEN

Psychosocial Integrity

- Allow patients the opportunity to express concerns about the disruption of lifestyle and considerations for end-of-life care as a result of kidney failure. **Patient-Centered Care** QSEN
- Use language and terminology that are comfortable for the patient. **Patient-Centered Care** QSEN

- Assess the patient for depression and nonacceptance of the diagnosis or treatment plan. **Patient-Centered Care** QSEN
- Refer patients to community resources and support groups. **Informatics** QSEN

Physiological Integrity

- Report immediately any condition that obstructs urine flow. **Safety** QSEN
- Collaborate with the dietitian to teach patients about needed fluid, sodium, potassium, or dietary protein restriction. **Teamwork and Collaboration** QSEN
- Inform the health care provider urgently or immediately about hemodynamic instability, change in cognition, manifestations of infection, newly abnormal serum electrolytes, and urine output less than 0.5mL/kg/hr for more than 2-4 hours (unless the patient is oliguric or anuric from ESKD). **Teamwork and Collaboration** QSEN
- Teach patients in the early stages of CKD the manifestations of dehydration. **Patient-Centered Care** QSEN
- Teach patients in the later stages of CKD the manifestations of fluid overload and hyperkalemia. **Patient-Centered Care** QSEN
- Avoid all invasive procedures in the 4 to 6 hours following hemodialysis. **Evidence-Based Practice** QSEN

UNIT XVI

Problems of Reproduction: Management of Patients with Problems of the Reproductive System

OUTLINE

Concept Overview: Sexuality

Unlike the physiologic human needs introduced in other section openers of this text, *sexuality* is a complex integration of many physiologic, emotional, social, and cultural aspects of well-being. It is closely associated with self-concept, self-esteem, role relationships, sexual response, gender identity, and reproduction. Sexuality comprises other related human needs, such as belonging, intimacy (e.g., touching, kissing), sharing, and caring. When these needs are met, a person is sexually healthy (Fig. 1).

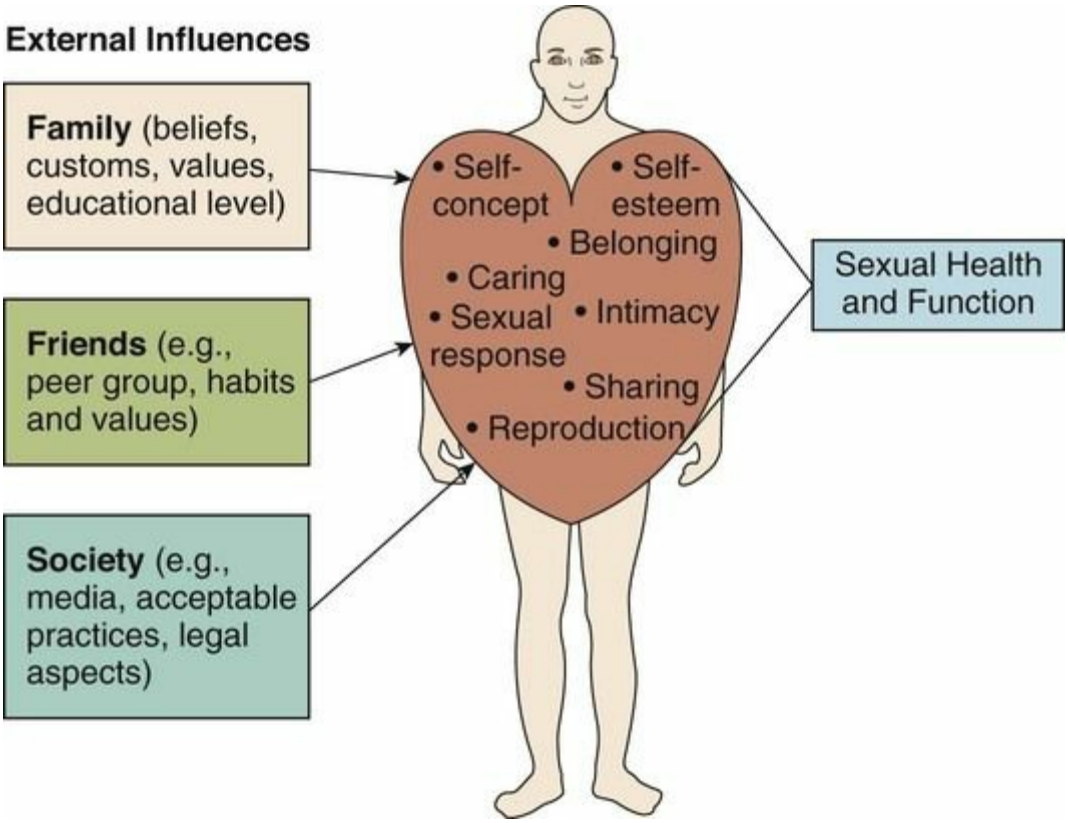

FIG. 1

Sexuality, therefore, is a vital part of one's holistic being from birth to death. During the stages of human development, a person's attitudes, beliefs, and values related to sexuality are influenced and shaped by the environment, including family, friends, and society. For example, cultural beliefs affect the nature of physical sexual pleasure. The media also play a large role in developing one's views on sexuality. Some societies, such as the United States, tend to value youth and beauty more than aging and wisdom. As a result, people in these societies may feel less physically attractive and desirable for intimacy and belonging as they age.

Various external and internal risk factors can alter or impair sexual health. In many cases, they cause physical sexual dysfunction, which then affects emotional needs such as self-esteem (Fig. 2). These factors include:

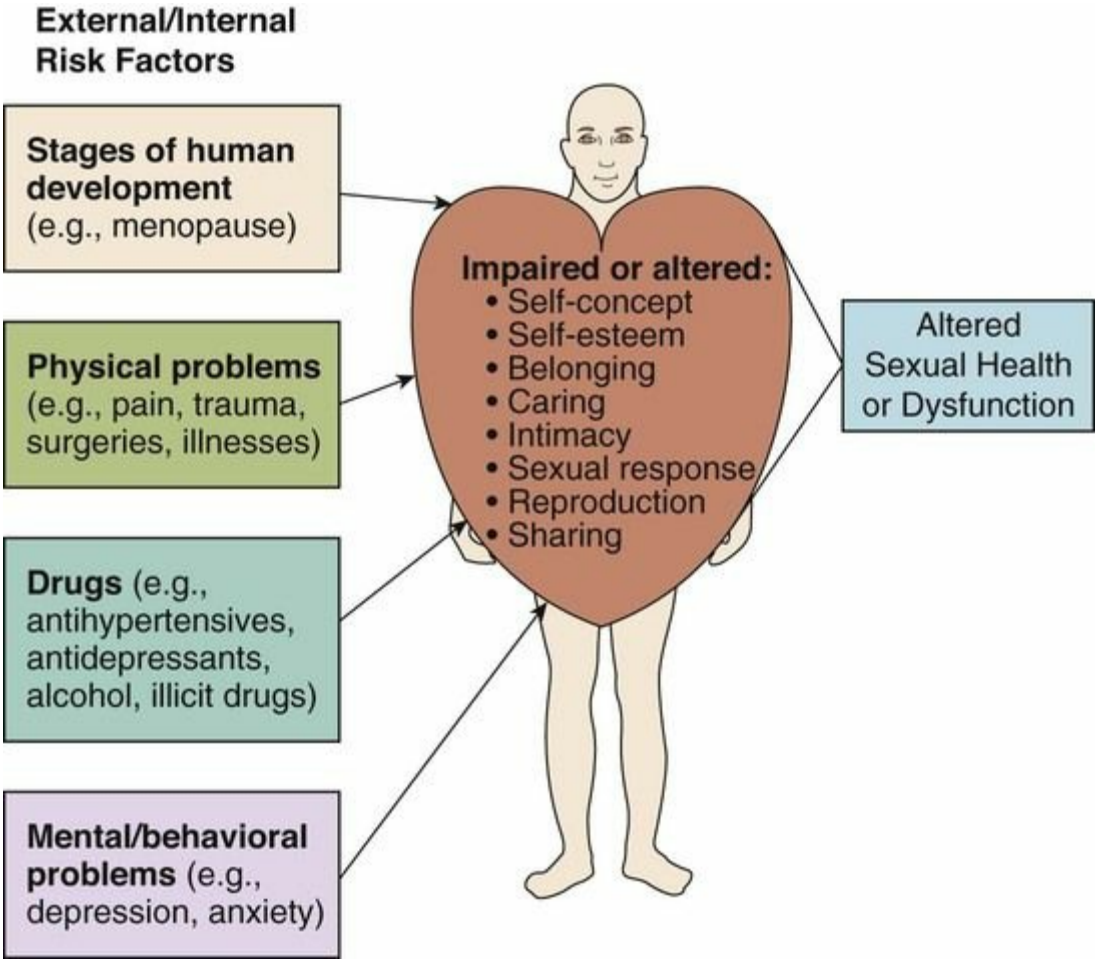

FIG. 2

- Stages of human development
- Physical health problems
- Drugs
- Mental/behavioral health problems

The *stages of human development* typically influence human sexuality, especially when menopause occurs in middle adulthood. Although each woman's response is different, menopause may result in a decreased libido (desire for sexual contact or intercourse). Relationships with her sexual partner(s) are altered, and interpersonal conflict can occur.

Physical health problems also can negatively affect sexual health. For example, chronic pain may cause decreased physical contact and a lowered self-concept along with chronic fatigue and decreased energy. Sexual dysfunction commonly occurs in people with chronic diseases such as diabetes and hypertension. Reproductive diseases (e.g., sexually transmitted diseases, testicular cancer) and their treatments (e.g., radiation therapy, surgery) can also affect sexuality, both physically and emotionally. Physical trauma such as spinal cord injury may prevent a person from having sexual intercourse.

Certain prescription or recreational *drugs* can cause impotence

(inability to have an erection) or infertility. Alcohol and many antihypertensive agents, antidepressants, and illicit drugs interfere with sexual function in men.

Mental/behavioral health problems can also result in altered sexual health. Common examples include depression and severe anxiety states. In some cases, concern about physical performance can lead to sexual dysfunction.

CHAPTER 69

Assessment of the Reproductive System

Donna D. Ignatavicius

PRIORITY CONCEPTS

- Pain
- Sexuality
- Infection

Learning Outcomes

Health Promotion and Maintenance

1. Teach patients about recommended guidelines for selected reproductive screening tests.

Psychosocial Integrity

2. Identify general psychological responses to reproductive health problems that affect sexuality.

Physiological Integrity

3. Review the anatomy and physiology of the male and the female reproductive systems.
4. Identify reproductive changes associated with aging and their implications for nursing care.
5. Perform a focused physical assessment of the patient with male or female reproductive system problems.
6. Explain the use of laboratory testing for patients with suspected or actual reproductive health problems.
7. Develop an evidence-based teaching plan for a patient undergoing endoscopic studies for reproductive health problems.

http://evolve.elsevier.com/Iggy/

The first health care professional to assess the patient with a reproductive system health problem or hear a patient's concern about a reproductive problem is often the nurse. These problems typically affect the need for sexuality, both its physical and psychosocial aspects, and are difficult for many people to discuss. Assessment of the male and the female reproductive systems should be part of every complete physical assessment. *Be aware of and sensitive to differences in sexual orientation and practices.*

This chapter reviews the focused reproductive system assessment that a nurse generalist performs. An advanced practice nurse or other health care provider performs the comprehensive reproductive examination. A more detailed discussion of human sexuality is found in a fundamentals or basic nursing text.

Anatomy and Physiology Review

Structure and Function of the Female Reproductive System

The female reproductive system is located both outside (external) and inside (internal) the body.

External Genitalia

The external female genitalia, or **vulva,** extend from the mons pubis to the anal opening. The mons pubis is a fat pad that covers the symphysis pubis and protects it during coitus (sexual intercourse).

The labia majora are two vertical folds of adipose tissue that extend posteriorly from the mons pubis to the perineum. The size of the labia majora varies depending on the amount of fatty tissue present. The skin over the labia majora is usually darker than the surrounding skin and is highly vascular. It protects inner vulval structures and enhances sexual arousal.

The labia majora surround two thinner, vertical folds of reddish epithelium called the *labia minora*. The labia minora are highly vascular and have a rich nerve supply. Emotional or physical stimulation produces marked swelling and sensitivity. Numerous sebaceous glands in the labia minora lubricate the entrance to the vagina. The clitoris is a small, cylindric organ that is composed of erectile tissue with a high concentration of sensory nerve endings. During sexual arousal, the clitoris becomes larger and increases sexual sensation.

The vestibule is a longitudinal area between the labia minora, the clitoris, and the vagina that contains Bartholin glands and the openings of the urethra, Skene's glands (paraurethral glands), and vagina. The two Bartholin glands, located deeply toward the back on both sides of the vaginal opening, secrete lubrication fluid during sexual excitement. Their ductal openings are usually not visible.

The area between the vaginal opening and the anus is the perineum. The skin of the perineum covers the muscles, fascia, and ligaments that support the pelvic structures.

Internal Genitalia

The internal female genitalia are shown in Fig. 69-1. The vagina is a hollow tube that extends from the vestibule to the uterus. Ovarian hormones (primarily *estrogen*) influence the amounts of glycogen and lubricating fluid secreted by the vaginal cells. The normal vaginal

bacteria (flora) interact with the secretions to produce lactic acid and maintain an acidic pH (3.5 to 5) in the vagina. This acidity helps prevent infection in the vagina.

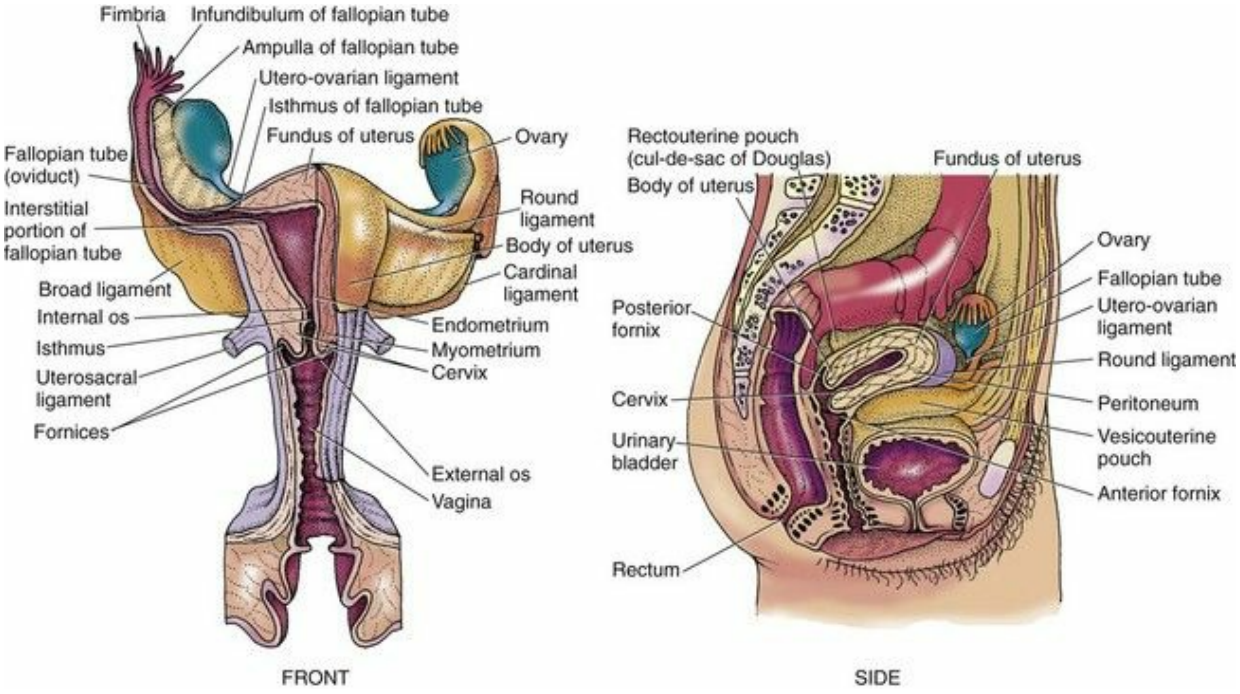

FIG. 69-1 Internal female genitalia.

At the upper end of the vagina, the uterine cervix projects into a cup-shaped vault of thin vaginal tissue. The recessed pockets around the cervix permit palpation of the internal pelvic organs. The posterior area provides access into the peritoneal cavity for diagnostic or surgical purposes.

The uterus (or "womb") is a thick-walled, muscular organ attached to the upper end of the vagina. This inverted pear–shaped organ is located within the true pelvis, between the bladder and the rectum. The uterus is made up of the body and the cervix.

The cervix is a short (1 inch [2.5 cm]), narrowed portion of the uterus and extends into the vagina. The surfaces of the cervix and the canal are the sites for Papanicolaou (Pap) testing. (See discussion on p. 1454.)

The fallopian tubes (uterine tubes) insert into the fundus of the uterus and extend laterally close to the ovaries. They provide a duct between the ovaries and the uterus for the passage of ova and sperm. In most cases, the ovum is fertilized in these tubes.

The ovaries are a pair of almond-shaped organs located near the lateral walls of the upper pelvic cavity. After menopause, they become smaller. These small organs develop and release ova and produce the sex steroid hormones (estrogen, progesterone, androgen, and relaxin). Adequate

amounts of these hormones are needed for normal female growth and development and to maintain a pregnancy.

Breasts

The female breasts are a pair of mammary glands that develop in response to secretions from the hypothalamus, pituitary gland, and ovaries. The breasts are an accessory of the reproductive system that nourish the infant after birth.

Breast tissue is composed of a network of glandular and ductal tissue, fibrous tissue, and fat. The proportion of each component of breast tissue depends on genetic factors, nutrition, age, and obstetric history. The breasts are supported by ligaments that are attached to underlying muscles. They have abundant blood supply and lymph flow that drain from an extensive network toward the axillae (Fig. 69-2).

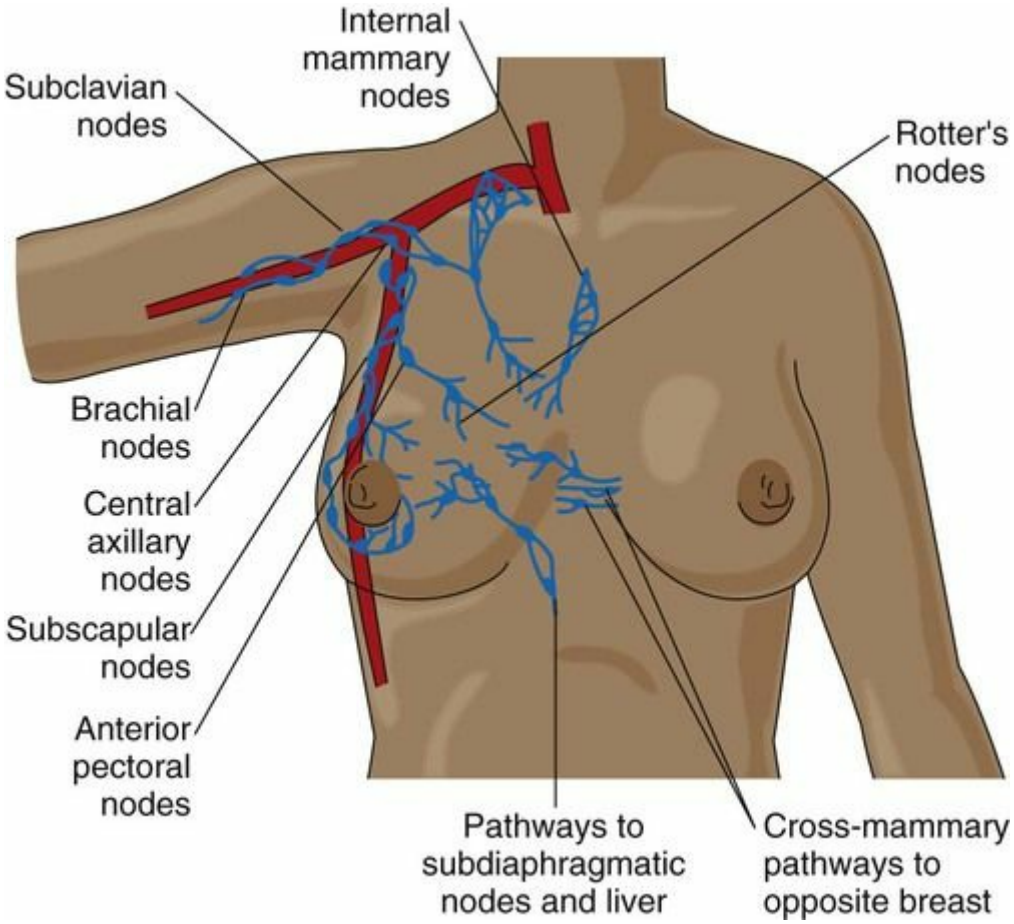

FIG. 69-2 Lymphatic drainage of the female breast.

Structure and Function of the Male Reproductive System

The male reproductive system also consists of external and internal genitalia. The primary male hormone for sexual development and function is *testosterone.* Testosterone production is fairly constant in the adult male. Only a slight and gradual reduction of testosterone production occurs in the older adult male until he is in his 80s. Low testosterone levels decrease muscle mass, reduce skin elasticity, and lead to changes in sexual performance.

The penis is an organ for urination and intercourse consisting of the body or shaft and the glans penis (the distal end of the penis). The glans is the smooth end of the penis and contains the opening of the urethral meatus. The urethra is the pathway for the exit of both urine and semen. A continuation of skin covers the glans and folds to form the prepuce (foreskin). Surgical removal of the foreskin **(circumcision)** for religious or cultural reasons is a common procedure in the United States and other Western countries.

The scrotum is a thin-walled, fibromuscular pouch that is behind the penis and suspended below the pubic bone. This pouch protects the testes, epididymis, and vas deferens in a space that is slightly cooler than inside the abdominal cavity. The scrotal skin is darkly pigmented and contains sweat glands, sebaceous glands, and few hair follicles. It contracts with cold, exercise, tactile stimulation, and sexual excitement.

The internal male genitalia are shown in Fig. 69-3. The major organs are the testes and prostate gland. The testes are a pair of oval organs in the scrotum that produce sperm and testosterone. Each testis is suspended in the scrotum by the spermatic cord, which provides blood, lymphatic, and nerve supply to the testis. Sympathetic nerve fibers are located on the arteries in the cord, and sympathetic and parasympathetic fibers are on the vas deferens. When the testes are damaged, these autonomic nerve fibers transmit excruciating pain and a sensation of nausea.

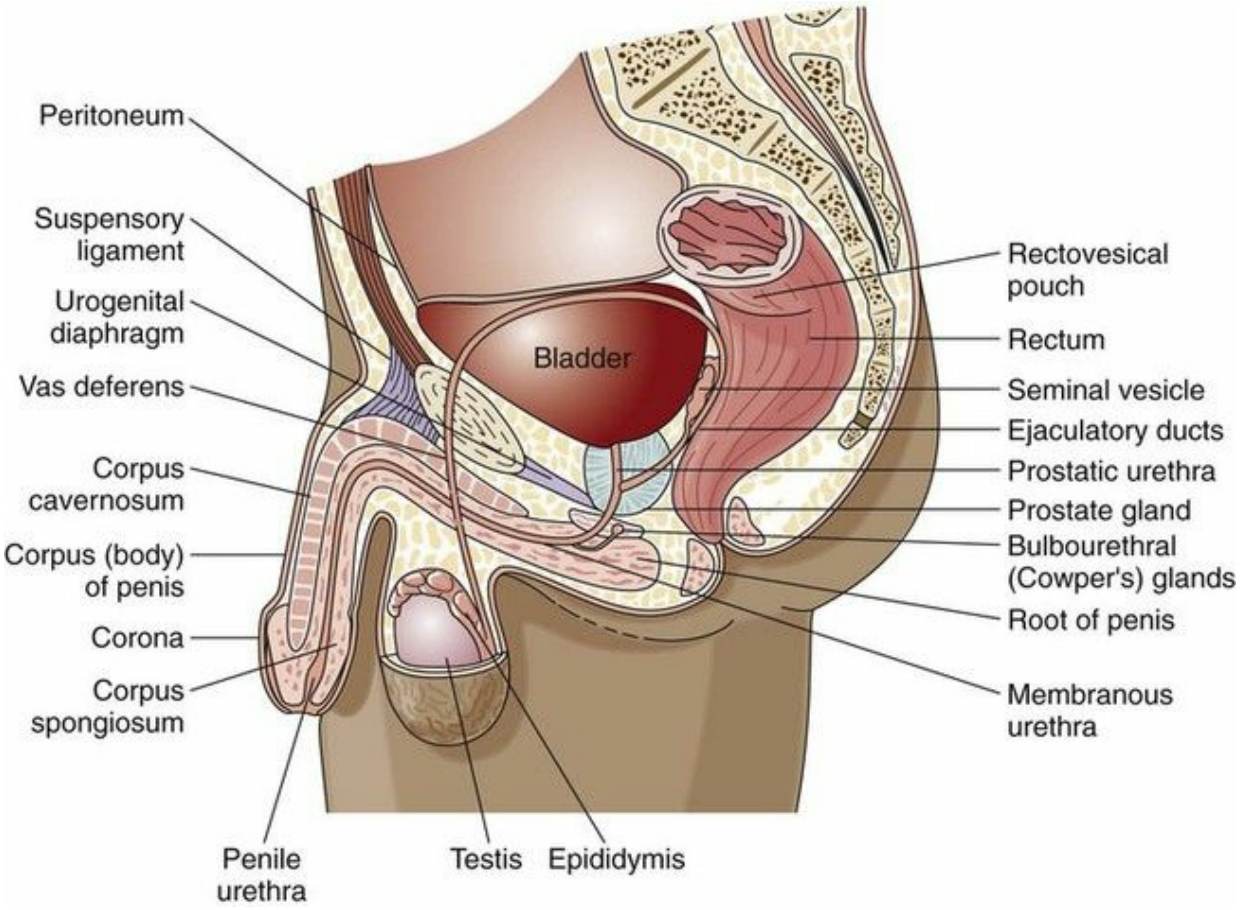

FIG. 69-3 Internal male genitalia.

The epididymis is the first portion of a ductal system that transports sperm from the testes to the urethra and is a site of sperm maturation. The vas deferens, or ductus deferens, is a firm, muscular tube that continues from the tail of each epididymis. The end of each vas deferens is a reservoir for sperm and tubular fluids. They merge with ducts from the seminal vesicle to form the ejaculatory ducts at the base of the prostate gland. Sperm from the vas deferens and secretions from the seminal vesicles move through the ejaculatory duct to mix with prostatic fluids in the prostatic urethra.

The prostate gland is a large accessory gland of the male reproductive system that can be palpated via the rectum. The gland secretes a milky alkaline fluid that adds bulk to the semen, enhances sperm movement, and neutralizes acidic vaginal secretions. Men older than 50 years commonly have an enlarged prostate (benign prostatic hyperplasia [BPH]), which can cause problems such as overflow incontinence and nocturia (nighttime urination). Prostate function depends on adequate levels of testosterone.

Reproductive Changes Associated with Aging

Age affects the function of both the male and the female reproductive systems. Many changes in the reproductive system occur as people age (Chart 69-1).

Chart 69-1 Nursing Focus on the Older Adult

Changes in the Reproductive System Related to Aging

PHYSIOLOGIC CHANGE	NURSING INTERVENTIONS	RATIONALES
Women		
Graying and thinning of the pubic hair Decreased size of the labia majora and clitoris	Discuss changes with the patient (applies to all structures for both women and men).	Education helps prevent problems with body image (applies to all structures for both women and men).
Drying, smoothing, and thinning of the vaginal walls	Provide information about vaginal estrogen therapy and water-soluble lubricants.	Education enables the patient to make informed decisions about the treatment of vaginal dryness, which can cause painful intercourse.
Decreased size of the uterus Atrophy of the endometrium Decreased size and marked convolution of the ovaries Loss of tone and elasticity of the pelvic ligaments and connective tissue	Provide information about Kegel exercises to strengthen pelvic muscles. Urinary incontinence can be a major problem.	Strengthening exercises may prevent or reduce pelvic relaxation and urinary incontinence.
Increased flabbiness and fibrosis of the breasts, which hang lower on the chest wall; decreased erection of the nipples	Teach or reinforce the importance of breast self-awareness, clinical breast examinations, and mammography.	These methods can detect masses or other changes that may indicate the presence of cancer.
Men		
Graying and thinning of the pubic hair	Teach or reinforce the importance of testicular self-examination (TSE).	TSE may detect changes that may indicate cancer.
Increased drooping of the scrotum and loss of rugae		
Prostate enlargement, with an increased likelihood of urethral obstruction	Teach the patient the signs of urethral obstruction and the importance of prostate cancer screening.	Education helps the patient detect enlargement or obstruction, which may indicate the presence of cancer.

Assessment Methods

Patient History

Establish a trusting relationship with the patient. Many patients are hesitant to share their reproductive history or concerns about sexuality. Respect their choice to refuse to answer questions about their reproductive problems or sexual practices. Assess the patient's health habits, such as diet, sleep, and exercise patterns. Low levels of body fat may be related to ovarian dysfunction. Assess for alcohol, tobacco, and drug use (prescribed, over-the-counter [OTC], and illicit drugs), because **libido** (sex drive), sperm production, and the ability to have or sustain an erection can be affected by these substances.

Ask female patients about the date and result of their most recent Pap test, breast self-examination, and vulvar self-examination. Determine when male patients older than 50 years had their last prostate examination and prostate-specific antigen test.

Ask about childhood illnesses that could have an effect on the reproductive system. For example, mumps in men may cause **orchitis** (painful inflammation and swelling of the testes) and can lead to testicular atrophy and sterility. Also ask whether the patient has had any infections. Pelvic inflammatory disease or a ruptured appendix followed by peritonitis can cause pelvic scarring and strictures or adhesions in the fallopian tubes. **Salpingitis** (uterine tube infection) is often caused by chlamydia and can result in female infertility. A history of infections or prolonged fever in males may have damaged sperm production or caused obstruction of the seminal tract, which can cause infertility.

Assess for chronic illnesses or surgeries that could affect reproductive function. Disorders that affect a woman's metabolism or nutrition can depress ovarian function and cause **amenorrhea** (absence of menses). Patients with diabetes mellitus may experience physiologic changes such as vaginal dryness or impotence. Chronic disorders of the nervous system, respiratory system, or cardiovascular system can alter the sexual response.

Ask whether the patient has been treated with radiation therapy. Inquire about the prolonged use of corticosteroids, internal or external estrogen, testosterone, or chemotherapy drugs, which can lead to reproductive system dysfunction.

Data about sexual activity are vital parts of the patient's history. Sexual orientation should not be assumed. Patients who are lesbian, gay, bisexual, transgender, and queer/questioning (LGBTQ) are often not fully assessed by health care professionals. These patients feel more

comfortable sharing this information about their reproductive health and sexual activity when approached in a caring, nonjudgmental way. Chapter 1 describes sensitive interviewing techniques that are appropriate for LGBTQ patients. Chapter 73 in this unit discusses assessment and care of transgender patients in detail.

Cultural Considerations

Patient-Centered Care QSEN

Other cultural beliefs and practices influence lifestyle and sexual activity. A person's religious beliefs often influence specific sexual practices, the acceptable number of sexual partners, and contraceptive use. Be sensitive to these differences by being nonjudgmental and showing acceptance.

Nutrition History

A nutrition history is important when assessing the reproductive system. Fatigue and low libido may occur as a result of poor diet and anemia. The World Cancer Research Fund estimates that about one quarter to one third of the new *preventable* cancer cases expected to occur in the United States in 2014 will be related to overweight or obesity, physical inactivity, and poor nutrition (American Cancer Society [ACS], 2014a). Ask the patient to recall his or her dietary intake for a recent 24-hour period to assess nutritional quality.

Assess the patient's height, weight, and body mass index. The patient may be hesitant to discuss practices such as bingeing, purging, anorexic behaviors, or excessive exercise. A certain level of body fat and weight is necessary for the onset of menses and the maintenance of regular menstrual cycles. Decreased body fat results in insufficient estrogen levels.

Gender Health Considerations

Patient-Centered Care QSEN

Women have special nutrition needs. Heavy menstrual bleeding, particularly in women who have intrauterine devices, may require iron supplements. Teach all women about their body's need for calcium. Although adequate calcium intake throughout life is needed, it is especially important during and after menopause to help prevent osteoporosis due to decreased estrogen production (see Chapter 50).

Family History and Genetic Risk

The family history helps determine the patient's risk for conditions that affect reproductive functioning. A delayed or early development of secondary sex characteristics may be a familial pattern.

The current age and health status of family members are important. Evidence of medical diseases or reproductive problems in family members (e.g., diabetes, endometriosis, reproductive cancer) provides a fuller understanding of the patient's current symptoms. For example, daughters of women who were given diethylstilbestrol (DES) to control bleeding during pregnancy are at increased risk for infertility and reproductive tract cancer.

Specific *BRCA1* and *BRCA2* gene mutations increase the overall risk for breast or ovarian cancer (ACS, 2014c). Men with first-degree relatives (e.g., father, brother) with prostate cancer are at greater risk for the disease than are men in the general population.

Current Health Problems

Patients often seek medical attention as a result of pain, bleeding, discharge, and masses (Chart 69-2). Pain related to reproductive system disorders may be confused with symptoms usually associated with GI or urinary health problems (e.g., urinary frequency). Ask the patient to describe the nature of the pain, including its type, intensity, timing and location, duration, and relationship to menstrual, sexual, urinary, or GI function. Assess the factors that exacerbate (worsen) or relieve the pain. Ask about sleeping patterns and if pain or other symptoms affect the ability to get adequate rest (Ruhl, 2010).

Chart 69-2 Best Practice for Patient Safety & Quality Care QSEN

Assessing the Patient with Reproductive Health Problems

PATIENT CONCERN	NURSING ASSESSMENT
Pain	Type and intensity of pain Location and duration of pain Factors that relieve or worsen pain Relationship to menstrual, sexual, urinary, or GI function Medications
Bleeding	Presence or absence of bleeding Character and amount of bleeding Relationship of bleeding to events or other factors (e.g., menstrual cycle) Onset and duration of bleeding Presence of associated symptoms, such as pain
Discharge	Amount and character of discharge Presence of genital lesions, bleeding, itching, or pain Presence of symptoms or discharge in sexual partner
Masses	Location and characteristics of mass Presence of associated symptoms, such as pain Relationship to menstrual cycle

Heavy *bleeding* or a lack of bleeding may concern the patient. The possibility of pregnancy in any sexually active woman with amenorrhea must be considered. Postmenopausal bleeding needs to be evaluated. Ask the patient to describe the amount and characteristics of abnormal vaginal bleeding. Assess whether the bleeding occurs in relation to the menstrual cycle or menopause, intercourse, trauma, or strenuous exercise. For male patients, ask about the presence of penile bleeding. Ask any patient who has abnormal bleeding about associated symptoms, such as pain, cramping or abdominal fullness, a change in bowel habits, urinary difficulties, and weight changes.

Discharge from the male or female reproductive tract can cause irritation of the surrounding tissues, itching, pain, embarrassment, and anxiety. Ask about the amount, color, consistency, odor, and chronicity of discharge that may be present from orifices used during sexual activity. Drugs (e.g., antibiotics) and clothing (e.g., tight jeans, synthetic underwear fabric) may cause or worsen genital discharge. Many types of discharge are caused by sexually transmitted diseases (STDs) or other infection (see Chapter 74).

Masses in the breasts, testes, or inguinal area must be evaluated. Patients can sometimes relate changes in character or size of masses to menstrual cycles, heavy lifting, straining, or trauma. Ask about associated symptoms such as tenderness, heaviness, pain, dimpling, and tender lymph nodes.

Physical Assessment

Assessment of the Female Reproductive System

The nurse generalist does not perform a comprehensive female or male reproductive examination. However, you should perform a focused assessment related to specific concerns of the patient. The primary care provider conducts a more detailed gynecologic assessment as described below; the generalist nurse often assists with the examination.

Immediately before the pelvic and breast examinations, ask the patient to empty her bladder and undress completely. Drape the patient adequately to provide modesty throughout the examination. Remove drapes only over the region being examined, and replace them after that area has been assessed. Mirrors can be used to facilitate teaching if the patient so desires. The examination should be performed in a room that has adequate lighting for body inspection, that has comfortable temperature, and that ensures privacy.

The physical examination of the female reproductive system includes the breasts (see Chapter 70), cardiovascular system, and abdomen. The patient's arms should be at her sides or over her chest to allow better relaxation of the abdominal muscles. During the gynecologic examination, the primary care provider palpates for symptomatic and asymptomatic abdominopelvic masses, which can be of reproductive, intestinal, or urinary tract origin. Gynecologic masses, such as ovarian masses, may be further differentiated from lesions on the body of the uterus during the bimanual portion of the pelvic examination.

Inspection of the female genitalia and the pelvic examination are usually performed at the end of a head-to-toe physical assessment. The patient is often more apprehensive about these portions of the examination than about any other part. Pain or lack of privacy during previous pelvic or breast examinations may prevent the patient from relaxing.

Other than determining pregnancy or infertility, a pelvic examination is indicated to assess for:

- Menstrual irregularities
- Unexplained abdominal or vaginal pain
- Vaginal discharge, itching, sores, or infection
- Rape trauma or other pelvic injury
- Physical changes in the vagina, cervix, and uterus

Assessment of the Male Reproductive System

Unless a male patient seeks health care for a specific problem, the health

care provider may not perform a reproductive assessment, depending on the setting and the age of the patient. Men are often embarrassed and anxious when the reproductive system is assessed. The patient may be concerned about discomfort, the developmental stage of his genitalia, or the possibility of an erection during the examination. If he does have an erection, the examiner should assure him that this is a normal response to a tactile stimulus (touch) and should continue the examination.

Explain each step of the assessment procedure before it is performed. The patient needs to be reassured that the health care provider will stop and change the assessment plan or technique if the patient experiences pain during the examination. Teach relaxation techniques and provide nonjudgmental support during the examination to increase comfort.

Psychosocial Assessment

The psychosocial assessment may provide information about factors that affect the patient's health status. During the social history, ask about sources of support, strengths, and coping reactions to illness or dysfunction.

A patient's personal experiences, culture, and/or spiritual beliefs may influence his or her ability to enjoy a satisfactory sexual life. These factors may include:

- Sexual trauma or abuse inflicted during childhood or adulthood
- Punishment for masturbation
- Psychological trauma
- Cultural influences, such as the idea of female passivity during intercourse
- Concerns about sexual partners or sexual lifestyle
- Use of alcohol or street drugs

Fears may affect the patient's satisfaction with sexuality or body image. He or she may also be concerned about the potential or actual reaction of family members to reproductive health problems (see Chart 69-2). Use nonjudgmental listening to continue development of trust between yourself and the patient, allowing the patient to openly express feelings or concerns.

Diagnostic Assessment

Laboratory Assessment

Chart 69-3 summarizes important laboratory tests associated with reproductive function. The **Papanicolaou test (Pap test),** or **Pap smear,** is

a cytologic study that is effective in detecting precancerous and cancerous cells within the female patient's cervix. It is done immediately before the pelvic examination. A speculum is inserted into the vagina, and several samples of cells from the cervix are obtained with a small brush or spatula. The specimens are placed on a glass slide and sent to the laboratory for examination.

Chart 69-3 Laboratory Profile

Reproductive Assessment

TEST	NORMAL RANGE FOR ADULTS	SIGNIFICANCE OF ABNORMAL FINDINGS
Serum Studies		
Follicle-stimulating hormone (FSH) (Follitropin)	*Men:* 1.42-15.4 IU/L	Decreased levels indicate possible infertility, anorexia nervosa, neoplasm. Elevations indicate possible Turner's syndrome.
	Women: follicular phase, 1.37-9.9 IU/L; midcycle, 6.17-17.2 IU/L; luteal phase, 1.09-9.2 IU/L; postmenopause, 19.3-100.6 IU/L	
Luteinizing hormone (LH) (Lutropin)	*Men:* 1.24-7.8 IU/L	Decreased levels indicate possible infertility, anovulation. Elevations indicate possible ovarian failure, Turner's syndrome.
	Women: follicular phase, 1.68-15 IU/L; midcycle, 21.9-56.6 IU/L; luteal phase, 0.61-16.3 IU/L; postmenopause, 14.2-52.3 IU/L	
Prolactin	*Men:* 3-13 ng/mL	Elevations indicate possible galactorrhea (breast discharge), pituitary tumor, disease of hypothalamus or pituitary gland, hypothyroidism.
	Women: 3-27 ng/mL	
	Pregnant women: 20-400 ng/mL	
Estradiol	*Men:* 10-50 pg/mL	Elevations of estradiol, total estrogens, and estriol in men indicate possible gynecomastia, decreased body hair, increased fat deposits, feminization, testicular tumor; in women, ovarian tumor.
	Women: follicular phase, 20-350 pg/mL; midcycle, 150-750 pg/mL; luteal phase, 30-450 pg/mL; postmenopause, ≤20 pg/mL	
Estriol	Men and nonpregnant women: N/A	Decreased levels of estradiol, total estrogens, and estriol in women indicate possible amenorrhea, climacteric, impending miscarriage, hypothalamic disorders.
Progesterone	*Men:* 10-50 ng/dL	Decreased levels in women indicate possible inadequate luteal phase, amenorrhea. Elevations in women indicate possible ovarian luteal cysts. Decreased levels may indicate ovarian neoplasm, ovarian dysfunction.
	Women: follicular phase, <50 ng/dL; luteal phase, 300-2500 ng/dL; postmenopausal, <40 ng/dL	
Testosterone	*Men:* 280-1080 ng/dL	Increased levels in men indicate possible testicular tumor, hyperthyroidism. Decreased levels in men indicate possible hypogonadism. Elevations in women indicate possible adrenal neoplasm, ovarian neoplasm, polycystic ovary syndrome.
	Women: <70 ng/dL	
Prostate-specific antigen	*Men:* 0-2.5 ng/mL	Increased levels may indicate prostatitis, benign prostatic hyperplasia, prostate cancer.
Urine Studies		
Total estrogens	*Men:* 4-25 mcg/24 hr	Elevations indicate possible testicular tumors. Decreased levels indicate possible ovarian dysfunction.
	Women: 4-60 mcg/24 hr	
Pregnanediol	*Men:* 0-1.9 mg/24 hr	Elevations indicate possible luteal ovarian cysts, ovarian neoplasms, adrenal disorders. Decreased levels indicate possible amenorrhea.
	Women: follicular phase, <2.6 mg/24 hr; luteal phase, 2.6-10.6 mg/24 hr	
17-Ketosteroids	Men (20-50 yr): 6-20 mg/24 hr	Elevations indicate possible Cushing's syndrome, increased androgen or cortisol production, severe stress. Decreased levels indicate possible Addison's disease, hypopituitarism.
	Women (20-50 yr): 6-17 mg/24 hr	
	Values decrease with age	

1 mcg, 1 microgram or 1 millionth of a gram; *1 ng,* 1 nanogram or 1 billionth of a gram; *1 pg,* 1 picogram or 1 trillionth of a gram.

Data from Pagana, K.D., & Pagana, T.J. (2014). *Mosby's manual of diagnostic and laboratory tests* (12th ed.). St. Louis: Mosby.

The Pap test should be scheduled between the patient's menstrual periods so that the menstrual flow does not interfere with laboratory analysis. Teach women not to douche, use vaginal medications or

deodorants, or have sexual intercourse for at least 24 hours before the test, because these may interfere with test interpretation.

The American Cancer Society (ACS) advises all women to begin having an annual Pap test at 21 years of age. Women younger than 21 years should not be tested (ACS, 2014a). Between ages 21 and 29 years, women should have a Pap test every 3 years; women between ages 30 and 65 years should have a Pap test plus a human papilloma virus (HPV) test ("co-testing") every 5 years. More information on the HPV test is found later in this chapter. In the absence of co-testing, this population should still have a Pap test every 3 years. According to the ACS, women older than 65 years who have had regular cervical cancer testing with normal results should not receive Pap tests (ACS, 2014a). Recommended guidelines from other health care organizations suggest a Pap test every 3 years for women older than 60 years. Those who have had a history of a serious cervical precancerous lesion should be tested annually for at least 20 years after that diagnosis, regardless of age (ACS, 2014a).

Other types of laboratory testing include cytologic vaginal *cultures*, which can detect bacterial, viral, fungal, and parasitic disorders. Examination of cells from the vaginal walls can evaluate estrogen balance.

The **human papilloma virus (HPV) test** can identify many high-risk types of HPV infection associated with the development of cervical cancer. This test can be done at the same time as the Pap test for women older than 30 years and for women of any age who have had an abnormal Pap test result (ACS, 2014a). It does not take the place of the Pap test because it tests for viruses that can cause cell changes in the cervix that, if not treated, could lead to cancer. Cells are collected from the cervix and sent to a laboratory for analysis. Women who have normal Pap test results and no HPV infection are at very low risk for developing cervical cancer. Conversely, women with an abnormal Pap test result and a positive HPV test are at higher risk if not treated.

Serum levels of follicle-stimulating hormone (FSH), luteinizing hormone (LH), and prolactin are helpful in the diagnosis of male and female reproductive tract disorders. No nutrition restrictions are necessary before the test. Serum testing can also detect estrogen, progesterone, and testosterone levels in men and women. See Chart 69-3 for normal values and the significance of abnormal findings.

Serologic studies detect antigen-antibody reactions that occur in response to foreign organisms. This form of diagnostic testing is helpful only after an infection has become well established. Serologic testing can be used in the evaluation of exposure to organisms causing syphilis, rubella, and herpes simplex virus type 2 (HSV2). Results may be read as

nonreactive, weakly reactive, or *reactive.* A single titer is not as revealing as serial titers, which can detect the rise in antibody reactions as the body continues to fight the infection (see Chapter 74).

The *prostate-specific antigen (PSA)* test is used to screen for prostate cancer and to monitor the disease after treatment. PSA levels less than 2.5 ng/mL may be considered normal, although there is no agreement on that value and how it is affected by age. Elevated PSA levels may be associated with prostate cancer. Older men, particularly African-American men, often have a higher normal PSA, especially as they age (Pagana & Pagana, 2014). Chapter 72 discusses this test in more detail.

NCLEX Examination Challenge

Health Promotion and Maintenance

A 27-year-old client asks the nurse if she needs a Pap smear. Her last Pap test was 2 years ago, and the results were normal. What is the appropriate nursing response?
A "Yes, you need a Pap test this year."
B "You are not due for another Pap test until next year."
C "A Pap smear is not needed unless you are sexually active."
D "You do not need a Pap smear, but you should have an HPV test."

Imaging Assessment

Computed Tomography.

CT scans for reproductive system disorders involve the abdomen and the pelvis. Health care providers can detect and evaluate masses and identify lymphatic enlargement from metastasis. This scan can differentiate solid tissue masses from cystic or hemorrhagic structures.

Hysterosalpingography.

A **hysterosalpingogram** is an x-ray that uses an injection of a contrast medium to visualize the cervix, uterus, and fallopian tubes (American Congress of Obstetricians and Gynecologists [ACOG], 2011). This test is used to evaluate tubal anatomy and patency and uterine problems such as fibroids, tumors, and fistulas. The study should not be attempted for at least 6 weeks after abortion, delivery, or dilation and curettage. Other contraindications include reproductive tract infection and uterine bleeding.

The examination is best performed in the first half (days 1-14) of the

patient's menstrual cycle, which reduces the chance that the patient may be pregnant (ACOG, 2011). Patients preparing to have a hysterosalpingogram should be instructed to follow the recommendations of their health care provider, which may include taking an over-the-counter pain reliever before the procedure (ACOG, 2011).

On the day of the examination, confirm the date of the patient's last menstrual period. Ask about allergies to iodine dye or shellfish. The health care provider will share benefits and risks of the procedure with the patient. You, as the nurse, may witness the signed informed consent. Be aware that the patient may experience some nausea and vomiting, abdominal cramping, or faintness during the procedure. Provide support and assistance with relaxation techniques as needed.

After the patient is placed in lithotomy position, the health care provider will insert a speculum to view the cervix. Dye is injected through the cervix to fill and highlight the interior of the cervix, uterus, and fallopian tubes. If the fallopian tubes are patent, the contrast material spills into the peritoneal cavity. Usually, only two or three views are obtained to show the path and distribution of the contrast medium.

The patient may experience pelvic pain after the study and should receive analgesic medications as ordered. Inform her that she may also have referred pain to the shoulder because of irritation of the phrenic nerve. Provide a perineal pad after the test to prevent soiling of clothes as the dye drains from the cervix. Instruct the patient to contact her health care provider if bloody discharge continues for 4 days or longer and to immediately report any signs of infection, such as lower quadrant pain, fever, malodorous discharge, or tachycardia.

Mammography.

Mammography is an x-ray of the soft tissue of the breast. Mammograms assess differences in the density of breast tissue. They are especially helpful in evaluating poorly defined masses, multiple masses or nodules, nipple changes or discharge, skin changes, and pain. Mammography can detect about 78% of cancers that are not palpable by physical examination in women younger than 50 years and 83% in women older than 50 years (Susan G. Komen, 2013). However, some actual cancers may not appear on mammography or may appear as benign (ACS, 2014b).

In young women's breasts, there is little difference in the density between normal glandular tissue and malignant tumors, which makes the mammogram less useful for evaluation of breast masses in these women. For this reason, annual screening mammograms are not recommended for women younger than 40 years (ACS, 2014b). In older

women, the amount of fatty tissue is higher and the fatty tissue appears lighter than cancers. Cancer and cysts may have the same density. Cysts usually have smooth borders, and cancers often have starburst-shaped margins.

No dietary restrictions are necessary before the mammogram. Remind the patient not to use creams, lotions, powders, or deodorant on the breasts or underarms before the study because these products may be visible on the mammogram and lead to misdiagnosis. If there is any possibility that the patient is pregnant, the test should be rescheduled. Explain the purpose of the study and its anticipated discomforts. Provide a gown and privacy to undress above the waist. Allow the patient to express concerns about the mammogram and the presence of any lumps.

When performing a standard mammogram, a technician positions the patient next to the x-ray machine with one breast exposed. A film plate and the platform of the machine are placed on opposite sides of the breast to be examined. The technician includes as much breast tissue as possible between the plates. The woman may experience some temporary discomfort when the breast is compressed (for about a minute for each of four positions). The entire test takes about 15 minutes. The patient usually is asked to wait until the films are reviewed in case a view needs to be repeated. If a digital mammogram is performed, the images are recorded and saved as computer files (ACS, 2014b).

Inform the patient when to expect the report of the results. Because this is a time when the patient is anxious about the health of her breasts, teach or reinforce the importance of breast self-awareness and provide instructions as needed.

Other Diagnostic Assessment

Ultrasonography.

Ultrasonography (US) is a technique that is used to assess fibroids, cysts, and masses. It can be used to monitor the progress of tumor regression after medical treatment. US is also helpful in differentiating solid tumors from cysts in breast examinations. In men, ultrasound can test for varicoceles, scrotal abnormalities, and problems of the ejaculatory ducts and seminal vesicles and the vas deferens (Pagana & Pagana, 2014).

For an abdominal, breast, or scrotal scan, the technician exposes the area and applies gel to the area to be scanned, which provides better transmission of sound waves from the transducer through the patient's skin. The transducer is moved in a linear pattern across the area being tested to outline and define soft-tissue masses and to differentiate tumor

type, ascites, and encapsulated fluid.

For a *transvaginal* or *transrectal* scan, the transducer is covered with a condom onto which transmission gel has been placed. The transducer is then inserted into the vagina or rectum as indicated. Women should have an empty or only partially filled bladder if they are having a transvaginal ultrasound. Patients having an internal ultrasound should be informed that they might feel some mild discomfort associated with pressure of the probe (Levin, 2012).

Magnetic Resonance Imaging.

MRI uses a magnetic field and radiofrequency energy to scan for pelvic tumors. This scan distinguishes between normal and malignant tissues. MRIs are used in addition to mammograms to assess for breast cancer in women who have a genetic risk (ACS, 2014c). The use of MRI in evaluating patients with dense breast tissue may reduce the need for biopsy.

Endoscopic Studies

Colposcopy.

A colposcope allows three-dimensional magnification and intense illumination of epithelium with suspected disease. **Colposcopy** is suited for inspection of a female patient's cervical epithelium, vagina, and vulvar epithelium. Because it provides accurate site selection, this procedure can locate the exact site of precancerous and malignant lesions for biopsy.

Inform the patient that she should not douche or use vaginal preparations for 24 to 48 hours before the test. This nearly painless procedure is better tolerated if it is explained in advance and if the actual colposcope instrument is shown to the patient. Explain that the health care provider may take a biopsy while performing colposcopy.

Provide the patient with a gown and privacy, and instruct her to undress from the waist down. Assist the patient to the lithotomy position. The health care provider locates the cervix or vaginal site through a speculum examination. Lubricants other than water should not be used. Cells in the area may be stained or left unstained to enhance visibility. The cervix will be cleaned and moistened with normal saline to increase the visibility of vascular patterns and the junction between the columnar epithelium and the squamous epithelium. Acetic acid is applied to the cervix to draw moisture from the tissue and to accentuate important features. The health care provider then uses a colposcope or colpomicroscope to inspect the area in question, and a biopsy specimen

can be taken if abnormal cells are seen. (See Cervical Biopsy section on p. 1458.)

After the procedure, allow the patient to rest for a few minutes, especially if she had a biopsy performed. Provide privacy and supplies to clean the perineum and a perineal pad to absorb any dye or discharge. Inform the patient that she may wish to wear a sanitary pad, as mild cramping, spotting, or dark or black-colored discharge (from medication applied to the cervix to reduce bleeding) may occur for several days (Johns Hopkins Medicine, 2014). Remind the patient to take pain relievers as recommended by her health care provider but to avoid aspirin to decrease the chance of bleeding. The patient should be instructed to refrain from douching, using tampons, and having sexual intercourse for 1 week (or as instructed by the health care provider) (Johns Hopkins Medicine, 2014).

Laparoscopy.

Laparoscopy is a direct examination of the pelvic cavity through an endoscope. This procedure can rule out an ectopic pregnancy, evaluate ovarian disorders and pelvic masses, and aid in the diagnosis of infertility and unexplained pelvic pain. Laparoscopy is also used during surgical procedures such as:

- Tubal sterilization
- Ovarian biopsy
- Cyst aspiration
- Removal of endometriosis tissue
- Lysis of adhesions around the fallopian tubes
- Retrieval of "lost" intrauterine devices

A laparoscopy may be used instead of a laparotomy for minor surgical procedures because it uses small incisions, involves less discomfort, and does not require overnight hospitalization.

The surgeon describes benefits and risks of the procedure to the patient. Risks include complications associated with the use of general anesthesia, postoperative shoulder pain from irritation of the phrenic nerve, effects of carbon dioxide gas and/or peritoneal stretching (Taş et al., 2013), irritation at the incision site, and the rare occurrence of infection or electrical burns. As the nurse, you may witness the patient signing the informed consent. A laparoscopy can be performed with a regional or general anesthetic.

After the patient is anesthetized and placed in the lithotomy position, a urinary catheter is inserted to drain the bladder. The operating table is placed in slight Trendelenburg position to allow the intestines to fall

away from the pelvis. The cervix is held with a cannula to allow movement of the uterus during laparoscopy (Fig. 69-4). The surgeon inserts a needle below the umbilicus to infuse carbon dioxide (CO_2) into the pelvic cavity, which distends the abdomen and permits better visualization of the organs. After the trocar and cannula are in place in the abdominal cavity, the surgeon removes the trocar and inserts the laparoscope. The surgeon can then visualize the pelvic cavity and reproductive organs. Further instrumentation is possible through one or more small incisions. The laparoscope is removed at the end of the procedure, and the abdomen is deflated. The small incision is closed with absorbable sutures and dressed with an adhesive bandage.

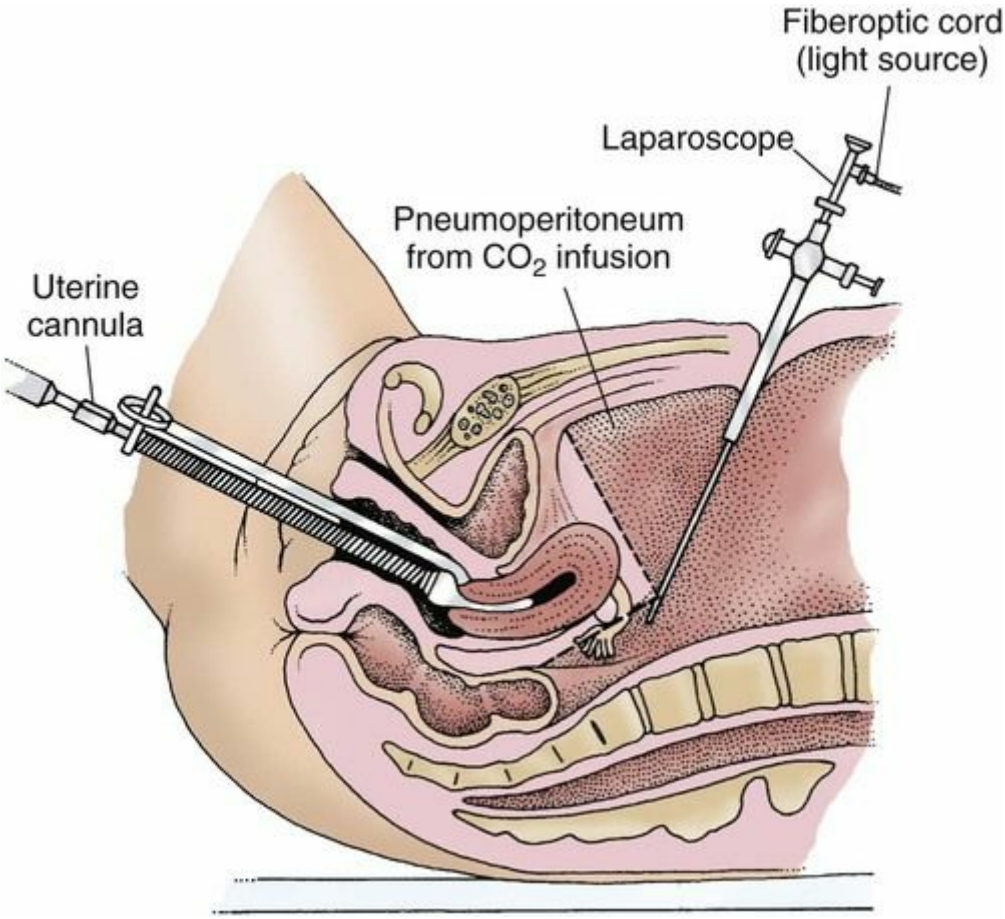

FIG. 69-4 Laparoscopy. CO_2, Carbon dioxide.

The patient is usually discharged on the day of the procedure. Discomfort from the incision is managed by oral analgesics. The greatest discomfort is due to referred shoulder pain. Most of these sensations disappear within 48 hours. Instruct the patient to change the small adhesive bandage as needed and to observe the incision for signs of infection or hematoma. Remind her also to avoid strenuous activity for the first week after the procedure.

Hysteroscopy.

Hysteroscopy is a procedure that uses a fiberoptic camera to visualize the uterus to diagnose and treat causes of abnormal bleeding (Cleveland Clinic, 2013). The hysteroscope includes a fiberoptic camera that is inserted into the vagina to examine the cervix and uterus. Diagnostic hysteroscopy is used to diagnose new problems with the uterus or to confirm results from other tests (Cleveland Clinic, 2013). Hysteroscopy can also be used before or during other procedures (e.g., laparoscopy) for infertility and unexplained bleeding. The procedure is best performed 5 days after menses has ceased to reduce the possibility of pregnancy.

The physician informs the patient of benefits and risks associated with the procedure and obtains consent. You may witness the patient signing the informed consent. The preparation is the same as for a pelvic examination. After the patient is placed in lithotomy position, she is usually anesthetized with a paracervical or other regional block before the cervix is dilated. The physician inserts the hysteroscope through the cervix. Because this distends the uterus, cells can be pushed through the fallopian tubes and into the pelvic cavity. Therefore hysteroscopy is contraindicated in patients with suspected cervical or endometrial cancer, in those with infection of the reproductive tract, and in pregnant patients.

Care is the same as that after a pelvic examination. Analgesics may be prescribed if the patient has cramping or shoulder pain.

Biopsy Studies

Cervical Biopsy.

In a cervical biopsy, cervical tissue is removed for cytologic study. A biopsy is indicated for an identifiable cervical lesion, regardless of the cytologic findings. The health care provider usually performs a biopsy in conjunction with colposcopy as a follow-up to a suspicious Pap test finding. The procedure may be performed in a clinic or office setting.

Several techniques can be used for a cervical biopsy. If a lesion is clearly visible, an endocervical curettage can be performed as an ambulatory care procedure and with little or no anesthetic. **Conization** (removal of a cone-shaped sample of tissue) and loop electrosurgical excision procedures (LEEPs) are usually not done unless the cervical biopsy findings are positive or the results of the colposcopy are unsatisfactory (Lowdermilk & Perry, 2014). Conization can be done as a cold-knife procedure, a laser excision, or an electrosurgical incision.

The biopsy is usually scheduled when the woman is in the early proliferative phase of the menstrual cycle, when the cervix is least vascular. Because a biopsy evaluates potentially cancerous cells, your patient may be anxious and need time to discuss her feelings and fears. The use of relaxation techniques may assist comfort. Assist her into the lithotomy position, recognizing that further preparation depends on the type of procedure to be performed.

The physician may anesthetize the patient according to the needs of the chosen procedure. He or she visualizes the cervix and obtains the tissue sample, which is immediately placed into a formalin solution. The type of anesthetic used for the procedure determines the type of immediate care that is needed after the procedure. Discharge instructions can be found in Chart 69-4.

Chart 69-4 Patient and Family Education: Preparing for Self-Management

The Patient Recovering from Cervical Biopsy

- Do not lift any heavy objects until the site is healed (about 2 weeks).
- Rest for 24 hours after the procedure.
- Report any excessive bleeding (more than that of a normal menstrual period) to your health care provider.
- Report signs of infection (fever, increased pain, foul-smelling drainage) to your health care provider.
- Do not douche, use tampons, or have vaginal intercourse until the site is healed (about 2 weeks).
- Keep the perineum clean and dry by using antiseptic solution rinses (as directed by your health care provider) and changing pads frequently.

Endometrial Biopsy.

Both endometrial biopsy and aspiration are used to obtain cells directly from the lining of the uterus to assess for cancer of the endometrium. Biopsy helps assess menstrual disturbances (especially heavy bleeding) and infertility (corpus luteum dysfunction).

When menstrual disturbances are being evaluated, the biopsy is generally done in the immediate premenstrual period to provide an index of progesterone influence and ovulation. A biopsy performed in the second half of the menstrual cycle (about days 21 and 22) evaluates corpus luteum function and the presence or absence of a persistent secretory endometrium. Postmenopausal women may undergo biopsies

at any time.

Menstrual data should be obtained from the patient and are included on the specimen request for the pathologist. Prepare the patient in the same way as you would for a pelvic examination. Advise her that she may experience some cramping when the cervix is dilated. Analgesia before the procedure and relaxation and breathing techniques during the procedure may be helpful to make her more comfortable.

An endometrial biopsy is usually done as an office procedure with or without anesthesia. After the uterus is measured and the cervix dilated, the physician inserts the curette or intrauterine cannula into the uterus. A portion of the endometrium is withdrawn using either the cuplike end of the curette or suction equipment and is placed into a formalin solution to be sent for histologic examination. The patient will likely have moderate cramping. Allow her to rest on the examining table until the cramping has subsided. Provide a perineal pad and a wipe to clean the perineum. Teach her that spotting may be present for 1 to 2 days but any signs of infection or excessive bleeding should be reported to the physician. Instruct the patient to avoid intercourse or douching until all discharge has ceased.

Breast Biopsy.

All breast masses should be evaluated for the possibility of cancer. It is important to recognize that breast cancer can occur in men as well as women (National Cancer Institute, 2014). Fibrocystic lesions, fibroadenomas, and intraductal papillomas can be differentiated by biopsy. Any discharge from the breasts is examined histologically.

Provide instructions to the patient depending on the type of biopsy performed and the type of anesthesia used. The patient usually receives a local anesthetic, and the tissue either is aspirated through a large-bore needle (core-needle biopsy) or is removed using a small incision to extract multiple samples of tissue.

Aspirated fluid from benign cysts may appear clear to dark green–brown. Bloody fluid suggests cancer. These specimens undergo histologic evaluation. If cancer is found, the tissue is evaluated for estrogen receptor analysis. Chapter 70 discusses types of breast cancer and their relationship to estrogen receptors.

Teach that discomfort after the procedure is usually mild and can be controlled with analgesics or the use of ice or heat, depending on the type and extent of the biopsy. Educate the patient about how to assess the area or incision for bleeding and edema. Tell women to wear a properly supportive bra continuously for 1 week after surgery or as recommended

by their surgeon. Remind the patient that numbness around the biopsy site may last several weeks. If cancer is identified, provide emotional support and reinforce information about follow-up treatment options.

Prostate Biopsy.

When prostate cancer is suspected, a biopsy must be performed. This can be done by transurethral biopsy, by inserting a needle through the area of skin between the anus and scrotum, or, most commonly, by transrectal biopsy (Mayo Clinic, 2013). Preparation for the procedure depends on the technique used to puncture the gland.

Explain to the patient that he may experience some discomfort. Teach him about breathing and relaxation techniques that may be helpful to use during the procedure. Because the purpose of this procedure is to evaluate prostate cells for cancer, allow him time to discuss his anxieties and fears.

Assist the patient who is undergoing transrectal biopsy into the side-lying position with his knees pulled up toward his chest (Mayo Clinic, 2013). The physician will cleanse the area, apply gel, and then insert a thin ultrasound probe into the patient's rectum to anesthetize (if needed) and guide the biopsy needle into place. The biopsy is collected over a 5- to 10-minute period. The patient may experience a brief, uncomfortable feeling each time the needle collects a sample.

After prostate biopsy, educate the patient to take the entire prescribed antibiotic. Remind him that he may experience slight soreness, light rectal bleeding, and blood in the urine or stools for a few days. Semen may be red or rust-colored for several weeks. Teach the patient to contact his health care provider if he has prolonged or heavy bleeding, worsening pain, swelling in the area of biopsy, and/or difficulty urinating (Mayo Clinic, 2013). Rarely, sepsis can develop after a prostate biopsy. Teach the patient to contact his health care provider immediately if he experiences fever, pain when urinating, or penile discharge.

NCLEX Examination Challenge

Physiological Integrity

A client has undergone a transrectal biopsy for suspected prostate cancer. The nurse teaches which postoperative condition should immediately be reported to the health care provider?

A Fever the next morning

B Blood in urine 1 day postprocedure

C Scant rectal bleeding for 2 days
D Reddish-tinted semen 3 weeks after biopsy

Nursing Concepts and Clinical Judgment Review

What might you EXPECT to see in a patient without reproductive health problems that affect sexuality?

Physical assessment:

- No vaginal bleeding other than normal menstruation
- No unusual vaginal discharge
- No penile bleeding or discharge
- No masses or lesions on internal or external genitalia
- Reports ability to have intercourse without pain

Psychosocial assessment:

- Reports satisfaction with sexual activity
- Reports satisfaction with body image

Laboratory assessment:

- Sex hormones within normal limits for age and gender
- Prostate-specific antigen within normal limits for age

Get Ready for the NCLEX® Examination!

Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

Health Promotion and Maintenance

- Encourage women to follow recommended Pap screening guidelines for early detection of precancerous and cancerous cells from the cervix. **Evidence-Based Practice** QSEN
- Assess and respect cultural preferences when identifying risks for certain reproductive problems and when evaluating health promotion practices. **Patient-Centered Care** QSEN

Psychosocial Integrity

- Allow the patient to express fear or anxiety regarding potential changes in sexual or reproductive function.
- Assess the patient's level of comfort in discussing issues related to reproductive health and sexuality. **Patient-Centered Care** QSEN
- Encourage patients to express feelings of anxiety or discomfort related to genital examinations and testing of the reproductive system.

Physiological Integrity

- Urge patients with pain, bleeding, discharge, masses, or changes in reproductive function to see their health care provider. **Safety** QSEN
- Provide privacy for patients undergoing examination or testing of the reproductive system.
- Recognize that reproductive changes occur with aging, as described in Chart 69-1.
- Recall the selected laboratory tests used for diagnosing reproductive health problems as outlined in Chart 69-3.
- Explain all diagnostic procedures, restrictions, and follow-up care to the patient scheduled for tests.
- Teach women to report symptoms of infection to their health care provider after endoscopic procedures and biopsies of the breast, cervix, and endometrium. **Safety** QSEN
- Instruct men to report symptoms of infection to their health care provider after a transrectal biopsy of the prostate. **Safety** QSEN

CHAPTER 70

Care of Patients with Breast Disorders

Mary Justice

PRIORITY CONCEPTS

- Infection
- Pain
- Sexuality

Learning Outcomes

Safe and Effective Care Environment

1. Collaborate with health care team members to identify community resources for patients with breast cancer.

Health Promotion and Maintenance

2. Describe the three-pronged approach to early detection of breast masses: mammography, clinical breast examination (CBE), and breast self-awareness.
3. Teach patients who choose breast self-examination (BSE) as an option to use correct technique.
4. Explain the options available to a person at high genetic risk for breast cancer.
5. Evaluate patient risk factors for breast cancer.

Psychosocial Integrity

6. Reduce the psychosocial impact for the patient and family who have received a diagnosis of breast cancer.
7. Discuss sexuality issues with the patient having breast surgery.
8. Describe body image changes that can result from breast cancer

surgery.

Physiological Integrity

9. Compare assessment findings associated with benign breast lesions with those of malignant breast lesions.
10. Explain implications of breast reduction and breast augmentation.
11. Discuss treatment options for breast cancer.
12. Develop a personalized postoperative collaborative plan of care for a patient with breast cancer, including pain management.
13. Describe the role of radiation and drug therapy in the care of patients with breast cancer.
14. Identify the role of complementary and alternative therapies in breast cancer management.
15. Explain evidence-based options that are available to a woman considering breast reconstruction.

 http://evolve.elsevier.com/Iggy/

Breast disorders may be benign or cancerous. Changes in the breast can cause a great deal of anxiety for women. An ever-increasing amount of health information is communicated through various types of media that often leads to anxiety and confusion about one's risk for breast cancer (Justice et al., 2012). As a result, many women seek advice for breast changes that they perceive to be abnormal. Nurses are often in the position of assisting patients by providing accurate information about benign breast disorders and breast cancer.

Benign Breast Disorders

Benign breast conditions are very common. Noncancerous changes to breast tissue can present as breast lumps, discomfort or pain, and nipple changes (Amin et al., 2013). Most breast lumps are benign. Because the incidence of breast disease is related to age, breast disorders are described below in an age-related order (Table 70-1).

TABLE 70-1

Typical Presentation of Benign Breast Disorders

BREAST DISORDER	DESCRIPTION	INCIDENCE
Fibroadenoma	Most common benign lesion; solid mass of connective tissue that is unattached to the surrounding tissue	During teenage years into the 30s (most commonly)
Fibrocystic breast condition	Breast pain and tender lumps; the lumps are rubbery, ill defined, and commonly found in the upper outer quadrant of the breast	Onset late teens and 20s; usually subsides after menopause
Ductal ectasia	Hard, irregular mass or masses with nipple discharge, enlarged axillary nodes, redness, and edema; difficult to distinguish from cancer	Women approaching menopause
Intraductal papilloma	Mass in duct that results in nipple discharge; mass is usually not palpable	Women 40 to 55 yr of age

Fibroadenoma

Fibroadenomas are the most common benign tumor in women during the reproductive years. However, they also may occur in a few postmenopausal women. A **fibroadenoma** is a mass of connective tissue that is unattached to the surrounding breast tissue and is usually discovered by the woman herself or during mammography. Although the immediate fear is that of breast cancer, the risk for cancer occurring within a fibroadenoma is very small. On clinical examination, the tumors are oval, freely mobile, and rubbery. Their size varies from smaller than 0.4 inch (1 cm) in diameter to as large as 6 inches (15 cm) in diameter.

Fibroadenomas may occur anywhere in the breast. The health care provider may request a breast ultrasound examination or may perform a needle aspiration to establish whether the lump is cystic (fluid-filled) or solid. If the lesion is solid, excision in an ambulatory care setting using local anesthesia is sometimes the treatment of choice.

Fibrocystic Breast Condition

Pathophysiology

Fibrocystic changes of the breast include a range of changes involving the lobules, ducts, and stromal tissues of the breast. Because these changes affect at least half of women over the life span, they are referred to as **fibrocystic breast condition (FBC)** rather than *fibrocystic disease*. This condition most often occurs in premenopausal women between 20 and 50 years of age and is thought to be caused by an imbalance in the normal estrogen-to-progesterone ratio. Typical symptoms include breast pain and tender lumps or swelling in the breasts. The symptoms are more noticeable before a woman's menstrual period (American Cancer Society [ACS], 2013a).

The two main features of FBC are fibrosis and cysts. Areas of fibrosis are made up of fibrous connective tissue and are firm or hard. Cysts are spaces filled with fluid lined by breast glandular cells. Microcysts are small, nonpalpable cysts inside the breast glands. Macrocysts occur when fluid continues to build up. They often enlarge in response to monthly hormonal changes, stretching the surrounding breast tissue, and become painful. Symptoms usually resolve after menstruation and then recur before the next menstrual period in a cyclic fashion. Breast ultrasound is used to confirm the presence of a cyst.

Postmenopausal women taking hormone replacement therapy (HRT) may develop FBC or experience worsening of symptoms. Having cysts or fibrosis does not increase a woman's chance of developing breast cancer. However, if a lump is very firm or has other features raising the concern about cancer, mammography is indicated. A needle biopsy or a surgical biopsy may be needed to make sure cancer is not present. Biopsy may be indicated in these situations:

- No fluid is aspirated.
- The mammogram shows suspicious findings.
- A mass remains palpable after aspiration.
- The aspirated fluid reveals cancer cells.

Symptoms often resolve after menopause when estrogen decreases.

Patient-Centered Collaborative Care

Management of FBC focuses on the symptoms of the condition. Suggest supportive measures for women with mild discomfort. The use of analgesics or limiting salt intake before menses to help decrease swelling may be helpful. Teach patients that wearing a supportive bra, even to bed, can reduce pain by decreasing tension on the ligaments. Local application of ice or heat may provide temporary relief of pain. For a

small number of women, draining the cysts by needle aspiration can help relieve painful symptoms. Many women find relief with the reduction of dietary caffeine and other stimulants, although research has not found stimulants to have a significant impact on FBC (ACS, 2013a).

In women with severe symptoms of FBC, hormonal drugs such as oral contraceptives or selective estrogen receptor modulators (SERMs) may be prescribed to suppress oversecretion of estrogen and correct luteal insufficiency. Vitamin supplements have also been suggested to relieve symptoms, but research has not consistently shown these to be effective; some may have dangerous side effects if taken in large doses. Diuretics may be prescribed to decrease premenstrual breast engorgement.

Nursing Safety Priority QSEN

Drug Alert

Explain to women the benefits and risks associated with hormonal drug therapy for FBC, such as stroke, liver disease, and increased intracranial pressure. Teach them to seek medical attention immediately if any signs or symptoms of these complications occur.

Encourage the patient to continue prescribed drug therapy, and monitor the effectiveness of these interventions. Teach the patient to become familiar with the normal feel and texture of her breasts so she is aware of any changes.

Ductal Ectasia

Ductal ectasia is a benign breast problem that is usually seen in women approaching menopause. It occurs when a breast duct dilates and its walls thicken, causing the duct to become blocked. The ducts in the subareolar area are most often affected. These ducts become distended and filled with cellular debris, which activates an inflammatory response. Two manifestations result from these changes:

- A mass develops that feels hard, has irregular borders, and may be tender.
- A greenish brown nipple discharge, enlarged axillary nodes, and redness and edema over the site of the mass are noted.

Ductal ectasia does not affect a woman's breast cancer risk. However, if a mass is present, it may be difficult to distinguish it from breast cancer. Because the risk for breast cancer is increased among women in the menopause age-group, accurate diagnosis is vital. A microscopic

examination of the nipple discharge is performed to detect any atypical or malignant cells, and the affected area is excised. Nursing care is directed at reducing the anxiety associated with the threat of breast cancer and at supporting the woman through the diagnostic and treatment procedures. Ductal ectasia may improve without treatment. Warm compresses and antibiotics may be helpful. If symptoms do not improve, the abnormal duct may be surgically removed.

Intraductal Papilloma

Intraductal papilloma occurs most often in women 40 to 55 years of age. A benign process in the epithelial lining of the duct forms a **papilloma** (pedunculated outgrowth of tissue). As it grows, trauma and erosion within the duct result in a bloody or serous nipple discharge. A mass is rarely palpable.

Diagnosis is aimed first at ruling out breast cancer. Microscopic examination of the nipple discharge and surgical excision of the mass and ductal area are usually indicated.

Issues of Large-Breasted Women

Although Western society emphasizes large breasts as a positive attribute, women with excessive breast tissue often have health problems and discomfort. For instance, a woman with large breasts may have difficulty finding clothes that fit well and in which she feels attractive. The breast size may be out of proportion to the rest of the body, which adds to the problem of finding clothes that fit. Larger bras are expensive and may need to be specially ordered. The woman may have large dents in the shoulders from bra straps. In addition, many large-breasted women develop fungal infections under the breasts, especially in hot weather, because it is difficult to keep this area dry and exposed to air.

Backaches from the added weight are also common. If well-fitting bras do not help and obesity is not part of the problem, the only alternative for this condition may be breast reduction surgery. The surgeon removes excess breast tissue and then repositions the nipple and remaining skin flaps to produce the best cosmetic effect. This operation is a major surgical procedure and is called a **reduction mammoplasty.**

The decision to have the procedure is usually made after years of living with the discomfort of excessive breast size. Listen to the woman verbalize her feelings, and reinforce information as appropriate. The nursing care after surgery is similar to that for the woman having reconstructive surgery. (See discussion of Breast Reconstruction, p. 1476,

in the Surgical Management section.)

Issues of Small-Breasted Women

Some women choose to have **breast augmentation** surgery to increase or improve the size, shape, or symmetry of their breasts. Most health insurers do not pay for this procedure. Most surgeries involve the implantation of saline-filled or silicon prostheses. Some are constructed from the women's own tissue in much the same way as for reconstruction after mastectomy. *Saline* implants are filled with sterile saline and can be filled with the amount needed to get the shape and firmness the woman wants. If the implant shell leaks, the saline will be safely absorbed by the body. *Silicone* implants are filled with an elastic gel, which can leak into the breast and will not be absorbed. The plastic surgeon reviews the advantages and disadvantages of each implant or natural procedure.

Nursing Safety Priority QSEN

Action Alert

Before breast augmentation surgery, teach the patient to stop smoking (to promote healing), avoid aspirin and other NSAIDs, and avoid herbs that can cause bleeding during the procedure, such as garlic, *Ginkgo biloba*, and ginseng. Tell her that the incisions will be hidden as much as possible, either under the pectoral muscle or directly behind the breast tissue as a submammary placement. One or more wound drains will be inserted during surgery, and she will need to know how to care for those drains at home. Review possible postoperative complications, including infection and implant leakage, which can cause severe pain and possible fever.

After surgery, the patient can be discharged to home the same day or the day after. Remind the family or significant other that someone should stay with her for at least 24 hours after surgery. The incisions may or may not have dressings depending on the surgeon and type of surgery.

Nursing Safety Priority QSEN

Action Alert

Remind the patient after breast augmentation that for the first few days she should expect soreness in her chest and arms. Her breasts will

feel tight and sensitive, and the skin over her breasts may feel warm or may itch. Teach the patient that she will have difficulty raising her arms over her head and should not lift, push, or pull anything until the surgeon permits. Teach her to also avoid strenuous activity or twisting above her waist. Remind the patient to walk every few hours to prevent deep vein thrombi. Tell her to expect some swelling of the breasts for 3 to 4 weeks after surgery.

An important issue for patients who have breast augmentation surgery is breast cancer surveillance. Breast self-examination (BSE) and clinical breast examination (CBE) can still be performed because the prosthesis is placed behind the woman's normal breast tissue, actually pushing it forward. However, screening mammography may not be as sensitive because the amount of visualized breast tissue is decreased. Additional x-rays, called *implant displacement views,* may be used to examine the breast tissue more completely (ACS, 2013a). Although there is no conclusive evidence that breast augmentation increases breast cancer risk, further research is needed regarding diagnosis and prognosis of breast cancer among women with cosmetic breast implants (Lavigne et al., 2013). Teach women desiring cosmetic breast augmentation about the differences in breast cancer screening.

Gynecomastia

Gynecomastia literally means "female breasts" and is a symptom rather than a disease. It is usually a benign condition of breast enlargement in *men* (Fig. 70-1). However, gynecomastia can be a result of a primary cancer such as lung or testicular cancer. The enlargement is usually bilateral but may be asymmetric in a few cases. The condition is caused by abnormal growth of the glandular tissue, including the mammary ducts and ductal tissue. In many instances it is difficult to determine gynecomastia from breast enlargement related to excess adipose tissue. Other causes of gynecomastia include:

FIG. 70-1 Gynecomastia.

- Drugs, such as anti-androgen agents and corticosteroids
- Aging
- Obesity
- Underlying disease causing estrogen excess, such as malnutrition, liver disease, or hyperthyroidism
- Androgen-deficiency states, such as age, chronic kidney disease, or alcoholism

Although gynecomastia is not common, men with abnormal breast findings, especially a breast mass, should be carefully evaluated for breast cancer.

Breast Cancer

Pathophysiology

Excluding skin cancers, breast cancer is the most commonly diagnosed cancer in women and is second only to lung cancer as a cause of female cancer deaths (ACS, 2013b). Therefore most references in this section are to women with breast cancer. Because of the high incidence of the disease, almost every woman knows of someone with the disease. Thus most women have strong reactions to the threat of breast cancer. These reactions greatly influence health habits, including breast self-examination (BSE) and the patient's readiness to seek care when a suspicious area is discovered. Nurses play a key role in early detection by educating women about screening guidelines, risk factors for breast cancer, and BSE. Men should also be taught about this disease.

Early detection is the key to effective treatment and survival. The 5-year relative survival rate is lower for women who are diagnosed with an advanced stage of breast cancer. The 5-year survival rate for localized breast cancer is 98.6%, whereas the rate drops to 83.8% when the cancer has spread to the regional lymph nodes (ACS, 2013b). Survival drops dramatically when breast cancer is metastatic (spread to distant sites).

Cancer of the breast begins as a single transformed cell that grows and multiplies in the epithelial cells lining one or more of the mammary ducts or lobules. It is a heterogeneous disease, having many forms with different clinical presentations and responses to therapy (Weigelt et al., 2010). Some breast cancers will present as a palpable lump in the breast, whereas others show up only on a mammogram.

There are two broad categories of breast cancer: noninvasive and invasive. About 20% are *noninvasive;* the remaining 80% are invasive. As long as the cancer remains within the duct, it is noninvasive. The cancer is classified as *invasive* when it penetrates the tissue surrounding the duct. Most of these cancers arise from the intermediate ducts. Metastasis occurs when cancer cells leave the breast via the blood and lymph systems, which permits spread of these cells to distant sites. The most common sites of metastasis are bone, lung, brain, and liver. The course of metastatic breast cancer is related to the site affected and to the function impaired. The processes involved in cancer development are described in Chapter 21.

Noninvasive Breast Cancers

Ductal carcinoma in situ (DCIS) is an early *noninvasive* form of breast

cancer. In DCIS, cancer cells are located within the duct and have not invaded the surrounding fatty breast tissue. Because of mammography screening and earlier detection, the number of women diagnosed with DCIS has increased. If left untreated, it is estimated that 14% to 53% of DCIS would become invasive and spread into the breast tissue surrounding the ducts over a period of 10 years (Morgan et al., 2011). Currently there is no way to determine which DCIS lesions will progress to invasive cancer and which ones will remain unchanged. This uncertainty causes anxiety and decisional conflict in many women diagnosed with DCIS. It is important to convey to patients the ways in which DCIS differs from invasive cancer and that DCIS cells lack the biologic capacity to metastasize.

Another type of noninvasive cancer is **lobular carcinoma in situ (LCIS).** This cancer is rare and occurs as an abnormal cell growth in the lobules (milk-producing glands) of the breast. It is not a true cancer, but having LCIS increases one's risk for developing a separate breast cancer later. It is usually diagnosed before menopause in women 40 to 50 years of age. Traditionally, LCIS is treated with close observation only. Women with LCIS and other breast cancer risk factors may want to consider prophylactic treatment options such as tamoxifen, raloxifene, or prophylactic mastectomy (ACS, 2013a).

Invasive Breast Cancers

The most common type of invasive breast cancer is **infiltrating ductal carcinoma.** As the name implies, the disease originates in the mammary ducts and grows in the epithelial cells lining these ducts. Once invasive, the cancer grows into the tissue around it in an irregular pattern. If a lump is present, it is felt as an irregular, poorly defined mass. As the tumor continues to grow, **fibrosis** (replacement of normal cells with connective tissue and collagen) develops around the cancer. This fibrosis may cause shortening of Cooper's ligaments and the resulting typical skin dimpling that is seen with more advanced disease (Fig. 70-2). Another sign, sometimes indicating late-stage breast cancer, is an edematous thickening and pitting of breast skin called *peau d'orange* (orange peel skin) (Fig. 70-3).

FIG. 70-2 Skin dimpling on a breast as a result of fibrosis or breast cancer.

FIG. 70-3 Breast edema giving the skin an "orange peel" *(peau d'orange)* appearance.

A rare but highly aggressive form of invasive breast cancer is **inflammatory breast cancer** (IBC). Symptoms include swelling, skin redness, and pain in the breasts. IBC seldom presents as a palpable lump and may not show up on a mammogram. Because it is usually diagnosed at a later stage than other types of breast cancer, it is often harder to treat successfully (ACS, 2013a).

Breast Cancer in Men

Male breast cancer is rare, occurring in fewer than 1% of all cases. The

average age of onset is 68 years (Mattarella, 2010). Causes are not completely understood, but there is a strong association between male breast cancer, family history, and genetic factors. (See discussion of genetic risk below.)

Men usually present with a hard, painless, subareolar mass; gynecomastia may be present. Occasionally the man may have nipple discharge, retraction, erosion, or ulceration. Because *men* usually do not suspect breast cancer when they feel a lump, diagnosis frequently is delayed (Mattarella, 2010). Thus men have a slightly lower overall survival than do women. However, there are more similarities than differences between male and female breast cancer (Greif et al., 2012). Treatment of breast cancer in men is the same as in women at a similar stage of disease.

Breast Cancer in Young Women

Media coverage and accounts of women with breast cancer often portray women younger than 60 years, misleading many to overestimate the incidence of breast cancer in younger women (National Breast Cancer Coalition [NBCC], 2012). Nevertheless, about 4.6% of breast cancer cases occur in women younger than 40 years (ACS, 2013b). Genetic predisposition is a stronger risk factor for younger women than older women (Pollán, 2010). Younger women frequently present with more aggressive forms of the disease, and the number of cases of advanced breast cancer in younger women is increasing (Johnson et al., 2013). Screening tools can be less effective for this group because the breasts are denser; therefore regular screening mammograms before the age of 40 years are not recommended for average-risk women (ACS, 2013a). Nurses should encourage women who have symptoms to seek evaluation and not watch and wait. Younger women with breast cancer face unique issues associated with treatment. These include surgical menopause, infertility after treatment, and sexual dysfunction (Kedde et al., 2013).

Etiology and Genetic Risk

There is no single known cause for breast cancer. *Being an older woman or man is the primary risk factor, although some people are at higher risk than others.* Several breast cancer risk factors have been identified; some are modifiable, whereas others are not (ACS, 2013b). Risk factors have varying degrees of influence on breast cancer development. Having several risk factors increases one's risk more than having a single risk factor. Table 70-2 lists major breast cancer risk factors according to the varying degree of risk. Assist women to clarify that not all risk factors are

the same.

TABLE 70-2
Risk Factors for Breast Cancer

FACTORS	COMMENTS
High Increased Risk (Relative Risk >4.0)	
Female gender	Ninety-nine percent of all breast cancers occur in women.
Age >65 years	Risk increases across all ages until age 80 years.
Genetic factors	Inherited mutations of *BRCA1* and/or *BRCA2* increase risk.
History of a previous breast cancer	The risk for developing a cancer in the opposite breast is 5 times greater than for the average population at risk.
Breast density	Dense breasts contain more glandular and connective tissue, which increases the risk for developing breast cancer.
Atypical hyperplasia	Biopsy-confirmed atypical hyperplasia is a high relative risk.
Moderate Increased Risk (Relative Risk 2.1–4.0)	
Family history	Two first-degree relatives with breast cancer increases risk.
Ionizing radiation	Women who received frequent low-level radiation exposure to the thorax had an increased risk, especially if the exposure occurred during periods of rapid breast formation.
High postmenopausal bone density	High estrogen levels over time both strengthen bone and increase breast cancer risk.
Low Increased Risk (Relative Risk 1.1–2.0)	
Reproductive history Nulliparity OR First child born after age 30 years	Childless women have an increased risk, as do women who bear their first child near or after age 30.
Menstrual history Early menstruation OR Late menopause OR Both	The risk for breast cancer rises as the interval between menarche and menopause increases. Women who undergo bilateral oophorectomy before age 35 years have less risk for breast cancer than women who undergo natural menopause.
Recent oral contraceptive use	There is a slight increase in breast cancer risk in women taking oral contraceptives. The risk returns to normal after 10 years of stopping the pill.
Recent hormone replacement therapy (HRT)	Use of HRT containing both estrogen and progestin increases risk; risk diminishes after 5 years of discontinuation.
Obesity	Postmenopausal obesity (especially increased abdominal fat), increased body mass, insulin resistance, and hyperglycemia have been reported to be associated with an increased risk for breast cancer.
Other Risk Factors	
Alcohol	Risk is dose-dependent; consumption of 3 to 14 drinks per week is associated with a slight increase in risk; risk increases with increased consumption.
High socioeconomic status	Breast cancer incidence is greater in women of higher education and socioeconomic background. This relationship is possibly related to lifestyle differences, such as later age at first birth.
Jewish heritage	Women of Ashkenazi Jewish heritage have higher incidences of *BRCA1* and *BRCA2* genetic mutations.

Modified from American Cancer Society. (2013). *Breast cancer facts & figures 2011-2012.* Atlanta: Author.

Genetic/Genomic Considerations

Patient-Centered Care QSEN

Mutations in several genes, such as *BRCA1* and *BRCA2*, are related to hereditary breast cancer. People who have specific mutations in either one of these genes are at a high risk for developing breast cancer as well as ovarian cancer. However, only 5% to 10% of all breast cancers are hereditary. Only women with a strong family history and a reasonable

suspicion that a mutation is present have genetic testing for *BRCA* mutations (ACS, 2013a). Encourage women to talk with a genetics counselor to carefully consider the benefits and potential harmful consequences of genetic testing before these tests are done.

Knowledge of modifiable risk factors can help women develop strategies for prevention of breast cancer. These include avoiding weight gain and obesity, engaging in regular physical activity, and minimizing alcohol intake. Breast-feeding for a year or more has been shown to have a protective influence on breast cancer as does avoidance of hormone replacement therapy (HRT) for menopausal symptoms. Encourage women seeking help for menopausal symptoms to discuss the benefits and risks of hormonal therapy with their health care provider. Environmental causes of breast cancer are the subject of increasing research and concern for many women. Environmental estrogens found to influence breast cancer development in animals include DDT found in pesticides, perfluorooctanoic acid (PFOA) found in nonstick cookware, and bisphenol A (BPA) found in plastic food containers. More research is needed to discover the effect of these chemicals on human breast cancer (Schmidt, 2012), but many women are choosing to avoid them as a precaution. (See the Evidence-Based Practice box.)

Evidence-Based Practice QSEN

Does Night-Shift Work Increase the Risk for Breast Cancer?

Kamdar, B., Tergas, A., Mateen, F., Bhayani, N., & Oh, J. (2013). Night-shift work and risk of breast cancer: A systematic review and meta-analysis. *Breast Cancer Research and Treatment, 138*(1), 291-301.

Researchers conducted a systematic review and meta-analysis of studies examining night-shift work and its relationship with breast cancer. Previous studies have suggested that night-shift workers, such as flight attendants and nurses, may lack adequate melatonin, which may contribute to an increase in breast cancer risk. Fifteen studies were included in the analysis. The researchers determined that the findings of these studies were limited due to unmeasured confounding and substantial heterogeneity observed among the studies. They concluded there is weak evidence to support previous findings that night-shift work is associated with an increased breast cancer risk.

Level of Evidence: 1

The study utilized a systematic review of the literature and meta-analysis

of multiple studies to make conclusions.

Commentary: Implications for Practice and Research

Nurses should be aware of the validity of publicized studies as well as ongoing research in this area. This meta-analysis found lack of consistencies among studies about shift work and breast cancer risk. Future studies involving large sample sizes and diverse occupational and geographic populations are necessary. The increasing number of around-the-clock workers raises important public health and policy issues.

Incidence and Prevalence

The American Cancer Society estimated the incidence of breast cancer in the United States to be 232,340 in 2013. Breast cancer is the second leading cause of cancer death in women, exceeded only by lung cancer, and 39,629 are likely to die of the disease (ACS, 2013b).

Cultural Considerations

Patient-Centered Care QSEN

One of every 8 women in the United States will develop breast cancer by age 70 years. Euro-American women older than 40 years are at a greater risk than other racial/ethnic groups, but the rate of breast cancer in African-American women *younger than 40 years* is higher than for others in that age-group. African-American women have a higher death rate at any age when compared with other women with the disease (ACS, 2013b). Cultural disparities with regard to breast cancer stage and mortality are persistent. Ooi et al. (2011) found that non-Hispanic white women are more likely to present with an earlier-stage breast cancer than American-Indian/Alaska-Native, Asian-Indian/Pakistani, Black, Filipino, Hawaiian, Mexican, Puerto Rican, and Samoan women. These groups are also more likely to present with more aggressive breast cancer that is harder to treat, such as *triple negative breast cancer.* In this type of breast cancer, cells lack receptors for estrogen, progesterone, and the protein *HER2.* African-American and Puerto Rican women have the highest risk for triple negative breast cancer. Breast cancer death rates are highest in African-American, Hawaiian, Puerto Rican, and Samoan women. Cultural disparities should be addressed with targeted interventions that are appropriate for specific cultural and ethnic groups. Nurses need to be culturally competent to assist women to

overcome barriers to care.

NCLEX Examination Challenge

Health Promotion and Maintenance

The nurse is caring for four clients. Which client does the nurse recognize as having the highest risk for development of breast cancer?
A 45-year-old male with gynecomastia
B 40-year-old female whose father had colon cancer
C 50-year-old male whose mother had ovarian cancer
D 65-year-old female with history of a prior episode of breast cancer

Health Promotion and Maintenance

The American Cancer Society (ACS) establishes evidence-based guidelines for breast cancer screening in women. Guidelines have not been recommended for screening men in the general population because breast cancer in men is so uncommon (ACS, 2013a). Encourage men with a strong family history or known genetic mutations to discuss screening with their health care provider.

The ACS recommendation for early detection by screening for breast masses is a screening mammogram for women ages 40 years and older and a clinical breast examination (CBE) by a health care professional at least every 3 years for women 20 to 40 years old. Monthly breast self-examination (BSE) is less emphasized today than in the past several decades. It is recommended as an option to women to increase breast self-awareness beginning at age 20.

Nursing Safety Priority QSEN

Action Alert

Teach women that no single method for early detection of breast cancer is effective when used alone. The best approach for average-risk women is screening mammogram, clinical breast examination, and breast self-awareness.

Mammography

The use of mammography (x-ray of the breasts) screening for healthy, average-risk women continues to be studied for its effectiveness. In 2009, the U.S. Preventive Services Task Force (USPSTF) recommended raising

the screening age for average-risk women from 40 to 50 years (USPSTF, 2009). Scientific evidence shows there are benefits as well as risks associated with mammography, and disagreement exists about the emphasis that should be placed on each one. However, the ACS and The American College of Obstetricians and Gynecologists (ACOG) continue to recommend that all women ages 40 years and older have a screening mammogram annually (ACOG, 2011). Educate women on the advantages and disadvantages of breast screening techniques so that they can make informed decisions about the screening methods best suited to their individual situations (Association of Women's Health, Obstetric, and Neonatal Nursing [AWHONN], 2010).

According to guidelines of the American Society of Clinical Oncology, women who are asymptomatic following breast cancer treatment should be screened with annual mammograms, without additional tests (Khatcheressian et al., 2013). A small number of women who have known genetic mutations and/or other high risk factors for breast cancer should have screening with MRI in addition to annual mammography (ACS, 2013a). Encourage women with moderate risk factors to discuss with their health care provider the benefits and limitations of adding MRI screening to their annual mammograms. MRI screening is not recommended for women with low breast cancer risk factors.

Breast ultrasound is sometimes used in addition to mammography when problems are found during routine screening and for some women with dense breast tissue. Although the use of ultrasound has added benefits over mammography alone, it is not recommended as part of routine breast cancer screening for women who are average risk for breast cancer (ACS, 2013a).

Breast Self-Awareness/Self-Examination

Nurses working with women should teach them the importance of becoming familiar with the appearance and feel of their breasts. Any changes detected by the woman should be reported to her health care provider. Teach a woman that lumps are not necessarily abnormal. For premenopausal women, lumps can come and go with the menstrual cycle. Most lumps that are detected and tested are not cancerous.

Some women may want to practice regular breast self-examination (BSE) as a method for breast self-awareness. Evidence shows that monthly BSE is no more beneficial than women simply being aware of what is normal for their own breasts and women are just as likely to find a lump by chance (ACS, 2013a). However, BSE should be presented as an option to women beginning in their early 20s. In addition to breast self-

awareness, emphasis should be placed on mammography and clinical breast examination for early detection of breast cancer. The combined approach is better than any single test (ACS, 2013a). A woman who chooses to perform BSE should be taught the correct technique and have it reviewed by a health care professional during her clinical breast examination.

The BSE technique is similar for women and men. Use teaching models of normal and abnormal breasts when teaching BSE. Discuss the proper timing for BSE. Instruct premenopausal women to examine their breasts 1 week after the menstrual period. At this time, hormonal influence on breast tissue is decreased, so fluid retention and tenderness are reduced. Teach women whose breast tissue is no longer influenced by hormonal fluctuations, such as after a total hysterectomy or menopause, to pick a day each month to do BSE, such as the first day of the month. Chart 70-1 describes the procedure for breast self-examination and may be used as a patient resource.

Chart 70-1

Best Practice for Patient Safety & Quality Care QSEN

Performing Breast Self-Examination

1. Lie down on your back, and place your right arm behind your head. Lying down spreads the breast tissue evenly over the chest wall, making it easier to feel all the breast tissue.
2. Use the finger pads of the three middle fingers on your left hand to feel for lumps in the right breast. Use overlapping dime-size circular motions of the finger pads to feel the breast tissue.
3. Use three different levels of pressure to feel all the breast tissue. Light pressure is needed to feel the tissue closest to the skin; medium pressure to feel a little deeper; and firm pressure to feel the tissue closest to the chest and ribs. It is normal to feel a firm ridge in the lower curve of each breast.
4. Move around the breast in an up-and-down pattern starting at an imaginary line drawn straight down your side from the underarm and moving across the breast to the middle of the chest bone (sternum or breastbone). Be sure to check the entire breast area going down until you feel only ribs, and up to the neck.
5. Repeat the exam on your left breast, putting your left arm behind your head and using the finger pads of your right hand to do the exam.
6. While standing in front of a mirror with your hands pressing firmly

down on your hips, look at your breasts for any changes of size, shape, contour, or dimpling and look at your nipples and breast skin for redness or scaling. (The pressing-down-on-the-hips position contracts the chest wall muscles and enhances any breast changes.)

7. Examine each underarm while sitting up or standing and with your arm only slightly raised so you can easily feel in this area. Raising your arm straight up tightens the tissue in this area and makes it harder to examine.

Adapted from the American Cancer Society. (2013). *Detailed guide: How to examine your breasts.* Atlanta: Author. Available from www.cancer.org.

Clinical Breast Examination

Clinical breast examination (CBE) is typically performed by advanced practice nurses and other health care providers. Clinicians who perform CBE ideally go through simulation training and exposure to patients to become proficient at the technique (Bryan & Snyder, 2013). It is recommended that the CBE be part of a periodic health assessment, at least every 3 years for women in their 20s and 30s, and every year for asymptomatic women at least 40 years of age (ACS, 2013a). Teach patients what to expect during this examination. First, they will be asked to undress from the waist up. The examiner inspects the breasts for abnormalities in size and shape and for skin and nipple changes. Then, using the pads of the fingers, the examiner palpates the breasts for any lumps and, if present, whether such lumps are attached to the skin or deeper tissues. The area under both arms is also examined.

Considerations for Older Adults

Patient-Centered Care QSEN

As women age, the breast tissue becomes flattened and elongated and is suspended loosely from the chest wall. On palpation, the breast tissue of the older woman has a finer, more granular feel than the lobular feel in a younger woman. The inframammary ridge may be more prominent as a result of atrophy of the breast tissue. Breast examination in older adults may be easier because of tissue atrophy and relaxation of the suspensory ligaments.

Women in nursing homes and other long-term care facilities often do not have clinical breast examinations and may not be deliberately aware of the normal appearance and feel of their breasts. Teach the importance of breast self-awareness and reporting any breast changes the woman may notice. Teach BSE as an option for older women who are comfortable with and able to perform this method. Collaborate with the health care provider to ensure that residents have clinical breast examinations.

Options for High-Risk Women

Women with a personal history of breast cancer are at risk for developing a recurrence or a new breast cancer. Those with known *BRCA1* and *BRCA2* genetic mutations, strong family history, or other high-risk factors are also considered high-risk. Women in this category usually practice *close surveillance* as a prevention option. It is referred to as "secondary prevention" and is used to detect cancer early in the initial stages. In

addition to annual mammography and clinical breast examination, high-risk women are recommended to have an annual breast MRI screening (ACS, 2013a). Close surveillance may begin as early as age 30 years, but evidence is limited regarding the best age at which to start screening. Encourage high-risk women to discuss their personal preferences for close surveillance with their health care providers.

Options currently available for reducing a woman's breast cancer risk are **prophylactic mastectomy** (preventive surgical removal of one or both breasts), prophylactic **oophorectomy** (removal of the ovaries), and anti-estrogen chemopreventive drugs. Although each option significantly reduces the risk for breast cancer, no option completely eliminates it. Each option has its own risks and potentially serious complications.

Even though a woman may decide to have a *prophylactic mastectomy,* there is a small risk that breast cancer will develop in residual breast glandular tissue because no mastectomy reliably removes all mammary tissue. Women must also understand that breast reconstruction after a prophylactic mastectomy is very different from breast augmentation. It is a more complex surgical procedure with a greater potential for complications. The decision to have this type of surgery can be a very difficult one to make. Women may find it helpful to reach out to a breast cancer support organization and talk to someone who has been through a prophylactic mastectomy. The majority of patients express long-term satisfaction with this surgical procedure (Soran et al., 2013).

Women undergoing *oophorectomy* will likely experience menopausal symptoms, although some estrogen remains in body fat tissue. *Anti-estrogen drugs* reduce breast cancer recurrence but carry other risks such as blood clots and endometrial cancer. Encourage women to carefully consider the benefits and risks of breast cancer–risk-reducing options and to discuss them with their health care provider.

Patient-Centered Collaborative Care

Assessment

History.

Often the history is taken after a mass has been discovered but before a diagnosis has been made for a woman or man with breast cancer. For some patients, the history may be obtained at the time they are seen for treatment of an identified cancer. The interview should focus on three major areas: risk factors, the breast mass, and health maintenance practices.

Record age, gender, marital status, weight, and height. Marital status and identifying the patient's primary support person provide information about who should be included in the patient's care, teaching, and support.

Cultural Considerations

Patient-Centered Care QSEN

Remember that some cultures do not allow the man to be part of a woman's care or only women are allowed to care for her (e.g., Arab Muslim women). Other cultures are male-predominant and all decisions about female care are made by the man (e.g., Nigerian women).

Ask specific information on personal and family histories of breast cancer. In addition to increasing the woman's own risk, these factors also affect any sisters' or daughters' risk and should be part of later counseling.

Ask about the woman's gynecologic and obstetric history, including:

- Age at menarche
- Age at menopause
- Symptoms of menopause
- Age at first child's birth
- Number of children/pregnancies

Prolonged hormonal stimulation (e.g., early menses, late menopause) increases a woman's risk, as do birth of the first child after 30 years of age and nulliparity (having no children).

A history of the breast mass or lump reveals not only the course of the disease but also information related to health care–seeking practices and health-promoting behaviors. Ask the patient about how, when, and by whom the mass was discovered and the time between discovery and seeking care. If the patient found the mass, ask how it was discovered. The answer to this question reveals the need for discussion and teaching about health promotion practices, regardless of whether the mass proves to be cancerous. If there was a delay between discovery and seeing the health care provider, ask what caused the delay. These questions are linked to the psychosocial assessment but also reveal the length of time that the tumor has been present. Ask what procedures have been performed to diagnose the problem. Also, ask patients if they have noticed any other changes in their body within the past year. This information can help determine whether there has been obvious cancer

spread. Ask especially about the presence of joint or bone pain.

Ask about the use of alcohol intake, because this is a factor that may increase breast cancer risk. Ask what prescribed and over-the-counter (OTC) drugs are used—specifically, hormonal supplements such as estrogen and natural or herbal substances that stimulate hormones. Estrogen can be taken orally, intravaginally, or via a transdermal patch. Document the type and form of hormones (birth control pills or patches, supplements) and length of use.

Physical Assessment/Clinical Manifestations.

Document in the electronic medical record any abnormal findings from the clinical breast examination. Describe specific information about a breast mass (Chart 70-2) such as location, using the "face of the clock" method; shape; size; consistency; and whether the mass is mobile or fixed to the surrounding tissue. Note any skin change, such as *peau d'orange* (dimpling, orange peel appearance), redness and warmth, nipple retraction, or ulceration, which can indicate advanced disease. Document the location of any enlargements of axillary and supraclavicular lymph nodes. Evaluate the presence of pain or soreness in the affected breast.

Chart 70-2 Best Practice for Patient Safety & Quality Care QSEN

Assessing a Breast Mass

- Identify the location of the mass by using the "face of the clock" method.
- Describe the shape, size, and consistency of the mass.
- Assess whether the mass is fixed or movable.
- Note any skin changes around the mass, such as dimpling *(peau d'orange)*, increased vascularity, nipple retraction, and ulceration.
- Assess the adjacent lymph nodes—both axillary and supraclavicular nodes.
- Ask patients if they experience pain or soreness in the area around the mass.

Psychosocial Assessment.

A breast cancer diagnosis is usually an unanticipated event in the life of a woman who feels physically well. It initiates a sudden and distressing transition into a potentially life-threatening illness. Feelings of fear, shock, and disbelief are predominant as a woman learns about her

disease and faces numerous treatment decisions. Psychological distress is common at cancer diagnosis and at the end of treatment. A previous history of mental illness, age, and life circumstances can contribute to increased psychological distress (Williams, 2012). Encourage expression of feelings, and determine if a referral to a breast cancer support group would be helpful. Talking with someone who has been through the experience is particularly helpful in dealing with the emotional aspects of the disease.

Assess the patient's need for information. Some people may not be ready for a lot of information at first. Most want to know how advanced the disease is, the likelihood of cure, treatment options and side effects, how treatment will affect their life and self-image, how family or partners will be affected, and what is required for home self-management. A previous experience with cancer, especially with other people who had breast cancer, influences the reactions to the disease. Ask patients and family members whether they have known anyone with breast cancer, and explore their feelings about the disease. The Internet is a primary source of information through which breast cancer information is sought and shared. Increasingly, the information on the Internet is provided by patients themselves (Quinn et al., 2013). Clarify health information the patient has received on the Internet, and provide current information about the stage of the disease and treatment options.

Assess the patient for problems related to sexuality. Sexual dysfunction affects most breast cancer survivors in some way. Sometimes the sexual dysfunction is related to the loss of a breast and the threat to one's femininity, but many women also equate a breast cancer diagnosis and treatment effects with the aging process (Klaeson et al., 2011). Lack of libido (sexual desire) related to hormonal changes, psychological distress, and severe anxiety is commonly experienced by women with breast cancer. If the patient does not discuss sexual concerns voluntarily, ask about the frequency of and satisfaction with sexual relations with her partner. Use resources that provide education about alternative expressions of intimacy and a focus on pleasure rather than performance. Refer the patient and her partner to counseling if appropriate.

Gender Health Considerations

Patient-Centered Care QSEN

Research is limited about breast cancer and women who identify as lesbian, but it is thought that breast cancer is more common in this group (Beredjick, 2012). A possible explanation is that risk factors for

breast cancer, such as smoking, alcohol use, obesity, and infrequent pregnancy, are more common in this group (ACS, 2013a). Lesbian and bisexual women are less likely to have health insurance and get regular cancer screenings (see Chapter 73). Factors include fear and distrust of culturally incompetent health care providers. They may also be less focused on their breasts and breast cancer risk. Nurses' awareness and sensitivity to these issues help establish trust. Emphasize the importance of screening and early detection. Assess the need for referrals to support organizations such as the National LGBT Cancer Network (2013).

Laboratory Assessment.

The diagnosis of breast cancer relies on pathologic examination of tissue from the breast mass. After the diagnosis of cancer is established, laboratory tests, including pathologic study of the lymph nodes, help detect possible metastases. Elevated liver enzyme levels indicate possible liver metastases, and increased serum calcium and alkaline phosphatase levels suggest bone metastases.

Imaging Assessment.

Mammography is a sensitive screening tool for breast cancer. The uniqueness of this test results from its ability to reveal preclinical lesions (masses too small to be palpated manually). Most breast centers now use *digital mammography*—a system that is able to read, file, and transmit mammograms electronically. Women should be screened with mammography annually beginning at age 40 years (ACS, 2013a). Patient preparation and the procedure for mammography are discussed in Chapter 69. Some women may voice concern about radiation exposure with mammograms. Reassure them the dose is very small and the risk for harm from radiation is minimal (ACS, 2013b). Breast *tomosynthesis* is an emerging technology that is similar to mammography but uses three-dimensional images. It has the potential to improve detection of breast cancer by better differentiating suspicious from normal tissue (Alakhras et al., 2013). Although tomosynthesis has been approved by the Food and Drug Administration (FDA), its role in breast cancer screening and diagnosis has not yet been established (ACS, 2013a).

Ultrasonography of the breast is an additional diagnostic tool used to clarify findings on mammography. If the mammogram reveals a lesion, ultrasonography is helpful in differentiating a fluid-filled cyst from a solid mass. Mammography screening combined with ultrasound may be

effective for detecting cancers in women with dense breasts, but currently it is not recommended for routine breast cancer screening (ACS, 2013a).

MRI is used for screening high-risk women and better examination of suspicious areas found by a mammogram (ACS, 2013b). MRI is more expensive than mammography. Most insurance companies will cover a portion of the cost if the woman is shown to be high risk. Although higher-quality images are produced, there is concern about high costs and access to quality breast MRI services for high-risk women (ACS, 2013b).

If the patient has an invasive breast cancer, other imaging tests may be done to rule out metastases. A chest x-ray is done to screen for lung metastases. Bone, liver, and brain scans and CT scans of the chest and abdomen can reveal distant metastases.

Other Diagnostic Assessment.

Whereas imaging techniques serve as tools for screening and more precise visualization of potential breast cancers, *breast biopsy (pathologic examination of the breast tissue) is the only definitive way to diagnose breast cancer.* Breast tissue is obtained by one of several types of biopsies (see Chapter 69). Tissue samples are analyzed by a pathologist to determine the presence of breast cancer. If breast cancer is identified, it is classified according to the size and type of breast cancer, the histologic grade, and the type of receptors on the cells. These characteristics are used to guide treatment. For example, a small, noninvasive breast cancer may be treated only with lumpectomy and radiation, whereas a larger, aggressive tumor (one with a high histologic grade) may be treated with a mastectomy and chemotherapy, followed by radiation. Cancer cells that contain estrogen receptors (*ER positive*) or progesterone receptors (*PR positive)* have a better prognosis and usually respond to hormonal therapy. If the type of breast cancer is *HER2,* or one in which the *neu* gene product is overexpressed, it may be treated successfully with trastuzumab (Herceptin), which is a breast cancer *targeted therapy* for this specific type.

Most women, even those with very small tumors, receive some sort of treatment in addition to surgery for breast cancer. Research has focused on ways to predict clinical outcomes so that low-risk women may avoid unnecessary treatments. Gene expression profiling systems, such as Oncotype DX and MammaPrint, have been developed to help predict clinical outcomes by analyzing genes in breast cancer tissue. Some clinicians use this information in addition to the pathologic analysis for

guiding treatment decisions. These multi-gene tests have been shown to be accurate predictors of patient prognosis and response to therapy in breast cancer (Jankowitz & Lee, 2013). Their role in clinical practice continues to evolve.

Analysis

The priority NANDA-I nursing diagnoses and collaborative problems for patients with breast cancer include:
1. Ineffective Coping related to unanticipated breast cancer diagnosis (NANDA-I)
2. Potential for metastasis of cancer to other parts of the body

Planning and Implementation

Developing Coping Strategies

Planning: Expected Outcomes.

The patient with breast cancer is expected to report the use of methods to help increase coping ability and reduce anxiety. The patient will maintain relationships and participate as an active partner in management of her disease.

Interventions.

The anxiety and uncertainty for the patient with breast cancer begin the moment a lump is discovered or when a mammogram reveals an abnormality. These feelings may be related to past experiences and personal associations with the disease. Assess the patient's perceptions of his or her own situation. Allow the patient to ventilate these feelings even if a diagnosis has not been established.

If the mass has been diagnosed as cancer, many people feel a partial sense of relief to be dealing with a known entity. A feeling of shock or disbelief usually occurs. It is difficult to accept a diagnosis of cancer when one feels basically well. Patients and their families or significant others deal in individual ways with the mix of feelings. Flexibility is the key to nursing care. Adjust your approach to care as the patient's emotional state changes. Those who have an interval between the diagnosis and treatment during which they actively participate in the choice of treatment cope more effectively after surgery, no matter which treatment is chosen.

An integral part of the plan to meet these emotional needs is the use of outside resources. Health care providers working with breast cancer may

know other patients willing to make a preoperative visit. For example, the patient who is worried in particular about the side effects of radiation therapy may benefit more from talking to someone who has undergone radiation than from talking to the nurse or health care provider. Be sure to assess his or her preference.

Assess the patient's need for knowledge. Some may want to read and discuss any available information. Provide accurate information, and clarify any misinformation the patient may have received by the media, on the Internet, or from family and friends. The American Cancer Society (www.cancer.org) and Breastcancer.org (www.breastcancer.org) are two Internet sources that provide evidence-based information in language a lay person can understand.

Nursing Safety Priority QSEN

Action Alert

Women are exposed to many misconceptions and much misinformation about breast cancer through various media. Clarify misconceptions and provide current information regarding risk factors, screening recommendations, and treatment for breast cancer.

Decreasing the Risk for Metastasis

Planning: Expected Outcomes.

The patient with breast cancer is expected to remain free of metastases or recurrence of disease, if possible. If cancer recurs, the patient will experience optimal health outcomes, including potential palliation and end-of-life care.

Interventions.

There are many surgical and nonsurgical options for breast cancer treatment. Because of the various options, the patient with breast cancer often faces difficult decisions. Although patients are living longer with metastatic disease, the 5-year survival rate remains low. Once cancer is diagnosed, the extent and location of metastases determine the overall therapeutic strategy. The emphasis of breast cancer treatment is on preventing or stopping the spread of tumor cells that leads to distant metastasis. Treatment is tailored specifically to each patient, taking into account other health problems and the patient's ability to tolerate a particular therapy.

Nonsurgical Management.

For patients with breast cancer at a stage for which surgery is the main treatment, follow-up with adjuvant (in addition to surgery) radiation, chemotherapy, hormone therapy, or targeted therapy is commonly prescribed. For those who cannot have surgery or whose cancer is too advanced, these therapies are used to promote comfort (palliation). These options are discussed in the Adjuvant Therapy section on p. 1476.

Complementary and Alternative Therapies.

Women with breast cancer often cope with distressing symptoms related to the disease itself or the side effects of chemotherapy, radiation, and hormonal therapy. Common symptoms associated with these therapies include pain, nausea, hot flashes, anxiety, depression, and fatigue. Physical and emotional symptoms associated with breast cancer may be eased with the use of complementary and alternative medicine (CAM). Up to 80% of women use some form of CAM during breast cancer treatment (Wyatt et al., 2010). The most frequently used types of CAM are biologically based therapies such as vitamins, special cancer diets, and herbal therapy. Prayer is also widely used. Other types of CAM are mind-body or body-based such as guided imagery and massage. Encourage women to seek a practitioner with a certification or license for the specific type of CAM therapy. In some states, a certification or license is required for acupuncture, chiropractic therapy, massage, and shiatsu. Some types of CAM can be self-taught or done alone after a few sessions of instruction. Table 70-3 lists complementary therapies for specific symptoms associated with breast cancer and its treatments.

TABLE 70-3

Complementary and Alternative Medicine (CAM) for Breast Cancer

SYMPTOM	CAM
Physical	
Pain	Acupuncture, chiropractic therapy, hypnosis, massage, music, reiki, shiatsu
Nausea/vomiting	Acupuncture, aromatherapy, ginger, hypnosis, progressive muscle relaxation, shiatsu
Fatigue	Acupuncture, massage, meditation, reiki, tai chi, yoga
Hot flashes	Acupuncture, black cohosh, flaxseed
Muscle tension	Aromatherapy, massage, shiatsu
Emotional	
Anxiety/stress/fear	Aromatherapy, guided imagery, hypnosis, journaling, massage, meditation, music therapy, progressive muscle relaxation, prayer, support groups, tai chi, yoga
Depression	Aromatherapy, yoga, journaling, progressive muscle relaxation

Although the use of CAM can improve quality of life, its use does not alter the outcome of breast cancer and should not be used in place of

standard treatment (Saquib et al., 2012). Encourage patients who are interested in trying CAM therapies to check with their health care provider before using them. Refer patients to reliable resources for information about CAM. The website *breastcancer.org* provides accurate information about complementary therapies and the extent to which they have been researched in breast cancer patients. Cost may be a factor in decision making since not all insurances provide coverage for CAMs. Teach the patient that all ingested CAM agents potentially risk interaction with conventional drugs.

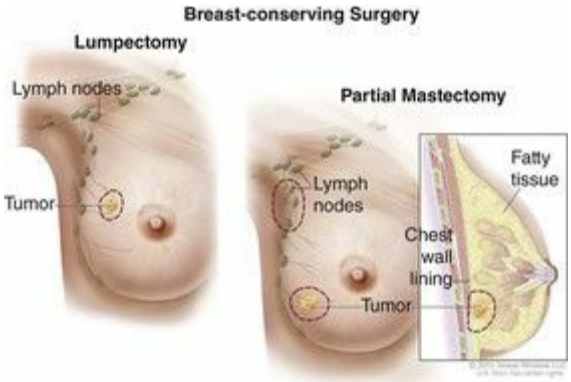
Nursing Safety Priority QSEN

Action Alert

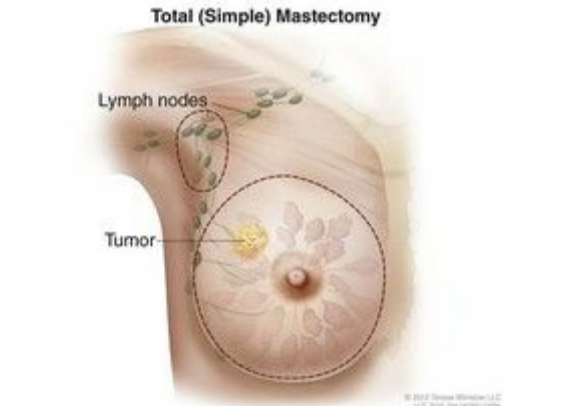
Teach women that some complementary and alternative therapies can have risks and side effects for women with breast cancer. Acupuncture should be avoided in women experiencing lymphedema, bleeding disorders, or a low white blood cell count from chemotherapy. There is concern that soy and soy products also may not be safe for women with breast cancer.

Surgical Management.

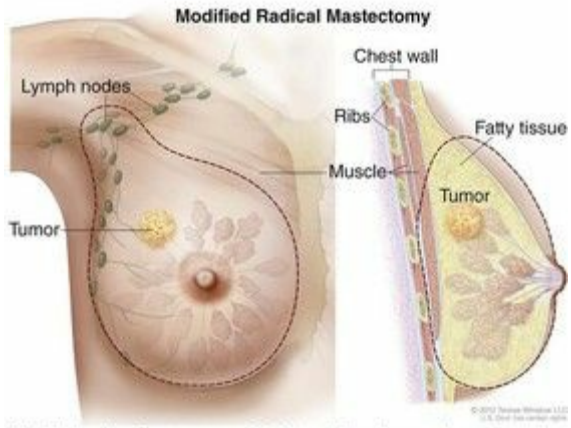
The most common types of breast surgeries are shown in Fig. 70-4. Although controversy exists concerning the best treatment for breast cancer, experts agree that the mass itself should be removed to reduce the risk for local recurrence. A large tumor is sometimes treated with chemotherapy, called **neoadjuvant therapy,** to shrink the tumor before it is surgically removed. An advantage of this therapy is that cancers can be removed by lumpectomy rather than mastectomy.



Breast-conserving surgery. Dotted lines show the area containing the tumor that is removed and some of the lymph nodes that may be removed.



Total (simple) mastectomy. The dotted line shows where the entire breast is removed. Some lymph nodes under the arm may also be removed.

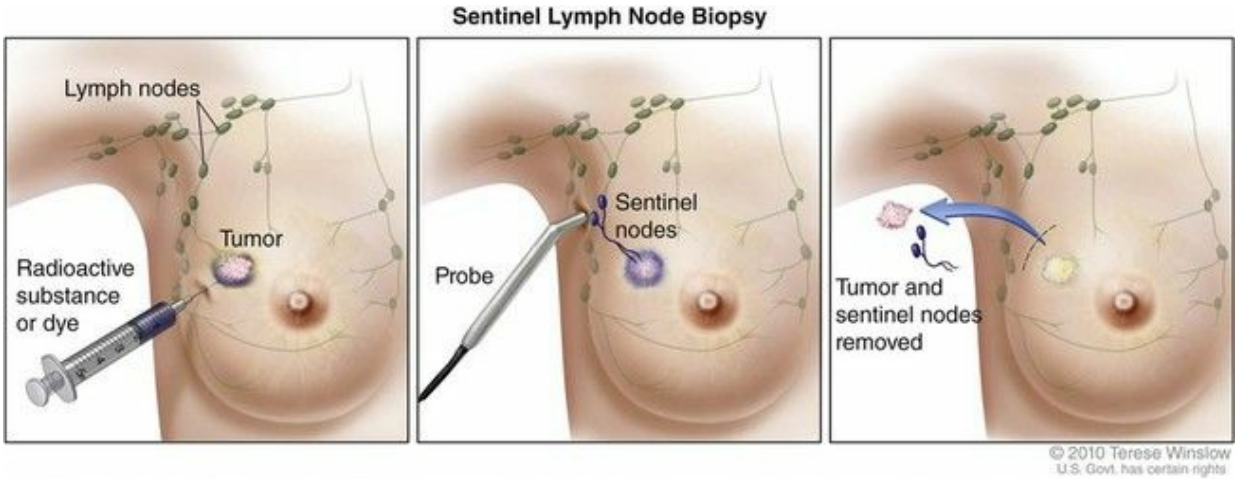


Modified radical mastectomy. The dotted line shows where the entire breast and some lymph nodes are removed. Part of the chest wall muscle may also be removed.

FIG. 70-4 Surgical treatment for breast cancer.

Axillary lymph nodes are analyzed for the presence of cancer and staging purposes. Axillary lymph node dissection (ALND) is usually done when there are palpable axillary lymph nodes or when cancer is suspected to be at a later stage. Sentinel lymph node biopsy (SLNB) is a much less invasive approach now preferred by most surgeons for analyzing lymph nodes in early-stage breast cancers with low to moderate risk for lymph node involvement. SLNB is shown in Fig. 70-5. In this method, the sentinel lymph node is identified during breast

surgery by injecting the breast with radioisotope and/or dye that travels via lymphatic pathways to the sentinel lymph node. The nodes that take up the dye (or give off a certain level of radiation picked up by a handheld counter) are removed and examined for the presence of cancer cells. It is believed that if cancer cells have traveled through the lymph channels, the cells will lodge in the sentinel nodes. Travel beyond these nodes to higher-level nodes may occur as a secondary event. Therefore the absence of cancer cells in the sentinel nodes is an indicator that no other nodes in the regional area are involved.



Sentinel lymph node biopsy of the breast. A radioactive substance and/or blue dye is injected near the tumor (first panel). The injected material is detected visually and/or with a probe that detects radioactivity (middle panel). The sentinel nodes (the first lymph nodes to take up the material) are removed and checked for cancer cells (last panel).

FIG. 70-5 Sentinel lymph node biopsy of the breast.

Preoperative Care.

Care of the patient facing surgery for breast cancer focuses on psychological preparation and preoperative teaching. Priority nursing interventions are directed toward relieving anxiety and providing information to increase patient knowledge. *Include the spouse or partner, who may be experiencing similar stress and confusion, in the health teaching unless the patient's culture does not permit this approach.*

Review the type of procedure planned. Use open-ended questions (e.g., "What type of surgery are you having? Can you explain what will happen?") to assess the current level of knowledge. Provide postoperative information, including:

- The need for a drainage tube
- The location of the incision
- Mobility restrictions
- The length of the hospital stay (if any)

- The possibility of adjuvant therapy
- General preoperative and postoperative information needed by any surgical patient (see Chapters 14 and 16)

Supplement teaching with written or electronic materials for the patient and family to take home as references. This information should include whom to call in case there are any complications. Address body image issues before surgery to correct misconceptions about appearance after surgery. If available, suggest that patients and their caregivers attend classes before surgery in an ambulatory care setting, such as a breast cancer center, to promote successful early discharge from the hospital. Programs that provide emotional support, information, and opportunities for discussion related to sexuality, body image, and preoperative and postoperative care enhance the recovery of the short-stay mastectomy patient.

Operative Procedures.

Types of breast surgeries are shown in Fig. 70-5. During **breast-conserving surgery,** such as a *lumpectomy,* the surgeon removes the tumor and a small amount of tissue rather than the entire breast. A partial mastectomy is surgery to remove part of the breast that contains cancer and some normal tissue around it. *Margins* refer to the distance between the tumor and the edge of the surrounding tissue. The desired outcome of breast-conserving surgery is to obtain negative *margins* in which no cancer cells extend to the edge of the tissue. Typically, radiation therapy follows to kill any residual tumor cells.

Breast-conserving procedures are usually performed in same-day surgical settings. The cosmetic results of these surgeries are good to excellent, and the psychological benefits of avoiding breast removal are significant for patients who choose this option.

Despite advances in breast-conserving surgery, mastectomy remains a popular option for breast cancer treatment and women are increasingly choosing it for prophylactic treatment (McLaughlin, 2013). Typically, indications for a mastectomy include multi-centric disease (tumor is present in different quadrants of the breast), inability to have radiation therapy, presence of a large tumor in a small breast, and patient preference. Mastectomy does not conserve the breast; the affected breast is completely removed. A total (simple) mastectomy is surgery to remove the whole breast that has cancer. A modified radical mastectomy removes the breast tissue, lymph nodes, and sometimes, part of the underlying chest wall muscle. If reconstruction is to be performed at the same time

as the mastectomy, less-invasive techniques, such as incising a ½-inch flap of skin around the nipple (excising the same amount of breast tissue as with conventional mastectomy), may be performed. Skin flaps or expanders may be used to create a breast mound at the time of the original procedure.

Postoperative Care.

Before the patient returns from surgery, inform the staff to avoid using the affected arm for measuring blood pressure, giving injections, or drawing blood. He or she returns from the postanesthesia care unit (PACU) as soon as vital signs return to baseline levels and if no complications have occurred. Assess vital signs on a schedule of decreasing frequency, such as every 30 minutes for 2 times, every hour for 2 times, and then every 4 hours. During these checks, assess the dressing for bleeding.

During a *modified radical mastectomy,* the surgeon places one or two drainage tubes, usually Jackson-Pratt drains, under the skin flaps and attaches the tubes to a small collection chamber (Fig. 70-6). Gentle suction is exerted, and fluid that would accumulate under the flaps and delay healing is collected. Various drains are available, but all allow the drainage to be seen and measured. When taking vital signs, monitor for the amount and color of drainage. Add this information to the intake and output record. Patients undergoing a *lumpectomy* may also have drainage tubes (usually Jackson-Pratt drains) placed if the lump is large or if axillary node dissection is performed.

FIG. 70-6 Jackson-Pratt drain in place after a mastectomy.

Nursing Safety Priority QSEN

Action Alert

Per TJC National Patient Safety Goal recommendations, to decrease the chance of surgical site infection, carefully observe the surgical wound after breast surgery for signs of swelling and infection throughout recovery. Assess the incision and flap of the post-mastectomy patient for signs of bleeding, infection, and poor tissue perfusion. With short hospital stays, drainage tubes are usually removed about 1 to 3 weeks after hospital discharge when the patient returns for an office visit. The drainage amount should be less than 25 mL in a 24-hour period. Inform the patient that tube removal may be uncomfortable although these tubes lie just under the skin. Provide or suggest analgesia before they are removed. Document all findings, and report any abnormalities to the surgeon immediately.

Assess the patient's position to ensure that the drainage tubes or collection device is not pulled or kinked. The patient should have the head of the bed up at least 30 degrees with the affected arm (the arm on the same side as the axillary dissection) elevated on a pillow while awake. Keeping the affected arm elevated promotes lymphatic fluid return after removal of lymph nodes and channels. Provide other basic comfort measures, such as repositioning and analgesics as prescribed on a regular basis until pain ceases. Patient-controlled analgesia may be used for some patients for a short time depending on the type of surgery that was performed.

The hospital stay after breast surgery is short, often same-day or just overnight, and recovery is usually not complicated. Because some managed care plans will not authorize an overnight stay in the hospital after a mastectomy, several states have enacted legislation mandating inpatient benefits. The patient who chooses an early discharge should have a home care visit within 24 hours of the discharge.

Ambulation and a regular diet are resumed by the day after surgery. While the patient is walking, the arm on the affected side may need to be supported at first. Gradually, the arm should be allowed to hang straight by the side. Instruct the patient to avoid the hunched-back position with the arm flexed because of the risk for elbow contracture. Beginning exercises that do not stress the incision can usually be started on the first day after surgery. These exercises include squeezing the affected hand around a soft, round object (a ball or rolled washcloth) and flexion/extension of the elbow. The progression to more strenuous exercises depends on the subsequent procedures planned (e.g., reconstruction) and the surgeon's prescription.

As soon as the patient is ambulatory and surgical pain is under control, he or she is discharged to home. Common instructions for exercises after mastectomy are listed in Chart 70-3.

Chart 70-3 Patient and Family Education: Preparing for Self-Management

Post-mastectomy Exercises

Hand Wall Climbing

- Face the wall, and put the palms of your hands flat against the wall at shoulder level.
- Flex your fingers so that your hands slowly "walk" up the wall.
- Stop when your arms are fully extended.

- Slowly "walk" your hands back down the wall until they return to shoulder level.

Pulley Exercise

- Drape a 6-foot-long rope over a shower curtain rod or over the top of a door. If you use a door for this exercise, have someone put a nail or hook at the top of the door so that the rope does not slip off.
- Grab the ends of the rope, one in each hand, and extend your arms out to your sides until they are straight.
- Keeping your arms straight, pull down with your left arm to raise your right arm as high as you can.
- Pull down with your right arm to raise your left arm as high as you can.

Rope Turning

- Tie a rope to the knob of a closed door.
- Hold the other end of the rope and step back from the door until your arm is almost straight out in front of you.
- Swing the rope in a circle. Start with small circles, and gradually increase to larger circles as you become more flexible.

NCLEX Examination Challenge

Physiological Integrity

The nurse is assigned to care for a client who has undergone a modified radical left mastectomy for breast cancer. When delegating care, which statement by the nursing assistant would require further teaching by the nurse?

A "I will report urine intake and output to you."
B "If the client appears to be in pain, I will tell you right away."
C "It is important for me to take blood pressure on the client's left arm."
D "When ambulating, I will assist the client to stand straight with arms hanging at the side."

Breast Reconstruction.

Breast reconstruction after or during mastectomy for women is common with few complications. Patients consult with the plastic surgeon to discuss the type of reconstruction, timing of the procedure, and technique desired. Many women prefer reconstruction immediately after mastectomy using their own tissue (autogenous reconstruction). Breast reconstruction at the time of mastectomy, both autogenous and

prosthetic, may lessen the psychological strain associated with undergoing a mastectomy.

The surgeon should offer the option of breast reconstruction before surgery is performed. If the woman does not choose immediate reconstructive surgery, a temporary prosthesis can be used. Refer the patient to the American Cancer Society's *Reach to Recovery* program (www.cancer.org). In this program, a volunteer who has had breast cancer surgery visits the woman at home, offering information on breast forms, clothing, coping with breast cancer, and possible reconstructive options. For this intervention to be as helpful as possible, the volunteer should be about the same age as the patient and have experienced the same surgical procedure.

Evaluate the woman's level of satisfaction with her prosthesis several weeks after surgery. Assess her attitude by asking about future plans for restoring appearance. Although reconstruction is not appropriate for some women and others may not be interested in it, the surgeon should discuss the indications and contraindications, advantages and disadvantages, and typical recovery. If immediate reconstruction is chosen, the surgeon should be aware of this before surgery so that plans can be coordinated with those of the plastic surgeon.

Several procedures are available for restoring the appearance of the breast (Table 70-4). Reconstruction may begin during the original operative procedure or later in one to several stages. Common types of breast reconstruction are:

TABLE 70-4

Examples of Breast Reconstruction Procedures

PROCEDURE	DESCRIPTION	PROCEDURE	DESCRIPTION
Implantation	An implant matching the size of the other breast is placed under the muscle on the operative side to create a breast mound. 	Myocutaneous flaps	A flap of skin, fat, and muscle is transferred from the donor site to the operative area. The flap contains an appropriate amount of fat to match the other breast and is similar in appearance to breast tissue. A blood supply is established by reanastomosis of vessels from the operative area to those with the flap when possible. A new nipple may be created with tissue from areas such as the labia or upper, inner thigh. Nipples can also be created by tattooing.  Tissue expansion	A tissue expander is placed under the muscle and gradually expanded with saline to stretch the overlying skin and create a pocket. After several weeks, the tissue expander is exchanged for an implant. 		

- Breast expanders (saline or gel)
- Autologous reconstruction using the patient's own skin, fat, and muscle

Breast expanders are the most common method of breast reconstruction used today in the United States. A tissue expander is a balloon-like device with a resealable metal port that is placed under the pectoralis muscle. A small amount of normal saline is injected intraoperatively into the expander to partially inflate it. The patient then receives additional weekly saline injections for about 6 to 8 weeks until the expander is fully inflated. When full expansion is achieved, the tissue expander is then exchanged for a permanent implant during surgery in

an ambulatory care center. The permanent implant is filled with either saline or silicone gel. Despite earlier claims that silicone gel caused autoimmune diseases like lupus and arthritis, silicone implants have been safely used in the majority of women who choose this type of breast implant.

Autologous reconstruction using the patient's own skin, fat, and muscle is advantageous because the donor site tissue is similar in consistency to the natural breast. Therefore the results more closely resemble a real breast as compared with implant reconstruction. Flap donor sites include the latissimus dorsi flap (back muscle); transverse rectus abdominis myocutaneous flap, known as the *TRAM flap* (abdominal muscle); and the gluteal flap (buttock muscle). Reconstruction of the nipple-areola complex is the last stage in the reconstruction of the breast. If necessary, a new nipple may be created with other body tissue, such as from the labia, abdomen, or inner thigh.

Women who have had a mastectomy and breast reconstruction in one breast should have close surveillance breast cancer screening in the contralateral (opposite) breast, including imaging with mammography or mammography and MRI. Mammography and MRI are not recommended to be routinely done in reconstructed breasts because most local recurrences of breast cancer in the residual tissue are palpable during clinical breast examination (Zakhireh et al., 2010). Nursing care of the woman who has undergone breast reconstruction is outlined in Chart 70-4.

Chart 70-4 Best Practice for Patient Safety & Quality Care QSEN

Postoperative Care of the Patient After Breast Reconstruction

- Assess the incision and flap for signs of infection (excessive redness, drainage, odor) during dressing changes.
- Assess the incision and flap for signs of poor tissue perfusion (duskiness, decreased capillary refill) during dressing changes.
- Avoid pressure on the flap and suture lines by positioning the patient on her nonoperative side and avoiding tight clothing.
- Monitor and measure drainage in collection devices, such as for Jackson-Pratt drains.
- Teach the patient to return to her usual activity level gradually and to avoid heavy lifting.
- Remind the patient to avoid sleeping in the prone position.

- Teach the patient to avoid participation in contact sports or other activities that could cause trauma to the chest.
- Teach the patient to minimize pressure on the breast during sexual activity.
- Remind the patient to refrain from driving until advised by the physician.
- Remind the patient to ask at the 6-week postoperative visit when full activity can be resumed.
- Reassure the patient that optimal appearance may not occur for 3 to 6 months postoperatively.
- If implants have been inserted, teach the proper method of breast massage to enhance expansion and prevent capsule formation (consult with the physician).
- Emphasize breast self-awareness; if the patient performs breast self-examination (BSE), review her technique.
- Remind the patient of the importance of clinical breast examination and follow-up surveillance by her physician.

Adjuvant Therapy.

The decision to follow the original surgical procedure with **adjuvant therapy** (in addition to surgery) for breast cancer is based on:

- The stage of the disease
- The patient's age and menopausal status
- Patient preferences
- Pathologic examination
- Hormone receptor status
- Presence of a known genetic predisposition

Adjuvant therapy for breast cancer consists of radiation therapy and drug therapy. The purpose of radiation therapy is to reduce the risk for local recurrence of breast cancer. Drug therapy includes chemotherapy, targeted therapy, and/or hormonal therapy. These drugs destroy breast cancer cells that may be present anywhere in the body. They are typically delivered after surgery for breast cancer, although **neoadjuvant** chemotherapy may be given to reduce the size of a tumor before surgery. Hormonal therapy is a chemoprevention option for high-risk women with a personal history of breast cancer.

Radiation Therapy.

Radiation therapy is administered after breast-conserving surgery to kill breast cancer cells that may remain near the site of the original tumor.

This therapy can be delivered to the whole breast or to only part of the breast. Whole-breast irradiation is delivered by external beam radiation over a period of 5 to 6 weeks. Partial breast irradiation (PBI) has become a newer option for women with early-stage breast cancer. PBI is a convenient alternative to whole breast radiation. Less time is needed for completion, and outcomes are comparable to whole breast radiation (Edwards et al., 2013). The advantage of this type of radiation is that it is delivered over a much shorter time interval, eliminating the need for daily trips for treatment. The types of methods available for delivering *partial-breast irradiation* include:

- Interstitial brachytherapy, in which several catheters loaded with a radioactive source are inserted at the lumpectomy cavity and surrounding margin, is given over a period of 4 to 5 days.
- Balloon brachytherapy, also known as *MammoSite,* involves the use of a single balloon-tipped catheter that is surgically placed near the tumor bed. The catheter is loaded with a radiation source and inflated to conform to the total cavity. Ten total treatments are given, with at least 6 hours between each treatment.
- Intraoperative radiation therapy is the most accelerated form of partial breast irradiation. It utilizes a high single dose of radiation delivered during the lumpectomy surgery.

Nursing care for the patient undergoing radiation therapy includes patient education and side effect management. Skin changes are a major side effect during this therapy (see Chapter 22). If brachytherapy is planned, instruct patients about the procedure. Assure them that they will be radioactive only while the radiation source is dwelling inside the breast tissue.

Nursing Safety Priority QSEN

Action Alert

Teach women undergoing brachytherapy for breast cancer that radiation is contained in the temporary implant. The risk for others to be exposed to radiation is very small. Body fluids and items contacted by patients with brachytherapy are not radioactive. However, during the time the radiation is delivered, it is recommended they limit visitors, including pregnant women and children.

Chemotherapy.

Chemotherapy for breast cancer is delivered systemically via the central

IV route, such as an implantable venous access device (Port-a-Cath). Its purpose is to kill undetected breast cancer cells that may have left the original tumor and moved to more distant sites. Chemotherapy is recommended for treatment of invasive breast cancer after surgery (adjuvant chemotherapy). It may also be given before surgery to reduce the size of the tumor (neoadjuvant chemotherapy). Chemotherapy is most effective when combinations of more than one drug are used. Table 70-5 lists common chemotherapy agents used in breast cancer and their mechanism of action. Chemotherapy drugs are usually delivered in four to six cycles, with each period of treatment followed by a rest period to give the body time to recover from the effects of the drugs. Each cycle is 2 to 3 weeks long. The total treatment time is 3 to 6 months, although treatment may be longer for advanced breast cancer. Many combinations of drugs are used, and no one combination has been proven to be superior over others (ACS, 2013a). A common chemotherapy regimen for breast cancer treatment is Cytoxan, Adriamycin, and fluorouracil, which is also known as 5-FU (CAF). In early-stage breast cancer, chemotherapy regimens lower the risk for breast cancer recurrence. In advanced breast cancer, chemotherapy regimens reduce cancer size in many patients.

TABLE 70-5
Drug Therapy for Breast Cancer

CATEGORY	MECHANISM OF ACTION	AGENTS
Chemotherapy		
Anthracyclines	Inhibit DNA synthesis in susceptible cells	doxorubicin (Adriamycin) (A) epirubicin (Ellence) (E) daunorubicin (Cerubidine) mitoxantrone (Novantrone)
Taxanes	Inhibit microtubule network in rapidly dividing cells	docetaxel (Taxotere) (D) paclitaxel (Taxol) (P) paclitaxel, protein-bound (Abraxane)
Alkylating agents	Interfere with the replication of susceptible cells	cyclophosphamide (Cytoxan) (C) thiotepa (Thioplex)
Antimetabolites	Inhibit DNA synthesis and cellular replication in rapidly dividing cells	methotrexate (Mexate) (M) fluorouracil (5-FU) (F) capecitabine (Xeloda) gemcitabine (Gemzar)
Additional Chemotherapy Drugs Used in Advanced Breast Cancer		
Vinca alkaloids	Interfere with genes, stopping cells from reproducing	vinorelbine (Navelbine) vincristine (Oncovin)
Platinum-based	Weakens or destroys breast cancer cells by damaging genetic material	carboplatin (Paraplatin)
Microtubule inhibitor	Disrupts cells division by interfering with microtubulin	eribulin (Halaven)
Epothilone	Interferes with cancer cell division	ixabepilone (Ixempra)
Antitumor antibiotic	Damages genes, interfering with reproduction	mitomycin (Mutamycin)
Targeted Therapy	Selectively targets critical steps in the processes required for tumor growth, viability, or invasion	trastuzumab (Herceptin) lapatinib (Tykerb) pertuzumab (Perjeta) everolimus (Afinitor) T-DM1 (Kadcyla)
Hormonal Therapy		
LH-RH agonists	Block release of LH and FSH, thereby preventing ovarian production of estrogen	goserelin (Zoladex) leuprolide (Lupron)
Selective estrogen receptor modulators (SERMs)	Bind to estrogen receptors; have both agonist and antagonist properties (selectively block action of estrogen in the breast but not in other organs)	tamoxifen (Nolvadex) raloxifene (Evista) toremifene (Fareston)
Aromatase inhibitors	Prevent conversion of adrenal and ovarian androgens to estrogens by inhibiting the aromatase enzyme	anastrozole (Arimidex) letrozole (Femara) exemestane (Aromasin)
Estrogen receptor down-regulators	Induce degradation of estrogen receptor	fulvestrant (Faslodex)

FSH, Follicle-stimulating hormone; *LH,* luteinizing hormone; *LH-RH,* luteinizing hormone–releasing hormone.

Nurses must be very proficient in the preparation and administration of chemotherapy drugs and knowledgeable about various venous access devices. They must also be able to manage the distressing symptoms associated with side effects of chemotherapy. Chapter 22 discusses general nursing management of alopecia, nausea and vomiting, mucositis, and bone marrow suppression. Fatigue and sleep disturbance are often major concerns as side effects of chemotherapy.

Nursing Safety Priority QSEN

Action Alert

Teach patients undergoing chemotherapy with anthracyclines such as doxorubicin (Adriamycin) to be aware of cardiotoxic effects. Instruct them to report excessive fatigue, shortness of breath, chronic cough, and edema to the health care provider.

Chemotherapy is unpleasant and expensive and can have life-threatening short-term and long-term side effects. Because more women are living longer with breast cancer, long-term effects are increasingly emerging. Although targeted therapy is effective with fewer side effects, some side effects are nevertheless life threatening. For example, cardiac toxicity is a risk associated with the use of Herceptin, particularly when it is combined with other chemotherapy. Chemotherapy and ovarian suppression can result in infertility, a devastating effect for women of childbearing age. Hormonal therapy can result in long-term ill effects from bone loss. Discuss patient concerns, provide accurate information, and assist him or her in decision making.

Targeted Therapy.

Targeted cancer therapies are drugs that target specific characteristics of cancer cells, such as a protein, an enzyme, or the formation of new blood vessels. The advantage of targeted therapy over traditional chemotherapy is that targeted therapy is less likely to harm normal, healthy cells and therefore it has fewer side effects. Table 70-5 lists targeted chemotherapy drugs used in breast cancer. One of the first targeted therapies developed for breast cancer is the monoclonal antibody *trastuzumab* (Herceptin). This drug targets the *HER2/neu* gene product in breast cancer cells. Several other targeted therapies have been developed since Herceptin.

Hormonal Therapy.

Table 70-5 lists hormonal therapy drugs used in breast cancer prevention and treatment. The purpose of hormonal therapy is to reduce the estrogen available to breast tumors to stop or prevent their growth. *Premenopausal* women whose main estrogen source is the ovaries may benefit from *LH-RH agonists* that inhibit estrogen synthesis. These drugs include leuprolide (Lupron) and goserelin (Zoladex), which suppress the hypothalamus from making luteinizing hormone–releasing hormone (LH-RH). When LH-RH is inhibited, the ovaries do not produce estrogen. Although the suppression of ovarian function decreases breast cancer risk, the drastic drop in estrogen causes significant menopausal

symptoms. Therefore the decision to use these drugs is not made lightly.

Selective estrogen receptor modulators (SERMs), on the other hand, do not affect ovarian function. Rather, they block the effect of estrogen in women who have estrogen receptor (ER)–positive breast cancer. SERMs are also used as chemoprevention in women at high risk for breast cancer and in women with advanced breast cancer. For women with hormone receptor–positive breast cancer, tamoxifen reduces the chances of the cancer coming back by about half (ACS, 2013a). A recent study demonstrated that taking tamoxifen for 10 years, rather than 5 years, achieves the best benefit for risk reduction (Davies et al., 2013). Common side effects of SERMs include hot flashes and weight gain. Rare but serious side effects of these drugs include endometrial cancer and thromboembolic events.

Aromatase inhibitors (AIs) are used in *postmenopausal* women whose main source of estrogen is not the ovaries but, rather, body fat. AIs reduce estrogen levels by inhibiting the conversion of androgen to estrogen through the action of the enzyme *aromatase.* AIs are beneficial when given to postmenopausal women for up to 5 years. Treatment with AIs usually follows treatment with tamoxifen. Studies are underway to determine whether it is beneficial to take AIs longer than 5 years (ACS, 2013a). A side effect of AIs, not seen with tamoxifen, is loss of bone density. Women taking AIs are candidates for bone-strengthening drugs and must be closely monitored for osteoporosis. Fulvestrant (Faslodex), a second-line hormonal therapy for postmenopausal women with advanced breast cancer, is used after other hormonal treatments have stopped working.

Stem Cell Transplantation.

Autologous or allogeneic stem cell transplantation is an option for patients with a high risk for recurrence or who have advanced disease. **Autologous bone marrow transplantation** (taken from the patient's bone marrow), peripheral blood stem cell transplantation (taken from circulating blood), or **allogeneic bone marrow transplantation** (taken from a healthy donor's bone marrow or peripheral blood) is performed as a means of rescue therapy after very high doses of chemotherapy. The general care of the patient undergoing bone marrow or stem cell transplantation is discussed in Chapter 22.

Community-Based Care

Home Care Management.

In collaboration with the case manager and members of the interdisciplinary health care team, make the appropriate referrals for care after discharge. Preoperative teaching and arrangements for home care management and referrals (*Reach to Recovery,* social services, home care) can be started before surgery or other treatment.

The patient who has undergone breast surgery can be discharged to the home setting unless other physical disabilities exist. Some are discharged the day after surgery with Jackson-Pratt or other types of drains in place. Many patients are discharged to home on the day of surgery. Older adults should not be sent home without a family member or friend who can stay with them for 1 to 2 days. These patients may need some assistance at home with drain care, dressings, and ADLs because of pain and impaired range of motion of the affected arm. Summaries of continuing care instructions are given in Charts 70-5 and 70-6.

Chart 70-5 Patient and Family Education: Preparing for Self-Management

Recovery from Breast Cancer Surgery

- There may be a dry gauze dressing over the incision when you leave the hospital. You may change this dressing if it becomes soiled.
- A small, dry dressing will be around the site where a drain is placed. Often there is some leakage of fluid around the drain. Check the gauze dressing for drainage, and change it if it becomes soiled. Some leakage is normal, but if the dressing becomes soaked more than once a day, call your health care provider.
- You have been taught how to empty the reservoir from your drain and how to measure the volume of drainage. You should empty the reservoir twice a day and record the measurements.
- Drains are generally removed when drainage is less than 25 mL in 24 hours.
- Drains are often removed at the same time as the stitches or staples, generally 7 to 10 days (could be as long as 3 weeks if needed) after surgery.
- You may take sponge baths or tub baths, making certain that the area of the drain and incision stays dry. You may shower after the stitches, staples, and drains are removed.
- You can begin using your arm for normal activities, such as eating or combing your hair. Exercises involving the wrist, hand, and elbow, such as flexing your fingers, circular wrist motions, and touching your hand

to your shoulder, are very good. You can usually resume more strenuous exercises after the drains have been removed.
- You can expect some discomfort or mild pain after surgery, but within 4 to 5 days, most women have no need for pain medication or require medication only at bedtime.
- Numbness in the area of the surgery and along the inner side of the arm from the armpit to the elbow occurs in almost all women. It is the injury to the nerves that causes sensation to the skin in those areas. Women have described sensations of heaviness, pain, tingling, burning, and "pins and needles." Neuropathic pain is sometimes relieved by gabapentin (Neurontin). These sensations change over the months and usually resolve by 1 year.
- Pamphlets on exercises, hand and arm care, and general facts about breast cancer are available from us or from a volunteer visitor. The American Cancer Society has volunteers who have had surgery similar to yours and are available to visit you.

Chart 70-6 Home Care Assessment

Patients Recovering from Breast Cancer Surgery

Assess cardiovascular, respiratory, and urinary status:
- Vital signs
- Lung sounds
- Urine output patterns

Assess for pain and effectiveness of analgesics.

Assess dressing and incision site:
- Excess drainage
- Manifestations of infection
- Wound healing
- Intact staples

Assess drain and site:
- Drainage around drain site and in drain reservoir
- Color and amount of drainage
- Manifestations of infection

Review patient's recordings of drainage.

Evaluate patient's ability to care for and empty drain reservoir.

Assess status of affected extremity:
- Range of motion
- Ability to perform exercise regimen
- Lymphedema

Assess nutritional status:
- Food and fluid intake
- Presence of nausea and vomiting
- Bowel sounds

Assess functional ability:
- Activities of daily living
- Mobility and ambulation

Assess home environment:
- Safety
- Structural barriers

Assess patient's compliance and knowledge of illness and treatment plan:
- Follow-up appointment with surgeon
- Manifestations to report to health care provider
- Hand and arm care guidelines
- Referral to *Reach to Recovery*

Assess patient and caregiver coping skills:
- Whether patient and/or caregiver has looked at incision site
- Patient's and/or caregiver's reaction to incision site

Teach patients that activities involving stretching or reaching for heavy objects should be avoided temporarily. This restriction can be discussed with a family member or significant other who can perform these tasks or place the objects within easy reach.

Self-Management Education.

The teaching plan for the patient after surgery includes:
- Measures to improve body image
- Information about interpersonal relationships and roles
- Exercises to regain full range of motion
- Measures to prevent infection of the incision (per The Joint Commission's National Patient Safety Goals)
- Measures to avoid lymphedema
- Measures to avoid injury, infection, and swelling of the affected arm (per The Joint Commission's National Patient Safety Goals)
- Care of the incision and drainage device

Teach incisional care to the patient, family, and/or other caregiver. The patient may wear a light dressing to prevent irritation. Explain that no lotions or ointments should be used on the area and that the use of deodorant under the affected arm should be avoided until healing is complete. Although swelling and redness of the scar itself are normal for

the first few weeks, swelling, redness, increased heat, and tenderness of the surrounding area indicate infection and should be reported to the surgeon immediately. If a lymph node dissection was performed, instruct the patient to elevate the affected arm on a pillow for at least 30 minutes a day for the first 6 months. Ask the patient to have someone bring a loose-fitting, non-wire bra or camisole for her to try before discharge with a soft, cotton-filled or polyester fiber–filled form supplied by the hospital or by *Reach to Recovery*. The patient wears this form until the incision is completely healed and the health care provider approves the fitting of a more sophisticated prosthesis, usually 6 to 8 weeks after discharge. Encourage the patient to dress in loose-fitting street clothes at home, not pajamas, to further enhance a positive self-image.

Teach the patient to continue performing the exercises that began in the hospital. Active range-of-motion exercises should begin 1 week after surgery or when sutures and drains are removed. Emphasize that reaching and stretching exercises should continue only to the point of pain or pulling, never beyond that. Some YWCA locations have a free program called *ENCORE,* which supports women and men following breast cancer surgery. The program includes exercise to music, exercise in water, and peer psychological support. Patients may participate as early as 3 weeks after surgery. Before discharge, the surgeon may prescribe precautions or limitations specific to plans for future procedures, such as reconstruction.

Lymphedema, an abnormal accumulation of protein fluid in the subcutaneous tissue of the affected limb after a mastectomy, is a commonly overlooked topic in health teaching. Risk factors include injury or infection of the extremity, obesity, presence of extensive axillary disease, and radiation treatment. Once it develops, it can be very difficult to manage, and *lifelong measures must be taken to prevent it.* Nurses play a vital role in educating patients about this complication. Teach your patient to immediately report symptoms of lymphedema such as sensations of heaviness, aching, fatigue, numbness, tingling, and/or swelling in the affected arm, as well as swelling in the upper chest (Mohler & Mondry, 2013).

Nursing Safety Priority QSEN

Action Alert

Provide information needed to help the patient avoid infection and subsequent lymphedema of the affected arm after the mastectomy. Teach

the importance of avoiding having blood pressure measurements taken on, having injections in, or having blood drawn from the arm on the side of the mastectomy. Instruct the patient to wear a mitt when using the oven, wear gloves when gardening, and treat cuts and scrapes appropriately. If lymphedema occurs, early intervention provides the best chance for control. Nurses should not assume that women with lymphedema are disabled; they are able to live full lives within this limitation (Ridner et al., 2012). A referral to a lymphedema specialist may be necessary for the patient to be fitted for a compression sleeve and/or glove, to be taught exercises and manual lymph drainage, and to discuss ways to modify daily activities to avoid worsening the problem. Management is directed toward measures that promote drainage of the affected arm. Teach patients, especially those who have had axillary lymph nodes removed, that measures to prevent lymphedema are lifelong and include avoiding trauma to the arm on the side of the mastectomy.

Psychosocial Preparation.

Concerns about appearance after surgery are common and are often a threat to the patient's self-concept as a woman. Before breast surgery, the woman and her partner can benefit from an explanation of the expected postoperative appearance. After a modified radical mastectomy, the chest wall is fairly smooth and has a horizontal incision from the axilla to the midchest area. After breast-conserving surgery, scars vary according to the amount of breast tissue removed. Women are sometimes shown pictures of post-mastectomy reconstruction but are disappointed with their own results. Emphasize that scars will fade and edema will lessen with time. Scars may be red and raised at first, but these features lessen in the first few months. After surgery, encourage the woman to look at her incision when she is ready. Do not push her to accept this body image change immediately.

Much of one's body image is a reflection of how others respond. Therefore the response of the patient's family or partner to the surgery is crucial in determining the effect on self-concept. These people may also need the support of the nurse. They may have concerns about their ability to accept the changes and need to discuss these feelings with an objective listener. They may also need help with communicating their feelings, both negative and positive, with their loved one. Involving them in teaching may also help reinforce learning and increase retention.

Discuss sexual concerns before discharge. Most surgeons recommend avoiding sexual intercourse for 4 to 6 weeks. Patients may prefer to lay a

pillow over the surgical site or to wear a bra, camisole, or T-shirt to prevent contact with the surgical site during intercourse. He or she may be embarrassed to discuss the topic of *sexuality*. Be sensitive to possible concerns, and approach the subject first.

For young women, issues related to childbearing may be a concern. Chemotherapy and radiation are considered serious teratogenic (birth defect–causing) agents. Advise sexually active patients receiving chemotherapy or radiotherapy to use birth control during therapy. The method and length of birth control should be discussed with the health care provider.

Health Care Resources.

Resources available to the patient after discharge include personal support and community programs. After discharge, the spouse or partner may need help in planning support for home responsibilities. For example, a partner who may be assuming additional duties at home and work may feel stressed. Discussing the need for ongoing emotional support is also beneficial to both the patient and partner. Leaving the hospital and appearing normal do not end the anxiety and fear. Identifying a support person with whom the patient or couple can explore these feelings and discussing the need to ventilate feelings enhance personal and family recovery.

Numerous support and educational resources are available to those diagnosed with breast cancer. Nurses must provide accurate and current information to patients who may have obtained inaccurate information from various media. There are over 2 million breast cancer survivors in the United States, and many men and women are active in breast cancer support and advocacy organizations. National breast cancer organizations are accessible online, and many of them have local affiliates. Examples of such organizations are Susan G. Komen for the Cure, the National Breast Cancer Coalition, Y-Me, Sisters Network, Young Survival Coalition, and Pink Ribbon Girls. Local support organizations can be accessed through the health care provider, the local hospital, wellness centers, home care agencies, or by word of mouth. The American Cancer Society (ACS) (www.cancer.org) is a comprehensive resource for information and support.

Clinical Judgment Challenge

Patient-Centered Care; Safety; Evidence-Based Practice QSEN

A 46-year-old Caucasian lesbian woman is diagnosed with breast cancer and scheduled for a radical right mastectomy and chemotherapy. She tells you that she often feared developing cancer because her mother and aunt were both diagnosed with breast cancer in their 40s. She says she is fearful because her employer does not offer insurance and she is not eligible to be covered under her partner's insurance plan. She also shares that she feels sad because she has been attempting to get pregnant for the first time and she now realizes that this will not be possible for the foreseeable future.

1. What evidence-based risk factors does this patient have?
2. What discharge instructions will you provide for her and why?
3. What will you teach the patient about chemotherapy to maintain her safety?
4. How might you help address the patient's emotional concerns?

Nursing Concepts and Clinical Judgment Review

What might you NOTICE if a patient is experiencing impaired sexuality as a result of breast cancer or other disorder?

- Breast swelling or lump (with or without pain)
- Discharge from nipple(s)
- Skin dimpling or orange peel appearance
- Asymmetric breast tissue
- Very large or very small breasts
- Skin redness and warmth

What should you INTERPRET and how should you RESPOND to a patient having impaired sexuality as a result of breast cancer or other disorder?

Perform and interpret physical assessment, including:

- Taking a thorough patient and family history
- Examining each breast, comparing sides, and documenting
- Assessing pain and documenting
- Assessing psychosocial reaction to the breast changes

Respond by:

- Checking recent mammogram test or other imaging assessment results
- Acknowledging patient's concerns about body image and sexuality changes
- Asking the patient about resources for support that have been used in

the past for coping with crisis
- Preparing the patient for testing and possible biopsy
- Listening to the patient's concerns in a nonjudgmental manner

On what should you REFLECT?

- Consider what health care resources (team members) the patient and family will need throughout disease management.
- Think about what other community resources the patient and family will need.
- Observe the patient's progress in adapting to body image changes.

Get Ready for the NCLEX® Examination!

Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- In collaboration with the health care team, identify community resources for patients with breast cancer, including *Reach to Recovery* of the American Cancer Society. **Teamwork and Collaboration** QSEN

Health Promotion and Maintenance

- Identify patients at high risk for breast cancer, especially women with family history of breast cancer at a young age; those who have had early menarche, late menopause, or first pregnancy after 30 years of age; or those who are nullipara.
- Discuss benefits and risks of options available to women who are high risk for breast cancer, including close surveillance and prophylactic surgery.
- Teach women to become self-aware of breasts and any breast changes; teach breast self-examination (BSE) to women who choose this method of breast self-awareness. **Patient-Centered Care** QSEN
- Encourage women to have screening mammography according to recommended guidelines. Baseline screening should begin at 40 years of age and continue yearly. In high-risk women, screening should be started earlier. **Evidence-Based Practice** QSEN
- Encourage women to have a clinical breast examination (CBE) according to recommended guidelines. **Evidence-Based Practice** QSEN

Psychosocial Integrity

- Assess patients' reactions to the diagnosis of breast cancer and the effect of breast cancer treatment on their body image and sexuality. **Patient-Centered Care** QSEN
- Identify resources that facilitate patients' grief work and coping skills.
- Allow patients opportunities to express feelings of grief, fear, and anxiety.
- Teach women ways to minimize surgical area deformity and enhance body image, such as use of a breast implant (prosthesis) or the option of breast reconstruction.
- Address the reactions of family and significant others to the diagnosis

of breast cancer; provide support and education.

Physiological Integrity

- Assess benign lumps as mobile and round or oval; assess possible malignant lumps as fixed and irregularly shaped, often in the upper outer breast quadrant.
- A breast reduction is an option to promote comfort for women with very large, heavy breasts.
- A breast augmentation is an elective procedure for women with small breasts or for women who desire reconstruction after breast removal.
- After breast cancer surgery, assess vital signs, dressings, drainage tubes, and amount of drainage.
- Notify the health care team that the arm of the surgical mastectomy side should not be used for blood pressures, blood drawing, or injections. **Safety** QSEN
- Assess the return of arm and shoulder mobility after breast surgery and axillary dissection.
- Assess for the presence of lymphedema, and assist the patient to perform therapeutic measures to reduce lymphedema in the affected arm. **Safety** QSEN
- Teach the patient measures to prevent lymphedema after axillary node dissection.
- Observe for and report other complications of breast cancer surgery or breast reconstruction, especially infection and inadequate vascular perfusion. **Safety** QSEN
- After an axillary lymph node dissection, elevate the affected arm on a pillow.
- Radiation and drug therapy are used most often as adjuvant therapy after breast surgery but may be used before surgery to shrink the tumor.

CHAPTER 71

Care of Patients with Gynecologic Problems

Donna D. Ignatavicius

PRIORITY CONCEPTS

- Infection
- Pain
- Sexuality
- Elimination

Learning Outcomes

Safe and Effective Care Environment

1. Collaborate with members of the health care team when providing care for patients with gynecologic cancers.
2. Teach patients about community-based resources for patients with gynecologic health problems.
3. Develop a community-based plan of care for patients with gynecologic cancers.

Health Promotion and Maintenance

4. Identify risk factors for gynecologic cancers.
5. Describe evidence-based health promotion and maintenance measures to help prevent or early-detect gynecologic cancers.

Psychosocial Integrity

6. Reduce the psychological impact for the patient who has received a diagnosis of a gynecologic health problem.
7. Discuss ways to help patients adapt to physical changes, including impaired sexuality, caused by gynecologic problems and their treatment.

Physiological Integrity

8. Describe the mechanisms of action, side effects, and nursing implications of drug therapy for endometriosis.
9. Develop a teaching plan for a patient with a vaginal inflammation or infection.
10. Prioritize care after surgery for the woman undergoing an anterior and/or posterior repair.
11. Develop a plan of care for a patient undergoing a hysterectomy.
12. Explain the purpose and side effects of radiation and chemotherapy for patients with gynecologic cancers.
13. Teach patients about complementary and alternative therapies that they may wish to explore.

 http://evolve.elsevier.com/Iggy/

Common gynecologic symptoms that women experience are pain, vaginal discharge, and bleeding. Some patients also have urinary elimination symptoms associated with their gynecologic problem. Women are often hesitant to seek medical attention for these problems because of fear of a life-threatening disease diagnosis or concern about privacy and dignity. Be sensitive to the woman's concerns and encourage discussion about menstrual or other reproductive problems. Teach women about their bodies, and help them recognize when professional help should be sought. Teach them how to make informed decisions about treatments. Assess the effects of gynecologic disorders on sexuality in any setting. These health problems often impair sexual function and therefore can affect the woman's relationship with her partner. Remember that sexuality affects a woman's sense of being, self-esteem, and body image.

Endometriosis

Pathophysiology

Endometriosis is endometrial (inner uterine) tissue implantation *outside* the uterine cavity. The tissue typically appears on the ovaries and the cul-de-sac (posterior rectovaginal wall) and less commonly on other pelvic organs and structures (Fig. 71-1). A "chocolate" cyst, also called an *endometrioma,* is an area of endometriosis on an ovary. The disease affects millions of women in their 30s and 40s. Endometriosis responds to cyclic hormonal stimulation just as if it were in the uterus. Monthly cyclic bleeding occurs at the **ectopic** (out of place) site of implantation, which irritates and scars the surrounding tissue. Scarring can lead to adhesions, causing infertility (inability to become pregnant). Endometriosis progresses slowly and regresses during pregnancy and at menopause. The most common site for endometriosis is the ovaries (Saul, 2013). Although cancer of the endometrium is possible, simply having endometriosis does not mean that a patient is at high risk. Estrogen, tamoxifen, hereditary conditions, and amount of body fat are more strongly linked to development of endometrial cancer (National Cancer Institute [NCI], 2013a).

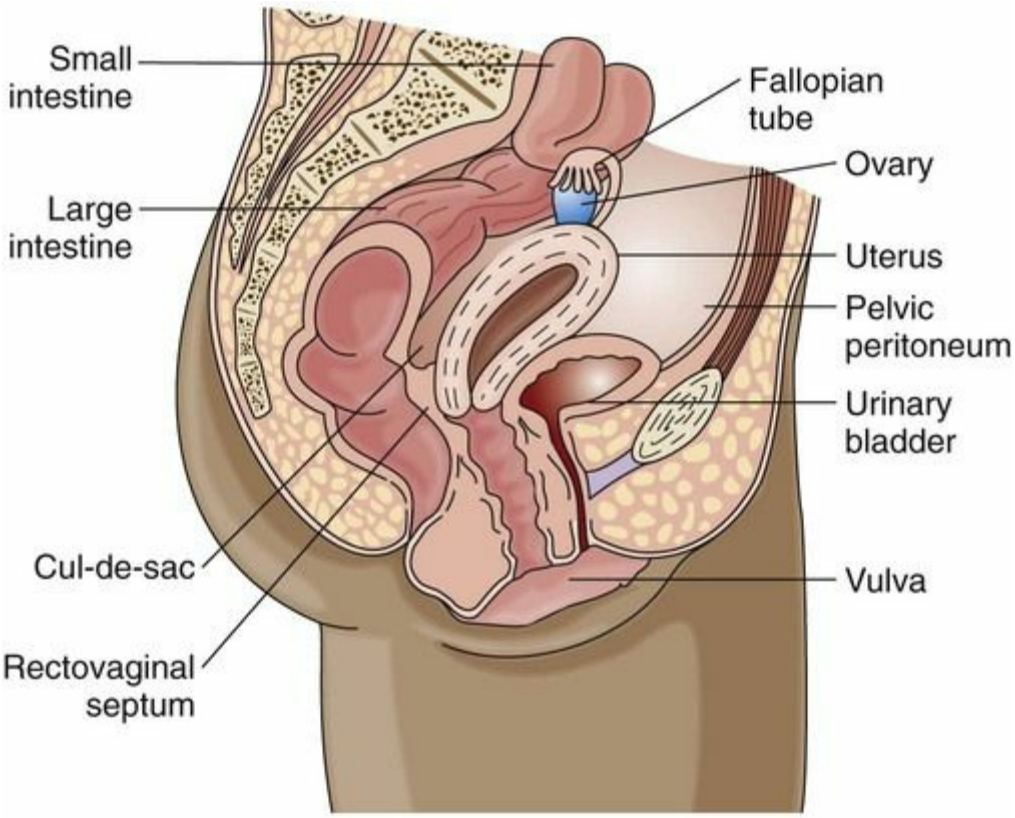

FIG. 71-1 Common sites of endometriosis.

The cause of endometriosis is unknown. Retrograde menstruation, a condition in which the menstrual blood (which contains endometrial cells) may flow back through the fallopian tube, emptying into the pelvic cavity (instead of outside the body), is thought to be a cause. The displaced cells stick to surfaces within the pelvic cavity and grow, thicken, and bleed during each menstrual cycle. Embryonic cell growth, surgical scar implantation, endometrial cell transport (via the lymphatic system), and immune system disorders are also thought to be possible causes for endometriosis (Mayo Clinic, 2013).

Patient-Centered Collaborative Care

Assessment

Take a detailed history, including the woman's menstrual history, sexual history (including any patient concerns regarding history of abuse), and bleeding characteristics. A thorough menstrual history includes onset, duration, flow type and characteristics, and regularity. *Pain is the most common symptom of endometriosis.* The pain usually peaks just before the menstrual flow. It is usually located in the lower abdomen, causing many women to feel a sense of rectal pressure. The degree of pain is not related to the extent of the endometriosis but, instead, to the site. Often, women with minimal disease have more severe pain than do women with

extensive disease. Other manifestations include **dyspareunia** (painful sexual intercourse), painful defecation, low backache, and infertility. GI disturbances such as nausea and diarrhea are also common.

A pelvic examination performed by the health care provider may reveal pelvic tenderness, tender nodules in the posterior vagina, and limited movement of the uterus. A psychosocial assessment may reveal anxiety because of uncertainty about the diagnosis or frustration because of pain. The woman may also have concerns about her self-concept if she is infertile but wants to become pregnant.

Diagnostic tests may rule out pelvic inflammatory disease caused by chlamydia or gonorrhea. Serum cancer antigen *CA-125* may be positive in women with endometriosis (Mayo Clinic, 2011). Transvaginal ultrasound is used to determine whether pelvic masses are endometriosis or malignant.

Interventions

Hormonal and surgical management may be used, depending on the symptoms, the extent of disease, the woman's desire for childbearing, and her treatment option preferences. Collaborative care consists of interventions that:

- Reduce pain
- Restore sexual function
- Alleviate anxiety related to the disease and the uncertainty of the diagnosis
- Educate the patient about the disease and its treatment
- Alleviate fear related to the possibility of laparoscopy or surgery
- Prevent self-concept disturbance related to infertility

Nonsurgical Management.

Several resources, such as the Endometriosis Association (www.endometriosisassn.org) and RESOLVE (an organization for infertile couples) (www.resolve.org), offer information on endometriosis that is helpful for patients and caregivers.

Menstrual cycle control using oral contraceptives or progestins, such as oral medroxyprogesterone acetate (Provera, Alti-MPA Novo-Medrone) and norethindrone acetate (Aygestin, Norlutate), may be prescribed. Injectable forms of progestins, such as medroxyprogesterone acetate (Depo-Provera), may be more convenient because these drugs are given less frequently.

Continuous low-level heat using wearable heat packs may provide temporary pain relief. Relaxation techniques, yoga, massage, and

biofeedback may decrease muscle tissue hypoxia and hypertonicity and relieve ischemia by increasing blood flow to the affected areas. Calcium and magnesium may also relieve muscle cramping for some patients.

Surgical Management.

Surgical management of endometriosis for a woman who wants to remain fertile involves ablation, a laparoscopic removal of endometrial implants and adhesions, in a same-day surgical setting. Chapter 16 describes the general postoperative care for patients having surgery. The surgeon may use a laser to treat endometriosis by vaporizing adhesions and endometrial implants. Teach patients that temporary postoperative pain from carbon dioxide, used during laparoscopy to better visualize internal organs, can occur in the shoulders and chest.

Dysfunctional Uterine Bleeding

Pathophysiology

Dysfunctional uterine bleeding (DUB) is excessive and frequent bleeding (more than every 21 days). It is a diagnosis of exclusion, made after ruling out anatomic or systemic conditions such as drug therapy or disease. DUB occurs most often at the beginning or end of a woman's reproductive years—when ovulation is becoming established or when it is becoming irregular at or after menopause.

Normally the menstrual cycle is a series of delicately timed hormonal events regulated by hypothalamic, pituitary, ovarian, and uterine functions. **Menses,** the sloughing of the endometrial lining, is an expected result. DUB occurs when there is a hormonal imbalance, generally when the ovaries fail to ovulate. This decreases progesterone production, which is needed to mature the uterine lining and prevent overgrowth. Without progesterone, prolonged estrogen stimulation causes the endometrium to grow past its hormonal support, causing disordered shedding of uterine lining. Most cases of DUB are classified into two types: anovulatory DUB (most common) and ovulatory DUB. Common risk factors for DUB during the reproductive years are listed in Table 71-1.

TABLE 71-1

Risk Factors for Dysfunctional Uterine Bleeding

• Obesity • Extreme weight loss or gain • Age older than 40 years • High stress levels • Polycystic ovary disease • Long-term drug use (e.g., oral contraceptives) • Excessive exercise

Patient-Centered Collaborative Care

Assessment

Take a complete menstrual history. Ask about illnesses, changes in weight or nutritional intake, exercise, drug ingestion, and whether the woman experiences pain.

Assess for symptoms of anemia or systemic disease, such as:

- Renal or hepatic disease
- Abnormal weight

- Signs of hormonal dysfunction, such as thyroid enlargement or male hair pattern
- Evidence of abdominal pain or masses

The health care provider inspects the external genitalia, does a bimanual pelvic examination, performs a Papanicolaou (Pap) test to assess for the presence of cervical cancer, and does a rectal examination to identify infections, lesions, or tenderness. Vaginal specimens are also tested for sexually transmitted diseases (STDs) such as chlamydia. Women at high risk for endometrial cancer should also have an endometrial biopsy. Risk factors are described later in this chapter.

A complete blood count may be taken to determine whether the patient is anemic. Thyroid-stimulating hormone and reproductive hormone levels may also be evaluated.

Transvaginal ultrasound may reveal **leiomyomas** (fibroids) and measure an excessively thick endometrium. *Sonohysterography* uses vaginal ultrasound to visualize the uterus after sterile saline is infused through the cervix, thus outlining the inner uterine cavity (American Congress of Obstetricians and Gynecologists [ACOG], 2011).

Interventions

Nonsurgical Management.

As with endometriosis, hormone manipulation is usually the treatment of choice for women with anovulatory DUB. The drugs used depend on the severity of bleeding and age of the patient. Progestin or combination hormone therapy (estrogen and progestin) may be given when bleeding is heavy and acute. For nonemergent bleeding, contraceptives (oral or patch) provide the progestin (artificial progesterone) needed to stabilize the endometrial lining. Progestin-only pills (e.g., norethindrone [Aygestin, Norlutate]) or long-acting progestins (e.g., injectable medroxyprogesterone acetate [Depo-Provera]) are preferable for women older than 35 years who smoke or are at risk for thrombophlebitis.

Explain the desired outcomes and the side effects of these drugs, and evaluate the woman's knowledge of the effects, dosage, and schedule. Remind her to take the drug exactly as prescribed and not to skip a dose or run out of it. If bleeding worsens, teach her to call her health care provider immediately.

Surgical Management.

Removal of the built-up uterine lining, called **endometrial ablation,** stops the blood flow to fibroids that are causing excessive bleeding. This is a

safe alternative for women who do not respond to medical management. Other invasive options include uterine artery embolization, dilation and curettage, and hysterectomy. A hysterectomy is performed only after other treatments have failed. (Hysterectomy is discussed under Surgical Management on p. 1489 of the Uterine Leiomyoma section.)

Vulvovaginitis

Pathophysiology

Vaginal discharge and itching are two common problems experienced by most women at some time in their lives. Vaginal infections may be transmitted sexually and non-sexually. Gonorrhea, syphilis, chlamydia, and herpes simplex virus infections are sexually transmitted diseases (STDs) discussed in Chapter 74.

Vulvovaginitis is inflammation of the lower genital tract resulting from a disturbance of the balance of hormones and flora in the vagina and vulva. It may be characterized by itching, change in vaginal discharge, odor, or lesions. The most common causes include:

- Fungal (yeast) infections *(Candida albicans)*
- Bacterial vaginosis
- STDs *(Trichomonas vaginalis)*
- Postmenopausal vaginal atrophy
- Changes in the normal flora or pH (from douching)
- Chemical irritant or allergens (vaginal spray, fabric dyes, detergent) or foreign body (tampon)
- Drugs, especially antibiotics
- Immunosuppression from diabetes or human immune deficiency virus (HIV)

Primary infections that affect the vulva include *herpes genitalis* and *condylomata acuminata* (human papilloma virus, venereal warts) (see Chapter 74). Secondary infections of the vulva are caused by organisms responsible for the many types of vaginitis, including *candidiasis.* Pediculosis pubis (crab lice, or "crabs") and scabies (itch mite) are common parasitic infestations of the skin of the vulva. Other causes of vulvitis include:

- Atrophic vaginitis
- Lichen planus (thickened, leathery skin from scratching)
- Vulvar leukoplakia (postmenopausal atrophy and thickening of vulvar tissues)
- Vulvar cancer
- Urinary incontinence

Some women may have an *itch-scratch-itch cycle,* in which the itching leads to scratching, which causes excoriation that then must heal. As healing takes place, itching occurs again. If the cycle is not interrupted, the chronic scratching may lead to the white, thickened skin of lichen planus. This dry, leathery skin cracks easily, increasing the risk for

infection.

Patient-Centered Collaborative Care

Assess for vulvovaginitis by asking questions about the symptoms, assisting with a pelvic examination, and obtaining vaginal smears for laboratory testing. Ask if the patient is experiencing an itching or burning sensation, **erythema** (redness), edema, and/or superficial skin ulcers. Use a nonjudgmental approach and provide reassurance during the assessment because the patient may be embarrassed or afraid to discuss her symptoms. Encourage her to talk about her problem and its effect on her sexual health.

Interventions for vulvovaginitis depend on the specific vaginal infection. Proper health habits can benefit treatment. Instruct the patient to get enough rest and sleep, observe good dietary habits, exercise regularly, and use good personal hygiene. Teach her about how to manage her infection (Chart 71-1) and how to prevent further infections (Chart 71-2).

Chart 71-1 Patient and Family Education: Preparing for Self-Management

Vaginal Infections

- Your risk for getting vaginal infections increases if you have sex with more than one person.
- When you have a vaginal infection, do not have sexual intercourse, if possible, or at least make sure that your partner wears a condom.
- All sexual partners may need to be treated for infection.
- The only way to identify what infection you have is to be examined by a health care provider and to follow up to get the results of laboratory tests.
- Take all of your medicine as prescribed, not just until your symptoms go away.

Chart 71-2 Patient and Family Education: Preparing for Self-Management

Prevention of Vulvovaginitis

- Wear cotton underwear.
- Avoid wearing tight clothing, such as pantyhose or tight jeans, because they can cause chafing. You can also get hot and sweaty, which can

increase the risk for infection.
- Always wipe front to back after having a bowel movement or urinating.
- During bath or shower, cleanse inner labial mucosa with water, not soap.
- Do not douche or use feminine hygiene sprays.
- If your sexual partner has an infection of the sex organs, do not have intercourse with him or her until he or she has been treated.
- You are more likely to get an infection if you are pregnant, have diabetes, take oral contraceptive drugs, or are menopausal.
- Practice vulvar self-examination monthly.

Wet compresses, warm or tepid sitz baths for 30 minutes several times a day, and topical drugs such as estrogens and lidocaine can help relieve itching. Encourage the patient to wear breathable fabrics such as cotton and to avoid irritants or allergens in products such as laundry detergents or bath products.

Treatment of pediculosis and scabies is used if needed and includes:
- Applying lindane (Kwell, Kwellada) lotion, shampoo, or cream to the affected area as directed
- Cleaning affected clothes, bedding, and towels
- Disinfecting the home environment (lice cannot live for more than 24 hours away from the body)

NCLEX Examination Challenge

Health Promotion and Maintenance

A client tells the nurse that she has vaginal itching. Which client statement would cause the nurse to further assess for symptoms of vaginitis? **Select all that apply.**

A "I always use the same detergent when washing clothes."
B "All of my immunizations, including Gardasil, are up to date."
C "I've scratched so hard that it gets raw, but then it feels better for awhile."
D "My boyfriend and I broke up last month, but we are together again now."
E "My health care provider prescribed antibiotics for my sinus infection last week."

Toxic Shock Syndrome

Pathophysiology

Toxic shock syndrome (TSS) can result from menstruation and tampon use. Other conditions associated with TSS include surgical wound infection, nonsurgical infections, gynecologic surgeries, and use of internal contraceptives.

In infection related to menstruation, menstrual blood provides a growth medium for *Staphylococcus aureus* (or, less frequently, Group A *Streptococcus* [GAS], also known as *Streptococcus pyogenes*). Exotoxins produced from the bacteria cross the vaginal mucosa to the bloodstream via microabrasions from tampon insertion or prolonged use. TSS can be fatal. Extensive public education has led to a decreased number of women developing the infection.

Patient-Centered Collaborative Care

TSS usually develops within 5 days after the onset of menstruation. Most common symptoms include fever, rash, myalgias, sore throat, edema, and hypotension (Low, 2013). The rash associated with TSS often looks like a sunburn, and patients often develop broken capillaries in the eyes and skin. Educate all women on prevention of TSS (Chart 71-3).

Chart 71-3 Patient and Family Education: Preparing for Self-Management

Prevention of Toxic Shock Syndrome

- Wash your hands before inserting a tampon.
- Do not use a tampon if it is dirty.
- Insert the tampon carefully to avoid injuring the delicate tissue in your vagina.
- Change your tampon every 3 to 6 hours.
- Do not use superabsorbent tampons.
- Use sanitary napkins (instead of tampons) at night.
- Call your health care provider if you suddenly experience a high temperature, vomiting, or diarrhea.
- Do not use tampons at all if you have had toxic shock syndrome.
- Not using tampons almost guarantees that you will not get toxic shock syndrome.

Treatment includes removal of the infection source, such as a tampon; restoring fluid and electrolyte balance; administering drugs to manage hypotension; and IV antibiotics. Other measures may include transfusions to reverse low platelet counts and corticosteroids to treat skin changes.

Pelvic Organ Prolapse

❖ Pathophysiology

The pelvic organs are supported by a sling of muscles and tendons, which sometimes become weak and no longer able to hold an organ in place. **Uterine prolapse,** the most common type of **pelvic organ prolapse (POP),** can be caused by neuromuscular damage of childbirth; increased intra-abdominal pressure related to pregnancy, obesity, or physical exertion; or weakening of pelvic support due to decreased estrogen. The stages of uterine prolapse are described by the degree of descent of the uterus (Fig. 71-2) through the pelvic floor.

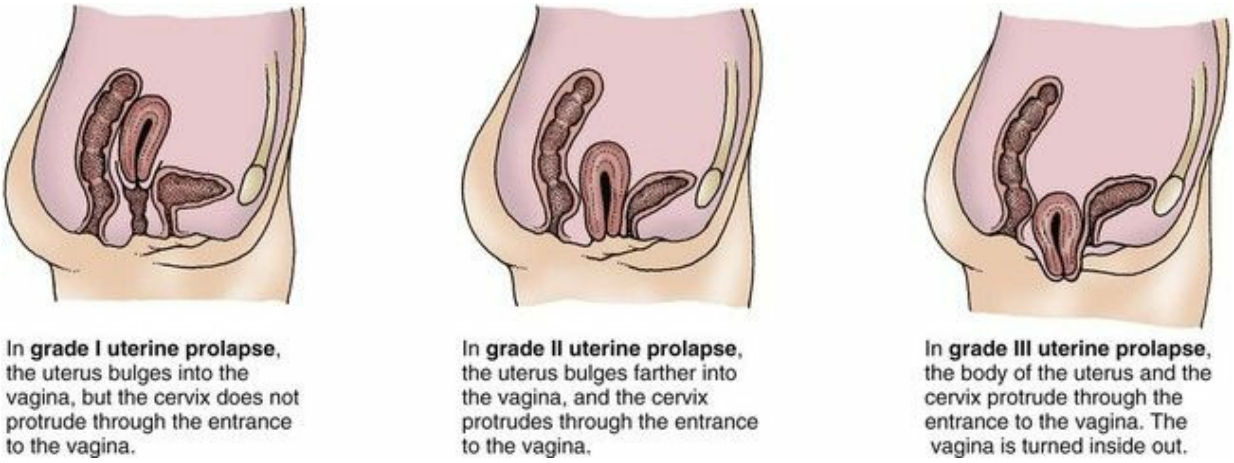

FIG. 71-2 Types of uterine prolapse.

Whenever the uterus is displaced, other structures such as the bladder, rectum, and small intestine can protrude through the vaginal walls (Fig. 71-3). A **cystocele** is a protrusion of the bladder through the vaginal wall (urinary bladder prolapse), which can lead to stress urinary incontinence (SUI) and urinary tract infections (UTIs). A **rectocele** is a protrusion of the rectum through a weakened vaginal wall (rectal prolapse).

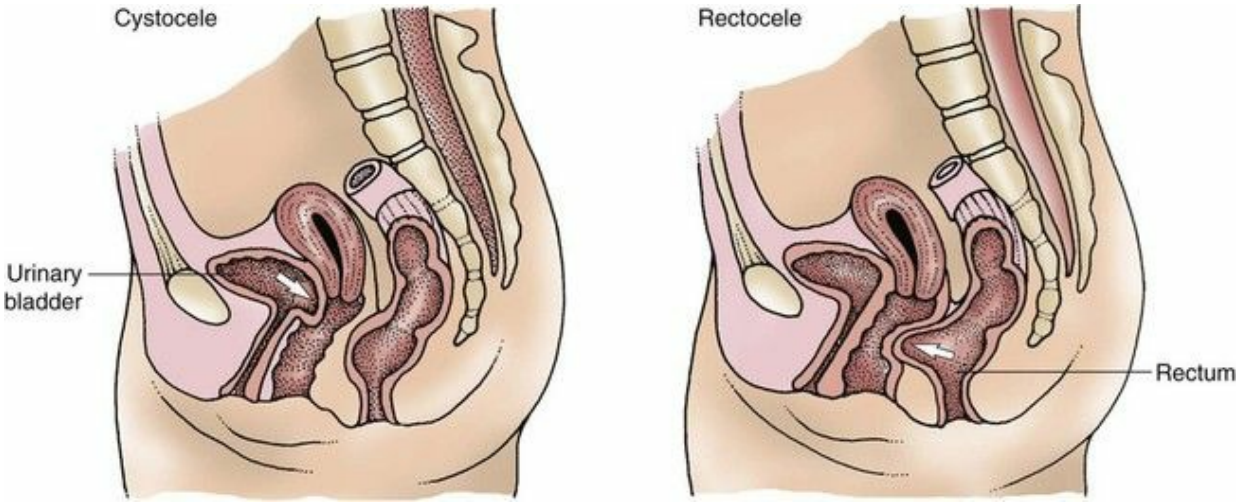

FIG. 71-3 In cystocele, the urinary bladder is displaced downward, causing bulging of the anterior vaginal wall. In rectocele, the rectum is displaced, causing bulging of the posterior vaginal wall.

Patient-Centered Collaborative Care

Assessment

Patients with suspected uterine prolapse may report a feeling of "something falling out," dyspareunia (painful intercourse), backache, and heaviness or pressure in the pelvis. A pelvic examination may reveal a protrusion of the cervix or anterior vaginal wall when the woman is asked to bear down. Listen to her concerns, and note signs of anxiety or depression from having long-term symptoms.

Ask the patient whether she has urinary elimination problems, such as difficulty emptying her bladder, urinary frequency and urgency, a urinary tract infection, or **stress urinary incontinence (SUI)** (loss of urine during activities that increase intra-abdominal pressure, such as laughing, coughing, sneezing, or lifting heavy objects). These symptoms may be associated with a *cystocele* (bladder prolapse).

Diagnostic tests include cystography (to show the presence of bladder herniation), measurement of residual urine by bladder ultrasound, and urine culture and sensitivity testing. Radiographic imaging of urinary anatomy and voiding function is useful in determining the degree of *cystocele* (prolapse).

Rectocele assessment usually includes symptoms of constipation, hemorrhoids, fecal impaction, and feelings of rectal or vaginal fullness. A vaginal and rectal examination may show a bulge of the posterior vaginal wall when the woman is asked to bear down.

Interventions

Interventions are based on the degree of the POP. Conservative treatment is preferred over surgical treatment when possible.

Nonsurgical Management.

Teach women to improve pelvic support and tone by doing pelvic floor muscle exercises (PFMEs, or Kegel exercises). Space-filling devices such as pessaries or spheres can be worn in the vagina to elevate the uterine prolapse. Intravaginal estrogen therapy may be prescribed for the postmenopausal woman to prevent atrophy and weakening of vaginal walls. Women with bladder symptoms may benefit from bladder training and attention to complete emptying. Management of a rectocele focuses on promoting bowel elimination. The health care provider usually prescribes a high-fiber diet, stool softeners, and laxatives.

Surgical Management.

Surgery may be recommended for severe symptoms of POP, with preference given to the least invasive approach. Address the fears and concerns of the patient and her family.

Transvaginal repair for pelvic organ prolapse (POP) using surgical vaginal mesh or tape is a commonly performed minimally invasive technique. It is particularly useful for women who are very obese. Depending on the procedure that is planned, the patient has either local or general anesthesia. The surgeon creates a sling with the mesh or tape, and the woman is discharged the same day. Procedures done under local anesthesia can be done in the surgeon's office. Since 2008, patient report of complications associated with the use of transvaginal mesh has required the U.S. Food and Drug Administration (2011) to release an initial report and update advising about the safety and effectiveness of the use of this product for POP. Complications associated with the use of transvaginal mesh for POP include vaginal mesh erosion, painful sexual intercourse, infection, urinary elimination problems, bleeding, and organ perforation (U.S. Food and Drug Administration [USFDA], 2011). Three deaths associated with this procedure (two bowel perforations and one hemorrhage) were also reported between 2008 and 2010 (USFDA, 2011).

Nursing Safety Priority QSEN

Action Alert

To help the patient decide if she should have any surgical procedure

using mesh or tape, be sure that she is provided with information regarding informed consent prior to surgery. Reinforce information about possible adverse events, the signs and symptoms of infection, and when she should contact her surgeon. Provide the patient with the manufacturer's labeling and written information.

Teach patients who have had the mesh or tape procedure to avoid strenuous exercise, heavy lifting, and sexual intercourse for 6 weeks. After 6 weeks, the patient may gradually begin to return to regular activities but must be educated about prevention of increasing intra-abdominal pressure (e.g., constipation, weight-lifting, cigarette smoking) for a minimum of 3 months to allow proper healing and prevent POP recurrence (Lazarou, 2012).

Alternatives to minimally invasive surgery are open surgical techniques. An **anterior colporrhaphy** (anterior repair) tightens the pelvic muscles for better *bladder* support. A vaginal surgical approach is used and may be done as a laparoscopic-assisted procedure. Nursing care for a woman undergoing an anterior repair is similar to that for a woman undergoing a vaginal hysterectomy.

After surgery, instruct the patient how to splint her abdomen to protect sutures and to limit her activities. Teach her to *avoid lifting anything heavier than 5 pounds, strenuous exercises, and sexual intercourse for 6 weeks.* For discomfort, she may use heat either as a moist heating pad or warm compresses applied to the abdomen. A hot bath may also be helpful. Sutures do not need to be removed because some are absorbable and others will fall out as healing occurs. Tell the woman to notify her health care provider if she has signs of infection, such as fever, persistent pain, or purulent, foul-smelling discharge. Encourage her to keep her follow-up appointment after surgery.

Posterior colporrhaphy (posterior repair) reduces *rectal* bulging. If both a cystocele and a rectocele are present, an *anterior and posterior colporrhaphy (A&P repair)* is performed.

The nursing care after a posterior repair is similar to that after any rectal surgery. After surgery, a low-residue (low-fiber) diet is usually prescribed to decrease bowel movements and allow time for the incision to heal. Instruct the patient to avoid straining when she does have a bowel movement so that she does not put pressure on the suture line. Bowel movements are often painful, and she may need pain medication before having a stool. Provide sitz baths or delegate this activity to unlicensed nursing personnel to relieve the woman's discomfort. Health teaching for the patient undergoing a posterior repair is similar to that

for the patient undergoing an anterior repair. Vaginal hysterectomy may accompany any uterine prolapse repair surgery unless the woman wants to become pregnant. This procedure is described on p. 1489.

Benign Neoplasms

Ovarian Cyst

Functional ovarian cysts can occur in a woman of any age but are rare after menopause. Other cysts and tumors of the ovaries are not related to the menstrual cycle but arise from ovarian tissue. Primary assessment involves pelvic examination and transvaginal ultrasound. Further testing with CT, MRI, or laparoscopic biopsy to rule out cancer may be needed. Some ovarian cysts disappear over time, and others cause discomfort for a prolonged period. Laparoscopic surgery to remove the cyst or ovary may be needed.

Uterine Leiomyoma

❖ Pathophysiology

Leiomyomas, also called **fibroids** or **myomas,** are benign, slow-growing solid tumors of the uterine myometrium (muscle layer). They are classified according to their position in the layers of the uterus: intramural, submucosal, and subserosal (Fig. 71-4).

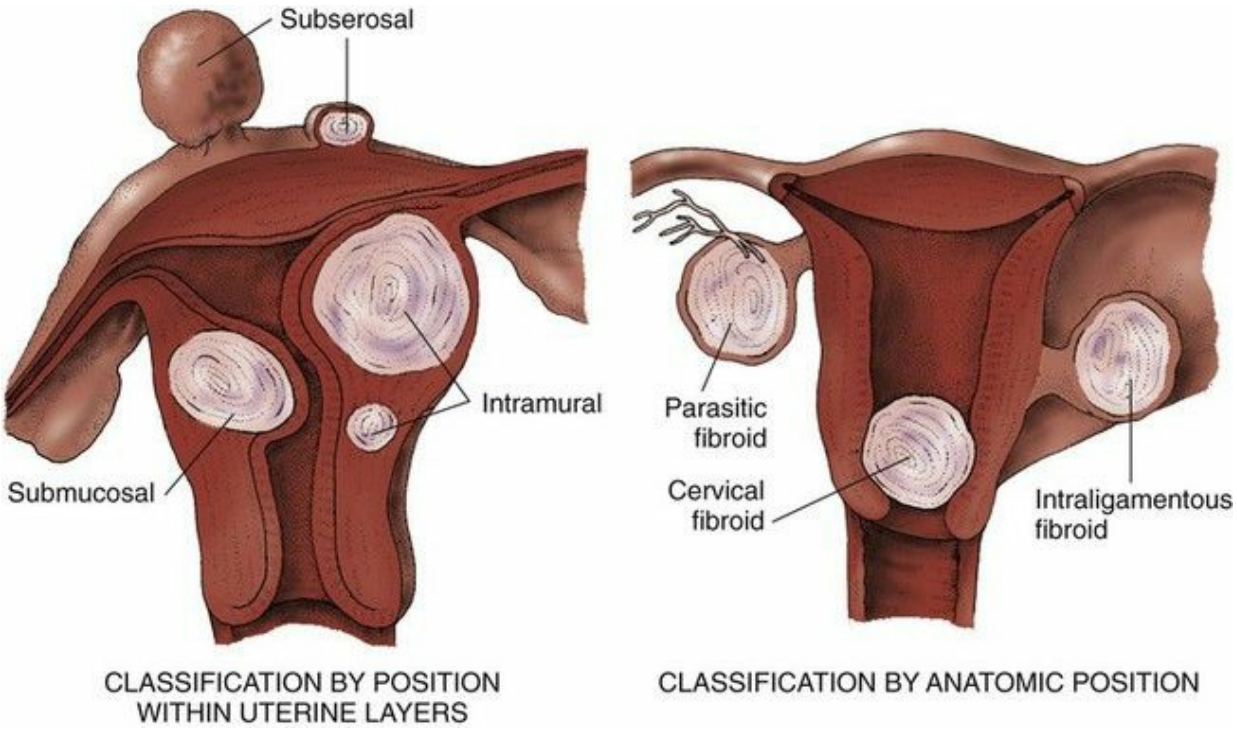

FIG. 71-4 Classification of uterine leiomyomas.

Intramural leiomyomas are contained in the uterine wall within the myometrium. *Submucosal* leiomyomas protrude into the cavity of the uterus and can cause bleeding and disrupt pregnancy. *Subserosal*

leiomyomas protrude through the outer surface of the uterine wall and may extend to the broad ligament, pressing other organs (McCance et al., 2014).

Although most fibroids develop within the uterine wall, a few may appear in the cervix. Pedunculated leiomyomas are attached by a pedicle (stalk) to the outside of the uterus and occasionally break off and attach to other tissues (parasitic fibroids).

Although the cause is not known, leiomyomas develop from excessive local growth of smooth muscle cells. This may be a genetic error causing a lack of ability to halt growth. The growth of leiomyomas may be related to stimulation by estrogen, progesterone, and growth hormone. This explains why fibroids sometimes enlarge during pregnancy and diminish in size after menopause.

The incidence of leiomyomas increases as women get older. Women who have never been pregnant also are at a high risk. Many women have asymptomatic fibroids, whereas others have severe symptoms.

Patient-Centered Collaborative Care

Assessment

Women with fibroids usually do not have pain, although acute pain may occur with twisting of the fibroid on its stalk. *The patient often seeks medical attention because of heavy vaginal bleeding.* Ask about how many tampons or menstrual pads she uses a day. She may report a feeling of pelvic pressure, constipation, or urinary frequency or retention. These symptoms result when an enlarged fibroid presses on other organs. The patient may notice that her abdomen has increased in size. Assess the woman's abdomen for distention or enlargement. Ask if she has dyspareunia (painful intercourse) and/or infertility (inability to become pregnant).

Abdominal, vaginal, and rectal examinations usually reveal the presence of a uterine enlargement. Further diagnostic procedures are needed to differentiate benign tumors from cancerous ones.

Symptoms such as dyspareunia may significantly lower the patient's quality of life. A woman who is symptomatic may fear that she has cancer or may have anxiety about abnormal bleeding or her failure to conceive. She may also be concerned if surgery is recommended if she desires pregnancy. Assess the woman's feelings and concerns about her symptoms and fears of the unknown. If hysterectomy is recommended, explore the significance of the loss of the uterus for the woman and her partner. Discuss sexuality issues with the patient based on your

assessment.

A complete blood count may identify iron deficiency anemia (related to bleeding). A pregnancy test is done to determine whether pregnancy is the cause of the uterine enlargement. An endometrial biopsy may be performed to evaluate for endometrial cancer.

Transvaginal ultrasound alone or with saline infusion (saline sonogram) provides a picture of a submucosal fibroid that may protrude into the uterine cavity. The health care provider may then choose to directly view a tumor and perform a biopsy using *laparoscopy* (for tumors on the outside of the uterus) or *hysteroscopy* (for tumors accessible inside the uterus). *MRI* can differentiate between benign and malignant lesions.

Interventions

Asymptomatic fibroids do not need treatment. Management depends on the size and location of the tumor and the woman's desire for future pregnancy. Women who still desire pregnancy can take drug therapy or have magnetic resonance–guided focused ultrasound surgery or laparoscopic myomectomy to remove the tumor. Uterine artery embolization and hysterectomy are choices for women who no longer desire pregnancy.

Nonsurgical Management.

If the woman is menopausal, the fibroids usually shrink and surgery may not be necessary. *Teach the patient who is receiving hormone replacement therapy for menopausal symptoms that the fibroids may continue to grow because of estrogen stimulation.*

If the woman has few symptoms or desires childbearing, the health care provider may recommend intermittent observation and examination. As with dysfunctional uterine bleeding, mild leiomyoma symptoms can be managed with oral contraception.

Magnetic resonance–guided focused ultrasound is a noninvasive, painless technique for women with few smaller fibroids who wish to preserve their fertility. The woman lies prone on an MRI scanner, which provides a three-dimensional image of the pelvis. The radiologic clinician then guides a focused pulse of ultrasound to heat the tumor to destroy it.

An alternative to surgery for the woman who does not desire pregnancy is **uterine artery embolization** (also called *uterine fibroid embolization [UFE]*) under conscious sedation. The interventional radiologist uses a percutaneous catheter inserted through the femoral artery to inject polyvinyl alcohol pellets into the uterine artery. The resulting blockage starves the tumor of circulation, allowing it (or them)

to shrink.

Nursing Safety Priority QSEN

Action Alert

After uterine artery embolization, the woman may have severe cramping within the first 24 hours caused by decreased blood flow to the uterus. Cramping can last from a few days to 2 weeks. Assess her pain level, and provide analgesics as needed. If a vascular closure device is used at the arterial insertion site (most commonly), raise the head of the bed. Help the patient ambulate in about 2 hours after the procedure. If a closure device was not used, keep her on bedrest with the legs immobilized for 4 hours before ambulating to prevent bleeding. Patients generally recover quickly, returning to normal activities within 7 to 10 days after the procedure (Storck, 2012.)

Before discharge, tell the patient to observe for post-embolectomy syndrome—a flu-like illness that some women develop that lasts about 5 to 7 days (Northwest Radiology Associates, 2014). Teach her to resume usual activities slowly. Most patients can return to work or daily routine within a week. She should avoid strenuous activity until the physician recommends it.

Surgical Management.

When possible, minimally invasive surgical (MIS) techniques are performed, such as a myomectomy. If not, a hysterectomy is the procedure of choice.

Uterus-Sparing Surgeries.

If the woman desires children, the surgeon may perform a laparoscopic or hysteroscopic **myomectomy** (the removal of leiomyomas from the uterus) (Bradley, 2013). During this procedure, a laser may be used to remove the tumors. This minimally invasive procedure is usually performed in the early phase of the menstrual cycle to minimize blood loss and to avoid the possibility of interrupting an unsuspected pregnancy. A small percentage of leiomyomas recur after surgery. Scarring makes the uterus more likely to rupture during labor, so future deliveries will be planned cesarean deliveries. Nursing care is similar to that for a woman undergoing a hysterectomy (see below).

In selected cases (e.g., submucous fibroids, menorrhagia), a

transcervical endometrial resection (TCER) is performed via hysteroscopy. A hysteroscope (endoscope) is inserted into the uterus, and the endometrium is destroyed using diathermy (heat) or radioablation.

Nursing Safety Priority QSEN

Critical Rescue

Monitor for rare but potential complications of hysteroscopic surgery, which include:

- Fluid overload (fluid used to distend the uterine cavity can be absorbed)
- Embolism
- Hemorrhage
- Perforation of the uterus, bowel, or bladder and ureter injury
- Persistent increased menstrual bleeding
- Incomplete suppression of menstruation

Monitor for any indications of these problems, and report signs and symptoms, such as severe pain and heavy bleeding, to the surgeon immediately. Scarring may cause a small risk for complications in future pregnancies.

Hysterectomy.

Leiomyomas are the most common reason for hysterectomies. Hysterectomies may be performed abdominally, vaginally, or with laparoscopic or robotic assistance based on the patient's clinical reason for hysterectomy and the surgeon's area of technical expertise (Falcone, 2014).

A *total abdominal hysterectomy (TAH)* is usually performed for leiomyomas larger than the size of a 16-week pregnancy. The uterus and cervix are most often removed by laparoscopic-assisted minimally invasive surgery (MIS), which requires one or more very small umbilical incisions. The traditional open surgery is performed through a horizontal bikini incision. A *total vaginal hysterectomy (TVH)* requires no skin incision because the uterus is removed through the vagina.

Some surgeons use robotic technology to assist in performing a TAH, although it is much more expensive than a traditional vaginal or laparoscopic approach (ACOG, 2013). Robotic surgery is helpful when performing hysterectomies on patients who are extremely obese (Gallo et al., 2012). In both vaginal and abdominal hysterectomies, the surgeon removes the uterus from the five supporting ligaments, which are then attached to the vaginal cuff so that normal depth of the vagina is

maintained (Table 71-2).

TABLE 71-2
Common Gynecologic Surgeries

Total Hysterectomy All of the uterus, including the cervix, is removed. The procedure may be vaginal or abdominal, with laparoscopic or robotic assistance.
Bilateral Salpingo-Oophorectomy (BSO) Fallopian tubes and ovaries are removed.
Panhysterectomy Total abdominal hysterectomy and BSO: The uterus, ovaries, and fallopian tubes are removed.
Radical Hysterectomy The uterus, cervix, adjacent lymph nodes, the upper third of the vagina, and the surrounding tissues (parametrium) are removed.

Preoperative teaching by the health care team begins in the surgeon's office. Explain procedures that routinely take place before surgery, including laboratory tests and expected drugs such as a prophylactic antibiotic. Depending on the type of surgical technique planned, teach about the need for turning, coughing, and deep-breathing exercises; incentive spirometry; early ambulation; and pain relief. (See Chapter 14 for a discussion of general patient care before surgery.)

Psychological assessment is essential. Assess the significance of the surgery for the woman and her partner related to sexuality. If it involves loss of the uterus, she may feel a great loss if she wishes to become pregnant. Many women relate their uterus to self-image and femininity or believe that their sexual function is related to their uterus. Although surgical menopause by hysterectomy can create loss of libido and vaginal changes if the ovaries are also removed, teach the patient that vaginal estrogen cream and gentle dilation can help correct that. Reassure her regarding any misperceptions about the effects of hysterectomy, such as association with masculinization and weight gain. Assess the patient's support system. She may fear rejection by her sexual partner. Include the partner in all teaching sessions (if the patient prefers) unless this practice is not culturally acceptable.

Patients who have *uterus-sparing surgeries* usually go home the same

day of surgery. They often experience less postoperative pain and fewer complications when compared with patients who have their uterus and cervix removed. Teach patients that they usually return to usual daily activities in 2 weeks but sexual intercourse should be avoided for at least 6 weeks.

Postoperative care of the woman who has undergone a *TAH* is similar to that of any patient who has had laparoscopic or traditional open abdominal surgery (see Chapter 16). Assess (Chart 71-4):

Chart 71-4 Focused Assessment

Postoperative Nursing Care of the Patient after Total Abdominal Hysterectomy

- Assess cardiovascular, respiratory, renal, and gastrointestinal status, including:
  - Vital signs
  - Heart, lung, and bowel sounds
  - Urine output
  - Temperature and color of the skin
  - Red blood cell, hemoglobin, and hematocrit levels
  - Activity tolerance
  - Dressing and drains for color and amount of drainage
  - Perineal pads for vaginal bleeding and clots
  - Fluid intake (IVs until peristalsis returns and patient is tolerating oral intake)
- Teach the patient to use these interventions to prevent postoperative complications:
  - Cough and deep-breathing exercises
  - Incentive spirometry
  - Sequential compression devices
  - Ambulation
  - Avoidance of heavy lifting or strenuous activity
  - Adequate hydration
- Assess the home care teaching needs of the patient related to the illness and surgery, including:
  - Physiologic effects of the surgery
  - Signs or symptoms to report
  - Side or toxic effects of medications
  - Activity limitations related to driving and use of stairs
  - Follow-up care

- Postoperative restrictions related to sexual activity, use of tampons, and bathing
- Care of wound and/or drains

• Assess the patient's coping skills and reaction to the diagnosis and surgical procedure.

• Vaginal bleeding (there should be less than one saturated perineal pad in 4 hours)
• Abdominal bleeding at the incision site(s) (a small amount is normal)
• Intactness of the incision(s)
• Urine output per urinary catheter for 24 hours or less (for open surgery only)
• Pain

Specific postoperative interventions for a *vaginal hysterectomy* include:

• Assessment of vaginal bleeding (there should be less than one saturated pad in 4 hours)
• Urinary catheter care
• Perineal care

NCLEX Examination Challenge

Physiological Integrity

A client returns from surgery after a total vaginal hysterectomy. Upon initial assessment, which finding by the nurse requires immediate intervention?

A Clean, intact dressing
B Excessive vaginal bleeding
C Temperature of 99° F
D Client statement that pain is "4" on scale of 0-10

Community-Based Care

If the patient had a hysterectomy, teach her to limit stair climbing for several weeks. If she lives alone and is not permitted to drive for several weeks, she may need to arrange for transportation for follow-up surgical visits.

Teach the woman who has undergone an abdominal hysterectomy about the expected physical changes, any activity restrictions, diet, sexual activity, wound care, complications, and the need for follow-up care. Chart 71-5 lists areas to include for health teaching.

Chart 71-5 Patient and Family Education: Preparing for Self-Management

Care after a Total Vaginal or Abdominal Hysterectomy

Expected Physical Changes

- You will no longer have a period, although you may have some vaginal discharge for a few days after you go home.
- It will not be possible for you to become pregnant, and birth control methods are no longer needed. (Condoms should still be used to decrease the chance of getting a sexually transmitted disease [STD].)
- If your ovaries were removed, you may have some menopause symptoms such as hot flushes, night sweats, and vaginal dryness.
- It is normal to tire more easily and require more sleep and rest during the first few weeks after surgery.

Activity

- Limit stair climbing to fewer than 5 times per day.
- Do not lift anything heavier than 5 to 10 lbs.
- Gradually increase walking as exercise, but stop before you become fatigued.
- Avoid the sitting position for any extended period. When you sit, do not cross your legs at the knees.
- Avoid jogging, aerobic exercise, participating in sports, and any strenuous activity for 2 to 6 weeks, depending on what type of surgical procedure was performed.
- Do not drive until your surgeon has told you it is alright.

Sexual Activity

- Do not engage in sexual intercourse for 4 to 6 weeks or as prescribed by your surgeon.
- If you had a vaginal "repair" as part of your surgery, the first time you have intercourse you may have some tenderness or pain because the vaginal walls are tighter. Careful intercourse and the use of water-based lubricants can help reduce this discomfort. This discomfort usually goes away with time and stretching of the vagina.

Complications

- Take your temperature twice each day for the first 3 days after surgery. Report fevers of over 100° F (38° C).
- Check your incision, if you have any, daily for signs of infection

(increasing redness, open areas, drainage that is thick or foul-smelling, incision pain).

Symptoms to Report to Your Surgeon

- Increased vaginal drainage or change in drainage (bloodier, thicker, foul-smelling)
- Temperature over 100° F (38° C)
- Pain, tenderness, redness, or swelling in your calves
- Pain or burning on urination

Generally, women are more accepting of surgery if they have completed childbearing, have interests outside the home, work, have no misconceptions about the effects of hysterectomy, and have support from the family, especially their sexual partner. Psychological reactions can occur months to years after surgery, particularly if sexual functioning and libido are diminished. Women identified as being at high risk for psychological problems may need long-term follow-up care or referral. They may need to be counseled about signs of depression. Intermittent sadness is normal, but continued feelings of low self-esteem or loss of interest or pleasure in usual activities and pastimes is not expected and should be evaluated. Provide written materials, and focus on the positive aspects of the woman's life to help decrease adverse psychological reactions.

Bartholin Cyst

Bartholin cyst is a common disorder of the vulva. It results from obstruction of the duct of the Bartholin gland. The secretory function of the gland continues, and the fluid fills the obstructed duct. The main causes of the obstruction are infection, thickened mucus near the ductal opening, or trauma, such as lacerations.

The patient may be asymptomatic if the cyst is small. Ask if she has dyspareunia (painful intercourse) or inadequate genital lubrication. Assess for swelling in the perineal area. A large cyst usually causes constant local pain and may cause difficulty walking or sitting. Assessment of the vulva reveals a unilateral swelling immediately beneath the skin in the posterior portion of the vulva. The cyst may appear brown or bloody, depending on its contents. Vaginal discharge may be present with a Bartholin *abscess* if an infection, such as one caused by a sexually transmitted organism, is present (Braun, 2014).

If the cyst is draining, a fluid sample is sent to the laboratory to culture

for gonorrhea and/or other organisms. If the woman is older than 40 years, a biopsy of the cyst may be done to identify possible cancer.

If the woman is asymptomatic, no intervention is needed. An abscess usually ruptures spontaneously within 72 hours of forming. Teach the patient to take over-the-counter or prescribed analgesics and apply moist heat (sitz baths or hot wet packs) to the vulva. Cultures most often reveal *Escherichia coli* or *S. aureus,* for which antibiotics are prescribed.

Simple incision and drainage (I&D) may provide temporary relief. However, cysts tend to recur when the opening of the duct re-obstructs. Usually the surgeon establishes a permanent opening for drainage. **Marsupialization** (formation of a pouch that is a new duct opening) is performed using local, regional, or general anesthesia. Discomfort after surgery may be relieved with analgesics and sitz baths. Prophylactic antibiotics may be prescribed.

The Bartholin glands may be totally removed in older women when cancer is suspected or if infections with abscess formation recur. Care after surgery includes:

- Application of ice packs or sitz baths several times a day for comfort and promotion of healing
- Analgesics for pain
- Prophylactic antibiotics
- Assessment of the incision for signs of healing or infection

Cervical Polyp

Cervical polyps are *pedunculated* (on stalks) tumors that arise from the mucosa and extend through the opening of the cervical os. Although the cause is not completely understood, they may result from a hyperplasia (overgrowth) of the endocervical epithelium in response to estrogen, chronic inflammation, and/or clogged blood vessels in the cervix (Storck, 2014). Polyps may also be due to inflammation or to localized vascular congestion of the cervical blood vessels. They are the most common benign growth of the cervix and occur most often in women older than 40 years who have had several children.

Some patients are asymptomatic; others may have premenstrual or postmenstrual bleeding, experience bleeding after douching or intercourse, and/or have leukorrhea (white or yellow mucus) (Storck, 2014). A speculum examination may reveal a small single polyp or multiple polyps. They are bright red, are soft and fragile, and may bleed when touched.

Polyp removal is usually accomplished as a simple office procedure.

The base of the polyp is grasped with a clamp, and the polyp is gently twisted off and sent to the pathology laboratory for evaluation. Cautery usually stops any bleeding at the site of removal and is also effective when removing larger polyps (Storck, 2014). The woman does not feel any pain during the procedure. Instruct her to avoid tampon use, douches, and sexual intercourse for a week or until healing has taken place.

Gynecologic Cancers

Endometrial (Uterine) Cancer

Pathophysiology

Endometrial cancer (cancer of the inner uterine lining) is the most common gynecologic malignancy (Nguyen et al., 2013). This chapter includes two other common gynecologic cancers, but the disease can affect any organ in the reproductive tract.

Endometrial cancer grows slowly in most cases, and early symptoms of vaginal bleeding generally lead to prompt evaluation and treatment. As a result, this type of cancer has a good prognosis. *Adenocarcinoma* is the most common type of tumor. It arises from the glandular part of the endometrium and usually follows endometrial hyperplasia (overgrowth).

The initial growth of the cancer is within the uterine cavity, followed by extension into the myometrium and the cervix. Stage I endometrial cancer is confined to the endometrium. Stage II cancer also involves the cervix, and stage III reaches the vagina or lymph nodes. Stage IV endometrial cancer has spread to the bowel or bladder mucosa and/or beyond the pelvis (McCance et al., 2014).

Metastasis outside the uterus occurs in these ways:

- Through lymphatic spread to the ovaries and parametrial, pelvic, inguinal, and para-aortic lymph nodes
- By blood to the lungs, liver, or bones
- By transtubal or intra-abdominal spread to the peritoneal cavity

Etiology and Genetic Risk

Endometrial cancer is strongly associated with conditions causing prolonged exposure to estrogen without the protective effects of progesterone. Risk factors for endometrial cancer are listed in Table 71-3. Although most cases of endometrial cancer do not have a genetic predisposition, it is more common in families who have gene mutations for hereditary nonpolyposis colon cancer (HNPCC) (National Cancer Institute [NCI], 2013b).

TABLE 71-3

Risk Factors for Endometrial (Uterine) Cancer and Cervical Cancer

ENDOMETRIAL (UTERINE) CANCER	CERVICAL CANCER
• Women in reproductive years • Family history of endometrial cancer or HNPCC • Diabetes mellitus • Hypertension • Obesity • Uterine polyps • Late menopause • Nulliparity (no childbirths) • Smoking • Tamoxifen (Nolvadex) given for breast cancer	• Girls and young women • Infection with HPV • Multiparity (multiple births) • Smoking • Younger than 18 years at first intercourse • Multiple sex partners • African American • Oral contraceptive use • History of STDs • Obesity or poor diet • Family history of cervical cancer • HIV/AIDS • Lower socioeconomic status • Sexual partner had a previous partner who developed cervical cancer • Intrauterine exposure to DES

AIDS, Acquired immune deficiency syndrome; *DES,* diethylstilbestrol; *HIV,* human immune deficiency virus; *HNPCC,* hereditary nonpolyposis colon cancer; *HPV,* human papilloma virus; *STDs,* sexually transmitted diseases.

Incidence and Prevalence

In 2013, it was estimated that there will be 49,560 new cases of endometrial cancer in the United States, with 8,910 deaths associated with this condition. White women get the disease more often than African-American women, but African-American women die more often from the disease (American Cancer Society [ACS], 2013a). The causes for these differences are not known.

❖ Patient-Centered Collaborative Care

◆ Assessment

Physical Assessment/Clinical Manifestations.

The main symptom of endometrial cancer is postmenopausal bleeding. Ask the patient how many tampons or menstrual pads she uses each day. Some women also have a watery, bloody vaginal discharge, low back or abdominal pain, and low pelvic pain (caused by pressure of the enlarged uterus). Ask the patient to describe the exact location and intensity of her discomfort. A pelvic examination may reveal the presence of a palpable uterine mass or uterine polyp. The uterus is enlarged if the cancer is advanced.

Laboratory Assessment.

Several laboratory tests are used to determine the overall condition of the woman with possible or confirmed endometrial cancer. For example, the

complete blood count typically shows anemia because the patient has heavy bleeding. Serum tumor markers to assess for metastasis include CA-125 (cancer antigen–125) and alpha-fetoprotein (AFP), both of which may be elevated when ovarian cancer is present (Pagana & Pagana, 2013). A human chorionic gonadotropin (hCG) level may be taken to rule out pregnancy before treatment for cancer begins. Genetic testing may be done for the mutation causing hereditary nonpolyposis colorectal cancer (HNPCC) if there is a family history of this disease.

Other Diagnostic Assessment.

Transvaginal ultrasound and *endometrial biopsy* are the gold standard tests to determine the presence of endometrial thickening and cancer. Saline may be infused during the ultrasound to improve the image of the uterine cavity. The clinician then collects an endometrial biopsy from inside the uterus via a thin, flexible suction curette through the cervix (Pagana & Pagana, 2013).

Other diagnostic tests to determine the patient's overall health status and the presence of metastasis (cancer spread) include:

- Chest x-ray
- Intravenous pyelography (IVP) or excretory urography to assess renal function and to assess for renal metastasis
- Abdominal ultrasound
- CT of the pelvis
- MRI of the abdomen and pelvis
- Liver and bone scans to assess for distant metastasis

Some women also have a hysteroscopic examination of the uterus and proctosigmoidoscopy depending on the stage of their cancer.

Psychosocial Assessment.

Before a diagnosis is made, the woman may deny that the symptoms are related to cancer. During the diagnostic phase, the woman may express fears and concerns about having the disease. After the diagnosis is confirmed, she may express disbelief, anger, depression, anxiety, or withdrawal behaviors. Assess these emotional reactions, and encourage the patient to discuss her feelings. Ask her about how she copes with other stressful events, and assess her support systems.

Analysis

The priority NANDA-I nursing diagnoses and collaborative problems for patients with endometrial cancer include:

1. Potential for disease metastasis

2. Ineffective Coping related to the diagnosis of cancer and fear of dying (NANDA-I)

Planning and Implementation

Reducing the Risk for Metastasis

Planning: Expected Outcomes.

The patient is expected to be free of metastatic disease if she has been diagnosed without obvious metastasis. For patients whose cancer has already spread, the expected outcomes are to have the highest quality life for as long as possible. In some cases, palliation and end-of-life care are needed.

Interventions.

Surgical removal and cancer staging of the tumor with adjacent lymph nodes are the most important interventions for endometrial cancer. Cancer staging is often done using minimally invasive techniques, such as laparoscopic or robotic-assisted procedures.

Surgical Management.

For stage I disease, the gynecology oncologist usually removes the uterus, fallopian tubes, and ovaries **(total hysterectomy** and **bilateral salpingo-oophorectomy [BSO]),** as well as peritoneum fluid or washings for cytologic examination. Laparoscopic surgery has fewer complications, shorter hospital stay, and less cost. A radical hysterectomy with bilateral pelvic lymph node dissection and removal of the upper third of the vagina is performed for stage II cancer. Nursing care for a radical hysterectomy is the same as that for a simple hysterectomy except that the woman's hospitalization is usually longer and her convalescence may be extended. (See p. 1489 for discussion of hysterectomy in this chapter.) Radical surgery and node dissection can also be done as a minimally invasive procedure using laparoscopic or robotic-assisted technology.

Nonsurgical Management.

Nonsurgical interventions (radiation therapy and chemotherapy) are typically used postoperatively and depend on the surgical staging.

Radiation Therapy.

The oncologist may prescribe radiation therapy to be delivered by external beam and/or brachytherapy for stage II and stage III cancers.

Women with stage II disease may use brachytherapy (internal) radiation to prevent recurrence of vaginal cancer and improve survival.

The purpose of *brachytherapy* is to prevent disease recurrence. The radiologist places an applicator within the woman's uterus through the vagina. After the correct position of the applicator is confirmed by x-ray, the radioactive isotope is placed in the applicator and remains for several minutes. This procedure may be repeated between 2 and 5 times once or twice a week. Some patients also have external beam radiation while having brachytherapy treatment sessions. There are no restrictions for the woman to stay away from her family or the public between treatments.

While the radioactive implant is in place, radiation is emitted that can affect other people. The amount of time needed for the therapy depends on the amount of radiation emitted from the source. The radiologist calculates the time needed for a specific dose of radiation.

Inform the patient that she is restricted to bedrest during the treatment session. Excessive movement in bed is restricted to prevent dislodgment of the radioactive source. Chart 71-6 lists the health teaching for the patient having brachytherapy for gynecologic cancer. Teach patients about when to call the health care provider after each treatment session.

Chart 71-6 Best Practice for Patient Safety & Quality Care QSEN

Health Teaching for the Patient Having Brachytherapy for Gynecologic Cancer

- Teach the patient to report any of these signs and symptoms to the health care provider immediately:
  - Heavy vaginal bleeding
  - Urethral burning for more than 24 hours
  - Blood in the urine
  - Extreme fatigue
  - Severe diarrhea
  - Fever over 100° F (38° C)
  - Abdominal pain
- Teach the patient that she is not radioactive between treatments and there are no restrictions on her interactions with others.

External beam radiation therapy (EBRT or XRT) may be used to treat any

stage of endometrial cancer in combination with surgery, brachytherapy, and/or chemotherapy. Depending on the extent of the tumor, the treatment is given on an ambulatory care basis for 4 to 6 weeks. Tissue around the tumor and pelvic wall nodes also are treated. *Teach the patient to monitor for signs of skin breakdown, especially in the perineal area; to avoid sunbathing; and to avoid washing the markings outlining the treatment site.* Chapter 22 discusses nursing care of patients receiving radiation therapy in more detail.

Drug Therapy.

Chemotherapy is used as palliative treatment in advanced and recurrent disease when it has spread to distant parts of the body, but it is not always effective. Although the combination can vary, three of the most common agents used for endometrial cancer are doxorubicin (Adriamycin), cisplatin (Platinol), and paclitaxel (Taxol). Chapter 22 describes chemotherapy and general nursing care during treatment.

Every woman experiences cancer differently. Many complementary therapies have evidence of benefit in decreasing the side effects of drug therapy and boosting the immune system. Provide your patient with information that will help her make informed, evidence-based decisions. Encourage her to check with her oncologist and/or pharmacist because some alternative therapies can be harmful or interfere with cancer treatment. Current evidence-based information is available at the American Cancer Society website (www.cancer.org) about mind-body therapies, healing touch, herbs, vitamins, nutrition, and biologic therapies.

Helping the Patient Develop Coping Strategies

Planning: Expected Outcomes.

The patient is expected to develop coping strategies that will help her deal with the diagnosis and collaborative care for endometrial cancer.

Interventions.

Women need to discuss their concerns about the presence of cancer and the potential for recurrence. Provide emotional support, and create an atmosphere that encourages them to ask questions or express their fears and concerns. Include family members or significant others in discussions when the patient desires and when this is possible.

Reactions to radiation therapy vary. Some women feel "radioactive" or "unclean" after treatments and may exhibit withdrawal behaviors.

Reassure them by correcting any misconceptions. Patients who have chemotherapy may be upset if **alopecia** (hair loss) occurs. Warn them of this possibility before treatment starts. Wigs, scarves, or turbans can be worn until the hair grows back. Many women select these replacements before they lose their hair. Others shave their heads and begin wearing them immediately as the treatment begins. Tell women about these options so that they can make decisions with which they are personally comfortable.

Often patients experience emotional crises because of the physical effects of cancer treatments. Radical hysterectomy may be seen as mutilating. Both radiation and chemotherapy have side effects that change physical appearance and body image. Women may have a grief reaction to these changes. The feelings of loss depend on the visibility of the loss and the loss of function. Help the patient adapt to the body changes. Using a calm and accepting approach, encourage self-management as soon as her physical condition is stable.

Death can occur with or without treatment. The patient and family want the woman to pass the 5-year survival mark without a recurrence of disease. If there is a recurrence, they may be hostile and have manifestations of a grief reaction. Encourage patients and their families to discuss their feelings. Refer to support services such as certified hospital chaplain or other spiritual leader, social worker, or counselor. Response to loss and grieving is discussed in Chapter 7.

Community-Based Care

Home Care Management.

The woman with endometrial cancer is managed at home unless surgery is indicated. After surgery, she is usually discharged to her home. Home care after surgery for endometrial cancer is the same as that after a hysterectomy. (See discussion off Hysterectomy on p. 1489 in the Uterine Leiomyoma section.) Patients who are receiving chemotherapy or radiation therapy are treated on an ambulatory care basis. Most women are surprised by the fatigue caused by radiation and chemotherapy. Help the patient and her family plan daily activities around trips to the clinic or the health care provider's office. If the tumor recurs and cure is not likely, the woman and her family need to think about hospice care and whether she can be cared for in the home.

Self-Management Education.

Teach the patient to report vaginal or rectal bleeding, foul-smelling

discharge, abdominal pain or distention, and hematuria to the health care provider. These symptoms may be the result of the disease or its treatment.

The high dose of radiation causes sterility, and vaginal shrinkage can occur. Vaginal dilators can be used with water-soluble lubricants for 10 minutes each day until sexual activity resumes, generally within 4 weeks (ACS, 2013b). Reassure the woman that she is not radioactive and that her partner will not "catch" cancer by engaging in sexual intercourse.

Review all prescribed drugs, including the dosage and schedule, effects, and side effects. Emphasize the importance of keeping appointments for follow-up care.

Health Care Resources.

In the United States, local American Cancer Society chapters provide written materials about endometrial cancer and information about local support groups. Each province in Canada also has a division of the Canadian Cancer Society (www.cancer.ca). If the patient is in the terminal stages of cancer, hospice care may be appropriate (see Chapter 7). If nursing care is needed at home, the hospital nurse or case manager makes referrals to a home health care agency. A referral to a social services agency may be needed if the patient cannot meet the financial demands of treatment and long-term follow-up.

Cervical Cancer

❖ Pathophysiology

The uterine cervix is covered with squamous cells on the outer cervix and columnar (glandular) cells that line the endocervical canal. Papanicolaou (Pap) tests sample cells from both areas as a screening test for cervical cancer. The squamo-columnar junction is the *transformation zone* where most cell abnormalities occur. The adolescent has more columnar cells exposed on the outer cervix, which may be one reason she is more vulnerable to sexually transmitted diseases (STDs) and human immune deficiency virus (HIV). In contrast, in the menopausal woman, the squamo-columnar junction may be higher up in the endocervical canal, making it difficult to sample for a Pap test.

Premalignant changes are described on a continuum from *atypia* (suspicious) to *cervical intraepithelial neoplasia (CIN)* to *carcinoma in situ (CIS)*, which is the most advanced premalignant change. It generally takes years for the cervical cells to transform from normal to premalignant to invasive cancer. CIN, sometimes called *dysplasia*, is

graded on a scale of 1 to 3 depending on the appearance of the cervical tissue under a microscope (ACS, 2014b). Not much tissue appears abnormal in CIN1 (mild dysplasia), which is thought to be the least serious cervical pre-cancer; more tissue appears abnormal in CIN2 (moderate dysplasia). Most tissue looks abnormal in CIN3 (severe dysplasia as well as carcinoma *in situ*), which is the most serious pre-cancer (ACS, 2014b).

Most cervical cancers arise from the squamous cells on the outside of the cervix. The other cancers arise from the mucus-secreting glandular cells (adenocarcinoma) in the endocervical canal. The disease spreads by direct extension to the vaginal mucosa, lower uterine segment, parametrium, pelvic wall, bladder, and bowel. Metastasis is usually confined to the pelvis, but distant spread can occur through lymphatic spread and the circulation to the liver, lungs, or bones.

Etiology

Human papilloma virus infection (HPV) is the most common type of STD in the United States (Centers for Disease Control and Prevention [CDC], 2014b). Almost all women will have HPV sometime in their life, but not all types lead to cancer. Most cases of cervical cancer are caused by certain types of HPV. The high-risk HPV types, especially strains 16 and 18, impair the tumor-suppressor gene and cause most of the cervical cancers. The unrestricted tissue growth can spread, becoming invasive and metastatic. Strains 6 and 11 are associated with genital warts (McCance et al., 2014). Risk factors for cervical cancer are listed in Table 71-3.

Incidence and Prevalence

Invasive cancer of the cervix is the third most common cancer of the female genital system, after ovarian and uterine cancer. The number of cases of cervical cancer (and deaths from cervical cancer) has decreased significantly over the past 40 years because more women regularly get Pap tests (CDC, 2014a).

Health Promotion and Maintenance

Girls and young women (ages 9 through 26 years) should receive one of the two currently used HPV vaccines, *Gardasil* and *Cervarix,* ideally before their first sexual contact to receive protection against the highest-risk HPV types that are responsible for most cervical cancers. It is also given for boys and young men (ages 9 through 26 years) to prevent

genital warts because it protects against the 6 and 11 HPV strains and to prevent anal cancer, which is caused by HPV strains 16 and 18 (Merck Sharpe & Dohme Corporation, 2014). Cervarix protects girls and women ages 9 through 25 years against infection for HPV strains 16 and 18 to prevent cervical cancer (GlaxoSmithKline, 2012).

Teach all young adults and parents of minors about the importance of receiving the vaccine and the need to have the entire series (3 injections over 6 months). Tell them that the most frequent side effects are related to local irritation from the injections (e.g., pain, redness). Other common side effects include nausea, vomiting, dizziness, headache, and diarrhea.

The American Cancer Society (ACS) recommends that women have periodic pelvic examinations and Pap tests to screen for cervical cancer early. Teach women that they should begin these screening precautions at the age of 21 years. Between ages 21 and 29 years, women should have a Pap test every 3 years; women between ages 30 and 65 years should have a Pap test plus a human papilloma virus (HPV) test ("co-testing") every 5 years. More information on the HPV test is found later in this chapter. In the absence of co-testing, this population should still have a Pap test every 3 years. According to the ACS, women older than 65 years who have had regular cervical cancer testing with normal results should not receive Pap tests (ACS, 2014a). Recommended guidelines from other health care organizations suggest a Pap test every 3 years for women older than 60 years. Those who have had a history of a serious cervical pre-cancerous lesion should be tested annually for at least 20 years after that diagnosis, regardless of age (ACS, 2014a).

Patient-Centered Collaborative Care

Assessment

Physical Assessment/Clinical Manifestations.

The patient who has preinvasive cancer is often asymptomatic. *The classic symptom of invasive cancer is painless vaginal bleeding.* Ask the patient if she has had or now has bleeding. It may start as spotting between menstrual periods or after sexual intercourse or douching. As the cancer grows, bleeding increases in frequency, duration, and amount and may become continuous.

Ask the woman if she has a watery, blood-tinged vaginal discharge that becomes dark and foul-smelling (occurs as the disease progresses). Leg pain (along the sciatic nerve) or swelling of one leg may be a late symptom or may indicate recurrent disease. Flank pain may be a late

symptom of hydronephrosis, indicating advanced cancer pressing on the ureters, backing up the urine into the kidney. Ask the patient if she has had other signs of recurrence or metastasis such as:

- Unexplained weight loss
- **Dysuria** (painful urination)
- Pelvic pain (caused by pressure of the tumor on the bladder or the bowel)
- **Hematuria** (bloody urine)
- Rectal bleeding
- Chest pain
- Coughing

A physical examination may not reveal any abnormalities in early preinvasive cervical cancer. The internal pelvic examination may identify late-stage disease.

Diagnostic Assessment.

If Pap results are abnormal, an *HPV-typing DNA test* of the cervical sample can determine the presence of one or more high-risk types. The health care provider may perform a colposcopic examination to view the transformation zone. **Colposcopy** is a procedure in which application of an acetic acid solution is applied to the cervix. The cervix is then examined under magnification with a bright filter light that enhances the visualization of the characteristics of dysplasia or cancer. If abnormal tissue is recognized, multiple biopsies of the cervical tissue are performed.

If atypical glandular cells are suspected, the health care provider may perform an *endocervical curettage* (scraping of the endocervix wall) as well. Inform her that a small amount of bleeding is expected for up to 2 weeks after the biopsies.

◆ Interventions

Interventions for the woman with cervical cancer are similar to those for endometrial cancer: surgery, which is possibly followed by radiation and chemotherapy for later-stage disease.

Surgical Management.

Early stage I management techniques include local cervical ablation therapies of electrosurgical excision, laser therapy, or cryosurgery. Small tumors that are only microinvasive are managed with excisional conization or hysterectomy. Early-stage *invasive* cancers are managed with radical surgery and radiation. Advanced inoperable cancers are

treated with radiation. Factors that influence the choice of localized treatment versus surgical intervention include patient overall health, desire for future childbearing, tumor size, stage, cancer cell type, degree of lymph node involvement, and patient preference.

Early Surgical Procedures.

The **loop electrosurgical excision procedure (LEEP)** is short (10 to 30 minutes) and is performed in a physician's office or in an ambulatory care setting with a local anesthetic injected into the cervix. A thin loop-wire electrode that transmits a painless electrical current is used to cut away affected tissue. LEEP is both a diagnostic procedure and a treatment, because it provides a specimen that can be examined by a pathologist to ensure the lesion was completely removed. Little discomfort is associated with this procedure. Spotting after the procedure is common. Teach patients to adhere for 3 weeks to the restrictions listed in Chart 71-7.

Chart 71-7 Patient and Family Education: Preparing for Self-Management

Care after Local Cervical Ablation Therapies

- Refrain from sexual intercourse.
- Do not use tampons.
- Do not douche.
- Take showers rather than tub baths.
- Avoid lifting heavy objects.
- Report any heavy vaginal bleeding, foul-smelling drainage, or fever.

The usual time period for these restrictions is 3 weeks. Your health care provider may prescribe a different (longer or shorter) time frame for you.

Laser therapy is also an office procedure used for early cancers. A laser beam is directed to the abnormal tissues, where energy from the beam is absorbed by the fluid in the tissues, causing them to vaporize. A small amount of bleeding occurs with the procedure, and the woman may have a slight vaginal discharge. Healing occurs in 6 to 12 weeks. A disadvantage of this procedure is that no specimen is available for study.

Cryotherapy involves freezing of the cancer, causing subsequent necrosis. The procedure is often painless, although some women have slight cramping after the procedure. The patient has a heavy watery

discharge for several weeks after the procedure. Instruct her to follow the restrictions in Chart 71-7.

In cases of microinvasive cancer, a *conization* can remove the affected tissue while still preserving fertility. This procedure is done when the lesion cannot be visualized by colposcopic examination. A cone-shaped area of cervix is removed surgically and sent to the laboratory to determine the extent of the cancer. Potential complications from this procedure include hemorrhage and uterine perforation Long-term follow-up care is needed because new cancers can develop.

Hysterectomy.

A total hysterectomy may be performed as treatment of microinvasive cancer if the woman does not want children or more children. A laparoscopic approach is commonly used. A radical hysterectomy and bilateral pelvic lymph node dissection may be as effective as radiation is for treating cancer that has extended beyond the cervix but not to the pelvic wall. Care for patients undergoing hysterectomy is found in the Uterine Leiomyoma section on pp. 1489-1491.

Nonsurgical Management.

Radiation therapy is reserved for invasive cervical cancer. Brachytherapy and external beam radiation therapy are used in combination, depending on the extent and location of the lesion. The procedure is similar to that described on pp. 1492-1493 for endometrial cancer.

A combination of chemotherapy with cisplatin (Platinol) and radiation may also be used. This treatment modality shows increased survival times but increased toxicity for many patients. Examples of other drugs used alone or in combination include paclitaxel (Taxol), carboplatin, fluorouracil (5-FU), and mitomycin. See Chapter 22 for more information about the general nursing care for the patient on chemotherapy and radiation.

Ovarian Cancer

❖ Pathophysiology

Most ovarian cancers are epithelial tumors that grow on the surface of the ovaries. These tumors grow rapidly, spread quickly, and are often bilateral. Tumor cells spread by direct extension into nearby organs and through blood and lymph circulation to distant sites (McCance et al., 2014). Free-floating cancer cells also spread through the abdomen to seed new sites, usually accompanied by ascites (abdominal fluid).

Ovarian cancer seems to be disordered growth in response to excessive exposure to estrogen. This would explain the protective effects of pregnancies and oral contraceptive use, both of which interrupt the monthly estrogen exposure. Table 71-4 lists known and suspected risk factors for ovarian cancer.

TABLE 71-4

Risk Factors for Ovarian Cancer

• Older than 40 years • Family history of ovarian or breast cancer or HNPCC • Diabetes mellitus • Nulliparity • Older than 30 years at first pregnancy • Breast cancer	• Colorectal cancer • Infertility • *BRCA1* or *BRCA2* gene mutations • Early menarche/late menopause • Endometriosis • Obesity/high-fat diet

HNPCC, Hereditary nonpolyposis colon cancer.

Ovarian cancer is the leading cause of death from female reproductive cancers, but it is not the most common type of cancer (ACS, 2013a). The incidence increases in women older than 50 years, and most are diagnosed after menopause. Family history accounts for a small percentage of cases. These women carry *BCRA1* or *BCRA2* genetic mutations. Of these, some choose to have an elective **bilateral salpingo-oophorectomy (BSO)** (removal of both ovaries and fallopian tubes) to prevent ovarian cancer.

Survival rates are low because ovarian cancer is often not detected until its late stages. It is important for nurses to teach women to *"think ovarian"* if they have vague abdominal and GI symptoms.

Health Promotion and Maintenance

Health promotion measures to help prevent ovarian cancer include maintaining a normal weight and eating a well-balanced diet. Women who have had tubal ligation, used oral contraception, and breast-fed their children also have less risk for having the disease (ACS, 2014a).

❖ Patient-Centered Collaborative Care

◆ Assessment

Most women with ovarian cancer have had mild symptoms for several months but may have thought they were due to normal perimenopausal changes or stress. They may report abdominal pain or swelling or have vague GI disturbances such as dyspepsia (indigestion) and gas. Ask the patient if she has had urinary frequency or incontinence, unexpected

weight loss, and/or vaginal bleeding.

Complications of advanced metastatic cancer include:

- Pleural effusion
- Ascites
- Lymphedema
- Intestinal obstruction
- Malnutrition

On pelvic examination, an abdominal mass may not be palpable until it reaches a size of 4 to 6 inches (10 to 15 cm). Any enlarged ovary found after menopause should be evaluated as though it were malignant. A Pap smear is of limited value for detecting ovarian cancer.

A cancer antigen test, *CA-125*, measures the presence of damaged endometrial and uterine tissue in the blood. It may be elevated if ovarian cancer is present, but it can also be elevated in patients with endometriosis, fibroids, pelvic inflammatory disease, pregnancy, and even menses (Pagana & Pagana, 2013). It is also useful for monitoring a patient's progress during and after treatment. Transvaginal ultrasonography, chest radiography, and CT are part of a complete workup to evaluate for metastasis. Complete blood work includes a liver profile if there is ascites.

The woman with ovarian cancer has concerns similar to those described for the patient with endometrial cancer (see p. 1493 of this chapter). Because the cancer is often diagnosed in an advanced stage, thoughts of death and dying, menopause, and loss of fertility come as a shock.

Clinical Judgment Challenge

Patient-Centered Care; Evidence-Based Practice; Informatics; Teamwork and Collaboration QSEN

A 34-year-old woman is diagnosed with ovarian cancer today. She tells you that she "can't believe this," and that "this must be the wrong diagnosis." She states that she and her husband had planned to get pregnant later this year and that she "cannot lose" her ovaries. However, she is scheduled to have a bilateral salpingo-oophorectomy and hysterectomy in 2 days. Her oncologist told her that after she recovers from surgery, she may need to have adjuvant chemotherapy to destroy any remaining cancer cells.

1. What preoperative teaching will you provide for this patient and why?
2. How will you address this patient's statements about disbelief of the

diagnosis?
3. How will you approach the patient's feelings about getting pregnant later this year?
4. Do you believe that this patient understands the implications of a bilateral salpingo-oophorectomy? If not, what would be your next nursing action?
5. What will you tell her about chemotherapy that may be necessary after surgery?
6. Where would you search for evidence about her expected quality of life and prognosis?
7. To what community resources would you refer this patient after discharge?

Interventions

Nursing care of the patient with ovarian cancer is similar to that for endometrial or cervical cancer. The options for treatment depend on the extent of the cancer and usually include surgery first, followed by chemotherapy. Radiation is used for more widespread cancers.

Surgical Management.

Diagnosis depends on surgical exploration. Exploratory laparotomy (abdominal surgery) is performed to diagnose, treat, and stage ovarian tumors. A total abdominal hysterectomy, bilateral salpingo-oophorectomy (removal of the ovaries and fallopian tubes), and pelvic and para-aortic lymph node dissection are usually performed. Very large tumors that cannot be removed are debulked (cytoreduction). These procedures can be performed via laparoscopic technique to decrease recovery time, minimize pain, and reduce postoperative complications. (See p. 1489 for discussion of laparoscopic hysterectomy in this chapter.) Ovarian cancer is staged during surgery.

Nursing care of the patient is similar to that for any patient having abdominal surgery (see Chapter 16). As for any patient after abdominal surgery, assess vital signs and pain and maintain catheters and drains. Teach her the importance of antiembolism stockings, incentive spirometry, and early ambulation. Infections after ovarian cancer surgery commonly affect the respiratory and urinary tracts. Assess vital signs, and monitor the quantity and quality of urine output.

Nonsurgical Management.

After cytoreduction and staging of ovarian cancer, chemotherapy is the

treatment that is used most often. For all stages of ovarian cancer, cisplatin (Platinol), carboplatin, and taxanes of all types are the most common postoperative *drugs* used for treating ovarian cancer. They may be given IV and/or intraperitoneally. Intraperitoneal (IP) therapy is described in Chapter 13. New drugs continue to be tested that use monoclonal antibodies, hormones, and agents that target cell growth and tumor blood supply.

Community-Based Care

Patients having surgery usually return to their home. Teach them to avoid tampons, douches, and sexual intercourse for at least 6 weeks or as instructed by the health care provider. Remind them to keep their follow-up surgical appointment and talk with the health care provider about resuming usual activities. Refer patients and their families to Gilda's Club (www.gildasclub.org) and the National Ovarian Cancer Coalition (NOCC) (www.ovarian.org) for more information and support groups. In Canada, the National Ovarian Cancer Association (www.ovariancanada.org) is available for the same purpose.

For patients with advanced metastatic disease, collaborate with the case manager, patient, and family for possible referral to hospice. Chapter 7 discusses end-of-life care and hospice in detail. The woman who is faced with the diagnosis of advanced ovarian cancer is usually very anxious about dying. Encourage her to discuss her feelings. Provide realistic assurance, as well as accurate information about treatments. Patients report their most distressing moments in the hospital were when they thought they were not getting adequate information. Encourage them to use their support systems of family members, friends, and clergy, including the hospital chaplain. Grief counseling is very appropriate. A visit from another woman who has survived a similar disease or referral to a support group may decrease fears. Refer the patient who fears passing the *BRCA1* or *BRCA2* gene to her daughter for genetic counseling and testing.

Ovarian cancer has a high recurrence rate. After recurrence, the cancer is treatable but no longer curable. If this occurs, the patient may deny symptoms at first or express feelings of anger and grief. The family is often fearful of the outcome. Provide encouragement and support during this difficult time, and help the patient and her family work through their grief and prepare for death.

Nursing Concepts and Clinical Judgment Review

What might you NOTICE if the patient is experiencing impaired sexuality as a result of gynecologic problems?

- Irregular or abnormal vaginal bleeding
- Vaginal discharge
- Report of perineal itching or burning
- Report of painful intercourse
- Abdominal distention and discomfort
- Report of irritability, anxiety, or depression
- Report of decreased libido

What should you INTERPRET and how should you RESPOND to the patient experiencing impaired sexuality as a result of gynecologic problems?

Perform and interpret physical assessment, including:

- Conducting an abdominal assessment
- Conducting a thorough pain assessment
- Checking for bleeding and amount (number of pads or tampons)
- Listening to patient's concerns about her sexuality

Respond by:

- Helping the patient into a sitting position
- Providing pain-relief measures, such as heat and analgesia
- Referring the patient to a sexual or intimacy counselor (including the patient's partner if desired)

On what should you REFLECT?

- Think about what else you can do to help provide psychosocial support.
- Prepare for complications, such as hemorrhage, if the patient is bleeding.
- Evaluate pain level after interventions.

Get Ready for the NCLEX® Examination!

Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Refer patients with gynecologic problems to appropriate community resources such as the American Cancer Society and the Endometriosis Association. **Teamwork and Collaboration** QSEN
- Collaborate with the case manager when planning care for patients with gynecologic cancers. **Teamwork and Collaboration** QSEN

Health Promotion and Maintenance

- Teach women to follow the American Cancer Society's screening guidelines to prevent and early-detect for gynecologic cancers.
- Teach all women to have regular Pap tests based on their risk factors.
- Teach women to practice safe sex to prevent infection of the reproductive organs.
- Teach women about risk factors for gynecologic cancers as described in Tables 71-3 and 71-4.
- Teach women how to prevent toxic shock syndrome (TSS) as listed in Chart 71-3. **Safety** QSEN

Psychosocial Integrity

- Explain all tests, procedures, and treatments, especially if they cause pain during or after the procedures.
- Assess the patient's anxiety before any gynecologic surgery, and encourage the patient to discuss her feelings. **Patient-Centered Care** QSEN
- Encourage women who are having procedures that may interfere with fertility and/or sexuality to express feelings of fear or grief. **Patient-Centered Care** QSEN
- Encourage women with chronic or serious health problems to consider using support groups or counseling.

Physiological Integrity

- Urge any woman who experiences postmenopausal vaginal bleeding to consult with her gynecologic health care provider as soon as possible. **Safety** QSEN

- Assess for symptoms of problems associated with urinary elimination.
- Assess for symptoms associated with toxic shock syndrome.
- Teach patients about specific restrictions after local cervical ablation therapy (see Chart 71-7).
- When caring for a patient who has a radioactive implant, use best practices as described in Chart 71-6. **Teamwork and Collaboration** QSEN
- Teach the patient who is going home after a hysterectomy how to monitor for infection and other complications. **Safety** QSEN
- Instruct patients receiving external beam radiation to the abdomen to gently wash the area; to not apply creams or lotions (unless prescribed by the radiologist); to not wash off marking; to avoid exposing the area to sunlight or temperature extremes; and to wear soft, nonirritating clothing.

CHAPTER 72

Care of Patients with Male Reproductive Problems

Donna D. Ignatavicius

PRIORITY CONCEPTS

- Pain
- Elimination
- Infection
- Reproduction

Learning Outcomes

Safe and Effective Care Environment

1. Collaborate with health care team members to provide care for patients with male reproductive health problems.

Health Promotion and Maintenance

2. Teach men and their partners about community resources for reproductive cancers.
3. Develop a health teaching plan for men to prevent or detect early male reproductive cancers.

Psychosocial Integrity

4. Explain the psychosocial needs of men who have male reproductive problems.

Physiological Integrity

5. Identify the clinical manifestations of benign prostatic hyperplasia (BPH)

as they affect urinary elimination.

6. Describe the nursing implications for pharmacologic management of BPH.
7. Develop an evidence-based postoperative plan of care for a patient undergoing surgery for benign prostatic hyperplasia.
8. Evaluate patient risk factors for male reproductive cancers.
9. Identify complementary and alternative therapies to incorporate into the patient's plan of care.
10. Discuss treatment options for prostate cancer with patients, partners, and/or families.
11. Provide preoperative teaching for patients having a radical prostatectomy.
12. Identify adverse effects of radiation therapy for male reproductive cancers.
13. Develop a community-based plan of care for a man with prostate cancer.
14. Describe the options for treating erectile dysfunction.
15. Identify cultural considerations related to male reproductive problems.
16. Develop a plan of care for a patient with testicular cancer, including fertility issues.
17. Compare the assessment and treatment for hydrocele, spermatocele, and varicocele.

 http://evolve.elsevier.com/Iggy/

Male reproductive problems can range from short-term infections to long-term health care problems that require end-of-life care. Any health issue that affects the male reproductive system can affect the human needs for sexuality and urinary elimination. For example, some patients have surgeries that damage essential nerves that are needed to have an erection. Others have disorders that psychologically prevent the patient from engaging in his usual sexual activity.

The role of the nurse and other health care team members is to be open, supportive, and nonjudgmental when caring for men with reproductive problems. Respect the man's privacy at all times.

Benign Prostatic Hyperplasia

❖ Pathophysiology

Benign prostatic hyperplasia (BPH) is a very common health problem, but the exact cause is unclear. It is likely the result of a combination of aging and the influence of androgens that are present in prostate tissue, such as dihydrotestosterone (DHT) (McCance et al., 2014). With aging and increased DHT levels, the glandular units in the prostate undergo nodular tissue **hyperplasia** (an increase in the number of cells). This altered tissue promotes local inflammation by attracting cytokines and other substances (McCance et al., 2014).

As the prostate gland enlarges, it extends upward into the bladder and inward, causing *bladder outlet obstruction* (Fig. 72-1). In response, the urinary system is affected in several ways. First, the detrusor (bladder) muscle thickens to help urine push past the enlarged prostate gland (McCance et al., 2014). In spite of the bladder muscle change, the patient has increased residual urine (stasis) and chronic urinary retention. The increased volume of residual urine often causes **overflow urinary incontinence,** in which the urine "leaks" around the enlarged prostate causing dribbling. Urinary stasis can also result in urinary tract infections and bladder calculi (stones).

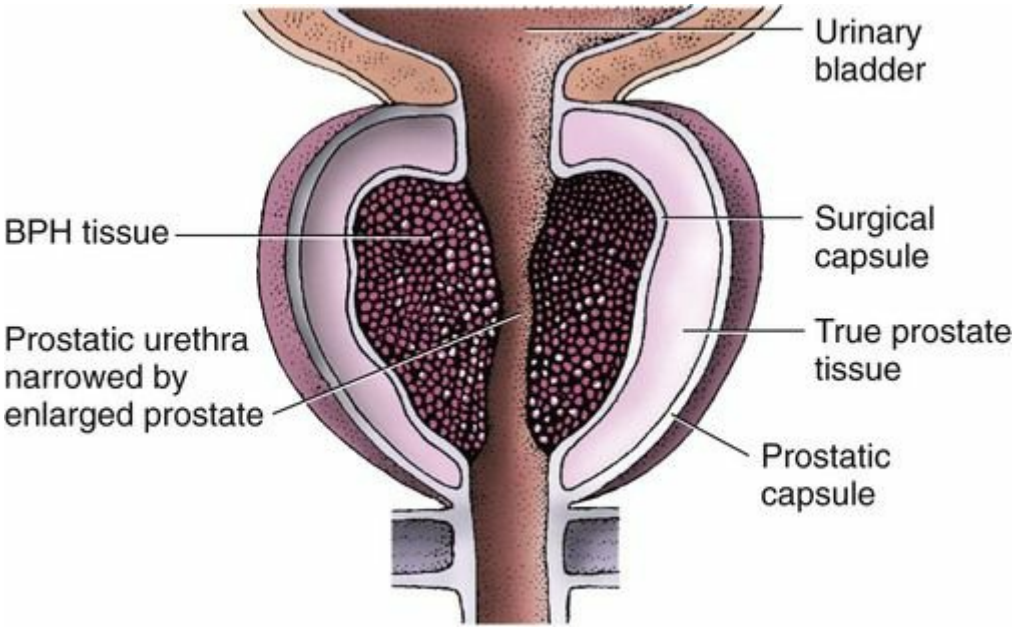

FIG. 72-1 Benign prostatic hyperplasia (BPH) grows inward, causing narrowing of the urethra.

In a few patients, the prostate becomes very large and the man cannot void (acute urinary retention [AUR]). The patient with this problem

requires emergent care. In other patients, chronic urinary retention may result in a backup of urine and cause a gradual dilation of the ureters **(hydroureter)** and kidneys **(hydronephrosis)** if BPH is not treated. These urinary elimination problems can lead to chronic kidney disease as described in Chapter 68.

Patient-Centered Collaborative Care

Assessment

History.

When taking a history, several standardized assessment tools are used to help the health care provider determine the severity of lower urinary tract symptoms (LUTS) associated with prostatic enlargement. One of the most commonly used assessments is the International Prostate Symptom Score (I-PSS), which incorporates the American Urological Association Symptom Index (AUA-SI) (Fig. 72-2) as questions 1 through 7. The additional question included on the I-PSS is the effect of the patient's urinary symptoms on quality of life. Most patients complete the questions as a self-administered tool because it is available in many languages. If the patient is illiterate (does not read) or does not feel like reading the questions, the nurse or health care provider can ask them. Be sure that older men wear their glasses or contact lenses if needed.

International Prostate Symptom Score (I-PSS)

Patient Name:_____ **Date of Birth:**_____ **Date Completed**_____

In the past month:	Not at All	Less Than 1 in 5 Times	Less Than Half the Time	About Half the Time	More Than Half the Time	Almost Always	Your Score
1. Incomplete Emptying How often have you had the sensation of not emptying your bladder?	0	1	2	3	4	5	
2. Frequency How often have you had to urinate less than every 2 hours?	0	1	2	3	4	5	
3. Intermittency How often have you found you stopped and started again several times when you urinated?	0	1	2	3	4	5	
4. Urgency How often have you found it difficult to postpone urination?	0	1	2	3	4	5	
5. Weak Stream How often have you had a weak urinary stream?	0	1	2	3	4	5	
6. Straining How often have you had to strain to start urination?	0	1	2	3	4	5	
	None	**1 Time**	**2 Times**	**3 Times**	**4 Times**	**5 Times**	
7. Nocturia How many times do you typically get up at night to urinate?	0	1	2	3	4	5	
Total I-PSS Score							

Score: 1-7: Mild 8-19: Moderate 20-35: Severe

Quality of Life Due to Urinary Symptoms	Delighted	Pleased	Mostly Satisfied	Mixed	Mostly Dissatisfied	Unhappy	Terrible
If you were to spend the rest of your life with your urinary condition just the way it is now, how would you feel about that?	**0**	**1**	**2**	**3**	**4**	**5**	**6**

About the I-PSS

The International Prostate Symptom Score (I-PSS) is based on the answers to seven questions concerning urinary symptoms and one question concerning quality of life. Each question concerning urinary symptoms allows the patient to choose one out of six answers indicating increasing severity of the particular symptom. The answers are assigned points from 0 to 5. The total score can therefore range from 0 to 35 (asymptomatic to very symptomatic).

The questions refer to the following urinary symptoms:

Questions	Symptom
1	Incomplete emptying
2	Frequency
3	Intermittency
4	Urgency
5	Weak Stream
6	Straining
7	Nocturia

Question 8 refers to the patient's perceived quality of life.

The first seven questions of the I-PSS are identical to the questions appearing on the American Urological Association (AUA) Symptom Index, which currently categorizes symptoms as follows:

Mild (symptom score less than or equal to 7)
Moderate (symptom score range 8 to 19)
Severe (symptom score range 20 to 35)

The International Scientific Committee (SCI), under the patronage of the World Health Organization (WHO) and the International Union Against Cancer (UICC), recommends the use of only a single question to assess the quality of life. The answers to this question range from "delighted" to "terrible," or 0 to 6. Although this single question may or may not capture the global impact of benign prostatic hyperplasia (BPH) symptoms or quality of life, it may serve as a valuable starting point for a doctor-patient conversation.

The SCI has agreed to use the symptom index for BPH, which has been developed by the AUA Measurement Committee, as the official worldwide symptoms assessment tool for patients suffering from prostatism.

The SCI recommends that physicians consider the following components for a basic diagnostic workup: history; physical examination; appropriate labs such as U/A, creatinine, etc.; and DRE or other evaluation to rule out prostate cancer.

FIG. 72-2 The International Prostate Symptom Score (I-PSS).

Physical Assessment/Clinical Manifestations.

Ask about the patient's current urinary elimination pattern. Assess for urinary frequency and urgency. Determine the number of times the patient awakens during the night to void **(nocturia).** Other symptoms of LUTS include:

• Difficulty in starting (hesitancy) and continuing urination

- Reduced force and size of the urinary stream ("weak" stream)
- Sensation of incomplete bladder emptying
- Straining to begin urination
- Post-void (after voiding) dribbling or leaking

If frequency and nocturia do not occur with restricted urinary flow, the patient may have an infection or other bladder problem. Ask whether the patient has had **hematuria** (blood in the urine) when starting the urine stream or at the end of voiding. BPH is a common cause of hematuria in older men.

The health care provider examines the patient for physical changes of the prostate gland. Remind the patient to void before the physical examination. Inspect and palpate the abdomen for a distended bladder. The health care provider may percuss the bladder. If the patient has a sense of urgency when gentle pressure is applied, the bladder may be distended. Obese patients are best assessed by percussion or bedside ultrasound bladder scanner rather than by inspection or palpation.

Prepare the patient for the prostate gland examination. Tell him that he may feel the urge to urinate as the prostate is palpated. Because the prostate is close to the rectal wall, it is easily examined by digital rectal examination (DRE). If needed, help the patient bend over the examination table or assume a side-lying fetal position, whichever is the easiest position for him. The health care provider examines the prostate for size and consistency. BPH presents as a uniform, elastic, nontender enlargement, whereas cancer of the prostate gland feels like a stony-hard nodule. Advise the patient that after the prostate gland is palpated, it may be massaged to obtain a fluid sample for examination to rule out **prostatitis** (inflammation and possible infection of the prostate), a common problem that can occur with BPH. If the patient has bacterial prostatitis, he is treated with broad-spectrum antibiotic therapy to prevent the spread of infection (McCance et al., 2014).

Psychosocial Assessment.

Patients who have nocturia and other LUTS may be irritable or depressed as a result of interrupted sleep and annoying visits to the bathroom. Assess the effect of sleep interruptions on the patient's mood and mental status.

Post-void dribbling and overflow incontinence may cause embarrassment and prevent the patient from socializing or leaving his home. For some patients, this social isolation can affect quality of life and lead to clinical depression and/or severe anxiety. Johnson et al. (2010) found a strong correlation between depression and BPH in older men.

Depressed patients were 3 times more likely to have severe symptoms.

Laboratory Assessment.

A *urinalysis* and urine *culture* are typically obtained to diagnose urinary tract infection and microscopic hematuria. If infection is present, the urinalysis measures the number of white blood cells (WBCs).

Other laboratory studies that may be performed include:

- A *complete blood count* (CBC) to evaluate any evidence of systemic infection (elevated WBCs) or anemia (decreased red blood cells [RBCs]) from hematuria
- *Blood urea nitrogen* (BUN) and serum creatinine levels to evaluate renal function (both are usually elevated with kidney disease)
- A *prostate-specific antigen* (PSA) and a serum acid phosphatase level if prostate cancer is suspected (both are typically elevated in patients who have prostate cancer)
- *Culture and sensitivity* of prostatic fluid (if expressed during the examination)

Other Diagnostic Assessment.

Imaging studies that are typically performed are *transabdominal ultrasound* and/or *transrectal ultrasound (TRUS).* The patient having a TRUS lies on his side while the transducer is inserted into the rectum for viewing the prostate and surrounding structures. A tissue biopsy may also be done if the health care provider is uncertain whether the prostatic problem is benign or malignant.

In some cases the physician uses a cystoscope to view the interior of the bladder, the bladder neck, and the urethra. This examination is used to study the presence and effect of bladder neck obstruction and is usually done in an ambulatory care setting. See Chapter 66 for a detailed description of *cystoscopy* and the nursing care needed for patients having this procedure.

Residual urine may be determined by *bladder ultrasound* immediately after the patient voids. As an alternative, because the patient voids before cystoscopy, residual urine may be measured when the cystoscope is inserted. *Urodynamic pressure-flow studies* may help diagnose and grade bladder outlet obstruction and detrusor muscle function.

◆ Analysis

The priority NANDA-I nursing diagnosis for the patient with benign prostatic hyperplasia (BPH) is Impaired Urinary Elimination related to

bladder outlet obstruction (NANDA-I).

Planning and Implementation

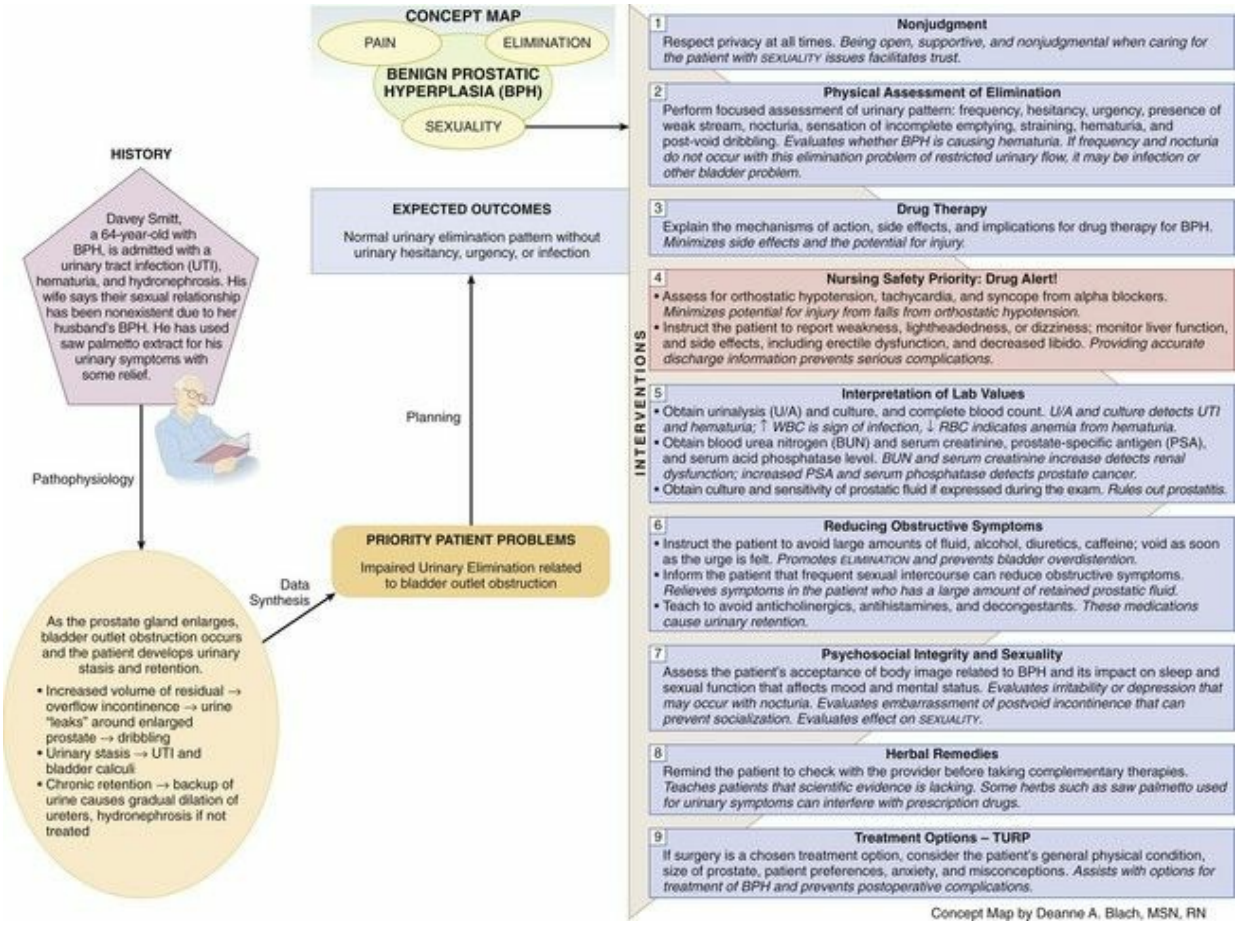
Improving Urinary Elimination

Planning: Expected Outcomes.

The patient with BPH is expected to have a normal urinary elimination pattern without urinary hesitancy, urgency, or infection.

Interventions.

Patients with symptomatic BPH are first treated with nonsurgical interventions, such as drug therapy. The Concept Map on p. 1504 shows nursing assessment and collaborative interventions for the patient with BPH.



Nonsurgical Management.

Drug therapy is a popular option for treating BPH. For patients with acute urinary retention (AUR) or for those who do not respond to or

cannot tolerate drug therapy, noninvasive procedures or surgery is the treatment of choice.

Drug Therapy.

Drugs from two major categories may be used alone, but most commonly they are given in combination. The health care provider usually prescribes a *5-alpha reductase inhibitor (5-ARI) as first-line drug therapy.* Examples of these drugs are finasteride (Proscar) and dutasteride (Avodart). Normally, testosterone is converted to DHT in the prostate gland by the enzyme *5-alpha reductase.* By taking an enzyme-inhibiting agent, the patient's DHT levels decrease, which results in reducing the enlarged prostate.

Nursing Safety Priority QSEN

Drug Alert

Remind patients who are being treated with a 5-ARI for BPH that they may need to take it for as long as 6 months before improvement is noticed. Teach them about possible side effects, which include erectile dysfunction (ED), decreased libido (sexual desire), and dizziness due to orthostatic hypotension. *Remind them to change positions carefully and slowly!*

The alpha-adrenergic receptors in prostatic smooth muscle enable the prostate gland to respond to *alpha-1 selective blocking agents,* such as tamsulosin (Flomax), alfuzosin (Uroxatral), doxazosin (Cardura, Cardura-1), and silodosin (Rapaflo). Tamsulosin is also available as an over-the-counter (OTC) drug. These drugs relax smooth muscles in the prostate gland, creating less urinary resistance and improved urinary flow. They also cause peripheral vasodilation and reduced peripheral vascular resistance.

Nursing Safety Priority QSEN

Drug Alert

If giving alpha blockers in an inpatient setting, assess for orthostatic (postural) hypotension, tachycardia, and syncope ("blackout"), especially after the first dose is given to older men. If the patient is taking the drug at home, teach him to be careful when changing position and to report any weakness, lightheadedness, or dizziness to the health care provider immediately. Bedtime

dosing may decrease the risk for problems related to hypotension. Teach patients taking a 5-ARI or alpha-blocking drug to keep all appointments for follow-up laboratory testing because both drug classes can cause liver dysfunction.

The most effective drug therapy approach for many patients is a combination of a 5-ARI drug and an alpha-1 selective blocking agent. A commonly prescribed drug regimen is finasteride and doxazosin. Newer drugs, such as Jalyn, provide a combination of dutasteride and tamsulosin in a once-a-day capsule.

Other drugs may be helpful in managing specific urinary symptoms. For example, low-dose oral desmopressin, a synthetic antidiuretic analog, has been used successfully for nocturia (Wang et al., 2011). Tadalafil (Cialis), a drug usually given to treat erectile dysfunction, has also been approved for some men with BPH because it can improve lower urinary tract symptoms.

Complementary and Alternative Therapies.

Although many men use *Serenoa repens* (saw palmetto extract), a plant extract, to help manage the urinary symptoms associated with BPH, studies on the effectiveness of this herb have not shown that it is effective (Barry et al., 2011). Teach patients who want to try these herbs and other natural substances that scientific evidence to prove they are useful is lacking. However, if they choose to take them, remind them to check with their health care provider before taking any OTC natural substance. Some herbs interfere with prescription drugs the patient may be taking for other health problems.

Other Nonsurgical Interventions.

Other interventions that may reduce obstructive symptoms include those that cause the release of prostatic fluid such as frequent sexual intercourse. This approach is helpful for the man whose obstructive symptoms result from an enlarged prostate with a large amount of retained prostatic fluid.

Teach patients with BPH to avoid drinking large amounts of fluid in a short time; to avoid alcohol, diuretics, and caffeine; and to void as soon as they feel the urge. These measures are aimed at preventing overdistention of the bladder, which may result in loss of detrusor muscle tone. Teach patients to avoid any drugs that can cause urinary retention, especially anticholinergics, antihistamines, and decongestants. *Emphasize the importance of telling any health care provider about the*

diagnosis of BPH so that these drugs are not prescribed.

If drug therapy or other measures are not helpful in relieving urinary symptoms, several noninvasive techniques are available to destroy excess prostate tissue using a variety of heat methods **(thermotherapy).** These procedures are often done in a physician's office or another ambulatory care setting. Examples include:

- **Transurethral needle ablation (TUNA)** (low radiofrequency energy shrinks the prostate)
- **Transurethral microwave therapy (TUMT)** (high temperatures heat and destroy excess tissue)
- **Interstitial laser coagulation (ILC),** also called **contact laser prostatectomy (CLP)** (laser energy coagulates excess tissue)
- **Electrovaporization of the prostate (EVAP)** (high-frequency electrical current cuts and vaporizes excess tissue)

Prostatic stents may be placed into the urethra to maintain permanent patency after a procedure for destroying or removing prostatic tissue. All of these highly technical treatments use local or regional anesthesia and do not require an indwelling urinary catheter. They are also associated with less risk for complications such as intraoperative bleeding and erectile dysfunction when compared with traditional surgical approaches. Patients can return to their usual activities in a day or two.

Surgical Management.

For patients who are not candidates for nonsurgical management or do not want to take drugs or have other treatment options, surgery may be performed. The gold standard continues to be a **transurethral resection of the prostate (TURP)** in which the enlarged portion of the prostate is removed through an endoscopic instrument. The newer holmium laser enucleation of the prostate (HoLEP) procedure is a minimally invasive surgical technique that is gaining popularity. For a few men, an open prostatectomy (entire prostate removal) may be performed. (See discussion of Surgical Management on p. 1509 in the Prostate Cancer section.) Some or all of these criteria indicate the need for surgery:

- Acute urinary retention (AUR)
- Chronic urinary tract infections secondary to residual urine in the bladder
- Hematuria
- Hydronephrosis

Preoperative Care.

When planning surgical interventions, the patient's general physical

condition, the size of the prostate gland, and the man's preferences are considered. The patient may have many fears and misconceptions about prostate surgery, such as believing that automatic loss of sexual functioning or permanent incontinence will occur. Assess the patient's anxiety, correct any misconceptions about the surgery, and provide accurate information to him and his family. Regardless of the type of surgery to be performed, reinforce information about anesthesia (see Chapter 15). Remind patients taking anticoagulants that the drugs will be discontinued prior to a TURP or open prostate surgery to prevent postoperative bleeding. Other general preoperative care is described in Chapter 14.

The patient may have other medical problems that increase the risk for complications of general anesthesia and may be advised to have regional anesthesia. Epidural and spinal anesthesia are the most common types of anesthesia used for a TURP. Because the patient is awake, it is easier to assess for hyponatremia (low serum sodium), fluid overload, and water intoxication, which can result from large-volume bladder irrigations.

After a TURP, all patients have an indwelling urethral catheter. *Be sure that they know that they will feel the urge to void while the catheter is in place.* Tell the patient that he will likely have traction on the catheter that may cause discomfort. However, reassure him that analgesics will be prescribed to relieve his pain. Explain that it is normal for the urine to be blood-tinged after surgery. Small blood clots and tissue debris may pass while the catheter is in place and immediately after it is removed. Some patients also have a continuous bladder irrigation (CBI) depending on the procedure performed.

Operative Procedures.

The traditional TURP is a "closed" surgery. To perform the procedure, the surgeon inserts a resectoscope (an instrument similar to a cystoscope, but with a cutting and cauterizing loop) through the urethra. The enlarged portion of the prostate gland is then removed in small pieces (prostate chips). A similar procedure is the transurethral incision of the prostate (TUIP) in which small cuts are made into the prostate to relieve pressure on the urethra. This alternate technique is used for smaller prostates. To prevent bleeding and excess clotting, a fibrinolytic inhibitor like tranexamic acid (Cyklokapron) may be used during surgery.

The disadvantage of a TURP is that, because only small pieces of the gland are removed, remaining prostate tissue may continue to grow and cause urinary obstruction, requiring additional TURPs. Also, urethral trauma from the resectoscope with resulting urethral strictures is

possible.

In many large medical centers around the world, specialists can perform newer surgical treatments, such as the *holmium laser enucleation of the prostate (HoLEP)* (Eltabey et al., 2010). For this procedure, the surgeon uses the laser to remove the obstructive prostatic tissue and then pushes the tissue into the bladder for removal. Very little blood is lost during the short procedure and is therefore safe for patients taking anticoagulants.

Postoperative Care.

After both the TURP and HoLEP procedures, a urinary catheter is placed into the bladder. Traction is often applied on the catheter for the patient having a TURP by pulling it taut and taping it to the patient's abdomen or thigh. If the catheter is taped to the patient's thigh, instruct him to keep his leg straight. The patient having the HoLEP procedure has a urinary catheter overnight, but the patient with a TURP may have a catheter and continuous bladder irrigation (CBI) in place for several days. In some cases the patient is discharged with the catheter in place.

For patients with a CBI, a 3-way urinary catheter is used to allow drainage of urine and inflow of a bladder irrigating solution. Be sure to maintain the flow of the irrigant to keep the urine clear. When measuring the fluid in the urinary drainage bag, be sure to subtract the amount of irrigating solution that was used to determine actual urinary output.

NCLEX Examination Challenge

Physiological Integrity

A client has a urinary catheter and continuous bladder irrigation after a transurethral resection of the prostate this morning. The amount of bladder irrigating solution that has infused over the past 12 hours is 1000 mL. The amount of fluid in the urinary drainage bag is 1725 mL. The nurse records that the client had ____ mL urinary output in the past 12 hours.

Considerations for Older Adults

Patient-Centered Care QSEN

When caring for older men who may become confused after surgery, reorient them frequently and remind them not to pull on the catheter. If the patient is restless or "picks" at tubes, provide a familiar object such

as a family picture for him to hold for distraction and a feeling of security. Do not restrain the patient unless all other alternatives have failed.

Remind the patient that because of the urinary catheter's large diameter and the pressure of the retention balloon on the internal sphincter of the bladder, he will feel the urge to void continuously. This is a normal sensation, not a surgical complication. Advise the patient not to try to void around the catheter, which causes the bladder muscles to contract and may result in painful spasms. Chart 72-1 summarizes the nursing care for patients having a TURP.

Chart 72-1 Best Practice for Patient Safety & Quality Care QSEN

Care of the Patient After Transurethral Resection of the Prostate

- Monitor the patient closely for signs of infection. Older men undergoing prostate surgery often also have underlying chronic diseases (e.g., cardiovascular disease, chronic lung disease, diabetes).
- Help the patient out of the bed to the chair as soon as permitted to prevent complications of immobility. Older men may need assistance because of underlying changes in the musculoskeletal system (e.g., decreased range of motion, stiffness in joints). These patients are at *high risk* for falls.
- Assess the patient's pain every 2 to 4 hours, and intervene as needed to control pain.
- Provide a safe environment for the patient. Anticipate a temporary change in mental status for the older patient in the immediate postoperative period as a result of anesthetics and unfamiliar surroundings. Reorient the patient frequently. Keep catheter tubes secure.
- Maintain the rate of the continuous bladder irrigation to ensure clear urine without clots and bleeding.
- Use normal saline solution for the intermittent bladder irrigant unless otherwise prescribed. Normal saline solution is isotonic.
- Monitor the color, consistency, and amount of urine output.
- Check the drainage tubing frequently for external obstructions (e.g., kinks) and internal obstructions (e.g., blood clots, decreased output).
- Assess the patient for reports of severe bladder spasms with decreased

urinary output, which may indicate obstruction.
- If the urinary catheter is obstructed, irrigate the catheter per agency or surgeon protocol.
- Notify the physician immediately if the obstruction does not resolve by hand irrigation or if the urinary return becomes ketchup-like.

Nursing Safety Priority QSEN

Critical Rescue

After a TURP, monitor the patient's urine output every 2 hours and vital signs, including pain assessment, every 4 hours for the first postoperative day. Assess for postoperative bleeding. *Patients who undergo a TURP or open prostatectomy are at risk for severe bleeding or hemorrhage after surgery. Although rare, bleeding is most likely within the first 24 hours.* Blood transfusions may be given after a TURP surgery but are not needed after the HoLEP procedure. Bladder spasms or movement may trigger fresh bleeding from previously controlled vessels. This bleeding may be arterial or venous, but venous bleeding is more common.

If arterial bleeding occurs, the urinary drainage is bright red or ketchup-like with numerous clots. Notify the surgeon immediately, and irrigate the catheter with normal saline solution per physician or hospital protocol. In rare instances the surgeon may prescribe aminocaproic acid (Amicar) to control bleeding. If this drug does not work, surgical intervention may be needed to clear the bladder of clots and to stop bleeding.

If the bleeding is *venous,* the urine output is burgundy, with or without any change in vital signs. *Inform the surgeon of any bleeding.* Closely monitor the patient's hemoglobin (Hgb) and hematocrit (Hct) levels for anemia as a result of blood loss.

When the urinary catheter is removed, the patient may experience burning on urination and some urinary frequency, dribbling, and leakage. Reassure him that these symptoms are normal and will decrease. The patient may also pass small clots and tissue debris for several days after the TURP. *Instruct him to increase fluid intake to at least 2000 to 2500 mL daily, which helps decrease dysuria and keep the urine clear.* An older patient who has renal disease or who is at risk for heart failure may not be able to tolerate this much fluid. By the time of discharge (usually 2 to 3 days after surgery depending on age and progress), he should be voiding 150 to 200 mL of clear yellow urine every 3 to 4 hours.

By discharge, pain is minimal and analgesics may not be required.

Observe for other possible but uncommon complications of TURP, such as infection and incontinence. Teach the patient that sexual function should not be affected after surgery but that retrograde ejaculation is possible. In this case, most of the semen flows backwards into the bladder so only a small amount will be ejaculated from the penis.

Community-Based Care

The patient with benign prostatic hyperplasia (BPH) is typically managed at home. Patients who have surgery are also discharged to their home or other setting from where they were admitted. Some patients, especially those who have had a TURP, may have temporary loss of control of urination or a dribbling of the urine. Reassure the patient that these symptoms are almost always temporary and will resolve. Also remind him that reproduction ability should not be affected by surgery.

Assist the patient and his family in finding ways to keep his clothing dry until sphincter control returns. Instruct him to contract and relax his sphincter frequently to re-establish urinary elimination control (Kegel exercises). External urinary (condom) catheters are not used except in extreme cases because they may give the patient a false sense of security and delay urinary control.

Patients having the HoLEP procedure typically stay in the hospital overnight and usually have no urinary symptoms after surgery. This procedure may soon replace the TURP as the gold standard for surgical management of the patient with BPH.

NCLEX Examination Challenge

Physiological Integrity

A client had a transurethral resection of the prostate (TURP) with continuous bladder irrigation yesterday. The staff nurse notes that the urinary drainage is bright red and thick. What is the nurse's best action?

A Notify the charge nurse as soon as possible.
B Increase the rate of the bladder irrigation.
C Document the assessment in the medical record.
D Prepare the patient for a blood transfusion.

Prostate Cancer

❖ Pathophysiology

Prostate cancer is the second most common type of cancer in men in the world and if found early has a nearly 100% cure rate. Men older than 65 years have the greatest risk for the disease. In the United States, it affects African-American men more commonly than Euro-American men and at an earlier age. The exact cause for this difference is not known (Hegarty & Bailey, 2011).

Testosterone and dihydrotestosterone (DHT) are the major androgens (male hormones) in the adult male. Testosterone is produced by the testis and circulates in the blood. DHT is a testosterone derivative in the prostate gland. In some patients the prostate grows very rapidly, leading to noncancerous high-grade prostatic intraepithelial neoplasia (PIN). Patients with PIN are at a higher risk for developing prostate cancer than are men who do not have that growth pattern.

Many prostate tumors are androgen-sensitive (McCance et al., 2014). Most are adenocarcinomas and arise from epithelial cells located in the posterior lobe or outer portion of the gland (Fig. 72-3).

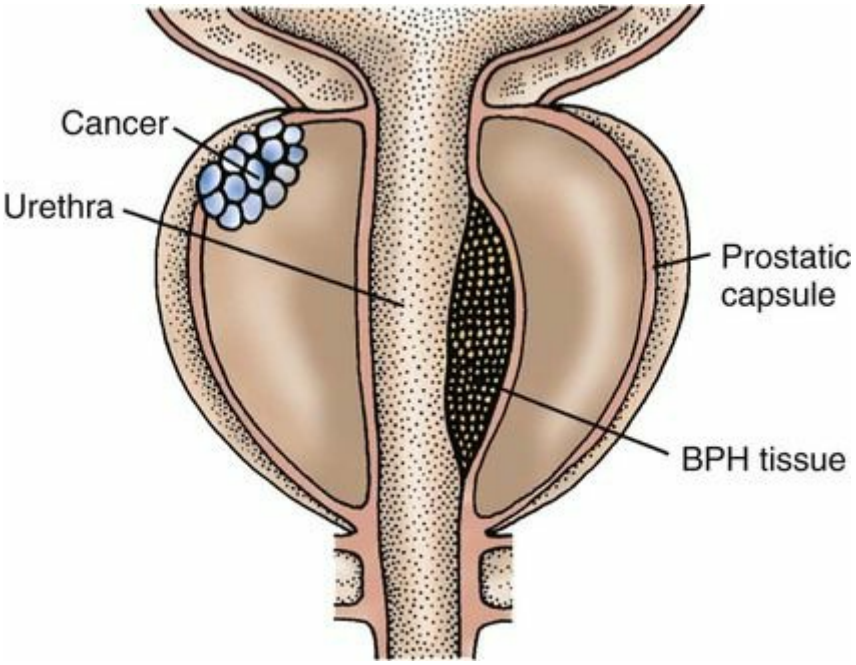


FIG. 72-3 The prostate gland with cancer and benign prostatic hyperplasia (BPH). Note that cancer normally arises in the periphery of the gland, whereas BPH occurs in the center of the gland.

Of all malignancies, prostate cancer is one of the slowest growing, and

it metastasizes (spreads) in a predictable pattern. Common sites of metastasis are the nearby lymph nodes, bones, lungs, and liver (McCance et al., 2014). The bones of the pelvis, sacrum, and lumbar spine are most often affected. Chapter 21 describes staging categories of localized and advanced cancers.

Prostate cancer is caused by a number of factors. Advanced age is the leading risk factor. Race is the second most common risk factor, and family history of prostate cancer is the third most common risk factor for this malignancy. The risk increases twofold for men who have a first-degree relative (brother, father) with the disease.

Cultural Considerations

Patient-Centered Care QSEN

Race is the second most common risk factor for prostate cancer because the disease affects African Americans more often than other ethnic/racial groups, followed by Caucasians (Euro-Americans) and Hispanic-American men. The reasons for these differences are not known but may be related to socioeconomic factors, health care access, health insurance, education, and diet (Dunn & Kazer, 2011).

Other risk factors that may play a role are eating a diet high in animal fat (e.g., red meat) and complex carbohydrates or having a low-fiber intake. Men who have had a vasectomy or those who were exposed to environmental toxins, such as arsenic, may also be at increased risk for the disease (McCance et al., 2014). Although controversial, some researchers believe that excessive intake of vitamin E and omega-3 fish oil supplements may increase the risk for prostate cancer (American Cancer Society [ACS], 2014a).

Genetic/Genomic Considerations

Patient-Centered Care QSEN

Many gene mutations play a role in various types of prostate cancer. Some men with the most aggressive prostate cancers have *BRCA2* mutations similar to those women who have *BRCA2*-associated breast and ovarian cancers. The most common genetic factor that increases the risk for prostate cancer is a mutation in the glutathione S-transferase *(GST P1)* gene. This gene is normally part of the pathway that helps prevent cancer (McCance et al., 2014).

Health Promotion and Maintenance

Teach men about the most recent American Cancer Society (ACS) guidelines for prostate cancer screening and early detection (ACS, 2014a). The current recommendations are that men should make an informed decision about whether to have prostate cancer screening. Although not agreed upon by all authoritative sources, starting at the age of 50 years, men should discuss the options of having prostate-specific antigen testing with their health care provider (see the Evidence-Based Practice box). Men at a higher risk for prostate cancer, including African Americans or men who have a first-degree relative with prostate cancer before the age of 65 years, should have this discussion at age 45 years. Men who have multiple first-degree relatives with prostate cancer at an early age should discuss screening at age 40 years (O'Rourke, 2011).

Evidence-Based Practice QSEN

What Are the Evidence-Based Recommendations for Prostate-Specific Antigen Screening for Prostate Cancer?

O'Rourke, M.E. (2011). The prostate-specific antigen screening conundrum: Examining the evidence. *Seminars in Oncology Nursing, 27*(4), 251-259.

The researchers reviewed the current guidelines and recommendations for prostate-specific antigen (PSA) screening from a variety of nursing and medical literature. They found multiple recommendations from randomized controlled trials (RCTs) and various national and international organizations, including the National Comprehensive Cancer Network, The American College of Preventive Medicine, and the Advisory Committee on Cancer Prevention of the European Union. However, there was no consensus regarding the normal values of PSA for age-groups or when PSA screening is needed. Most guidelines made adjustments for age and race because the PSA normal value is likely to increase as a man ages and African-American men tend to have higher normal PSA values than other groups.

Level of Evidence: 1

The researchers used a systematic literature review of RCTs and guidelines from various professional international and national organizations.

Commentary: Implications for Practice and Research

Nurses need to explain to men that there is no consensus regarding PSA screening. Instead, men should talk with their primary health care provider and identify risk factors that may influence the decision for PSA screening. More RCTs are needed to establish guidelines for prostate screening to assist health care providers as they counsel their patients.

Although a family history of prostate cancer cannot be changed, certain nutritional habits can be altered to possibly decrease the risk for the disease. First, teach men to eat a healthy, balanced diet, including decreasing animal fat (e.g., red meat). Instead of red meat, remind them to eat more fish and other foods high in *omega-3 fatty acids* because they are thought to be helpful in preventing cancer. Also reinforce the need to increase fruits, vegetables, and high-fiber foods (Carmody et al., 2012).

Patient-Centered Collaborative Care

Assessment

History.

Assess the patient's age, race/ethnicity, and family history of prostate cancer. Ask about his nutritional habits, especially focusing on the intake of red meat, fish, and fruits and vegetables. Assess whether the patient has any problems with urinary elimination. Take a drug history to determine if he is taking any medication that could affect voiding. The first symptoms that the man may report are related to bladder outlet obstruction, such as difficulty in starting urination, frequent bladder infections, and urinary retention. Ask about urinary frequency, **hematuria** (blood in the urine), and **nocturia** (voiding during the night). Ask if he has had any pain during intercourse, especially when ejaculating. Inquire if the patient has had or currently has any other pain (particularly bone pain), a symptom associated with advanced prostate cancer. Ask him if he has had any recent unexpected weight loss.

Take a sexual history for recent changes in desire or function. Ask about current or previous sexually transmitted diseases, penile discharge, or scrotal pain or swelling.

Physical Assessment/Clinical Manifestations.

Most *early* cancers are diagnosed while the patient is having a routine physical examination or is being treated for benign prostatic hyperplasia

(BPH). Gross blood in the urine (hematuria) is a common clinical manifestation of *late* prostate cancer. Assess for pain in the pelvis, spine, hips, or ribs. Complete a thorough pain assessment. Palpate for swollen lymph nodes, especially in the groin areas. Pain and swollen nodes also indicate advanced disease that has spread. Take and record the patient's weight because unexpected weight loss is also common when the disease is advanced.

Prepare the patient for a digital rectal examination (DRE). On rectal examination, a prostate that is found to be stony hard and with palpable irregularities or indurations is suspected to be malignant.

Psychosocial Assessment.

A diagnosis of any type of cancer causes fear and anxiety for most people. Some men, particularly African Americans, develop the disease in their 40s and 50s when they are perhaps planning their retirements, putting their children through college, and/or enjoying their middle years. Assess the reaction of the patient to the diagnosis, and observe how his family reacts to the illness. Men may describe their feelings as shock, fear, anger, and "roller coaster." Expect that patients usually go through the grieving process and may be in denial or depressed. Determine what support systems they have, such as spiritual leaders or community group support, to help them through diagnosis, treatment, and recovery.

One of the biggest concerns for the man may be his ability for sexual function after cancer treatment. Tell him that function will depend on the type of treatment he has. Common surgical techniques used today do not involve cutting the perineal nerves that are needed for an erection. A dry climax may occur if the prostate is removed because it produces most of the fluid in the ejaculate. Refer the patient to his surgeon (urologist), sex therapist, or intimacy counselor if available.

Laboratory Assessment.

Prostate-specific antigen (PSA) is a glycoprotein produced by the prostate. *PSA analysis is used as a screening test for prostate cancer.* If the test is performed, it should be drawn before the DRE because the examination can cause an increase in PSA due to prostate irritation.

Most authoritative sources agree that the normal blood level of PSA in men younger than 50 years is less than 2.5 ng/mL. PSA levels increase to as high as 6.5 ng/mL when men reach their 70s. *African-American men have a slighter higher normal value, but the reason for this difference is not known. Because other prostate problems also increase the PSA level, it is not specifically diagnostic for cancer.* The level associated with prostate cancer,

however, is usually much higher than those occurring with problems such as prostatitis and benign prostatic hyperplasia (Pagana & Pagana, 2014).

An elevated PSA level should decrease a few days after a prostatectomy for cancer. An increase in the PSA level several weeks after surgery may indicate that the disease has recurred.

Because PSA is not absolutely specific to prostate cancer, another test, *early prostate cancer antigen (EPCA-2),* may be a serum marker for prostate cancer. It can detect changes in the prostate gland early and is a very sensitive test. EPCA-2 may also eliminate the need to perform a biopsy of prostate tissue (Pagana & Pagana, 2014).

Other Diagnostic Assessment.

After assessments by DRE and PSA, most patients have a *transrectal ultrasound (TRUS)* of the prostate in an ambulatory care or imaging setting. The technician inserts a small probe into the rectum and obtains a view of the prostate using sound waves. If prostate cancer is suspected, a *biopsy* is usually performed in the physician's office to obtain an accurate diagnosis. Prior to the procedure, the physician uses lidocaine jelly on the ultrasound probe and/or injects lidocaine into the prostate gland to promote patient comfort (Dunn & Kazer, 2011).

Nursing Safety Priority QSEN

Action Alert

After a *transrectal ultrasound with biopsy,* instruct the patient about possible complications, although rare, including hematuria with clots, signs of infection, and perineal pain. Teach him to report fever, chills, bloody urine, and any difficulty voiding. Advise him to avoid strenuous physical activity and to drink plenty of fluids, especially in the first 24 hours after the procedure. Teach him that a small amount of bleeding turning the urine pink is expected during this time. However, bright red bleeding should be reported to the health care provider immediately.

After prostate cancer is diagnosed, the patient has additional imaging and blood studies to determine the extent of the disease. Common tests include lymph node biopsy, CT of the pelvis and abdomen, and MRI to assess the status of the pelvic and para-aortic lymph nodes. A radionuclide bone scan may be performed to detect metastatic bone disease. An enlarged liver or abnormal liver function study results

indicate possible liver metastasis.

Patients with advanced prostate cancer often have *elevated* levels of *serum acid phosphatase.* Most men with bone metastasis have *elevated serum alkaline phosphatase* levels and severe pain.

Interventions

As with any cancer, accurate staging and grading of prostate tumors guide treatment planning and monitoring during the course of the disease. Patients are faced with several treatment options. A urologist and oncologist are needed to help patients make the best decision. Because prostate cancer is slow growing with late metastasis, older men who are asymptomatic and have other illnesses may choose observation without immediate active treatment, especially if the cancer is early stage. This option is known as **active surveillance (AS)**. This form of treatment involves initial surveillance with active treatment only if the symptoms become bothersome. The average time from diagnosis to start of treatment is up to 10 years. During the AS period, men are monitored at regular intervals through DRE and PSA testing. Factors that are considered in choosing AS include potential side effects of treatment (e.g., urinary incontinence, erectile dysfunction), estimated life expectancy, and the risk for increased morbidity and mortality from not seeking active treatment (Hegarty & Bailey, 2011).

Patients who have very early–stage cancer of the prostate who choose AS require close follow-up by their health care provider. If obstruction occurs, a transurethral resection of the prostate (TURP) may be done. The care of patients having this procedure is described in the discussion of Surgical Management on p. 1505 in the Benign Prostatic Hyperplasia section.

Specific management is based on the extent of the disease and the patient's physical condition. The patient may undergo surgery for a biopsy, staging and removal of the tumor, or palliation to control the spread of disease or relieve distressing symptoms. As with AS, the health care provider and patient must weigh the benefits of treatment against potential adverse effects such as incontinence and erectile dysfunction (ED).

Surgical Management.

Surgery is the most common intervention for a cure. Minimally invasive surgery (MIS) or, less commonly, an open surgical technique for radical prostatectomy (prostate removal) is usually performed. A **bilateral**

orchiectomy (removal of both testicles) is another palliative surgery that slows the spread of cancer by removing the main source of testosterone.

Preoperative Care.

Preoperative care depends on the type of surgery that will be done. Minimally invasive surgery (MIS) is most appropriate for localized prostate cancer and is used as a curative intervention. The most common procedure is the *laparoscopic radical prostatectomy (LRP),* most often with robotic assistance (Chitlik, 2011). Other newer procedures include transrectal high-intensity focused ultrasound (HIFU) and cryosurgery. Patients who qualify for LRP must have a PSA less than 10 ng/mL and have no previous hormone therapy or abdominal surgeries. Remind the patient that the advantages of this procedure over open surgery are (Dunn & Kazer, 2011):

- Decreased hospital stay (1 to 2 days)
- Minimal bleeding
- Smaller or no incisions and less scarring
- Less postoperative discomfort
- Decreased time for urinary catheter placement
- Fewer complications
- Faster recovery and return to usual activities
- Nerve-sparing advantages

For the patient undergoing an *open* radical prostatectomy, provide preoperative care as for any patient having surgery (see Chapter 14).

Operative Procedures.

For the *LRP procedure,* the patient is placed in lithotomy positioning with steep Trendelenburg. Nurses in the OR ensure that the patient maintains a balanced body temperature and positions the patient to prevent injury (Chitlik, 2011). The urologist makes one or more small punctures or incisions into the abdomen. A laparoscope with a camera on the end is inserted through one of the incisions while other instruments are inserted into the other incisions. The robotic system may be used to control the movement of the instruments by a remote device. The prostate is removed along with nearby lymph nodes, but perineal nerves are not affected.

The *open* radical prostatectomy can be performed via several surgical approaches, depending on the patient's desired outcomes and the staging of the disease. The transperineal and retropubic (nerve-sparing) approaches are most commonly used. The surgeon removes the entire prostate gland along with the prostatic capsule, the cuff at the bladder

neck, the seminal vesicles, and the regional lymph nodes. The remaining urethra is connected to the bladder neck. The removal of tissue at the bladder neck allows the seminal fluid to travel upward into the bladder rather than down the urethral tract, resulting in retrograde ejaculations.

Postoperative Care.

Provide postoperative care of the patient after *open* radical prostatectomy as summarized in Chart 72-2. Nursing interventions include all the typical care for a patient undergoing major surgery. Maintaining hydration, caring for wound drains (open procedure), managing pain, and preventing pulmonary complications are important aspects of nursing care. (See general postoperative care in Chapter 16.)

Chart 72-2 Best Practice for Patient Safety & Quality Care QSEN

Care of the Patient After an Open Radical Prostatectomy

- Encourage the patient to use patient-controlled analgesia (PCA) as needed.
- Help the patient get out of bed into a chair on the night of surgery and ambulate by the next day.
- Maintain the sequential compression device until the patient begins to ambulate.
- Monitor the patient for deep vein thrombosis and pulmonary embolus.
- Keep an accurate record of intake and output, including Jackson-Pratt or other drainage device drainage.
- Keep the urinary meatus clean using soap and water.
- Avoid rectal procedures or treatments.
- Teach the patient how to care for the urinary catheter because he may be discharged with the catheter in place.
- Teach the patient how to use a leg bag.
- Emphasize the importance of not straining during bowel movement. Advise the patient to avoid suppositories or enemas.
- Remind the patient about the importance of follow-up appointments with the physician to monitor progress.

Assess the patient's pain level, and monitor the effectiveness of pain management with opioids given as patient-controlled analgesia (PCA), a common method of delivery during the first 24 hours after surgery. Administer a stool softener if needed to prevent possible constipation

from the drugs. Patients having the minimally invasive surgery have much less pain and fewer complications.

The patient has an indwelling urinary catheter to straight drainage to promote urinary elimination. Monitor intake and output every shift and record, or delegate this activity to and supervise unlicensed assistive personnel (UAP). An antispasmodic may be prescribed to decrease bladder spasm induced by the indwelling urinary catheter. The time for catheter removal depends on the type of procedure that is performed and overall patient condition. Those with open surgical procedures use the catheter for 7 to 10 days or longer.

Ambulation should begin no later than the day after surgery. Provide assistance in walking the patient when he first gets out of bed. Assess for scrotal or penile swelling from the disrupted pelvic lymph flow. If this occurs, elevate the scrotum and penis and apply ice to the area intermittently for the first 24 to 48 hours.

Many patients who have the minimally invasive techniques are discharged in 1 to 3 days after surgery and can resume usual activities in about a week or two. Those who have open procedures are discharged in 2 to 3 days or longer, depending on their progress.

Remind patients that common potential long-term complications of open radical prostatectomy are erectile dysfunction (ED) and urinary incontinence. For ED, drugs such as sildenafil (Viagra) may be effective. *Urge incontinence* may occur because the internal and external sphincters of the bladder lie close to the prostate gland and are often damaged during the surgery. Kegel perineal exercises may reduce the severity of urinary incontinence after radical prostatectomy. Teach the patient to contract and relax the perineal and gluteal muscles in several ways. For one of the exercises, teach him to:

1. Tighten the perineal muscles for 3 to 5 seconds as if to prevent voiding, and then relax.
2. Bear down as if having a bowel movement.
3. Relax and repeat the exercise.

Show him how to inhale through pursed lips while tightening the perineal muscles and how to exhale when he relaxes. To regain urinary control, teach the patient to practice holding an object, such as a pencil, in the fold between the buttock and the thigh. He may also sit on the toilet with the knees apart while voiding and start and stop the stream several times.

Nonsurgical Management.

Nonsurgical management may be an adjunct to surgery or alternative

intervention if the cancer is widespread or the patient's condition or age prevents surgery. Available modalities include radiation therapy, hormone therapy, and chemotherapy (less often).

Radiation Therapy.

External or internal radiation therapy may be used in the treatment of prostate cancer or as "salvage" treatments when cancer recurs. It may also be done for palliation of the patient's symptoms.

External beam radiation therapy (EBRT or XRT) comes from a source outside the body. Patients are usually treated 5 days a week for 4 to 6 weeks (Dunn & Kazer, 2011). Three-dimensional conformal radiation therapy (3D-CRT) can more accurately target prostate tissue and can reduce side effects such as damage to the rectum. An advanced type of this radiation called *intensity-modulated radiation therapy* provides very high doses to the prostate. EBRT can also be used to relieve pain from bone metastasis or given following radical prostatectomy. Teach patients that external beam radiation causes ED in many men well after the treatment is completed.

Teach patients that other complications from EBRT include urinary frequency, diarrhea, and *acute radiation cystitis,* which causes persistent pain and hematuria. Symptoms are usually mild to moderate and subside in 6 weeks after treatment. Drugs to prevent urinary urgency such as tolterodine (Detrol LA) may be prescribed. Teach the patient to avoid caffeine and continue drinking plenty of water and other fluids.

Radiation proctitis (rectal mucosa inflammation) may also develop but is less likely with 3D-CRT. The man reports rectal urgency and cramping and passes mucus and blood. Teach him to report these symptoms to the health care provider. Like cystitis, this problem usually resolves in 4 to 6 weeks after the treatment stops. If proctitis occurs, teach patients to limit spicy or fatty foods, caffeine, and dairy products.

Low-dose brachytherapy (internal radiation) can be delivered by implanting low-dose radiation seeds, needles, or wires directly into and around the prostate gland. This treatment includes ultrasonically guided interstitial or radioactive implantation. These procedures are done on an ambulatory care basis and are the most cost-effective treatment for early-stage prostate cancer. Reassure the patient that the dose of radiation is low and that the radiation will not pose a hazard to him or others. Teach him that ED, urinary incontinence, and rectal problems do occur in a small percentage of cases. Fatigue is also common and may last for several months after the treatment stops. Chapter 22 describes general nursing care for patients having radiation therapy.

Drug Therapy.

Drug therapy may consist of either hormone therapy (androgen deprivation therapy [ADT]) or chemotherapy.

Hormone Therapy.

Because most prostate tumors are hormone dependent, patients with extensive tumors or those with metastatic disease may be managed by androgen deprivation. Luteinizing hormone–releasing hormone (LH-RH) agonists or anti-androgens can be used.

Examples of *LH-RH agonists* are leuprolide (Lupron), goserelin (Zoladex), and triptorelin (Trelstar). These drugs first stimulate the pituitary gland to release the luteinizing hormone (LH). After about 3 weeks, the pituitary gland "runs out" of LH, which reduces testosterone production by the testes.

Nursing Safety Priority QSEN

Drug Alert

Teach patients taking LH-RH agonists that side effects include "hot flashes," erectile dysfunction, and decreased **libido** (desire to have sex). Some men also have **gynecomastia** (breast tenderness and growth). These drugs can also cause osteoporosis. Bisphosphonates like pamidronate (Aredia) are prescribed to prevent bone fractures. They can also be used to slow the damage caused by bone metastasis.

Anti-androgen drugs, also known as *androgen deprivation therapy (ADT),* work differently in that they block the body's ability to use the available androgens (Dunn & Kazer, 2011). These drugs are the major treatment for metastatic disease. Examples include flutamide (Eulexin, Euflex), bicalutamide (Casodex), and nilutamide (Nilandron). These drugs inhibit tumor progression by blocking the uptake of testicular and adrenal androgens at the prostate tumor site.

Anti-androgens may be used alone or in combination with LH-RH agonists for a total or maximal androgen blockade (hormone ablation). Patients who have this drug combination often have "hot flashes" similar to those experienced by menopausal women, and they can decrease the patient's perceived quality of life. Ask the patient if he has been experiencing this problem. Megestrol acetate may be prescribed for this uncomfortable condition.

Chemotherapy.

Systemic chemotherapy may be an option for patients whose cancer has spread and for whom other therapies have not worked. For example, small cell prostate cancer is rare and is more responsive to chemotherapy than to hormone therapy. Docetaxel (Taxotere) plus prednisone given every 3 weeks is the preferred treatment. A combination of cisplatin (Platinol) and etoposide (VP-16, VePesid) may also be effective for this type of cancer. Chapter 22 describes general nursing care for patients receiving chemotherapy.

Community-Based Care

Patient-centered collaborative care of the man with prostate cancer should include his partner, if any, and family. The diagnosis and treatment of cancer greatly affect couples who survive the disease. Recognize that the patient and partner have specific physical and psychosocial needs that should be addressed before hospital discharge and management should continue in the community setting.

Patients with prostate cancer may require care in a wide variety of settings: at the hospital, the radiation therapy department, the oncologist's office, or home at any stage of the disease process. Specific interventions depend on which treatment the patient had or if he had a combination of treatments. This section focuses on the needs of those who had a radical prostatectomy.

Home Care Management.

Discharge planning and health teaching start early, even before surgery. A patient can better plan home care management when he knows what to expect. Collaborate with the case manager to coordinate the efforts of various health care providers, surgical unit nursing staff, and possibly a home care nurse. As specified by The Joint Commission and other accrediting agencies, continuity of care is essential when caring for this patient because he may need weeks or months of therapies.

Self-Management Education.

An important area of teaching for the patient going home after an *open* radical prostatectomy may be urinary catheter care. An indwelling urinary catheter may be in place for up to several weeks, depending on the surgical technique that was used. Teach him and his family how to care for the catheter, use a leg bag, and identify manifestations of infection and other complications. See Chart 72-3 for patient and family education.

Chart 72-3 Patient and Family Education: Preparing for Self-Management

Urinary Catheter Care at Home

- Once a day, gently wash the first few inches of the catheter starting at the penis and washing outward with mild soap and water.
- Rinse and dry the catheter well.
- If you have not been circumcised, push the foreskin back to clean the catheter site; when finished, push the foreskin forward.
- Change the drainage bag at least once a week as needed:
  - Hold the catheter with one hand and the tubing with the other hand, and twist in opposite directions to disconnect.
  - Place the end of the catheter in a clean container to catch leakage of urine.
  - Remove the rubber cap from the tubing of the leg bag or clean drainage bag.
  - Clean the end of the new tubing with alcohol swabs.
  - Insert the end of the new tubing into the catheter, and twist to connect securely.
- Clean the drainage bag just removed by pouring a solution of one part vinegar to two parts water through the tubing and bag. Rinse well with water, and allow the bag to dry.

Encourage the patient to walk short distances. Lifting may be restricted to no more than 15 pounds for up to 6 weeks if an open procedure was done. Remind him to maintain an upright position and not walk bent or flexed. Vigorous exercise such as running or jumping should be avoided for at least 12 weeks and then gradually introduced. By contrast, patients having the minimally invasive laparoscopic surgery can usually return to work or usual activities in about a week.

Teach the patient to not strain to defecate. A stool softener may be prescribed to reduce the need for straining. If an opioid is prescribed for pain management, encourage the patient to drink adequate water to prevent constipation.

If the patient had an *open* radical prostatectomy, teach him to shower for the first 2 to 3 weeks rather than soak in a bathtub. Patients who had a laparoscopic procedure can usually shower in 1 to 2 days. Teach them to remove the small bandage but leave the Steri-Strips in place (they should fall off in about a week). Show patients how to inspect the incision or puncture site(s) daily for signs of infection. Remind them to keep all follow-

up appointments. PSA blood tests are taken 6 weeks after surgery and then every 4 to 6 months to monitor progress.

Health Care Resources.

Refer the patient and partner to agencies or support groups such as the American Cancer Society's *Man to Man* program to help cope with prostate cancer. This program provides one-on-one education, personal visits, educational presentations, and the opportunity to engage in open and candid discussions. Another prostate cancer support group is *Us TOO International* (www.ustoo.com) sponsored by the Prostate Cancer Education and Support Network. This group provides education and support with national and international chapters. Information can also be obtained from the Prostate Cancer Foundation (www.prostatecancerfoundation.org) or the National Prostate Cancer Coalition (www.fightprostatecancer.org). Other personal and community support services such as spiritual leaders or churches and synagogues are also important to many patients.

For same-sex couples surviving prostate cancer, *Malecare* (http://malecare.org) is an excellent resource. This nonprofit organization provides support groups for gay and bisexual men and their partners (Galbraith et al., 2011). Another resource is *A Gay Man's Guide to Prostate Cancer,* which was updated in 2011.

Some men have erectile dysfunction (ED) for the first 3 to 18 months after a prostatectomy. Refer them to a specialist who can help with this problem. (ED is discussed briefly in the Erectile Dysfunction section, p. 1512.) Refer patients with urinary incontinence to a urologist who specializes in this area. Drug therapy and other strategies may be used. Chapter 66 discusses incontinence management in detail.

Clinical Judgment Challenge

Patient-Centered Care QSEN

A urologist tells a 70-year-old man that his biopsy revealed stage 2 prostate cancer. The patient has lived with his male life partner for 20 years; they are both very upset about his diagnosis and prognosis. The urologist states that the patient is a candidate for laparoscopic prostatectomy.

1. As the office nurse, what is your best response to the patient and his partner at this time?
2. How would you describe his likely prognosis?

3. What health teaching will the patient and partner need?
4. What community resources will you recommend and why?

Prostatitis

❖ Pathophysiology

Prostatitis is an inflammation of the prostate gland. Duration of symptoms, presence or absence of WBCs in the urine, and urinary culture results determine the classification.

Bacterial prostatitis often occurs with urethritis or an infection of the lower urinary tract. Organisms may reach the prostate via the bloodstream or the urethra. The most common organisms are *Escherichia coli, Enterobacter, Proteus,* and group D streptococci. Acute bacterial prostatitis may be manifested by fever, chills, **dysuria** (painful urination), urethral discharge, and a boggy, tender prostate. Gentle palpation of the prostate usually results in a urethral discharge, which has WBCs in the prostatic secretions.

Chronic bacterial prostatitis generally occurs in older men and has a less dramatic presentation than acute bacterial prostatitis and without the systemic manifestations. The patient reports experiencing hesitancy, urgency, dysuria, difficulty initiating and terminating the flow of urine, and decreased strength and volume of urine. Also, there may be discomfort in the perineum, scrotum, and penis.

❖ Patient-Centered Collaborative Care

The patient with chronic prostatitis usually reports backache, perineal pain, mild dysuria, and urinary frequency. Hematuria may be present. The prostate may feel irregularly enlarged, firm, and slightly tender when palpated. The patient often has an elevated serum WBC count and prostate-specific antigen (PSA) level.

Complications of prostatitis are **epididymitis** (inflammation of the epididymis) and **cystitis** (inflammation of the bladder). The patient with either acute or chronic bacterial prostatitis is likely to develop urinary tract infections. Sexual functioning may be impaired because of discomfort.

Early diagnosis and treatment of prostatitis with antimicrobials are important. Treatment may last from weeks to many months because there is poor penetration of antibiotics into prostatic tissue. Acute bacterial prostatitis may require hospitalization with aggressive IV antibiotics.

Emphasize the importance of comfort measures, such as sitz baths, muscle relaxants, and NSAIDs. Stool softeners are prescribed to prevent straining and rectal irritation of the prostate during a bowel movement.

Alpha blockers such as tamsulosin (Flomax) may be given to promote voiding. Teach patients to avoid alcohol, coffee, tea, and spicy foods that irritate symptoms. Instruct them to avoid over-the-counter cold preparations containing decongestants or antihistamines that may cause urinary retention.

Teach the patient with chronic prostatitis about the long-term nature of the problem. Because prostatitis can cause other urinary tract infections, explain the importance of long-term antibiotic therapy and increasing fluid intake. Remind him to take the prescribed antibiotics on schedule. Because sulfamethoxazole-trimethoprim (Bactrim, Septra) diffuses into the prostatic fluid, it is often the antibiotic of choice. *Before drug administration, be sure that the patient does not have any allergy to sulfa drugs.*

Teach the patient about activities that drain the prostate (sexual intercourse, masturbation), which may help in the management of chronic prostatitis. Inform him that prostatitis is not infectious or contagious.

Erectile Dysfunction

❖ Pathophysiology

Erectile dysfunction (ED), also known as *impotence,* is the inability to achieve or maintain an erection for sexual intercourse. It affects millions of men in the United States. There are two major types of ED: organic and functional.

Organic ED is a gradual deterioration of function. The man first notices diminishing firmness and a decrease in frequency of erections. Causes include (McCance, et al., 2014):

- Inflammation of the prostate, urethra, or seminal vesicles
- Surgical procedures such as prostatectomy
- Pelvic fractures
- Lumbosacral injuries
- Vascular disease, including hypertension
- Chronic neurologic conditions, such as Parkinson disease or multiple sclerosis
- Endocrine disorders, such as diabetes mellitus (a major cause) or thyroid disorders
- Smoking and alcohol consumption
- Drugs, such as antihypertensives
- Poor overall health that prevents sexual intercourse

If the patient has episodes of ED, it usually has a *functional* (psychological) cause. Men with functional ED usually have normal nocturnal (nighttime) and morning erections. Onset is usually sudden and follows a period of high stress.

❖ Patient-Centered Collaborative Care

If possible, the physician determines the cause of the ED through a variety of diagnostic testing, including measuring serum hormone levels and using Doppler ultrasonography to determine blood flow to the penis. The most common intervention for ED is drug therapy. Other interventions include vacuum devices, intracorporal injections, intraurethral applications, and prostheses (implants).

First-line oral drugs used to manage ED, phosphodiesterace-5 (PDE-5) inhibitors, work by relaxing the smooth muscles in the corpora cavernosa so blood flow to the penis is increased. The veins exiting the corpora are compressed, limiting outward blood flow and resulting in penile **tumescence** (swelling). Teach patients to take the pill 1 hour before sexual intercourse. For some drugs, such as sildenafil (Viagra) and

vardenafil (Levitra), sexual stimulation is needed within ½ to 1 hour to promote the erection. With other drugs, such as tadalafil (Cialis), erection can be stimulated over a longer period. Because the erection occurs more naturally compared with other treatment options, most men and their partners prefer this option.

Nursing Safety Priority QSEN

Drug Alert

Instruct patients taking PDE-5 inhibitors to abstain from alcohol before sexual intercourse because it may impair the ability to have an erection. Common side effects of these drugs include dyspepsia (heartburn), headaches, facial flushing, and stuffy nose. If more than one pill a day is being taken, leg and back cramps, nausea, and vomiting also may occur. *Teach men who take nitrates to avoid PDE-5 inhibitors because the vasodilation effects can cause a profound hypotension and reduce blood flow to vital organs.* For patients who cannot take these drugs or do not respond to them, other methods are available to achieve an erection.

The basic design of a *vacuum constriction device (VCD)* is a cylinder that fits over the penis and sits firmly against the body. Using a pump, a vacuum is created to draw blood into the penis to maintain an erection. A rubber ring (tension band) is placed around the base of the penis to maintain the erection, and the cylinder is removed.

Injecting the penis with vasodilating drugs can make the penis erect by engorging it with blood. The most common agents used for this purpose include (Lilley et al., 2014):

- Alprostadil (Caverject), a synthetic vasodilator identical to prostaglandin E_1 produced in the body
- Paverine, also a vasodilator
- Phentolamine (Regitine), an alpha-1, alpha-2 selective adrenergic receptor antagonist
- A combination of any or all of these drugs

Adverse drug effects include priapism (prolonged erection), penile scarring, fibrosis, bleeding, bruising at the injection site, pain, infection, and vasovagal responses.

Penile implants (prostheses) are used when other modalities fail. Devices include semirigid, flexible, or hydraulic inflatable and multi-component or one-piece instruments. The three-piece inflatable device is the most commonly implanted prosthesis. A reservoir is placed in the

scrotum. Tubes carry the fluid into the inflatable pieces that are placed in the penis. To inflate the prosthesis, the man squeezes the pump located in the scrotum. To deflate the prosthesis, a release button is activated. Advantages include the man's ability to control his erections. The major disadvantages include device failure and infection. The device is implanted as an ambulatory care surgical procedure. *Teach the patient to observe the surgical site for bleeding and infection.*

NCLEX Examination Challenge

Health Promotion and Maintenance

The nurse is teaching a client about taking sildenafil (Viagra) for erectile dysfunction. Which statement by the client indicates a need for further teaching?

A "I should have sex within an hour after taking the drug."
B "I should avoid alcohol when on the drug or it might not work well."
C "I can expect to maybe get a stuffy nose or headache when I take the drug."
D "If I have chest pain during sex, I should take a nitroglycerin tablet."

Testicular Cancer

Pathophysiology

Testicular cancer is a rare cancer that most often affects men between 20 and 35 years of age but can affect men of any age (American Cancer Society [ACS], 2014b). It usually strikes men at a productive time of life and thus has significant economic, social, and psychological impact on the patient and his family and/or partner. With early detection by testicular self-examination (TSE) (Chart 72-4) and treatment, testicular cancer has a 95% cure rate (Viatori, 2012). It can occur in one testicle or both.

Chart 72-4 Patient and Family Education: Preparing for Self-Management

Testicular Self-Examination

- Examine your testicles monthly immediately after a bath or a shower, when your scrotal skin is relaxed.
- Examine each testicle by gently rolling it between your thumbs and fingers. Testicular tumors tend to appear deep in the center of the testicle.
- Look and feel for any lumps; smooth, rounded masses; or any change in the size, shape, or consistency of the testes.
- Report any lump or swelling to your doctor as soon as possible.

Primary testicular cancers fall into two major groups:

- Germ cell tumors arising from the sperm-producing cells (account for most testicular cancers)
- Non–germ cell tumors arising from the stromal, interstitial, or Leydig cells that produce testosterone (account for a very small percentage of testicular cancers)

Testicular germ cell tumors are classified into two broad categories: seminomas and nonseminomas (Table 72-1). The most common type of testicular tumor is *seminoma*. Patients with seminomas have the most favorable prognoses because the tumors are usually localized, metastasize late, and respond to treatment (Viatori, 2012). They often are diagnosed when they are still confined to the testicles and retroperitoneal lymph nodes.

TABLE 72-1

Classification of Testicular Tumors

GERM CELL (GERMINAL) TUMORS	NON–GERM CELL (NONGERMINAL) TUMORS

• Seminoma
• Nonseminoma:
  • Embryonal carcinoma
  • Teratoma
  • Choriocarcinoma
	• Interstitial cell tumor
	• Androblastoma

Non–germ cell tumors are classified as either *interstitial cell tumors* or *androblastomas* (testicular adenomas). Most of these tumors do not metastasize. Interstitial cell tumors arise from the Leydig cells, which secrete testosterone into the bloodstream. Androblastomas sometimes secrete estrogen, which accounts for the feminization and **gynecomastia** (breast enlargement) occasionally seen in these men.

The risk for testicular tumors is higher in males who have an undescended testis **(cryptorchidism)** or have human immune deficiency virus (HIV) infection (McCance, et al., 2014).

Genetic/Genomic Considerations

Patient-Centered Care QSEN

Men are at a higher risk for testicular cancer if they have a family history of the disease (Viatori, 2012). The incidence is higher among identical twins, brothers, and other close male relatives. Euro-American men are at a higher risk for testicular cancer than men of other races or ethnicities (Viatori, 2012). The reason for these differences is not known.

Primary testicular cancer is rarely bilateral. Other cancers such as leukemia, lymphoma, and metastatic carcinomas may invade the testes. A man with bilateral testicular tumors is more likely to have metastatic disease to the testes than primary cancer.

Patient-Centered Collaborative Care

Assessment

Physical Assessment/Clinical Manifestations.

When taking a history from a patient with a suspected testicular tumor, consider the risk factors. Assess for other risk factors, including a history

or presence of an undescended testis and a family history of testicular cancer.

The most common manifestation is a painless, hard swelling or enlargement of the testicle. Patients with discomfort such as heaviness or aching in the lower abdomen or the scrotum may have metastatic disease. Determine how long any manifestations have been present.

Assess the patient's family situation. Is the patient sexually active? If so, what is his sexual preference? Does he have children? Does he want children in the future? Depending on the treatment plan chosen, would he be interested in sperm storage in a sperm bank?

If the man has one healthy testis, he can function sexually and may not have any problem with reproduction. If he has a retroperitoneal lymph node dissection or chemotherapy, he may become sterile because of treatment effects on the sperm-producing cells or surgical trauma to the sympathetic nervous system resulting in retrograde ejaculations.

The testes, lymph nodes, and abdomen should be thoroughly examined. Patients may feel embarrassed about having this examination. Provide privacy, and explain the procedure to the patient. Inspect the testicles for swelling or a lump that the patient reports is painless. An advanced practice nurse or other health care provider palpates the testes for lumps and swelling that are not visible (Chart 72-5). The presence of any testicular pain, lymph node swelling, bone pain, abdominal masses, sudden hydrocele (fluid in the scrotum), or gynecomastia often indicates metastatic disease.

Chart 72-5 Focused Assessment

The Patient with a Testicular Lump

- Obtain a medical history from the patient:
  - When was the lump discovered?
  - Are there any other symptoms (sensation of heaviness, dragging in testicle, pain, discharge from penis)?
  - Is there a history of cryptorchidism?
- An advanced practice nurse or other health care provider will assess the genital system. They will:
  - Inspect and palpate the scrotal contents, have the patient perform a Valsalva maneuver, and palpate for a varicocele.
  - Any lump or enlargement that does not transilluminate should be suspected as malignant.
- Palpate for any enlarged lymph nodes. Always wear gloves during the

examination of the male genitalia. The most common areas for lymphadenopathy are in the inguinal or supraclavicular regions.
- Assess the abdomen for a possible mass or hepatomegaly.

Psychosocial Assessment.

Because testicular cancer and its treatment often lead to sexual dysfunction, pay close attention to the psychosocial aspects of the disease. Sexuality is an issue for men of any age, but it may be even more of an issue for younger men. Even if the cancer is detected at an early stage and the patient is cured after surgery, he may be afraid that he will be sexually deficient. He may also think of himself as "less than a whole person." These fears can disrupt the psychosocial and sexual development of young males and can threaten their identity. The patient may be afraid that he will be unable to perform sexually, will no longer be sexually attractive or desirable, and will face rejection. Feelings of sexual inadequacy may be denied, repressed, or displaced, causing increased stress on the man's personal and work relationships.

Assess the man's support systems, including his partner, family members, and friends. Ask him where he feels that he can be supported, such as a religious or spiritual group, community club, or social group. Friends are often very helpful during this difficult time.

Laboratory Assessment.

Common serum tumor markers that confirm a diagnosis of testicular cancer are:
- Alpha-fetoprotein (AFP)
- Beta human chorionic gonadotropin (hCG)
- Lactate dehydrogenase (LDH)

Serum testosterone levels are increased when the tumor affects the Leydig cells, which produce this hormone. Drugs such as alcohol and antiepileptic drugs can also cause an increase in testosterone (Pagana & Pagana, 2014).

Other Diagnostic Assessment.

When a patient has a change in testis size, shape, or texture, *ultrasonography* can determine whether the mass is solid or fluid filled. It also can help differentiate benign masses from malignant ones.

After the diagnosis of testicular cancer, the patient should have a *CT* scan of the abdomen and the chest to identify small metastatic lesions. *Lymphangiography* shows a view of the body's lymph system to look for

spread to other areas.

MRI is used to detect enlarged lymph nodes and abnormal nodules in certain organs that may indicate metastasis from the testicles. Chest x-rays and bone scans may also be performed if metastasis is suspected.

Interventions

At diagnosis, the incidence of **oligospermia** (low sperm count) and **azoospermia** (absence of living sperm) is common in patients with testicular cancer. This problem is thought to be related to higher testicular temperatures created by cancer cell metabolism. The man may not discover that he has reduced sperm count until he has a sperm count performed before surgery.

Health teaching about reproduction, fertility, and sexuality is started in the pretreatment phase. Review the normal reproductive function, as well as the possible effects of cancer and its treatment on reproductive function. Explore with the patient various reproductive options if desired (Chart 72-6). A sperm bank facility provides comprehensive information on semen collection, storage of semen, the storage contract, costs, and the insemination process.

Chart 72-6 Patient and Family Education: Preparing for Self-Management

Sperm Banking

- You may want to investigate sperm storage in a sperm bank as a way to preserve your sperm for future use.
- No one knows how long sperm can be stored successfully, but pregnancies have resulted from sperm stored for longer than 10 years.
- Check with the sperm bank to see how much it charges to process and store your sperm and to see whether you must pay when the service is provided.
- Investigate whether your health insurance company will reimburse you for sperm collection and storage.

When preparing the patient for the collection and storage of sperm, assume the role of patient advocate and keep in mind the effect of the cancer diagnosis. The psychological benefit of having stored sperm may be important for the man and may influence his response to treatment. For some men, knowing that the potential for being a father still exists may help them cope with other fears, such as alopecia or erectile

dysfunction (ED).

Suggest that the patient arrange for semen storage, if desired, as soon as possible after diagnosis. Sperm collection should be completed before he begins radiation therapy or chemotherapy or undergoes a radical lymph node dissection. After radiation therapy or chemotherapy has been started, the patient is at increased risk for producing mutagenic sperm, which may not be viable or may result in fetal abnormalities.

The patient's diagnosis and his physical condition may not allow treatment to be postponed, thus making sperm storage impossible. Also, some men may have personal or religious beliefs that do not allow sperm storage. For those who are not candidates for sperm storage in a sperm bank and for those who choose not to bank, discuss other options for reproduction such as donor insemination or adoption.

Surgical Management.

Surgery is the main treatment for testicular cancer. For stage 0 or 1 (localized disease), the surgeon performs a unilateral **orchiectomy** to remove the affected testicle. Every effort is made to remove the cancerous testis as an intact organ to prevent releasing cancer cells into the surgical site. Depending on the type and stage of the cancer, radical retroperitoneal lymph node dissection (RPLND) may also be done.

Preoperative Care.

Like most patients with cancer, the man with testicular cancer is very apprehensive. Offer support, and reinforce the teaching provided by the surgeon. Teach the patient and his family or partner about what to expect after surgery. For patients with very early disease, minimally invasive surgery (MIS) using a laparoscope is performed rather than using an open incision. For patients having MIS, teach them that carbon dioxide may be used as part of the surgery. Carbon dioxide can cause chest or shoulder pain from diaphragmatic irritation after the procedure.

Operative Procedures.

Most patients with seminoma have only one surgery to remove the diseased testicle through the groin (inguinal) for a cure. A frozen section of the tumor is examined to confirm the type and stage of the cancer. A gel-filled silicone prosthesis may be surgically implanted into the scrotum at the time of the orchiectomy or later if the patient desires. Reassure the patient that this procedure does not impair fertility or sexual function. He cosmetically appears to have two testes (reconstructive surgery).

Some men have more advanced disease or tumor types that are more aggressive. Two options are available for the lymph node dissection: a traditional open approach and minimally invasive surgery (MIS) using a laparoscope. To perform the *open* approach, the surgeon removes the retroperitoneal nodes in the iliac and lumbar regions. Because the blood supply and the lymphatic vessels of the testes and kidneys are directly related, an extensive midline incision from the xiphoid process to the pubis is necessary. Removal of the sympathetic ganglia eliminates peristalsis in the vas deferens and contractions of the seminal vesicles. This disruption results in sterility because the man's ejaculate no longer contains sperm. However, having a normal erection and experiencing orgasm usually are not affected.

The MIS procedure involves using a laparoscope through several small "keyhole" incisions through which the nodes are dissected for examination. This technique shortens the time the patient is in the operating suite, minimizes bleeding, and causes less pain after surgery. The patient has fewer postoperative complications and a shorter hospital stay.

Postoperative Care.

Nursing care for the patient after surgery depends on the type of surgical procedure that was performed and the extent of the disease process.

Nursing Safety Priority QSEN

Action Alert

Because of the length of the *open* orchiectomy and lymph node dissection approach, manipulation of the abdominal and retroperitoneal viscera, and the loss of lymphatic fluid, observe, assess, and report any complications of this major abdominal surgery (e.g., paralytic ileus) (see Chapter 16). Monitor vital signs (including pain), hydration, and pulmonary function carefully for the first 24 to 48 hours. Ambulate the patient as soon as possible, and teach him how to use the incentive spirometer. Assess the patency of the urinary catheter. Be sure the patient wears antiembolism stockings or devices, and provide care for surgical incisions and wound drains.

The patient having the *laparoscopic* procedure may have a urinary catheter in place for 1 to 2 days. The other advantages of the MIS procedure are that patients have less pain and fewer complications than those who had the open surgery. Chapter 15 describes laparoscopic

surgery in detail.

NCLEX Examination Challenge

Physiological Integrity

A client had an orchiectomy and laparoscopic radical retroperitoneal lymph node dissection this morning. What is the nurse's priority for care?
A Assess the client's pain level and provide pain management.
B Ensure that the client's urinary catheter is draining clear yellow urine.
C Observe the client's incision for redness, swelling, and drainage.
D Apply oxygen therapy via nasal cannula at 2 L/min.

Nonsurgical Management.

Combination *chemotherapy* may be used as adjuvant therapy for nonseminomatous testicular tumors or as primary treatment when there is evidence of metastatic disease. Many drug regimens are used, including varying combinations of bleomycin, etoposide, and cisplatin (BEP). The specific combination of drugs and the frequency, cycling, and duration of treatment vary from patient to patient, depending on the extent of the disease and the protocol being followed. Chapter 22 discusses the general nursing care for the patient receiving chemotherapy.

Patients having chemotherapy are at risk for certain health problems that are associated with these drugs. Examples of these problems include hypertension, hyperlipidemia, lung toxicity, anemia, and leukemia (Viatori, 2012). Teach patients taking these drugs about the long-term effects for which they should be continually and carefully monitored by their health care providers.

After orchiectomy for localized disease, *external beam radiation therapy* (EBRT) may be used. The remaining testis is shielded with a lead cup to preserve reproductive function. Even with these precautions, the patient may have a temporary decreased sperm count as a result of radiation scatter. Normally the sperm count returns to the pretreatment level within 24 to 30 months after the radiation treatment is completed. If metastases develop outside the lymphatic system, the man may still be cured with radiation therapy if the area of involvement is limited. If lymphatic involvement is extensive or if the visceral organs are involved, combination chemotherapy is used.

Community-Based Care

The patient is usually hospitalized for multiple days after an *open* radical retroperitoneal lymph node dissection but for just 1 to 2 days for the *MIS* laparoscopic procedure.

After an open *orchiectomy*, unless the patient has a wound complication, he is discharged without a dressing on the inguinal incision. A scrotal support may be needed for several days. He may want to wear a dry dressing to prevent clothing from rubbing on the sutures and causing irritation. Tell him that the sutures will be removed in the physician's office 7 to 10 days after surgery. Patients who also had an *open retroperitoneal lymph node dissection* recover more slowly. They should not lift anything over 15 pounds, should avoid stair climbing, and should not drive a car for several weeks. Be sure that bathroom facilities are on the first floor of the house where he can easily access them.

Nursing Safety Priority QSEN

Action Alert

For the patient who has undergone testicular surgery, emphasize the importance of scheduling a follow-up visit with the surgeon to examine the incision for healing and complications. Instruct him to notify the surgeon if chills, fever, increasing tenderness or pain around the incision, drainage, or dehiscence of the incision occurs. These manifestations may indicate infection for which antibiotics are needed. Instruct the patient who had a laparoscopic orchiectomy that he will be able to resume most of his usual activities within 1 week after discharge. He can take a shower in 1 or 2 days after surgery, but be sure he does not remove the Steri-Strips. These strips will loosen and fall off in about a week after surgery.

Explain the importance of performing monthly testicular self-examination (TSE) on the remaining testis and scheduling follow-up examinations with the physician. The patient who has had testicular cancer should schedule tests for urinary and serum levels of tumor markers and CT or MRI studies as part of his routine follow-up for at least 3 years.

Depending on the pathologic findings and the stage of the cancer, the patient may need further treatment. This information may not be known at the time of discharge. If it is known that the patient needs further surgery, he and his family need information about the future surgery. If it

is known that he must undergo radiation therapy or chemotherapy, he needs education about these treatments as soon as possible.

The man who has testicular cancer needs emotional support. If permanent sterility occurs and sperm storage has not been feasible, he may desire counseling about other reproductive options. Refer the patient to agencies or support groups, such as the American Fertility Society (www.theafa.org) or RESOLVE: The National Infertility Association (www.resolve.org) (organizations for infertile couples).

Other Problems Affecting the Testes and Adjacent Structures

Problems that develop inside the scrotum usually occur as a mass or as scrotal edema. Some problems produce pain, but others do not. Fig. 72-4 shows some of the most common conditions found in adult men, including hydrocele, spermatocele, and varicocele. In addition to local comfort measures, these masses are either drained or removed surgically. Scrotal support, heat, and analgesics are needed after surgery. Teach patients to follow up with their health care provider.

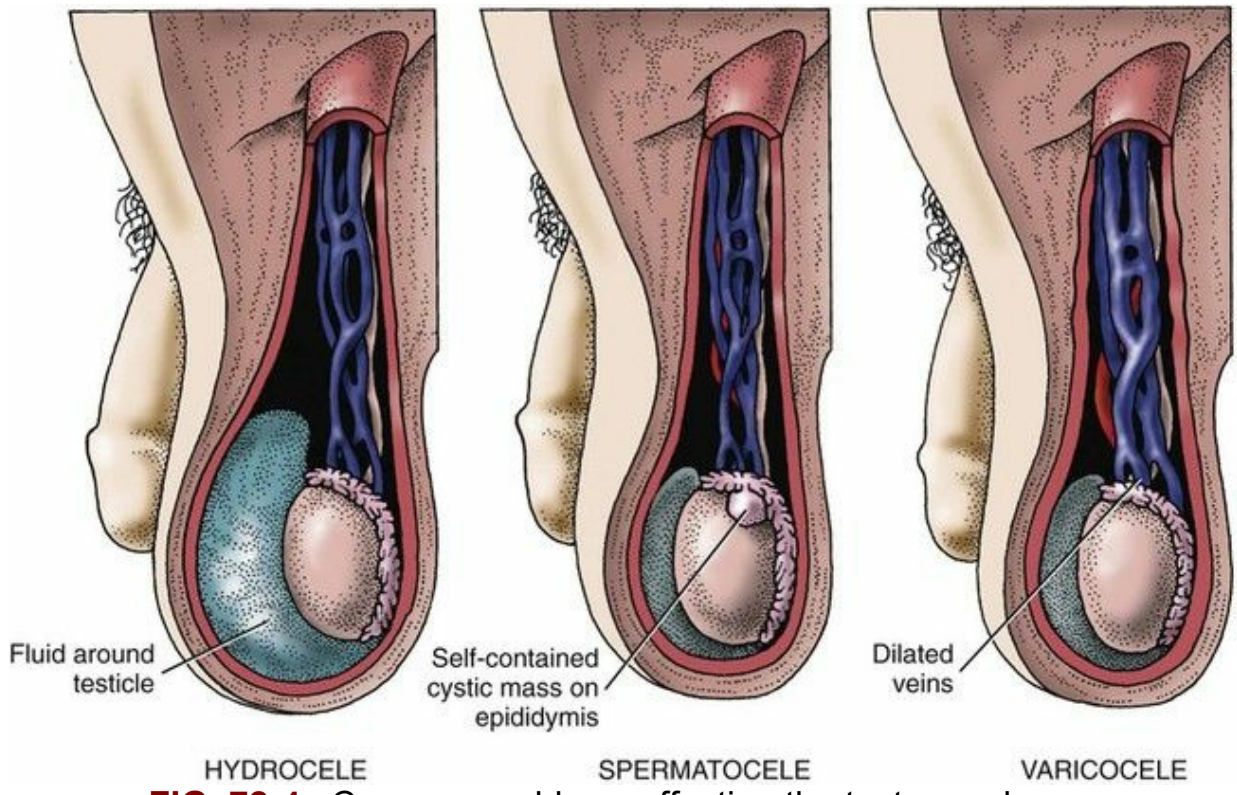

FIG. 72-4 Common problems affecting the testes and adjacent structures.

Nursing Concepts and Clinical Judgment Review

What might you NOTICE if the patient is experiencing impaired sexuality as a result of male reproductive problems?

- Lump or swelling in prostate or scrotum
- Report of pain in scrotum or during ejaculation
- Report of difficulty voiding (e.g., starting urine stream)
- Hematuria
- Report of dribbling of urine (incontinence)

- Report of inability to have a penile erection
- Report of decreased libido

What should you INTERPRET and how should you RESPOND to a patient experiencing impaired sexuality as a result of male reproductive problems?

Perform and interpret physical assessment, including:

- Conducting a complete pain assessment
- Inspecting and palpating bladder for distention
- Inspecting and palpating scrotum for swelling or masses
- Palpating lymph nodes for swelling, especially in the inguinal areas
- Sending urine sample for urinalysis and culture
- Checking most recent laboratory values for PSA, CBC, and serum tumor markers

Respond by:

- Catheterizing patient if retaining urine
- Providing pain-relief measures, such as ice or medication as prescribed
- Elevating scrotum if swollen
- Arranging for consultation with sex or intimacy therapist if patient desires

On what should you REFLECT?

- Evaluate patient for need for indwelling urinary catheter.
- Evaluate effectiveness of actions to control pain and swelling.
- Think about what additional resources the patient will need to cope with his problem.

Get Ready for the NCLEX® Examination!

Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Teach patients with prostate cancer about American Cancer Society's *Man to Man* program and the American Foundation for Urologic Disease's *Us TOO International* program to help men and their partners cope with prostate cancer.
- Teach patients to report signs of infection when caring for a urinary catheter in the home. **Safety** QSEN

Health Promotion and Maintenance

- Teach men at risk for prostate cancer to follow the current American Cancer Society's screening and early detection guidelines. **Evidence-Based Practice** QSEN
- Teach men how to perform testicular self-examination as described in Chart 72-4.
- Teach uncircumcised men the importance of keeping the penis clean to prevent penile cancer.

Psychosocial Integrity

- Because most patients with testicular cancer are young and middle-aged adults, assess their reaction to the possible loss of reproduction ability.
- Because of the high incidence of erectile dysfunction after radical prostatectomy, assess the patient's adjustment to these changes in body function. **Patient-Centered Care** QSEN
- Assess the patient's anxiety before prostate surgery, and allow him to express feelings of fear or grief. **Patient-Centered Care** QSEN

Physiological Integrity

- Perform a focused physical assessment for patients reporting lumps or swelling in their genital area; inspect and palpate bladder and scrotum.
- Observe for and report complications after radical prostatectomy, including infection, severe pain, urinary infection, urinary elimination problems, and erectile dysfunction. **Safety** QSEN
- Observe for and report bloody urine with clots after TURP; increase

continuous bladder irrigation or irrigate the bladder per agency or surgeon protocol. **Safety** QSEN

- Maintain traction on the urinary catheter and continuous bladder irrigation after a TURP. **Safety**
- Teach patients about drug therapies (5-ARIs and alpha blocking agents) used to treat BPH, including side effects such as orthostatic hypotension, erectile dysfunction, decreased libido, dizziness, and liver dysfunction. **Safety** QSEN
- Teach patients to avoid any drugs that can cause urinary retention, especially anticholinergics, antihistamines, and decongestants if BPH is present. **Evidence-Based Practice** QSEN
- Remind patients wanting to use complementary and alternative therapies to check with their health care providers before using them.
- Eating a well-balanced diet with plenty of fish and fruits and vegetables may help prevent prostate cancer.
- Reinforce the man's option for managing prostate cancer; some procedures and drugs cause erectile dysfunction and incontinence either temporarily or permanently.
- Use the information listed in Chart 72-3 to teach patients urinary catheter care after prostate cancer surgery.
- Teach patients about not lifting more than 15 lb (6.8 kg) after open prostate surgery. **Safety** QSEN
- Options for erectile dysfunction (ED) include drug therapy (most common), vacuum assist devices, penile injections, transurethral suppositories, or penile implants.
- Be aware that African-American middle-aged men are the most at risk for prostate cancer; Euro-American young men are the most at risk for testicular cancer.
- Teach patients to report symptoms of radiation cystitis or proctitis to their health care provider as soon as possible; these complications resolve in 4 to 6 weeks after the end of radiation therapy.
- Teach patients and their partners about hormone therapy used to manage prostate cancer: LH-RH agonists and anti-androgen drugs.
- Be aware that sexually transmitted diseases (STDs) are a major cause of male reproductive system infections.

CHAPTER 73

Care of Transgender Patients

Donna D. Ignatavicius and Stephanie M. Ignatavicius

PRIORITY CONCEPTS

- Sexuality
- Reproduction

Learning Outcomes

Safe and Effective Care Environment

1. Describe the need to collaborate with members of the health care team to provide high-quality care for transgender patients.
2. Explain the role of the nurse as a leader to promote advocacy for transgender people.

Health Promotion and Maintenance

3. Develop a health teaching plan for transgender patients who take hormone therapy and/or have gender reassignment surgery.
4. Identify appropriate resources for accurate trans-health information and ongoing preventive health care.

Psychosocial Integrity

5. Discuss how to use culturally sensitive terminology when providing care for transgender patients.
6. Identify the major sources of stress that contribute to transgender health issues.
7. Explain the major challenges for transgender patients in obtaining health care.

Physiological Integrity

8. Describe the side effects and adverse effects of feminizing and masculinizing hormone therapy, including effects of sexuality and reproduction.
9. Identify laboratory test values that require monitoring for patients taking hormone therapy.
10. Describe the preoperative care needed for male-to-female or female-to-male patients having genital surgery.
11. Prioritize postoperative nursing care for patients having feminizing or masculinizing genital surgery.

http://evolve.elsevier.com/Iggy/

The American Nurses Association (ANA) *Code of Ethics* states that the nurse practices with compassion and respect for the dignity and worth of every patient (ANA, 2001). The Institute of Medicine and the Quality and Safety Education for Nurses (QSEN) Institute further identified the need for nurses to be competent in patient-centered care (see Chapter 1). This competency ensures that nurses provide care with sensitivity and respect for diverse patients, even if those patients have values and preferences different from their own (ANA, 2001). Diversity is often discussed as ethnicity and race, but other cultural aspects such as sexual orientation and gender identity are part of the diverse human experience. An estimated 9 million people in the United States identify themselves as sexual and gender minorities (Gates, 2011).

People of minority sexual and gender identities are often grouped under one population category described by the acronym **LGBTQ**—lesbian, gay, bisexual, transgender, and queer/questioning (people who do not feel they belong in any other subgroup) (Table 73-1) (Eliason et al., 2013; Pettinato, 2012). Some literature includes only "LGBT." These evolving labels are misleading regarding people who identify as transgender. The grouping of sexuality (sexual attraction and behavior) and gender identity (sense of maleness or femaleness) suggests that these two concepts are related or dependent upon one another, but they are different. *LGB* refers to specific sexual orientation. However, transgender people may identify as heterosexual, homosexual, both, or neither. Nurses and other health care professionals should not assume that transgender patients have the same experiences or health care needs as those who identify as lesbian, gay, or bisexual.

TABLE 73-1

Appropriate Terminology Associated with Transgender Health

TERM	DEFINITION
Coming out	A lesbian, gay, bisexual, transgender, and queer/questioning (LGBTQ) person's public disclosure regarding sexual orientation or gender identity
Female-to-male	An adjective to describe people who were female at birth and are changing (or have changed) to a more masculine body or male
Gender dysphoria	Emotional or psychological distress caused by an incongruence between one's natal (birth) sex and gender identity
Gender identity	A person's inner sense of being a male, a female, or an alternative gender (e.g., genderqueer)
Genderqueer	An identity label used by some people whose gender identity does not conform to one of the two categories of male or female
Male-to-female	An adjective to describe people who were male at birth and are changing (or have changed) to a more feminine body or female
Sex (also called *natal sex*)	The gender assigned at one's birth
Sex reassignment surgery (SRS) (also called *gender reassignment surgery* or *gender affirmation surgery*)	A group of surgical procedures that change primary and/or secondary sex characteristics to affirm a person's gender identity
Transgender	An adjective to describe a person who crosses or transcends culturally defined categories of gender
Transition	The period of time when transgender people change from the gender role associated with their sex to a different gender role
Transsexual	Term often used by health care professionals to describe people who want to change or have changed their primary and/or secondary sex characteristics

Patient-Centered Terminology

Commonly, gender is categorized as one of two terms: *male* and *female.* For the majority of people, these descriptors are accurate. However, some people do not clearly fit into either category and may define themselves as *transgender.* Identifying oneself as transgender is not a choice or lifestyle but, rather, an inner sense of being born in the wrong body. When transgender people pursue ways of affirming their physical body and appearance with their gender identity, their interaction with the health care system requires knowledge, respect, compassion, and specialized nursing care.

Using appropriate terminology is essential to demonstrating respect (see Table 73-1). Of utmost importance is the distinction between gender and sex. Gender, also known as **gender identity**, describes a person's inner sense of maleness or femaleness and is not related to reproductive anatomy. Gender identity describes one's social role as a man or a woman (American Psychiatric Association [APA], 2013). Sex, also known as *biological* or **natal sex**, refers to a person's genital anatomy present at birth (Edwards-Leeper & Spack, 2013).

When babies are born, the gender of the child is determined by the genitalia present, but there is no way of knowing the child's true sense of gender. The sense of gender and feelings toward maleness or femaleness can develop in children as early as age 2 years and is usually present in most children during the early elementary years. Transgender people feel a mismatch between their gender identity and natal sex, often extending back into early childhood. When this incongruence occurs, they can experience **gender dysphoria**, or discomfort with one's natal sex (APA, 2013; Edwards-Leeper & Spack, 2013). Some people who have gender dysphoria may seek interventions for sex reassignment to transition to the preferred gender.

The term "transgender" is often used as an umbrella description for all people whose gender identity and presentation do not conform to social expectations (Aramburu Alegria, 2011). In this text, **transgender** describes patients who self-identify as the opposite gender or a gender that does not match their natal sex (APA, 2013; Jenner, 2010). For proper usage, transgender should be used only in adjective form. For example, a patient "is transgender," "identifies as transgender," or "is a transgender patient." Note that "transgender" never ends in "-ed." The term "transgender" should not be used as a noun, and a patient should never be described as "*a* transgender."

According to *The Diagnostic and Statistical Manual of Mental Disorders*

(APA, 2013), prevalence of gender dysphoria ranges from 5 to 14 in 1000 natal males and from 2 to 3 in 1000 natal females. However, these data describe the number of people who experience discontent with the gender they were assigned at birth and do not give an accurate estimate of the number of people who identify as transgender. Other studies have shown that the prevalence of transgender people is between 1 in 11,900 and 1 in 200,000 people (Coleman et al., 2011). Most scholars suggest that the prevalence is much higher, and more research is needed to collect more accurate demographic data for this population.

Another common term is **transsexual**, which generally describes a person who has modified his or her natal body to match the appropriate gender identity, either through cosmetic, hormonal, or surgical means (APA, 2013; Jenner, 2010). "Transsexual" can be used as both an adjective and a noun, such that a patient can be described "as transsexual" or "as a transsexual." People who were born with anatomically male parts but identify as and/or live as female are known as "male-to-female" or "MtF." Male-to-female people are also known as "transwomen," with the gender descriptor indicating the current-lived gender identity. Conversely, "transmen" are natal females who identify as and/or live as men. They are described as "female-to-male" or "FtM."

Transgender people are sometimes described as "transvestites" or "cross-dressers," often in a judgmental or negative manner. These terms should not be used unless the patient identifies as such. Other terms, such as "tranny," "he-she," or "shemale," are offensive and hurtful. These terms and other negative comments should never be used.

A patient may self-identify with any of the above terms or choose not to be defined at all. Become familiar with appropriate terms and concepts, but do not force definitions on your patients. Instead, if you are unsure how to address patients, during your nursing assessment ask them how they define their gender identity.

Transgender Health Issues

Transgender people (also referred to as *trans-people*) encounter frequent discrimination and are faced with numerous stressful situations related to their identity. Sources of stress such as job discrimination and bias-related harassment can have an impact on patients' physical and psychological health. In a 2011 national survey on discrimination, the majority of transgender people had experienced mistreatment in the workplace. Also, almost half of transgender respondents reported loss of job or denial of promotion due to their transgender identity (Grant et al., 2011). As a result, they may be homeless, use alcohol or drugs as coping mechanisms, and ignore their health needs (Grant et al., 2011). In some cases they may turn to sex work (prostitution) as a mechanism for survival (Chestnut et al., 2013; Grant et al., 2011). Only a small subset of primarily MtF transgender people engage in sex work, which can expose them to human immune deficiency virus (HIV) and sexually transmitted disease (STD).

Transgender people are also vulnerable to bias-related violence and verbal harassment, including threats and intimidation (Chestnut et al., 2013; Shipherd et al., 2011). MtF people are more than 2 times more likely to experience physical violence and discrimination than non-transwomen; the likelihood of harassment is even greater for transwomen of color (Chestnut et al., 2013). A recent report indicated that half of LGBTQ-related hate crime homicides in the United States were committed against transwomen (Chestnut et al., 2013). Factors that increase this risk for violence include poverty, homelessness, and sex work.

Having an identity that puts a person at risk for violence and mistreatment can lead to emotional distress, particularly if the person has been directly victimized. Transgender people who have experienced traumatic situations may demonstrate manifestations of posttraumatic stress disorder (PTSD) and/or depression (Shipherd et al., 2011). They may turn to a variety of coping strategies to deal with distress, some of which can negatively impact physical health. In a 2010 national survey, 26% of transgender people reported current or previous alcohol or drug use to cope with discrimination and mistreatment; however, the number of people who use substances recreationally may be higher (Grant et al., 2010). Rates of smoking in the transgender community are higher than the rates in the LGB community and general population of U.S. adults. Most important, major life stressors, emotional distress, and lack of resources can lead to suicidal ideation or suicide attempt when all other

methods of coping have failed. In a sample of over 7000 transgender adults, 41% reported at least one suicide attempt in their lifetime (Grant et al., 2010).

Stress and Transgender Health

Transgender people have additional sources of stress when attempting to access health care, such as lack of health insurance due to unemployment. This barrier to health care causes them to postpone both acute and preventive medical care. For those people who are insured, coverage for health care related to gender transition (gender reassignment), such as hormone use and surgery, is often denied (Grant et al., 2010; Lombardi, 2010).

When transgender people gain access to health care, they are often fearful and anxious about the providers and setting. In particular, they may be hesitant to disclose their transgender status due to fear of discrimination or ridicule (Aramburu Alegria, 2011; Lombardi, 2010). They may also fear that this information will be documented in health records and shared with family members. This reluctance is increased if they have had previous negative experiences with health care providers. One national survey found that 19% of transgender adults were refused health care services due to their gender identity, while 28% reported receiving verbal harassment in a health care setting. Male-to-female transgender people were more likely to encounter discrimination and avoid health care due to these experiences (Grant et al., 2010). Even with providers who seem tolerant and caring with transgender patients, there is still a risk for patients overhearing jokes in the hallway and defamatory comments (Rounds et al., 2013).

Another source of stress faced by many transgender people is lack of health care–professional knowledge regarding health care needs (Aramburu Alegria, 2011; Jenner, 2010). When this situation occurs, transgender patients are put in a position of acting as health care experts, which can limit the quality of their care. While most transgender patients generally expect their providers to have some level of knowledge or know where to seek answers (Rounds et al., 2013), at least half of them find they have to teach their providers. When they encounter providers who are unfamiliar with the specific health care needs of their population, patient confidence is likely to diminish drastically and affect desire for future health care.

Whereas transgender patients may encounter providers who do not understand or who overlook their gender identity, some may encounter health care professionals who over-focus on it. Although it is important to be generally knowledgeable about a patient's gender status and understand how it may affect health care needs, this factor is not always relevant for every health problem. For example, transgender patients

with fractures or influenza do not need to be extensively questioned about their gender identity. Whereas there are instances in which the presenting manifestations require transgender-specific care, there are also many other instances that require the same health care that all patients receive. At these times, most transgender patients prefer to be treated as any other patient (Rounds et al., 2013). Therefore use sound clinical judgment to decide if one's gender identity impacts patient assessment and care.

Need to Improve Transgender Health Care

During the past few years, several national documents were published by the U.S. Department of Health and Human Services and private health care organizations that call for improvement in LGBTQ health care. These important publications include:

- *Healthy People 2020*
- The Institute of Medicine's (IOM) report on LGBT health
- The Joint Commission field guide for care of LGBT patients
- World Professional Association for Transgender Health standards of care

The U.S. Department of Health and Human Services' *Healthy People 2010* publication did *not* include the need to improve health care for LGBT people. As a result of this omission, a companion document was developed by the Gay and Lesbian Medical Association (GLMA) to address special health care needs of this population across the life span. Ten common health problems affecting the LGBT group were identified, including cancer, nutrition and weight, and sexually transmitted disease.

The *Healthy People 2020* agenda added objectives for improving the health of LGBT people, including the need to recognize and address the special health needs of transgender patients of all ages.

One major objective is to develop a system to identify patients who identify as LGBTQ. This objective is similar to the recommendation in the Institute of Medicine's (IOM) publication entitled *The Health of LGBT People: Building a Foundation for Better Understanding* (IOM, 2011).

The IOM LGBT health report calls for the need for more research to identify the special health care concerns of LGBT people of all ages. To help meet this outcome, the document outlined the need to collect more demographic data to better identify this population. LGBTQ people need to feel safe when disclosing this very personal information.

In 2011, The Joint Commission (TJC) published a similar document that recommends ways for health care agencies to create a welcoming and safe environment for LGBT patients. In response to growing attention to the need for cultural competence for all health care professionals and to provide quality health care for sexual and gender minority patients, TJC published a field guide for health care agencies to improve LGBT patient care (TJC, 2011). Chart 73-1 lists the recommendations for health care agencies in designing a safe environment for LGBT patient care. Fig. 73-1 shows an example of a “safe zone” image that should be used to reassure these patients that they are in a safe place where they can receive respectful and knowledgeable

quality care.

Chart 73-1

Best Practice for Patient Safety & Quality Care QSEN

The Joint Commission Recommendations for Creating a Safe, Welcoming Environment for LGBTQ Patients

- Post the *Patients' Bill of Rights* and nondiscrimination policies in a visible place.
- Make waiting rooms inclusive of LGBTQ patients and families, such as posting *Safe Zone*, rainbow, or pink triangle signs.
- Designate unisex or single-stall restrooms.
- Ensure that visitation policies are equitable for families of LGBTQ patients.
- Avoid assumptions about any patient's sexual orientation and gender identity.
- Include gender-neutral language on all medical forms and documents; e.g., "partnered" in addition to married, single, or divorced categories.
- Reflect the patient's choice of terminology in communication and documentation.
- Provide information on special health concerns for LGBTQ patients.
- Become knowledgeable about LGBTQ health needs and care.
- Refer LGBTQ patients to qualified health care professionals as needed.
- Provide community resources for LGBTQ information and support as needed.

Adapted from The Joint Commission (TJC). (2011). *Advancing effective communication, cultural competence, and patient- and family-centered care for the lesbian, gay, bisexual, and transgender community.* Retrieved September 2013, from www.jointcommission.org/lgbt.

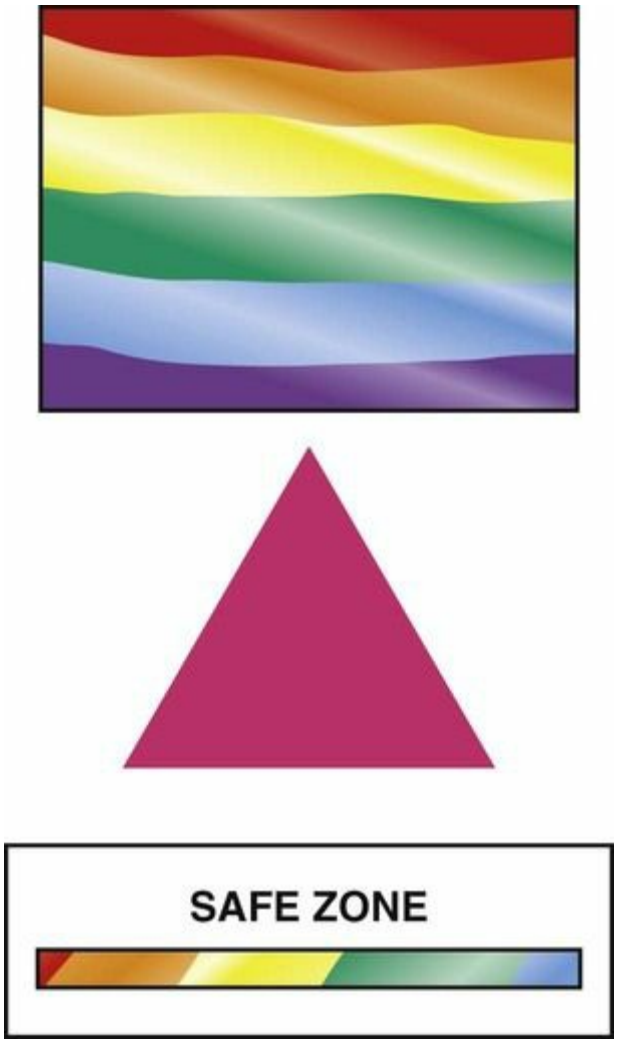

FIG. 73-1 The Safe Zone—rainbow or pink triangle signs welcome LGBTQ patients in a health care agency.

Also in 2011, the World Professional Association for Transgender Health (WPATH) updated its standards of care (Coleman et al., 2011). This document outlines core principles that nurses and other health care professionals should follow when caring for transgender patients (Table 73-2).

TABLE 73-2

Core Principles for Health Care Professionals Who Care for Transgender Patients

- Become knowledgeable about the health care needs of transgender and other gender-nonconforming people.
- Become knowledgeable about the treatment options for transgender patients and required follow-up care.
- Do not assume that all transgender patients are the same; treat each one as an individual and develop an individualized plan of care.
- Demonstrate respect for patients with nonconforming gender identities.
- Provide culturally sensitive care and use appropriate terminology that affirms the patient's gender identity.
- Facilitate patient access to appropriate and knowledgeable health care providers.
- Seek informed consent before providing treatment.
- Offer continuity of care or refer patients for ongoing quality health care.
- Advocate for patients within their families and communities.

Standards of care for the health of transsexual, transgender, and gender-nonconforming people (Version 7). *International Journal of Transgenderism, 13*, 165-232; Rounds, K.E., McGrath, B.B., & Walsh, E. (2013). Perspectives on provider behaviors: A qualitative study of sexual and gender minorities regarding quality of care. *Contemporary Nurse, 44*(1), 99-110.

Patient-Centered Collaborative Care

Assessment

As with any patient, it is best to ask during the nursing history and physical assessment how he or she prefers to be addressed. For example, for non-transgender patients, some people may go by a nickname or by their middle name and prefer to be addressed as such. For transgender patients, it is not uncommon for driver's licenses, insurance cards, and other forms of identification to retain their birth names (and by extension, birth sex) because it can be difficult to change this information, particularly if a person is in the process of transitioning. Therefore nurses may receive patient documentation with misleading patient data. For example, a nurse may receive a health care record listing a male name and birth sex yet encounter a patient presenting as female in appearance. It can be offensive and embarrassing for the patient who clearly identifies as female to be called "Mister," "sir," or the male birth name. Not only does it communicate disrespect, it also signals to the patient that she may receive inadequate care or that the environment is unsafe.

In addition to preferred names, correct pronoun usage is also important. Each patient has his or her own preference. For example, an MtF patient may visit a clinic during lunch hour at work. Because the patient has not disclosed the transgender identity at work, this patient maintains male dress and demeanor at the office. Though the patient may identify as female and live as female at home, the patient may request the nurse to use male pronouns (he, him, his) to match the

patient's current presentation and may not disclose the transgender identity to the nurse. Conversely, even though the patient presents at the time as male, the patient may request the nurse to use female pronouns (she, her, hers) because the patient identifies with a female gender identity.

In general, use pronouns that match the patient's physical presentation and dress. Even though the biological sex may not match, patients presenting as female should be addressed as female and patients presenting as male should be addressed as male. With changing styles and trends, it can sometimes be difficult to assess by clothing alone. However, with a patient whose birth sex is listed as female yet presents in traditionally male attire, facial hair, and a men's hairstyle, it is most appropriate to address this patient as male. Understandably, the clinical setting can be fast-paced and nurses may encounter multiple patients at a time; however, taking time to use clinical judgment is important. Appropriately interacting with a transgender patient can sometimes mean the difference between the patient continuing to seek health care or not.

In a few cases, patients may not identify as male or female and prefer to not use male or female pronouns. These patients often feel that the binary gender system in which a person must fit clearly into one category or the other is too limiting. Though this is a small subset of the transgender population, it is important to be aware of this subculture in case you encounter a patient who refuses to identify with a specific gender or instead identifies as genderqueer (the Q in LGBTQ). Genderqueer patients may request the use of gender neutral pronouns, or they may use these pronouns in the nurse's presence. For many genderqueer people, the pronoun "they" is preferred instead of "he" or "she."

Getting used to using the correct name or pronoun can take some time. Occasionally, nurses will know their patient's preferred name or pronoun but accidentally say the wrong one. Transgender patients encounter this situation often and typically anticipate an error at times. When this error occurs, it is best to self-correct and continue with care rather than make a prolonged apology. Focusing too much on the error may make the patient more uncomfortable because more attention has been drawn to the situation. Most transgender patients, particularly those who live full time in their gender-affirming role, wish to be treated like any other patient.

History.

Interventions for transgender people who experience gender dysphoria

(discomfort with one's natal sex) include one or more of these options (Coleman et al., 2011):

- Changes in gender expression that may involve living part time or full time in another gender role
- Psychotherapy to explore gender identity and expression, improve body image, or strengthen coping mechanisms
- Hormone therapy to feminize or masculinize the body
- Surgery to change primary and/or secondary sex characteristics (e.g., the breasts/chest, facial features, internal and/or external genitalia)

During the health history, inquire about which interventions the patient has had, if any, or if there are plans to have them in the future. Ask about current use of *drug therapy,* including hormones and other feminizing or masculinizing agents, including silicone injections. These medications are usually prescribed by endocrinologists or other specialists in transgender health care, but some patients may obtain them from nonmedical sources, including the Internet.

Exogenous hormone therapy can cause adverse health problems and requires careful patient monitoring, including laboratory testing. For example, estrogen therapy can cause increased health risks such as increased blood clotting causing venous thromboembolism (VTE), elevated blood glucose, hypertension, estrogen-dependent cancers, and fluid retention (Brennan et al., 2012). Smoking and obesity increase these risks. The risks also increase with higher doses of the medication. Ask the patient about a history of these problems.

Inquire about the patient's *surgical history*. For the MtF patient, ask about breast surgery and any surgical changes to the genitalia, such as a penectomy (removal of the penis) and vaginoplasty (creation of a vagina). The MtF patient still has the prostate gland. For older patients, ask about any problems with prostate health problems, such as urinary dribbling and retention. For the FtM patient, ask whether a hysterectomy, bilateral salpingo-oophorectomy (BSO), mastectomy, phalloplasty (creation of a penis), and/or scrotoplasty (creation of a scrotum) was performed.

Keep in mind that health insurance usually does not cover the cost of the transition process and patients may seek alternative care. For example, hormones may be obtained illegally or from countries that do not have quality controls for medication. MtF patients may seek silicone for creating breasts from nonmedical people, causing a high risk for hepatitis C and silicone complications (Brennan et al., 2012). Ask patients about the use of these alternatives as a part of their transition process.

Physical Assessment.

Be sure to review the transgender patient's health record carefully before performing a physical assessment. Be culturally sensitive, nonjudgmental, and respectful during the assessment. Be aware that transgender patients may be young, middle-aged, or older adults.

Considerations for Older Adults

Patient-Centered Care QSEN

Transgender patients who are older than 65 years lived in an era when most of them concealed their sexual orientation and true gender identity due to social stigma. These people have not been well studied as a group, but research indicates that those who lived with a partner have fewer mental health problems and better self-esteem compared with those who lived alone (Brennan et al., 2012).

When assessing transgender patients, be aware that they will be in varying stages of transition. Some patients present with no obvious physical signs that they are in the process of transitioning. Others have had gender reassignment surgery such that their new appearance matches their gender identity. Realize a transgender patient's genitalia may not match his or her physical appearance.

Psychosocial Assessment.

If gender and sexuality are relevant to the patient's presenting health problem, ask specific questions to determine how these factors may impact care. Reassure patients that their responses are confidential and will not be shared with any family, friends, or significant others without the patient's permission. However, evidence of abuse must be reported as mandated by law. Appropriate screening questions about gender and sexuality include (Coleman et al., 2011):

- Are you experiencing any challenges, concerns, or anxiety related to your sexuality?
- Related to your gender, how do you identify?
- Are you experiencing any sadness, depression, or thoughts of hurting yourself?
- Have you experienced any violence or discrimination in your personal or work life?
- Are you currently being seen by a counselor or psychologist related to your sexuality and gender identity? If so, why?

If the responses to these questions indicate that the patient has potential or actual mental health problems, consult with the health care

provider for further evaluation by a qualified mental health care professional, such as a clinical psychologist.

Interventions

Nurses care for transgender patients who are transitioning or have completed gender reassignment. They may care for them for health problems related to their transition process or for problems that are unrelated to the patient's sexuality or gender identity. In general, care for transgender patients with most health problems is the same as for any other patient. However, some interventions such as hormone therapy may affect nursing assessment and care. As a leader in health care, advocate for transgender patients and provide health teaching to promote their health. Encourage them to include their sexual partner, if any, in discussions about the transition process.

Nonsurgical Management.

The primary nonsurgical interventions for transgender patients include drug (hormone) therapy, counseling about reproduction and reproductive health, and vocal therapy. The type of intervention depends on whether the patient is transitioning from MtF or FtM.

Drug Therapy.

Drug therapy may be started after a psychosocial assessment by a qualified mental health care professional and informed consent has been obtained. According to WPATH's most recent standards of care, the criteria for hormone therapy include:

- Continuing and well-documented gender dysphoria
- Patient ability to make a fully informed decision and give consent to treatment
- Patient older than 18 years
- Well-controlled existing medical or mental health problems, if any

Drugs for MtF Patients.

Patients transitioning from male to female (MtF) typically take a combination of estrogen therapy and androgen-reducing medications to achieve feminizing effects. Expected physical changes from *estrogen therapy* are breast enlargement, thinning hair, decreased testicular size, decreased erectile function, and increased body fat compared with muscle mass (Table 73-3). Because oral estrogen (ethinyl estradiol) can increase the risk for venous thromboembolism, transdermal estrogen

(Climara) or injectable estradiol is preferred for use in transgender patients. The typical dosing is two 0.1-mg patches changed twice weekly (Aramburu Alegria, 2011). Injectable estradiol is usually prescribed in a dose between 5 and 20 mg IM every 2 weeks. Progesterone may also be prescribed for 10 days each month.

TABLE 73-3

Feminizing Drug Therapy for MtF Patients: Expected Changes and Monitoring

Expected Physical Changes
• Enlargement of breast tissue (gynecomastia) • Decreased testicular size • Decreased erectile function • Decreased libido (sex drive) • Decreased body hair growth • Decreased male pattern baldness • Increased fat compared with muscle • Softening of skin
Laboratory/Imaging Studies
• Chemistry panel (including glucose and electrolytes) • Liver function tests • Lipid profile • Complete blood count • Prostate-specific antigen (PSA) if recommended for age-group • Mammogram (when breast tissue develops) • Papanicolaou (Pap) smear (if vagina present)

Before the first dose of transdermal estrogen, teach the patient to apply the patch to an area that is hairless to ensure good contact with the skin. When changing to a new patch, wash any excess drug from the skin where the previous patch was applied.

Teach patients taking any form of estrogen about side effects such as headache, breast tenderness, nausea/vomiting, and weight gain (often due to fluid retention) or loss. Tell them to report increased feelings of anxiety or depression to their health care provider. Estrogens can also cause estrogen-dependent cancers, hypertension (due to fluid retention), venous thromboembolism (VTE) such as deep vein thrombosis (DVT), and gallbladder disease (Brennan et al., 2012). Teach patients to follow up with their health care provider to monitor for these potential adverse drug effects. Diagnostic testing is part of follow-up and monitoring, as listed in Table 73-3.

NCLEX Examination Challenge

Physiological Integrity

The nurse provides health teaching for a client receiving estrogen

therapy. Which statement by the client indicates a need for further teaching?
A "I need to check my blood pressure frequently when taking this drug."
B "I will call my doctor if I have any redness or swelling in my legs."
C "I will drink extra fluids because this drug will cause me to urinate a lot."
D "I will eat more oranges and bananas to replace the potassium I lose."

In addition to estrogen therapy, androgen-reducing agents (anti-androgens) are often given to block the effects of testosterone, including (Coleman et al., 2011):

- Spironolactone (Aldactone), a low-cost diuretic that also inhibits testosterone secretion and androgen binding to androgen receptors.
- 5-alpha reductase inhibitors (e.g., finasteride [Proscar]), drugs typically used to treat benign prostatic hyperplasia (BPH). These drugs block the conversion of testosterone to a more active ingredient to decrease the hair loss associated with estrogen therapy and shrink prostate tissue.
- GnRH agonists (e.g., goserelin [Zoladex]), neurohormones that block the gonadotropin-releasing hormone receptor, thus inhibiting the release of the follicle-stimulating hormone (FSH) and luteinizing hormone (LH). These drugs are more expensive and are available only as implants and parenteral preparations.

Nursing Safety Priority QSEN

Drug Alert

Teach patients taking *spironolactone* to monitor their blood pressure and have periodic laboratory tests to assess for hyperkalemia if the health care provider determines them to be at risk for these drug effects. Remind them that increased serum potassium can cause cardiac dysrhythmias and skeletal muscle spasticity.

Common side effects of finasteride and other *5-alpha reductase inhibitors* include dizziness, cold sweats, and chills. These manifestations typically decrease over time. If patients continue to have these side effects, instruct them to contact their health care provider.

Teach patients receiving *GnRH agonists* how to self-administer subcutaneous injections. Major side effects of these drugs are tachycardia and other cardiac dysrhythmias. Remind patients to follow up with their health care provider to monitor heart rate and rhythm.

Teach them to call 911 if they experience chest pain.

Drugs for FtM Patients.

Testosterone is the major drug used for achieving masculinizing effects in transgender people transitioning from female to male; however, much of the available drug converts to estrogen in the body (Coleman et al., 2011). This drug can be taken orally, transdermally, or parenterally (IM). Buccal and implantable forms of testosterone are also available. Oral testosterone (Andriol) is the least effective form of the drug. Depo-Testosterone, the most common IM preparation, is usually started in a low dose and increased to 100 to 200 mg every 1 to 2 weeks (Lilley et al., 2014). Teach patients the importance of not sharing needles to prevent bloodborne diseases such as hepatitis C.

AndroGel and Androderm are topical forms that are more expensive than other testosterone preparations but may provide more consistent (though slower) results. A new topical form of the drug, Axiron, can be applied to the armpits to increase serum testosterone levels. For all topical testosterone preparations, be sure that the patient washes his hands between applications and covers the area with clothing.

Expected effects of testosterone therapy include deepening of the voice, increased libido (sex drive), increased body hair growth, breast and ovarian atrophy, clitoral enlargement, and cessation of menses (Aramburu Alegria, 2011; Jenner, 2010) (Table 73-4). Teach the patient taking testosterone that some of these changes take up to a year to appear. If menses does not stop in the first few months of drug therapy, the patient is placed on Depo-Provera (progesterone) every 3 months until the testosterone becomes effective.

TABLE 73-4

Masculinizing Drug Therapy for FtM Patients: Expected Changes and Monitoring

Expected Changes
• Voice deepening • Body hair growth (hirsutism) • Breast atrophy • Increased libido • Increased aggression • Clitoral growth • Redistribution of fat • Laryngeal prominence
Laboratory/Imaging Studies
• Lipid profile • Liver function tests • Complete blood count • Papanicolaou (Pap) smear (if vagina present) • Mammogram (if breast tissue present)

Common side effects of testosterone therapy include edema, acne, seborrhea (oily skin), headaches, weight gain, and possible psychotic symptoms. Before taking this medication, the patient is screened for a history of liver and heart disease. Testosterone therapy can cause increased liver enzymes, increased low-density lipoproteins (LDLs, or "bad" cholesterol), and decreased high-density lipoproteins (HDLs, or "good" cholesterol). Increased blood glucose and decreased clotting factors can also occur when taking the drug (Aramburu Alegria, 2011). Teach patients that these changes can lead to diabetes, heart disease, and stroke. Therefore remind patients that they need to follow up with their health care providers for careful monitoring for these complications, including having extensive diagnostic and laboratory testing (see Table 73-4).

Reproductive Health Options.

Using feminizing or masculinizing hormone therapy affects reproductive health, especially fertility. Therefore be sure that patients know their options for reproduction, if desired, *before* transition begins (Coleman et al., 2011). MtF patients may want to consider sperm banking prior to drug therapy or gender reassignment surgery if they desire to have a biologic child. FtM patients may want to consider oocyte (egg) or embryo freezing. These frozen gametes or embryo could be implanted in a surrogate woman to become pregnant and carry to birth. Inform patients that these options are expensive, but be sure all patients are informed. Be sure to include the patient's sexual partner, if any, in discussions related to reproductive options.

Voice and Communication Therapy.

Communication is an essential aspect of human behavior and gender expression. Voice deepening for transgender people who are transitioning from female to male is accomplished by taking masculinizing hormones, such as testosterone. However, feminizing hormones have no effect on the adult MtF voice.

MtF patients may seek assistance from a voice and communication specialist to help them develop certain vocal characteristics, such as pitch and intonation. Vocal therapy can assist in management of gender dysphoria and be a positive step in the transition process. Specialists include speech-language pathologists and speech-voice clinicians. Remind patients to seek a specialist who is licensed, knowledgeable in transgender health, and has specialized training in assessment and development of communication skills for transgender patients (Coleman et al., 2011).

The purpose of vocal therapy is to help patients adapt their voice and communication such that it is authentic and reflects their gender identity. The voice therapist should take the patient's communication preferences and style into consideration as part of the assessment process to develop an individualized treatment plan. Some patients choose follow-up sessions for vocal therapy following voice feminization surgery, also called *feminization laryngoplasty.* This surgery is described in the next section.

Surgical Management.

Many transgender people are satisfied with their gender identity, role, and self-expression without surgery. Surgery, particularly procedures that affect the external or internal genitalia, is usually the last and most carefully considered option for transitioning from one's natal sex to one's inner gender identity. These procedures are often referred to as **gender** or **sex reassignment surgery (SRS)**. The patient has a number of surgical options to achieve either feminizing or masculinizing effects. Regardless of the procedure performed, the nurse collaborates with the patient, family, and health care team to promote positive outcomes for the transition process.

Gender reassignment surgeries are procedures that alter anatomically normal structures. Not all surgeons feel comfortable in performing procedures that could “harm” transgender patients. However, these procedures help treat gender dysphoria (discomfort with one's natal sex) (Coleman et al., 2011). Some patients elect to undergo the full range of surgeries, whereas others choose to have only some or none of them.

Most health insurance plans do not cover their cost (Aramburu Alegria, 2011).

Genital surgeries "below the waist" are the most invasive procedures. The criteria for genital surgery depend on the type of surgery being requested. For example, most surgeons (usually urologists or plastic surgeons) require 12 months of hormone therapy plus one or two referrals from qualified psychotherapists for MtF patients who desire an orchiectomy (removal of testes). The same requirements are needed for FtM patients who desire a hysterectomy (uterus removal) and bilateral salpingo-oophorectomy (BSO, or removal of both fallopian tubes and ovaries) (Reed, 2011).

The psychotherapist assesses the patient's readiness for genital surgery and hormone therapy, including a discussion of risks and out-of-pocket costs. The patient's support system is assessed to ensure that the patient makes the best possible decision and achieves the desired outcomes.

For MtF patients requesting a vaginoplasty (creation of a vagina) or FtM patients desiring a phalloplasty (creation of a penis), the required criteria include 12 continuous months of living in a gender role that is congruent with the patient's gender identity. It is also recommended that these patients have regular visits with a mental health care professional (Coleman et al., 2011).

Feminizing Surgeries for MtF Patients.

Feminizing surgeries are performed for MtF patients to create a functional and/or aesthetic (cosmetic) female anatomy, including (Brennan et al., 2012; Coleman et al., 2011):

- Breast/chest surgeries, such as breast augmentation (mammoplasty to increase breast tissue).
- Genital surgeries, such as partial penectomy (removal of the penis), orchiectomy (removal of the testes), vaginoplasty and labiaplasty vulvoplasty (creation of a vagina and labia/vulva), clitoroplasty (creation of a clitoris).
- Other surgeries, such as facial feminizing surgery (to achieve feminine facial contour), liposuction (fatty tissue removal), often from the waist or abdominal area, vocal feminizing surgery, gluteal augmentation (to enlarge buttocks), and other body-contouring procedures.

Breast augmentation creates breast tissue for the MtF patient through the use of silicone or saline implants. Although not a prerequisite, it is recommended that MtF patients take feminizing hormones for 12 months prior to surgery for the best results (Coleman et al., 2011).

Perioperative care of any patient having this procedure is discussed in Chapter 70 on p. 1463.

Voice surgery, such as reduction thyroid chondroplasty, is performed to decrease the size of the "Adam's apple." The procedure is done through a bronchoscope for cosmetic purposes. Nursing care of the patient having a bronchoscopy is discussed in Chapter 27.

The most common "below the waist" genital surgeries for MtF patients are bilateral *orchiectomy* to remove the testes and vaginoplasty with partial penectomy. Orchiectomy procedures and associated nursing care are the same for the transgender patient as they are for other natal males (see Chapter 72 for a detailed discussion).

A **vaginoplasty** is the construction of a neovagina (new vagina) usually with inverted penile tissue (obtained during a partial penectomy) or a colon graft. The procedure also includes creating a clitoris and labia using scrotal or penile tissue and skin grafts. Using penile tissue creates a less appealing appearance and low patient satisfaction (Reed, 2011).

Preoperative Care.

In addition to the required criteria to qualify for a vaginoplasty (also called *transvaginal surgery*), the transgender patient is medically evaluated like any other presurgical patient. Patients who have poorly controlled diabetes with vascular complications, coronary artery disease, or other systemic disease that limits functional ability are not candidates for gender reassignment surgery. Chapter 14 describes general preoperative care for any patient.

The surgeon explains the options for selected procedures, postoperative care expectations, and potential for complications after surgery. Postoperative recovery for transvaginal surgery takes a long time and has a high complication rate (Reed, 2011). Overweight patients have a higher incidence of wound infection and may have problems with adequate ventilation (breathing) and ambulation after surgery. Refer these patients for nutritional counseling as needed.

Written and verbal preoperative instructions are provided by the surgeon, including optional methods of body hair removal. A bowel preparation may be started 24 hours before surgery and includes a clear liquid diet, laxatives, and Fleet's enemas. Increased fluids are recommended until the patient goes to bed the night before surgery because the bowel "prep" can be very dehydrating. Antimicrobials such as neomycin sulfate and metronidazole (Flagyl) are typically given on the day of surgery to minimize the risk for infection.

Some surgeons require that the patient take supplements to prevent

bruising and promote tissue healing, such as vitamin C. Patients who are very thin are encouraged to eat a high-protein diet. A powdered protein supplement with arginine (an amino acid) may also be prescribed to promote wound healing.

Patients have a number of laboratory tests to ensure they are healthy before surgery. Adequate hemoglobin and hematocrit (H&H) levels are especially important because some blood is lost during surgery. For patients who have low H&H levels, an erythropoietin such as epoetin alfa (Procrit) or IM testosterone with iron is given. Most patients choose testosterone because it is a lower-cost drug.

Operative Procedures.

Because surgery requires multiple procedures to create a female anatomy, the patient is on the operating table for about 5 hours. The surgery may be performed in a hospital or specialized center for transgender surgeries. After general or epidural anesthesia is administered, the patient is placed in a lithotomy position (feet in stirrups) for the procedure. Epidural anesthesia is preferred for patients who are asthmatic or obese. The patient is transferred to the postanesthesia care unit (PACU) with a perineal dressing and packing, Jackson-Pratt drain, and indwelling urinary catheter.

Postoperative Care.

Provide general postoperative care as described in Chapter 16. In addition, immediately after surgery, apply an ice pack to the perineum to decrease pain and bruising. Monitor the patient's pain level carefully, and offer analgesia as needed. Genital surgery is painful because there is a high concentration of nerve endings in the perineum.

Although not a common postoperative complication, monitor the patient for bleeding. Observe the surgical dressing and surrounding area for oozing or bright red blood. Report and document any indication of bleeding immediately to the surgeon, and keep the patient in bed.

Encourage the patient to drink liquids after surgery; discontinue the patient's IV line once oral fluids are tolerated. Evaluate the patient's intake and output every 8 to 12 hours.

Nursing Safety Priority QSEN

Action Alert

Patients are in a lithotomy position for an extended period during

surgery. Therefore, after surgery, monitor lower extremity neurovascular status and encourage the patient to move the legs often during the first 24 hours after surgery. Report and document any unexpected findings, such as continued numbness or inability to move the lower legs or feet. Patients who had epidural anesthesia are not able to move their legs for several hours after surgery until the effect of the drug diminishes.

All patients stay in the hospital for at least one night after surgery, but some patients may stay longer depending on the number and complexity of the surgical procedures. Some agencies transfer the patient the day after surgery to a local hotel for continued follow-up and monitoring by a health care professional (usually a nurse) (Reed, 2011). Collaborate with the case manager for discharge planning and follow-up care.

The Jackson Pratt drain is removed typically in 3 to 5 days after surgery when drainage is less than 15 to 20 mL in a 24-hour period. In about a week after surgery, the surgical pressure dressing, packing, and external sutures are removed.

At this time, patients are taught how to douche and insert vaginal stents to dilate the vagina. Sexual intercourse also helps keep the vagina dilated. Remind patients that routine douching and douching after intercourse are needed to prevent infection in the new vagina. A solution of vinegar and water or a commercial product such as Massengill can be used. Vaginal stents (also called *dilators*) must be inserted several times a day for months after surgery. The stent should remain in the vagina for 30 to 45 minutes or as instructed by the surgeon. Teach patients the importance of using the stents with water-based lubrication. Collaborate with the surgeon to determine patient-specific instructions.

The urinary catheter is removed between postoperative day 7 and 12. Early removal can cause urinary retention (Reed, 2011).

Patients should continue follow-up visits with their health care provider for manifestations of complications. One of the worst complications is a vaginal-rectal fistula, which is caused by rectal perforation during surgery (Reed, 2011). Teach patients to report any leakage of stool into the vagina immediately to their surgeon. The treatment for this complication is a temporary colostomy and fistula wound management for many months. Other surgical complications of vaginoplasty are listed in Table 73-5.

TABLE 73-5

Postoperative Complications of Vaginoplasty Surgery

Most Serious Complications
• Vaginal-rectal fistula • Rectal perforation • Bleeding
Other Complications
• Surgical wound infection • Urinary leakage/incontinence • Chronic urinary tract infections • Urinary meatus stenosis • Vaginal stenosis • Vaginal collapse • Labial hematoma • Inadequate vaginal length or width • Lack of sensation • Lack of sexual pleasure

In addition to physical complications after surgery, some MtF patients are not satisfied with the quality of the results. For example, the neovagina may not be functional for sexual intercourse. Some patients request another surgery to achieve more satisfying results.

NCLEX Examination Challenge

Physiological Integrity

A client is admitted to the postanesthesia care unit (PACU) following a vaginoplasty. Which nursing interventions are appropriate for this client? **Select all that apply.**

A Irrigate the nasogastric tube every 4 hours.
B Keep the client in a sitting position to facilitate breathing.
C Apply an ice pack to the perineal area.
D Monitor drainage from the Jackson-Pratt tube.
E Perform frequent neurovascular assessments of the legs.

Masculinizing Surgeries for FtM Patients.

Masculinizing surgeries are performed for FtM patients to create a functional and/or aesthetic male anatomy, including (Brennan et al., 2012; Coleman et al., 2011):

- Breast/chest surgeries, usually a bilateral mastectomy (removal of both breasts) and chest reconstruction.
- Genital surgeries, such as a hysterectomy and bilateral BSO, vaginectomy (removal of the vagina), phalloplasty (creation of an average-size male penis) with ureteroplasty (creation of a urethra) or metoidioplasty (creation of a small penis using hormone-enhanced

clitoral tissue), and scrotoplasty (creation of a scrotum) with insertion of testicular prostheses.
- Other surgeries, such as liposuction, pectoral muscle implants, and other body-contouring procedures.

Care of transgender patients having a mastectomy, hysterectomy, and bilateral salpingo-oophorectomy (BSO) is similar to care for any patient having these procedures as described elsewhere in this text. If the transgender patient has not had previous abdominal surgery, a laparoscopic procedure is preferred for the hysterectomy and BSO surgery.

Surgery to create a penis has not been as successful as other gender reassignment procedures. Procedures to create a male anatomy are not performed as often as MtF surgeries. Phalloplasties are the most difficult reconstructive genital surgeries to perform and usually require several stages. Skin flaps from the radial forearm, anterior lateral thigh, or back are used to create the penis. Fat grafts may be needed to increase penile girth, and buccal mucosal tissue may be used to create the urethra. A penile prosthesis or implant is not inserted until months after surgery until the initial surgical healing has occurred.

Complications from phalloplasty include urinary tract stenosis, donor graft site scarring, and occasionally necrosis of the neopenis (new penis). In addition to these physical problems, the patient may not be satisfied with the results of the surgery, such as an inadequate length of the penis. For this reason, most FtM patients do not have this procedure and prefer to have only a laparoscopic hysterectomy and BSO (Coleman et al., 2011).

Clinical Judgment Challenge

Patient-Centered Care; Teamwork and Collaboration QSEN

A 58-year-old male-appearing patient visits the gender identity clinic to discuss the desire to have sex reassignment surgery (SRS). As the clinical nurse, you take the patient's history and find that the patient was married to a woman for 30 years and had three children. The couple divorced 3 months ago when the patient's wife discovered that her husband identified as a woman. The couple's children have no contact with the patient since they found out that their father has been dressing as a woman for the past few weeks. The patient is employed as the vice-president of a large commercial construction company and has health insurance. The patient is interested in learning about his options for male-to-female transitioning.

1. How would you address this patient?
2. What other data do you need to collect for the patient's history and why?
3. What options for transitioning to a female does this patient have?
4. Is SRS the best first step for MtF patients? Why or why not?
5. After a physical examination, the clinic physician prescribed estrogen and spironolactone for the patient. What instructions will you provide for the patient before beginning drug therapy?
6. What health teaching does the patient need regarding ongoing follow-up and monitoring while taking these feminizing drugs?
7. With whom might you need to collaborate to manage the patient's care now and in the future?

Community-Based Care

Transgender patients often take hormone therapy for many years. Teach them that ongoing follow-up with a qualified health care professional is needed to maintain health and detect any complications, such as diabetes or cardiovascular problems, as early as possible.

Long-term follow-up with the surgeon after gender reassignment is essential to detect and treat the frequent complications that occur. Assess the patient's support systems and coping strategies, including financial status and health insurance benefits. Collaborate with the case manager to ensure a smooth transition into the community, including the need for any ongoing mental health counseling or therapy.

Urogenital care is also needed for patients who have gender reassignment surgery. FtM patients usually do not have a vaginectomy and therefore may experience vaginal atrophy causing itching and burning. Recommend that they seek gynecologic care to treat this problem, although the examination can be physically and emotionally painful.

MtF patients need counseling about sexuality, genital hygiene, and prevention of sexually transmitted diseases. They are also at a high risk for frequent urinary tract infections as a result of a shortened urethra and urinary incontinence as a result of genital surgery (Coleman et al., 2011). Teach patients the importance of having follow-up care for these problems.

Preventive health care screenings for transgender patients are also important. For example, the MtF patient requires prostate health care screenings like natal males. Mammograms are also recommended to monitor for early signs of breast cancer.

A number of community resources and organizations are available for transgender support and information, such as:

- National Coalition for LGBT Health (http://lgbthealth.webolutionary.com/content/resources)
- National Resource Center for LGBT Aging (www.lgbtagingcenter.org)
- Services and Advocacy for Gay, Lesbian, Bisexual, and Transgender Elders (www.sageusa.org)
- University of San Francisco Center for Transgender Health (www.transhealth.ucsf.edu)
- World Professional Association for Transgender Health (www.wpath.org)

Get Ready for the NCLEX® Examination!

Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Depending on identified health care needs, collaborate with the primary health care provider, mental health professional, surgeon, pharmacist, and/or vocal/speech specialist when caring for the transgender patient. **Teamwork and Collaboration** QSEN
- Advocate for the transgender patient who is often distrustful of health care professionals and fearful when seeking health care. **Patient-Centered Care** QSEN

Health Promotion and Maintenance

- Teach patients taking hormone therapy about the need for ongoing health care monitoring for adverse drug events and health complications. **Safety** QSEN
- Refer the transgender patient and significant others, as appropriate, to community resources for information and support, such as the University of San Francisco Center for Transgender Health and the Services and Advocacy for Gay, Lesbian, Bisexual, and Transgender Elders (SAGE) organization.

Psychosocial Integrity

- Use culturally sensitive and accurate language when communicating with transgender patients; use pronouns that match the patient's physical appearance and dress unless the patient requests a specific term (see Table 73-1). **Patient-Centered Care** QSEN
- Provide transgender care with dignity and respect for all patients.
- Be aware that transgender people often have gender dysphoria, which presents an inner conflict between the person's natal (birth) sex and perceived gender identity.
- Assess transgender patients for sources of stress in the community that can lead to health issues, such as depression, anxiety, and substance abuse.
- Be aware that transgender patients may avoid health care settings because they are often unemployed, have no health insurance, and/or fear lack of respect and understanding based on previous experiences.

Patient-Centered Care QSEN

Physiological Integrity

- Monitor for expected, side, and adverse effects of hormone therapy as described in Tables 73-3 and 73-4.
- Recognize that patients receiving hormone therapy need to have periodic laboratory testing to monitor for complications as listed in Tables 73-3 and Table 73-4. **Evidence-Based Practice** QSEN
- Provide preoperative care for a patient having a vaginoplasty, including teaching about bowel preparation, food and fluid intake, hair removal methods, and the need for informed consent.
- Monitor for potentially life-threatening complications of sex reassignment surgery, such as fistula development, bleeding, and wound infection.

CHAPTER 74

Care of Patients with Sexually Transmitted Disease

Shirley E. Van Zandt

PRIORITY CONCEPTS

- Infection
- Pain
- Sexuality

Learning Outcomes

Safe and Effective Care Environment

1. Maintain patient confidentiality and privacy related to sexually transmitted diseases (STDs).

Health Promotion and Maintenance

2. Educate patients with STDs and their partners on self-care measures.
3. Describe the role of expedited partner therapy in reducing STD recurrence.
4. Develop a teaching plan for young adults and other at-risk people about risk factors, prevention, and treatment for STDs.
5. Explain the importance of respect for patients' personal values and beliefs regarding practices associated with sexuality.

Psychosocial Integrity

6. Assess patients' and their partners' responses to a diagnosis of STD.
7. Reduce the psychological impact for the patient who has been diagnosed with STD.

Physiological Integrity

8. Compare the stages of syphilis.
9. Identify the role of drug therapy in managing patients with STDs.
10. Develop a health teaching plan for patients on how to self-manage their STD, including antibiotic therapy.
11. Describe the assessment findings, including pain, that are typical in patients with STDs.
12. Develop a collaborative plan of care for a patient with pelvic inflammatory disease (PID).
13. Identify three sexually transmitted vaginal infections.

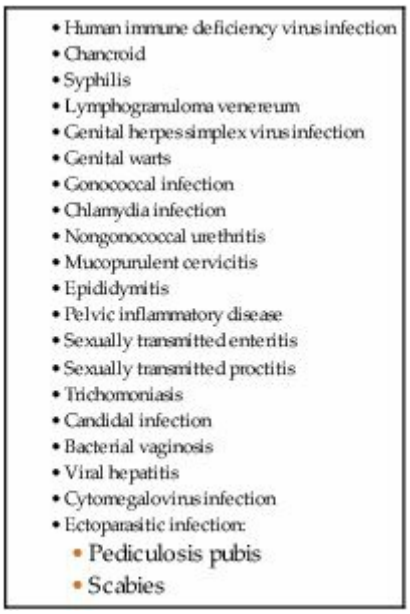
 http://evolve.elsevier.com/Iggy/

Overview

Sexually transmitted diseases (STDs) are caused by infectious organisms that have been passed from one person to another through intimate contact—usually oral, vaginal, or anal intercourse. Some organisms that cause these diseases are transmitted only through sexual contact. Other organisms are transmitted also by parenteral exposure to infected blood, fecal-oral transmission, intrauterine transmission to the fetus, and perinatal transmission from mother to neonate (Table 74-1). The term **sexually transmitted infections (STIs)** is used to describe the same group of health problems. This terminology is intended to focus on the management of acute infections and to decrease the social stigma of labeling them as diseases. If the STI continues to recur and become chronic, the term *STD* is used. *STD continues to be the most acceptable term used by the Centers for Disease Control and Prevention (CDC) and is therefore used in this chapter.*

TABLE 74-1

Sexually Transmitted Diseases



From Centers for Disease Control and Prevention (CDC). (2010). Sexually transmitted diseases treatment guidelines, 2010. *Morbidity and Mortality Weekly Report, 59*(RR-12), 1-110.

Improved diagnostic techniques, increased knowledge about organisms that can be sexually transmitted, and changes in sexual attitudes and practices have led to an increasing number of reported cases of STDs. *Sexual issues are often sensitive, personal, and controversial, and nurses must respect the patients' lifestyle. Providing confidentiality is essential for patients to receive correct information, make informed decisions,*

and obtain appropriate care.

The prevalence of STDs is a major public health concern worldwide. Populations at greatest risk for acquiring STDs and suffering from their complications are pregnant women, adolescents, and men who have sex with men (MSM). External factors such as an increasing population, cultural factors (e.g., earlier first intercourse), political and economic policies, incidences of sexual abuse and sexual trafficking, and international travel and migration affect the prevalence of STDs.

Considerations for Older Adults

Patient-Centered Care QSEN

Another factor contributing to STD prevalence is the increasing number of older adults that will continue as the baby boomers age. People older than 50 years may not realize their risk for STDs or feel comfortable discussing their sexuality with health care providers. Providers may also lack awareness of the sexual activity of older adults. Be sure to teach older adults who are sexually active about their risk for developing STDs (Jeffers & DiBartolo, 2011).

In the United States, one of the greatest factors associated with STD prevalence is the secrecy that surrounds sexuality, sexual behavior, and intimacy in the American culture. The stigma of STDs in the United States has been associated with higher rates of STDs as compared with rates in other developed countries. The prevalence of STDs is also affected by changing human physiology patterns such as earlier onset of menarche, comorbidities associated with human immune deficiency virus (HIV) and diabetes, treatments given for cancer or organ transplantation, and disparities in access to health care. Substance abuse has also been identified as a significant risk factor because of the effects illicit drugs have on sexual risk-taking behavior.

STDs cause complications that can contribute to severe physical and emotional suffering, including infertility, ectopic pregnancy, cancer, and death. Some of the most common complications caused by sexually transmitted organisms are listed in Table 74-2.

TABLE 74-2

Complications Caused by Sexually Transmitted Organisms

COMPLICATION	CAUSATIVE ORGANISMS
Salpingitis, infertility, and ectopic pregnancy	*Neisseria gonorrhoeae* *Chlamydia trachomatis* *Mycoplasma hominis* *Ureaplasma urealyticum*
Reproductive loss (abortion/miscarriage)	*N. gonorrhoeae* *C. trachomatis* Herpes simplex virus *M. hominis* *U. urealyticum* *Treponema pallidum*
Puerperal infection	*N. gonorrhoeae* *C. trachomatis*
Perinatal infection	Hepatitis B virus Human immune deficiency virus Human papilloma virus *N. gonorrhoeae* *C. trachomatis* Herpes simplex virus *T. pallidum* Cytomegalovirus Group B streptococcus
Cancer of genital area	Human papilloma virus
Male urethritis	*M. hominis* Herpes simplex virus *N. gonorrhoeae* *C. trachomatis* *U. urealyticum*
Vulvovaginitis	Herpes simplex virus *Trichomonas vaginalis* Bacterial vaginosis *Candida albicans*
Cervicitis	*N. gonorrhoeae* *C. trachomatis* Herpes simplex virus
Proctitis	*N. gonorrhoeae* *C. trachomatis* Herpes simplex virus *Campylobacter jejuni* *Shigella* species *Entamoeba histolytica*
Hepatitis	*T. pallidum* Hepatitis A, hepatitis B, and hepatitis C viruses
Dermatitis	*Sarcoptes scabiei* *Phthirus pubis*
Genital ulceration or warts	*C. trachomatis* Herpes simplex virus Human papilloma virus *T. pallidum* *Haemophilus ducreyi* *Calymmatobacterium granulomatis*

Chlamydia infection, gonorrhea, syphilis, chancroid, human immune deficiency virus (HIV) infection, and acquired immune deficiency syndrome

(AIDS) are reportable to local health authorities in every state (Centers for Disease Control and Prevention [CDC], 2013f). Other STDs such as genital herpes (GH) may or may not be reported, depending on local legal requirements. Positive results can be reported by clinicians and laboratories. Reports are kept strictly confidential.

Nurses in a variety of settings are responsible for identifying people at risk for STDs, caring for patients with diagnosed STDs, and preventing further cases through education and case finding. Nurses in primary care community settings and acute care settings have a responsibility to recognize patients who are at risk for or who have STDs, possibly while being treated for another unrelated health problem.

The CDC provides regularly updated guidelines for treatment of STDs. These best practice guidelines provide information, treatment standards, and counseling advice to help decrease the spread of these diseases and their complications (CDC, 2010b).

Evidence from the U.S. Preventive Services Task Force (USPSTF) has shown that education and counseling about STDs needs to be of high intensity and on multiple occasions for it to change behavior (USPSTF, 2014b). Health education messages that are short, nonspecific, and not related to the person's sexual behaviors have little effect in lowering the risk for acquiring STDs.

Gender Health Considerations

Patient-Centered Care QSEN

Because of the very vascular and large surface area of the mucous membranes of the vagina, women are more easily infected with STDs and are at greater risk for STD-related health problems than are men. Young women who are sexually active with men have the greatest risk for contracting an STD. Younger adults have greater rates of sexual activity, including more partners and more unprotected sex than older adults. Women are more vulnerable to infections because of the exposure of cervical basal epithelium cells. Lesbian women have a decreased risk for STDs because of fewer partners, although many have or have had sex with men.

Some young women may also be at high risk because they:

- Lack knowledge about the risk for disease
- Believe that they are not vulnerable to disease
- Mistakenly believe that contraceptives also protect them from STDs
- Drink alcohol in binges, which promotes risky sexual behavior

Postmenopausal women also may be at risk for STDs because many

perceive that pregnancy is no longer likely and thus do not use barrier protection. Changing social relationships (e.g., divorce and widowhood in the middle years) has changed risk for exposure to STDs. Physiologic changes during menopause such as mucosal tears from vaginal atrophy may also place them at risk.

Women have more asymptomatic infections that may delay diagnosis and treatment. Many STDs reside in the cervical os and cause little change in vaginal discharge or vulvar tissue so women are not aware that they are infected. This delay increases the likelihood of complications from STDs, including ascending infections that may cause reproductive organ damage and illness. Embarrassment, denial, or fear about STDs may further delay treatment, increasing the potential for serious complications.

Infections Associated with Ulcers

Syphilis

Pathophysiology

Syphilis is a complex sexually transmitted disease (STD) that can become systemic and cause serious complications, including death. The causative organism is a spirochete called *Treponema pallidum*. Although the organism can be seen only with a darkfield microscope, several serologic tests are used to screen for the presence of syphilis antibody. *T. pallidum* is damaged by dry air or any known disinfectant. The organisms die within hours at temperatures of 105.8° to 107.6° F (41° to 42° C) and are not airborne. *The infection is usually transmitted by sexual contact and blood exposure, but transmission can occur through close body contact such as kissing.*

Syphilis progresses through four stages: primary, secondary, latent, and tertiary. The appearance of an ulcer called a **chancre** is the first sign of *primary* syphilis. It develops at the site of entry (inoculation) of the organism from 10 to 90 days after exposure (3 weeks is average). Chancres may be found on any area of the skin or mucous membranes but occur most often on the genitalia, lips, nipples, and hands and in the mouth, anus, and rectum.

During this highly infectious stage, the chancre begins as a small papule. Within 3 to 7 days, it breaks down into its typical appearance: a painless, indurated, smooth, weeping lesion. Regional lymph nodes enlarge, feel firm, and are not painful. Without treatment, the chancre usually disappears within 6 weeks. However, the organism spreads throughout the body and the patient is still infectious.

Secondary syphilis develops 6 weeks to 6 months after the onset of primary syphilis. During this stage, syphilis is a systemic disease because the spirochetes circulate throughout the bloodstream. Commonly mistaken for influenza, manifestations include flu-like symptoms (malaise, low-grade fever, headache, muscular aches, sore throat) and a generalized rash. There is no typical appearance of this rash except for its presence on the palms and soles of the feet and on mucous membranes. It can appear as diffuse macules (reddish brown), papules (usually less than 5 mm) or pustules, scaly psoriasis-like lesions (Fig. 74-1), or gray-white wart-like lesions (condylomata lata). *All of these lesions are highly contagious and should not be touched without gloves.* Patchy alopecia on the scalp or facial hair (missing part of the eyebrow, "moth-eaten" appearance) is another symptom. The rash subsides without treatment in

4 to 12 weeks.

FIG. 74-1 Palmar and plantar secondary syphilis.

After the second stage of syphilis, there is a period of latency. *Early latent* syphilis occurs during the first year after infection, and infectious lesions can recur. *Late latent* syphilis is a disease of more than 1 year's duration after infection. This stage is not infectious except to the fetus of a pregnant woman. Patients with latent syphilis may or may not have reactive serologic test (e.g., Venereal Disease Research Laboratory [VDRL]) findings.

Tertiary, or late, syphilis occurs after a highly variable period, from 4 to 20 years. This stage develops in untreated cases and can mimic other conditions because any organ system can be affected. Manifestations of late syphilis include:

- Benign lesions (gummas) of the skin, mucous membranes, and bones
- Cardiovascular syphilis, usually in the form of aortic valvular disease and aortic aneurysms
- Neurosyphilis, causing central nervous system symptoms (e.g., meningitis, hearing loss, generalized paresis [weakness])

Cultural Considerations

Patient-Centered Care QSEN

Disparity exists between racial and ethnic groups in the incidence of primary and secondary syphilis. In the most recent reports from 2011, the rates increased among Hispanics, American Indians/Alaska Natives (from 2.5 to 2.7 cases per 100,000 population), Euro-Americans (from 2.1 to 2.3 cases per 100,000 population), and most dramatically (33%) among Asian/Pacific Islanders but impressively have decreased among African Americans. Nevertheless, African Americans have a 7 times greater rate of acquiring syphilis than whites. Compared with Euro-Americans, the 2011 rate for Hispanics was 2 times higher (CDC, 2013a). The reason for these differences is unclear, but status of health literacy and lack of access to health care may be factors.

Gender Health Considerations

Patient-Centered Care QSEN

Unique needs regarding sexual health and prevention and treatment of sexually related infections of lesbian, gay, bisexual, transgender, and questioning (LGBTQ) patients should be identified and addressed by the nurse. Because of discrimination, health care inequities, and health care provider lack of understanding, the overall health status of people in these populations may be poor. LGBTQ people may have difficulty finding health care that identifies and addresses their particular risks and concerns. Taking a health history that provides opportunity for the patient to identify his or her sexual orientation, sexual identity, and sexual activity is crucial. Especially among transgender people, opportunities for physical examination are avoided or missed by both the patient and care provider because of fears of being misunderstood or inadequately prepared to give or receive appropriate care (Williamson, 2010).

The CDC does not currently collect or report the incidence or prevalence of STDs among transgender people. There have been estimates from self-report that 11% to 28% of the transgender community are infected with HIV (Cobos & Jones, 2009).

Men who have sex with men (MSM) are at greatest risk for contracting primary and secondary syphilis and made up 75% of cases of these diseases in 2012 (CDC, 2014a). These men are 17 times more likely to have anal cancer than heterosexual men, and those infected with HIV are at even greater risk. Infection with high-risk human papilloma virus (HPV) has been associated with greater risk for anal cancers among this

population (CDC, 2012a).

A common perception that women who have sex with women (WSW) are at very low or no risk for getting STDs has not been supported in research because of the lack of data. Bacterial, viral, and protozoal infections have all been reported among WSW (CDC, 2014c). Identifying risk in this population may depend more on asking about sexual practices such as use of sex objects or oral-anal, digital-anal, or digital-vaginal sex. Being aware of these practices can increase the nurse's ability to identify risk factors for patients.

Assuming that lesbian women or gay men have sex only with same-gender partners or similarly assuming that heterosexual patients never have sexual encounters with partners of their same sex may limit the accuracy of the nurse's risk assessment. Nurses must be aware that patients may not reveal that they are bisexual. Establish a trusting relationship and be culturally sensitive and nonjudgmental when working with LGBTQ patients. Chapter 1 describes recommendations for communicating with this population. Chapter 73 discusses the special health care needs of transgender patients.

Health Promotion and Maintenance

One of the *Healthy People 2020* objectives is to completely eliminate syphilis in the United States (U.S. Department of Health and Human Services [USDHHS], 2014) (Table 74-3). One of the primary tools for prevention of sexually transmitted diseases (STDs), including syphilis, is education. All people, regardless of age, gender, ethnicity, socioeconomic status, education level, or sexual orientation, are susceptible to these diseases. Health literacy, motivation, and perceived risk can affect the health status of any patient. STDs are largely preventable through safer sex practices. *Do not assume that a person is not sexually active because of his or her age, education, marital status, profession, or religion.* Discuss prevention methods, including safer sex, with all patients who are or may become sexually active.

TABLE 74-3

Meeting *Healthy People 2020* Objectives and Targets for Improvement: Sexually Transmitted Diseases

• Reduce the proportion of adolescents and young adults with *Chlamydia trachomatis* infections (by 10%). • Reduce the proportion of females ages 15 to 44 years who have ever required treatment for pelvic inflammatory disease (by 10%). • Reduce gonorrhea rates (by 10%). • Reduce sustained domestic transmission of primary and secondary syphilis (by 10%). • Reduce the proportion of females with human papilloma virus (HPV) infection (no specific target). • Reduce the proportion of young adults with genital herpes due to herpes simplex type 2 (by 10%).

Safer sex practices are those that reduce the risk for nonintact skin or mucous membranes coming in contact with infected body fluids and blood. These practices include:

- Using a latex or polyurethane condom for genital and anal intercourse
- Using a condom or latex barrier (dental dam) over the genitals or anus during oral-genital or oral-anal sexual contact
- Wearing gloves for finger or hand contact with the vagina or rectum
- Abstinence
- Mutual monogamy
- Decreasing the number of sexual partners

Patient-Centered Collaborative Care

Assessment

Assessment of the patient who has manifestations of syphilis begins with a history to gather information about any ulcers or rash. Take a sexual history and conduct a risk assessment to include whether previous testing or treatment for syphilis or other STDs has ever been done (Chart 74-1). Ask about allergic reactions to drugs, especially penicillin. A woman may report inguinal lymph node enlargement resulting from a chancre in the vagina or cervix that is not easily visible to her. She may state a history of sexual contact with a male partner who had an ulcer that she noticed during the encounter. Men usually discover the chancre on the penis or scrotum.

Chart 74-1 Focused Assessment

The Patient with a Sexually Transmitted Disease

Assess history of present illness:

- Chief concern
- Onset
- Symptoms by quality and quantity, precipitating and palliative

factors
- Any treatments taken (self-prescribed or over-the-counter products)

Assess past medical history:
- Major health problems—including any history of STDs/PID or immunosuppression
- Surgeries—obstetric and gynecologic, circumcision

Assess current health status:
- Menstrual history for irregularities
- Sexual history:
  - Type and frequency of sexual activity
  - Number of lifetime and past 6 months sexual contacts/partners; monogamous
  - Sexual orientation
- Contraception history
- Medications
- Allergies
- Lifestyle risks—drugs, alcohol, tobacco

Assess preventive health care practices:
- Papanicolaou (Pap) tests
- Regular STD screening
- Use of barrier contraceptives to prevent STDs and pregnancy

Assess physical examination findings:
- Vital signs
- Oropharyngeal findings
- Abdominal findings
- Genital or pelvic findings
- Anorectal findings

Assess laboratory data:
- Urinalysis
- Hematology
- ESR or CRP if PID is being considered
- Cervical, urethral, oral, rectal specimens
- Lesion samples for microbiology and virology
- Pregnancy testing

CRP, C-reactive protein; *ESR,* erythrocyte sedimentation rate; *PID,* pelvic inflammatory disease; *STDs,* sexually transmitted diseases.

Conduct a physical examination, including inspection and palpation, to identify manifestations of syphilis. *Wear gloves while palpating any lesions because of the highly contagious treponemes that are present.* Observe for and document rashes of any type because of the variable presentation of

secondary syphilis.

After the physical examination, the health care provider obtains a *specimen of the chancre* for examination under a darkfield microscope. Diagnosis of primary or secondary syphilis is confirmed if *T. pallidum* is present.

Blood tests are also used to diagnose syphilis. The usual screening and/or diagnostic nontreponemal tests are the *Venereal Disease Research Laboratory (VDRL)* serum test and the more sensitive *rapid plasma reagin (RPR)*. These tests are based on an antibody-antigen reaction that determines the presence and amount of antibodies produced by the body in response to an infection by *T. pallidum*. They become reactive 2 to 6 weeks after infection. VDRL titers are also used to monitor treatment effectiveness. The antibodies are not specific to *T. pallidum*, and false-positive reactions often occur from such conditions as viral infections, hepatitis, and systemic lupus erythematosus (SLE) (Pagana & Pagana, 2014).

If a VDRL result is positive, the health care provider requests or the laboratory may automatically perform a more specific treponemal test, such as the *fluorescent treponemal antibody absorption (FTA-ABS)* test or the *microhemagglutination assay for T. palladum (MHA-TP)*, to confirm the infection. These tests are more sensitive for all stages of syphilis, although false-positive results may still occur. Patients who have a reactive test will have this positive result for their entire life, even after sufficient treatment. This poses a challenge when receiving a positive result for a patient who denies a history of or does not know he or she had syphilis.

Interventions

Patient-centered collaborative care includes drug therapy and health teaching to resolve the infection and prevent infection transmission to others.

Drug Therapy.

Benzathine penicillin G given IM as a single 2.4 million-unit dose is the evidence-based treatment for primary, secondary, and early latent syphilis (CDC, 2010b). Patients in the late latent stage receive the same dose every week for 3 weeks (CDC, 2010b). A different regimen, found in the CDC's *STD Treatment Guidelines*, is recommended for patients who are HIV-infected or pregnant.

Nursing Safety Priority QSEN

Drug Alert

Allergic reactions to benzathine penicillin G can occur. Monitor for allergic manifestations (e.g., rash, edema, shortness of breath, chest tightness, anxiety). Penicillin desensitization is recommended for penicillin-allergic patients. *Keep all patients at the health care agency for at least 30 minutes after they have received the antibiotic so that manifestations of an allergic reaction can be detected and treated. The most severe reaction is anaphylaxis. Treatment should be available and implemented immediately if symptoms occur.* Chapter 17 describes the management of drug allergies in detail.

After treatment, the CDC recommends follow-up evaluation including blood tests at 6, 12, and 24 months. Repeat treatment may be needed if the patient does not respond to the initial antibiotic.

The *Jarisch-Herxheimer reaction* may also follow antibiotic therapy for syphilis. This reaction is caused by the rapid release of products from the disruption of the cells of the organism. Symptoms include generalized aches, pain at the injection site, vasodilation, hypotension, and fever. They are usually benign and begin within 2 hours after therapy with a peak at 4 to 8 hours. This reaction may be treated symptomatically with analgesics and antipyretics.

Self-Management Education.

Teach about the cause of infection (sexual transmission); treatment, including side effects; possible complications of untreated or incompletely treated disease; and the need for follow-up care.

Nursing Safety Priority QSEN

Drug Alert

Discuss with the patient with syphilis the importance of partner notification and treatment, including the risk for re-infection if the partner goes untreated. All sexual partners must be prophylactically treated as soon as possible, preferably within 90 days of the syphilis diagnosis.

Inform the patient that the disease will be reported to the local health authority and that all information will be held in strict confidence. Encourage the patient to provide accurate information for this follow-up to ensure that all at-risk partners are treated appropriately. Provide a

setting that offers privacy and encourages open discussion. Urge the patient to keep follow-up appointments. For primary and secondary syphilis, medication treatment will be completed at the first visit, which may suggest to the patient that no further visits are indicated or important. Remind the patient that follow-up for partners and assessment that symptoms have resolved are imperative and part of continuing care. Recommend sexual abstinence until the treatment of both the patient and partner(s) is completed.

The emotional responses to syphilis vary and may include feelings of fear, depression, guilt, and anxiety. Patients may experience guilt if they have infected others or anger if a partner has infected them. If further psychosocial interventions are needed, encourage the patient to discuss these feelings or refer him or her to other resources such as psychotherapy, self-help support groups, or STD clinics.

NCLEX Examination Challenge

Physiological Integrity

The nurse gives a client an IM dose of penicillin G for primary syphilis. Which client statement indicates a need for further teaching?

A "I will wait in the clinic for 30 minutes to be sure I do not have a reaction."

B "When I get home, I will call my partner to tell them about my diagnosis."

C "If I have sex with someone, I do not have to worry about spreading the disease."

D "I plan to return to see my primary care provider for follow-up in 6, 12, and 24 months."

Genital Herpes

Pathophysiology

Genital herpes (GH) is an acute, recurring, incurable viral disease. It is the most common STD in the United States, with 17.0% of Americans currently infected with herpes simplex virus type 2 (HSV-2) and 57.7% with type 1 (HSV-1) (Warren et al., 2011).

The prevalence among African Americans is 39.2%, disproportionately affecting African-American women (48.0%) (CDC, 2010a). These rates are based on the presence of HSV-2 antibodies in the blood of those tested, the majority of whom have had no symptoms and most have never

received a diagnosis of GH infection (CDC, 2010a).

Two serotypes of herpes simplex virus (HSV) affect the genitalia: type 1 (HSV-1) and type 2 (HSV-2). Most *nongenital* lesions such as cold sores are caused by HSV-1, transmitted via oral-oral contact. Historically, HSV-2 caused most of the genital lesions. However, this distinction is academic because the transmission, symptoms, diagnosis, and treatment are nearly identical for the two types. Either type can produce oral or genital lesions through oral-genital or genital-genital contact with an infected person. HSV-2 recurs and sheds asymptomatically more often than HSV-1. Most people with GH have not been diagnosed because they have mild symptoms and shed virus intermittently, with possibly only 10% to 25% of those with HSV-2 realizing they have GH (Patel & Rompalo, 2012).

The incubation period of genital herpes is 2 to 20 days, with the average period being 1 week. Many people do not have symptoms during the primary outbreak. When subsequent outbreaks of genital herpes occur, they are usually more severe and occasionally require hospitalization.

Recurrences are not caused by re-infection. Additional episodes are usually less severe and of shorter duration than the primary infection episode. Some patients have no symptoms at all during recurrence or viral reactivation. *However, there is viral shedding and the patient is infectious.* Long-term complications of GH include the risk for neonatal transmission and an increased risk for acquiring HIV infection.

Patient-Centered Collaborative Care

Assessment

The diagnosis of GH is based on the patient's history and physical examination (see Chart 74-1). Ask the patient if he or she felt itching or a tingling sensation in the skin 1 to 2 days before the outbreak, known as the *prodrome.* These sensations are usually followed by the appearance of **vesicles** (blisters) in a typical cluster on the penis, scrotum, vulva, vagina, cervix, or perianal region at the site of inoculation. The blisters rupture spontaneously in a day or two and leave painful ulcerations that can become extensive. Assess for other symptoms such as headaches, fever, general malaise, and swelling of inguinal lymph nodes. Ask if urination is painful. External dysuria is a painful symptom when urine passes over the eroded areas. Patients with urinary retention may need to be catheterized. Lesions resolve within 2 to 6 weeks.

After the lesions heal, the virus remains in a dormant state in the sacral nerve ganglia. Periodically, the virus may activate and symptoms

recur. These recurrences may be triggered by many factors, including stress, fever, sunburn, poor nutrition, menses, and sexual activity. Assess the patient for these risk factors to provide anticipatory guidance for prevention of outbreaks.

GH is confirmed through a viral cell culture or polymerase chain reaction (PCR) assays of the lesions. PCR is the more sensitive test and is currently the gold standard; however, it is very expensive and usually not available. Fluid from inside the blister obtained within 48 hours of the first outbreak will yield the most reliable results because accuracy decreases as the blisters begin to heal (Patel & Rompalo, 2012). Serology testing, which is glycoprotein G antibody-based, can identify the HSV type, either 1 or 2. Serologic tests are used to identify infection in high-risk groups such as HIV-positive patients, patients who have partners with HSV, or men who have sex with men (MSM) (CDC, 2010b). Antibodies may take up to 12 weeks to develop, so false-negative results can occur if tested too soon after the initial infection. Because 80% to 90% of the population will become positive over their lifetime, using the antibody serology test to screen for infection in the general population is not effective or appropriate (Patel & Rompalo, 2012).

Interventions

The desired outcomes of treatment for HSV-infected patients are to decrease the discomfort from painful ulcerations, promote healing without secondary infection, decrease viral shedding, and prevent infection transmission (Chart 74-2).

Chart 74-2 Best Practice for Patient Safety & Quality Care QSEN

Care of or Self-Management for the Patient with Genital Herpes

- Administer oral analgesics as prescribed.
- Apply local anesthetic sprays or ointments as prescribed.
- Apply ice packs or warm compresses to the patient's lesions.
- Administer sitz baths 3 or 4 times a day.
- Urge an increase in fluid intake to replace fluid lost through open lesions.
- Encourage frequent urination.
- Pour water over the patient's genitalia while voiding, or encourage voiding while the patient is sitting in a tub of water or standing in a

shower.
- Catheterize the patient as necessary.
- Encourage genital hygiene, and encourage keeping the skin clean and dry.
- Wash hands thoroughly after contact with lesions, and launder towels that have had direct contact with lesions.
- Wear gloves when applying ointments or making any direct contact with lesions.
- Advise the patient to avoid sexual activity when lesions are present.
- Advise the patient to use latex or polyurethane condoms during all sexual exposures.
- Instruct the patient in the use, side effects, and risks versus benefits of antiviral agents.
- Advise the patient to discuss the diagnosis of genital herpes (GH) with current and new partners.

Drug Therapy.

Antiviral drugs are used to treat GH. *The drugs decrease the severity, promote healing, and decrease the frequency of recurrent outbreaks but do not cure the infection.*

Drug therapy should be offered to anyone with an initial outbreak of GH regardless of the severity of the symptoms. Topical therapy is not recommended. Acyclovir (Zovirax, Avirax), famciclovir (Famvir), or valacyclovir (Valtrex) may be prescribed. The main differences in these drugs are cost and frequency of use. Dosage and length of treatment differ for primary outbreaks (7 to 10 days) and recurrent outbreaks (1 to 5 days). Therapy for recurrent outbreaks is most beneficial if it is started within 1 day of the appearance of lesions or during the period of itching or tingling before lesions appear. Intermittent or continuous (daily) suppressive antiviral therapy is offered to patients to lessen the severity and frequency of or prevent outbreaks, even for those with infrequent recurrent episodes.

Suppression reduces recurrences in most patients, but it does not prevent viral shedding, even when symptoms are absent (CDC, 2010b). Patients receiving continuous therapy should periodically (possibly once a year) be reassessed for recurrences, usually by stopping the antiviral drug temporarily.

IV acyclovir and hospitalization may be indicated for patients with severe HSV infections, such as disseminated disease or encephalitis. These are severe complications of genital herpes and may be fatal.

Self-Management Education.

Nursing interventions focus on patient education about the infection, sexual transmission, the potential for recurrent episodes, and the correct use and possible side effects of antiviral therapy. Frank discussion about sexual activity, including whether the patient has new or multiple partners, is an essential component of the nurse's intervention.

Nursing Safety Priority QSEN

Action Alert

Remind patients to abstain from sexual activity while GH lesions are present. Sexual activity can be painful, and likelihood of viral transmission is higher. Urge condom use during all sexual exposures because of the increased risk for HSV transmission from viral shedding, which can occur even when lesions are not present. Teach the patient about how to use condoms (Chart 74-3).

Chart 74-3

Patient and Family Education: Preparing for Self-Management

Use of Condoms

- Use latex or polyurethane condoms rather than natural membrane condoms.
- Use a condom with every sexual encounter (including oral, vaginal, and anal).
- Female condoms (Reality)—polyurethane or nitrile sheaths in the vagina—are effective in preventing transmission of viruses, including HIV.
- Condoms infrequently (2 per 100) break during sexual intercourse.
- Keep condoms (especially latex) in a cool, dry place, out of direct sunlight.
- Do not use condoms that are in damaged packages or that are brittle or discolored.
- Always handle a condom with care to avoid damaging it with fingernails, teeth, or other sharp objects.
- Put condoms on before any genital contact. Hold the condom by the tip and unroll it on the penis. Leave a space at the tip to collect semen.
- If you use a lubricant with condoms, make sure that the lubricant is

water based and washes away with water. Oil-based products damage latex condoms.
- Use of spermicide (nonoxynol-9) with condoms, either lubricated condoms or vaginal application, has *not* been proven to be more or less effective against STDs than use without spermicide. Spermicide-coated condoms have been associated with *Escherichia coli* urinary tract infections in women. *Nonoxynol-9 may increase risk for transmission of HIV during vaginal intercourse and anal intercourse. Its use is discouraged.*
- If a condom breaks, replace it immediately.
- After ejaculation, withdraw the erect penis carefully, holding the condom at the base of the penis to prevent the condom from slipping off.
- Never use a condom more than once.

HIV, Human immune deficiency virus; *STDs,* sexually transmitted diseases.

Modified from Centers for Disease Control and Prevention (CDC). (2010). Sexually transmitted diseases treatment guidelines, 2010. *Morbidity and Mortality Weekly Report, 59*(RR-12), 4-5.

Assess the patient's and partner's emotional responses to the diagnosis of genital herpes. Many people are initially shocked and need reassurance that they can manage the disease. Infected patients may have feelings of disbelief, uncleanness, isolation, and loneliness. They may also be angry at their partner(s) for transmitting the infection or fear rejection because they have the infection. Help patients cope with the diagnosis by being sensitive and supportive during assessments and interventions. Encourage social support, and refer patients to support groups (e.g., local support groups of the National Herpes Resource Center [www.ashasexualhealth.org/std-sti/Herpes.html]) and therapists. Symptomatic care may include oral analgesics, topical anesthetics, sitz baths, and increased oral fluid intake (Bavis et al., 2009).

Emphasize the risk for neonatal infection to all patients, both male and female. Men and women who have genital herpes need to inform their pregnancy care provider of their history. Uninfected women will be advised to avoid unprotected intercourse with infected partners during pregnancy to avoid the risk for a new primary infection and outbreak during pregnancy. People who have tested serology positive to HSV-1 or HSV-2 but have never had GH symptoms should be counseled with the same information as for those who have symptoms (CDC, 2010b).

Infections of the Epithelial Structures

Condylomata Acuminata (Genital Warts)

Pathophysiology

Condylomata acuminata (also known as *genital warts*) are caused by certain types of *human papilloma virus (HPV)*, 90% of which are types 6 and 11 or low-risk HPV (Datta et al., 2012; Mark et al., 2012). These types *rarely* result in invasive cancer of the genital tract such as cervical cancer. *However, HPV types 16, 18, 31, 33, and 35, considered high-risk HPV, can be found on the skin of the genitalia and increase the risk for genital cancers, especially cervical cancer.* Infection with several HPV types can occur at the same time. The presence of one strain increases the risk for acquiring a higher-risk strain. Genital warts are the most common viral disease that is sexually transmitted and are often seen with other infections. Among American women ages 14 to 59 years, 26.8% are infected with either high- or low-risk HPV (Datta et al., 2012).

HPV infection has been established as the primary risk factor for development of cervical cancer (Datta et al., 2012). Sites commonly affected by infection include the urinary meatus, labia, vagina, cervix, penis, scrotum, anus, and perineal area. The incubation period is usually 2 to 3 months. There is growing evidence that HPV infection through oral and anal sex, especially in men who have sex with men (MSM), may be a risk factor for developing oral and anal cancers (Kim, 2010).

Patient-Centered Collaborative Care

Assessment

The diagnosis of condylomata acuminata is made by examination of the lesions. They are initially small, white or flesh-colored papillary growths that may grow into large cauliflower-like masses (Fig. 74-2). Multiple warts usually occur in the same area. Bleeding may occur if the wart is disturbed. Warts may disappear or resolve on their own without treatment. They may occur once or recur at the original site. Warts can occur on the external or internal surfaces of the genitalia, including the mucosal surfaces of the vagina and urethra.

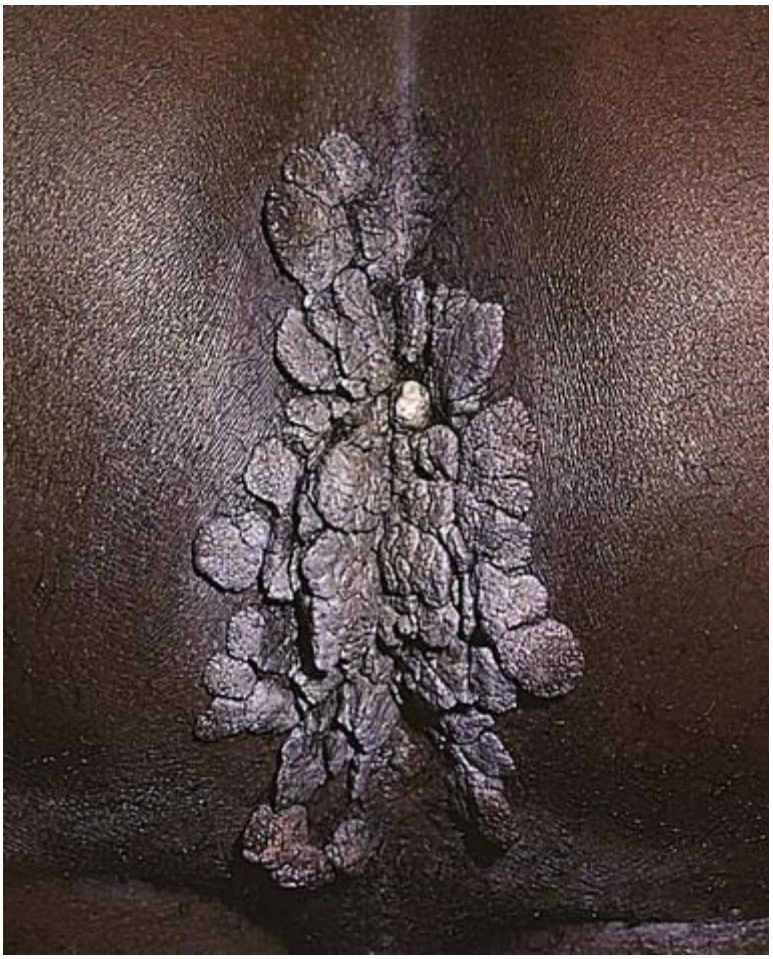


FIG. 74-2 Perianal condylomata acuminata.

Screening for HPV and dysplasia of the cervix is done by obtaining cervical specimens for Papanicolaou (Pap) and HPV DNA testing. The frequency of screening has changed significantly as new understanding about the course of HPV infection has evolved. Identifying high-risk strains of HPV and correlating with abnormal Pap smear findings is now the standard of care (Schiffman et al., 2011). High-risk HPV may coexist with low-risk HPV, the likely cause of the warts. The diagnosis should include consideration of condyloma lata or secondary syphilis since STDs frequently coexist. A VDRL test, HIV test, and cultures for chlamydia and gonorrhea infections are done. Condylomata lata (secondary syphilis) can resemble condylomata acuminata (genital warts). If a wartlike lesion bleeds easily, appears infected, is atypical, or persists, a biopsy of the lesion is performed to rule out other pathologic problems such as cancer. A biopsy of warts that are seen on the cervix should be performed prior to any treatment to eradicate them.

Interventions

The outcome of treatment is to remove the warts. No current therapy eliminates the HPV infection, and recurrences after treatment are likely.

It is not known whether removal of visible warts decreases the risk for disease transmission.

Drug Therapy.

Patients may apply podofilox (Condylox) 0.5% cream or gel twice daily for 3 days with no treatment for the next 4 days. This regimen should be repeated for four cycles. Other options are imiquimod (Aldara) 5% cream applied topically at bedtime 3 times a week and sinecatechins 15% ointment (made from green tea extract) applied 3 times a day, both until the warts disappear or for up to 16 weeks. Imiquimod boosts the immune system rather than simply destroying the warts. These self-treatments are less expensive than those performed in the health care provider's office, but they take longer for healing. *Teach patients that over-the-counter (OTC) wart treatments should not be used on genital tissue* (*CDC, 2010b*).

Cryotherapy, trichloroacetic acid (TCA) or bichloroacetic acid (BCA), and podophyllin (Pododerm) are provider-applied treatments. **Cryotherapy** (freezing), usually with liquid nitrogen, can be used every 1 to 2 weeks until lesions are resolved. TCA/BCA (80% to 90%) can be applied weekly. Podophyllin resin can be applied weekly but needs to be washed off 1 to 4 hours after application. Extensive warts have been treated with the carbon dioxide laser, intra-lesion interferon injections, and surgical removal (CDC, 2010b).

Self-Management Education.

The priority nursing intervention is patient and sexual partner education about the mode of transmission, incubation period, treatment, and complications, especially the association with cervical cancer. Reinforce instructions about local care of the lesions or patient-applied treatment for self-management.

Nursing Safety Priority QSEN

Drug Alert

Teach patients that after treatment with cryotherapy, podophyllin, or TCA, they may experience discomfort, bleeding, or discharge from the site or sloughing of parts of warts. Instruct patients to keep the area clean (shower or bath) and dry. Teach them to be alert for any signs or symptoms of infection or side effects of the treatment.

Inform patients that recurrence is likely, especially in the first 3

months, and that repeated treatments may be needed. Urge all patients to have complete STD testing, since exposure to one STD may increase risk for contracting another. Sexual partners should also be evaluated and offered treatment if warts are present. Teach patients to avoid intimate sexual contact until external lesions are healed. Recommend condoms to help reduce transmission even after warts have been treated (see Chart 74-3). Encourage women to have a Pap test annually, starting at age 21 years; after they have had three normal smears, they should have a Pap test every 3 years if no new risk factors are present (e.g., new partner, other STDs) (Murphy & Mark, 2012). The presence of warts should increase suspicion that the patient may have had exposure to other STDs, which warrants additional testing.

Gardasil (Merck Sharpe & Dohme Corporation, 2014) is used to provide immunity for HPV types 6 and 11 (predominantly types causing warts, low risk for cervical cancer) and 16 and 18 (high risk for cervical cancer). Initially approved for females, the vaccine is now also recommended for males ages 9 to 26 years. Cervarix (GlaxoSmithKline, 2012) may be given to 9- to 25-year-old females and protects only against HPV types 16 and 18. Both vaccines are recommended before onset of sexual activity (and before age 26 years) and possible exposure to HPV. Because exposure to HPV is likely for most sexually active young adults, vaccination protects them against the strains to which they have not yet been exposed. Vaccination is also especially encouraged for MSM and immunocompromised young adults up to the age of 26 years (CDC, 2012a).

Chlamydia Infection

❖ Pathophysiology

Chlamydia trachomatis is an intracellular bacterium and the causative agent of genital chlamydia infections. It invades the epithelial tissues in the reproductive tract. The incubation period ranges from 1 to 3 weeks, but the pathogen may be present in the genital tract for months without producing symptoms.

C. trachomatis is reportable to local health departments in all states. Diagnosed cases continue to increase yearly, which reflects more sensitive screening tests and increased public health efforts to screen high-risk people. Each year there are an estimated 2.9 million new cases in the United States (CDC, 2013a), with 1.4 million reported to the CDC in 2011 (CDC, 2012c). Because it is frequently asymptomatic, the estimated incidence is about double of what is reported. African-

American women between 15 and 24 years of age are at the highest risk for the disease (CDC, 2012c).

In women, 20% to 40% of those infected will develop pelvic inflammatory disease (PID) if not treated, discussed later in this chapter on p. 1541.

Patient-Centered Collaborative Care

Assessment

Obtain a complete history including a genitourinary review of systems and psychosocial history. This will include a sexual history (see Chart 74-1). In particular, ask about:

- Presence of symptoms, including vaginal or urethral discharge, **dysuria** (painful urination), pelvic pain, irregular bleeding
- Any history of sexually transmitted diseases (STDs)
- Whether sexual partners have had symptoms or a history of STDs
- Whether patient has had a new or multiple sexual partner(s)
- Whether patient or partner has had unprotected intercourse

About 70% of chlamydia infections are asymptomatic in women. For men and women, their history may reveal only risk factors associated with *C. trachomatis*, such as new or multiple sexual partners, age younger than 26 years and female, or a male having sex with a male (MSM). As with all interviews concerning sexual behavior, use a nonjudgmental approach and provide privacy and confidentiality.

Gender Health Considerations

Patient-Centered Care QSEN

For men, ask about dysuria, frequent urination, and a mucoid discharge that is more watery and less copious than a gonorrheal discharge. *These manifestations indicate urethritis, the main symptom of chlamydia infection in men.* Some men have the discharge only in the morning on arising. Complications include epididymitis, prostatitis, infertility, and Reiter's syndrome, a type of connective tissue disease discussed in Chapter 18.

In contrast, many women have no symptoms. Those with symptoms have mucopurulent vaginal discharge (typically yellow and more opaque), urinary frequency, and abdominal discomfort or pain. Cervical bleeding, from infected and therefore fragile tissue, may present as spotting or bleeding between menses and frequently after intercourse.

Complications of infection with *C. trachomatis* include salpingitis (inflammation of the fallopian tubes), PID, ectopic pregnancy, and infertility. These health problems are discussed in detail in maternal-child textbooks.

Diagnosis is made by sampling cells from the endocervix, urethra, or both, easily obtained with a swab. Because chlamydiae can reproduce only inside cells, cervical (or host) cells that harbor the organism (or parts of it) are required in the sample. Tissue culture (the gold standard) obtained from the cervical os during the female pelvic examination or male urethral examination obtained by swabbing has been replaced by genetic tests. As with gonorrhea, the nucleic acid amplification tests (NAATs) and gene amplification tests (ligand chain reaction [LCR] and polymerase chain reaction [PCR] transcription-mediated amplification) are the newest methods of detecting *Chlamydia* in endocervical samples, urethral swabs, and urine. They are more sensitive tests than the tissue culture. Samples can be obtained by swab by the examining clinician or by a patient-collected urine specimen. This urine self-collection method has been found to be more acceptable and highly sensitive and specific. The acceptability of urine testing has resulted in increased identification of asymptomatic people.

All sexually active women 24 years old or younger, and all women older than 25 years with new or multiple partners, should be screened annually for *Chlamydia* (CDC, 2010b; USPSTF, 2014a). There is no recommendation for or against screening asymptomatic men, regardless of age or other risk, and low-risk asymptomatic women.

Interventions

The treatment of choice for chlamydia infections is azithromycin (Zithromax) 1 g orally in a single dose or doxycycline (Monodox, Doxy-Caps, Doxycin) 100 mg orally twice daily for 7 days. The one-dose course, although more expensive, is preferred because of the ease in completing the treatment. Directly observing the patient taking the medication in the health care setting assures the nurse of compliance. Drugs that are prescribed for patients with allergies to these drugs include erythromycin, ofloxacin, and levofloxacin, all for 7 days (CDC, 2010b).

Sexual partners should be treated and tested for other STDs. Expedited partner therapy, or patient-delivered partner therapy, shows signs of reducing chlamydia infection rates (CDC, 2010b). **Expedited partner therapy (EPT)** is the practice of treating sexual partners of patients diagnosed with chlamydia infection or gonorrhea by providing

prescriptions or medication to the patient, which they can take to their partner(s), without the health care provider examining the partner(s) (CDC, 2013c). Legal questions have arisen about whether a drug can be prescribed without a relationship between the health care provider and the patient, but many states have now ruled that this is appropriate and legal (CDC, 2013d). When patients have been given the drug to give to their partner, rates of infection have decreased and more partners have reported receiving treatment (CDC, 2013c; Trelle et al., 2007).

Patient and partner education is a crucial nursing intervention. Explain:

- The sexual mode of transmission
- The incubation period
- The high possibility of asymptomatic infections and the usual symptoms if present
- Treatment of infection with antibiotics and need for completion of course of treatment
- The need for abstinence from sexual intercourse until the patient and partner(s) have all completed treatment (7 days from the start of treatment, including a single-dose regimen)
- That women should be re-screened for re-infection 3 to 12 months after treatment because of the high risk for PID; also, that there is less evidence of the need for re-screening of treated men, but it should be considered
- The need to return for evaluation if symptoms recur or new symptoms develop (most recurrences are re-infections from a new or untreated partner)
- Complications of untreated or inadequately treated infection, which may include PID, ectopic pregnancy, or infertility

Gonorrhea

Pathophysiology

Gonorrhea is a sexually transmitted bacterial infection that occurs in both men and women. The causative organism is *Neisseria gonorrhoeae,* a gram-negative intracellular diplococcus. It is transmitted by direct sexual contact with mucosal surfaces (vaginal intercourse, orogenital contact, or anogenital contact).

The first symptoms of gonorrhea may appear 3 to 10 days after sexual contact with an infected person. The disease can be present without symptoms and can be transmitted or progress without warning. In women, ascending spread of the organism can cause pelvic infection **(pelvic**

inflammatory disease [PID]), endometritis (endometrial infection), **salpingitis** (fallopian tube infection), and pelvic peritonitis. Rare complications of gonorrhea in adults include arthritis, meningitis, hepatitis, and disseminated infection (Bleich et al., 2012).

Cultural Considerations

Patient-Centered Care QSEN

Significant disparity exists between age and racial groups. In 2011, young (ages 15-24 years) African-American women had the highest gonorrhea rate, followed by young African-American men (CDC, 2012c). The reasons for these differences are not known, although lack of access to health care may be a factor.

In 2011, 321,849 new gonococcal infections were diagnosed and reported, but the CDC estimates that this represents only about half of the cases that occurred (CDC, 2012c). Over the years, gonorrhea has become resistant to penicillin, tetracycline, and ciprofloxacin and recently to cefixime. Cefixime is no longer the drug of choice because of the development of oral cephalosporin-resistant *N. gonorrhoeae.* Intramuscular injection of Rocephin (ceftriaxone) 250 mg in a single dose is now the drug of choice (CDC, 2012d).

Patient-Centered Collaborative Care

Assessment

A complete history includes reviewing the genitourinary systems, including taking a sexual history that includes sexual orientation and sites of sexual exposure or intercourse. Assess for allergies to antibiotics (see Chart 74-1). Establish a trusting relationship and use a nonjudgmental approach to gather more complete information. This approach may decrease the patient's anxiety and fear about having an STD.

The infection can be asymptomatic in both men and women, but women have asymptomatic, or "silent," infections more often than do men. If symptoms are present, men usually notice dysuria and a penile discharge that can be either profuse, yellowish green fluid or scant, clear fluid. The urethra is most commonly affected, but infection can extend to the prostate, the seminal vesicles, and the epididymis. Men seek curative treatment sooner, usually because they have symptoms, and thereby

avoid some of the serious complications.

Women may report a change in vaginal discharge (yellow, green, profuse, odorous), urinary frequency, or dysuria. The cervix and urethra are the most common sites of infection.

Anal manifestations may include itching and irritation, rectal bleeding or diarrhea, and painful defecation. Assess the mouth for a reddened throat, ulcerated lips, tender gingivae, and lesions in the throat. Fig. 74-3 shows common sites of gonococcal infections.

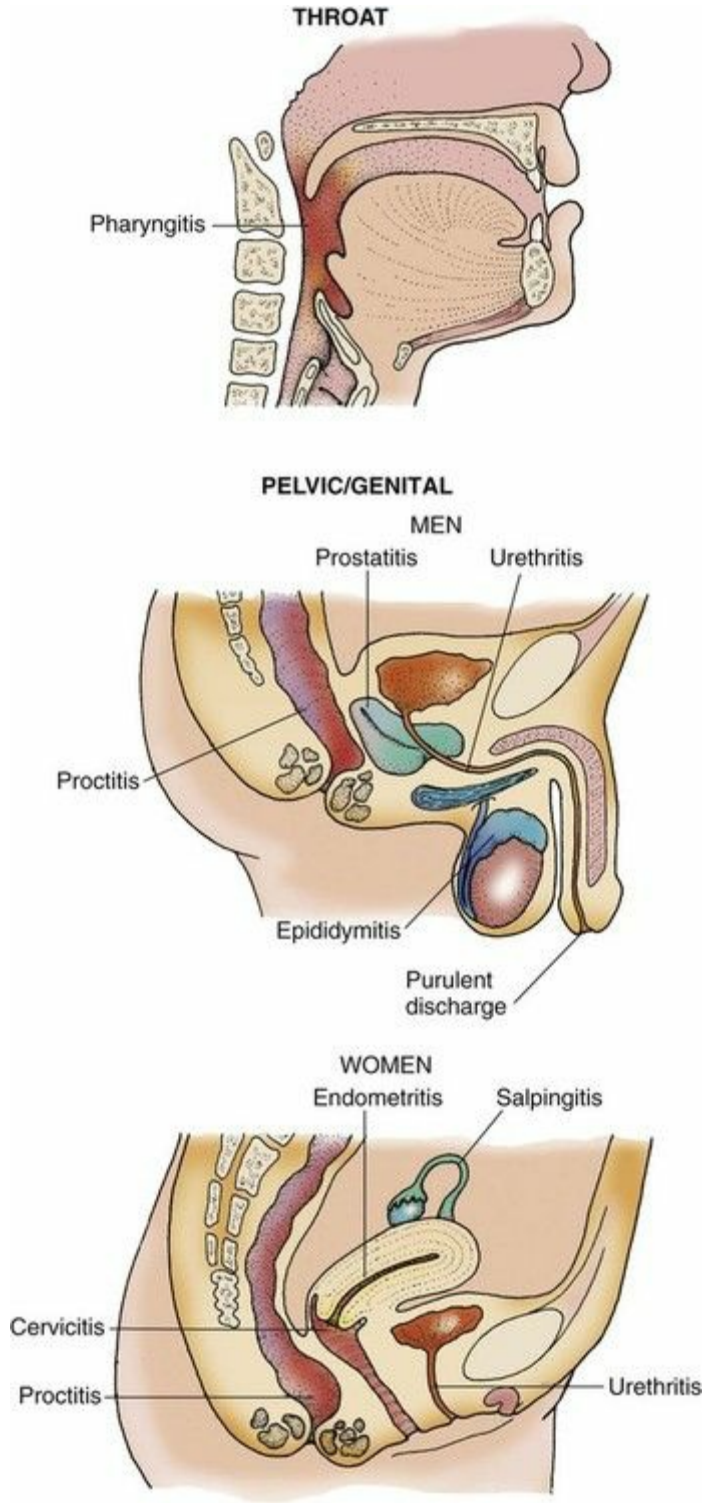

FIG. 74-3 Areas of involvement of gonorrhea in men and women.

If fever occurs, this may be a sign of an ascending (PID or epididymitis) or systemic infection (disseminated gonococcal infection). Symptoms could include joint or tendon pain, either in a single joint or as migratory arthralgias, especially of the knees, elbows, fingers or toes, and a rash usually on the palms and soles. The rash can be pustular or maculopapular (Bleich et al., 2012).

Clinical symptoms of gonorrhea can resemble those of chlamydia

infection and need to be differentiated. *Molecular testing for* N. gonorrhoeae *is currently the most widely used standard and preferred over cultures or microscopic examinations.* These nucleic acid amplification tests (NAATs) are highly sensitive and specific. During examination, providers can swab the male urethra or female cervix to obtain specimens. These specimens can be placed in medium for molecular testing, cultured on chocolate agar (gold standard), or viewed microscopically after Gram staining (male urethral specimens only). Patient-collected urine or vaginal swabs can also be used to diagnose both gonorrhea and chlamydia infections, allowing for testing without a full examination.

In men, gonorrhea can be diagnosed by Gram staining smears of urethral discharge that has been swabbed onto a glass slide, dried, and stained. The presence of gram-negative diplococci is diagnostic for gonococcal urethritis in men. If the man has symptoms, Gram stains are very sensitive and specific for gonorrhea and allow for immediate diagnosis and treatment in the clinical setting. Without symptoms, Gram stains are less reliable. Smears do not confirm the diagnosis in women because the female genital tract normally harbors other *Neisseria* organisms that resemble *N. gonorrhoeae.*

All patients with gonorrhea should be tested for syphilis, chlamydia, hepatitis B and hepatitis C, and HIV infection and, if possible, examined for HSV and HPV, because they may have been exposed to these STDs as well. Sexual partners who have been exposed in the past 30 days should be examined, and specimens should be obtained.

Interventions

Uncomplicated gonorrhea is treated with antibiotics. Chlamydia infection, which is 4 times more common, is frequently found in patients with gonorrhea. Because of this, patients treated for gonorrhea should also be managed with drugs that treat chlamydia infection.

Drug Therapy.

Drug therapy recommended by the CDC is ceftriaxone (Rocephin) 250 mg IM *plus* azithromycin (Zithromax) 1 g orally in a single dose *or* doxycycline (Monodox, Doxy-Caps, Doxycin) 100 mg orally twice daily for 1 week to treat a presumed co-infection with *Chlamydia* (up to 40%), unless a negative *Chlamydia* result has been obtained. These combinations seem to be effective for all mucosal gonorrheal infections; treatment failure is rare (CDC, 2012d). A test of cure is not required for treatment with ceftriaxone. Advise the patient to return for a follow-up examination if symptoms persist after treatment. Re-infection is usually

the cause of these symptoms.

Sexual partners must be treated, not only evaluated, to prevent re-infection. Sexual partners also need to receive education about the infection.

Because the best treatment for gonorrhea is injected Rocephin (ceftriaxone), expedited partner therapy (EPT) is not ideal for treating gonorrhea. If there is concern that the partner may not come to a health care facility for treatment, providing oral cefixime as an alternative has been recommended by the CDC. Because of the potential for resistance of gonorrhea to cefixime, a test of cure is recommended after treatment is completed.

Gonorrhea infection can become disseminated (disseminated gonococcal infection [DGI]), requiring hospitalization and IV or IM ceftriaxone 1 g every 24 hours. If symptoms resolve within 24 to 48 hours, the patient may be discharged to home to continue oral antibiotic therapy (cefixime 400 mg twice a day) for at least a week (CDC, 2010b).

Meningitis and endocarditis occur rarely. Hospitalization of patients with these problems is recommended for the initial treatment. Treatment includes IV antibiotic therapy, usually ceftriaxone 1 to 2 g every 12 hours. If meningitis or endocarditis is present, therapy is continued for 10 to 14 days for meningitis and at least 4 weeks for endocarditis. Collaborate with the infectious disease specialist for management of these infections.

Self-Management Education.

Teach the patient about transmission and treatment of gonorrhea. The use of medication to treat chlamydia infection at the same time as treating gonorrhea should be explained to the patient since the likelihood of co-infection is high. Discuss the possibility of re-infection, including the risk for pelvic inflammatory disease (PID), and resultant problems such as ectopic pregnancy, infertility, and chronic pelvic pain. Instruct patients to cease sexual activity until the antibiotic therapy is completed and they no longer have symptoms; but if abstinence is not possible, urge men and women to use condoms. Explain that gonorrhea is a *reportable disease*.

When a diagnosis of gonorrhea is made, patients may have feelings of fear or guilt. They may be concerned that they have contracted other STDs or see the disease as a punishment for promiscuity or "unnatural" sex acts. They may believe that acquiring gonorrhea (or any STD) is a risk that they must take to pursue their desired lifestyle. Such feelings can impair relationships with sexual partners. Encourage patients to express their feelings, and offer other information and professional resources to

assist them in having a correct understanding of their diagnosis and treatment. Ensuring privacy during your discussion with them and maintaining confidentiality of personal health information are essential in meeting psychosocial needs.

Clinical Judgment Challenge

Patient-Centered Care; Teamwork and Collaboration QSEN

A 39-year-old gay man has been diagnosed with a chlamydial infection and provided with treatment for the infection. After learning how the infection is transmitted, he states that he and his partner "broke up" briefly 3 months ago and he wonders if his partner became involved with someone who transmitted the infection to him. One week later, the patient and his partner return to the health care center. The partner states that he "slept with another man" during the break-up. As the nurse, you explain that medication treatment is available with expedited partner therapy (EPT) for the person the partner became involved with during the break-up. The patient becomes angry and tells his partner, "I don't want you ever speaking to him again!"

1. What is the best therapeutic approach for working with this patient and his partner?
2. How will you further explain to this couple the need for EPT for the other person?
3. In your presence, the patient tells his partner that he cannot imagine ever talking with "that jerk you slept with." What emotional feelings is this patient experiencing? How will you respond to the patient's statement?
4. Develop a collaborative plan of care for this patient to ensure that the needs of all involved parties will be met.

Other Gynecologic Conditions

Pelvic Inflammatory Disease

❖ Pathophysiology

Pelvic inflammatory disease (PID) is a complex infectious process in which organisms from the lower genital tract migrate from the endocervix upward through the uterine cavity into the fallopian tubes. The spread of infection to other organs and tissues of the upper genital tract occurs from direct contact with mucosal surfaces or through the fimbriated ends of the tubes to the ovaries, parametrium, and peritoneal cavity (Fig. 74-4). This may involve one or more pelvic structures, including the uterus, fallopian tubes, and adjacent pelvic structures. The most common site is the fallopian tube. Resulting infections include:

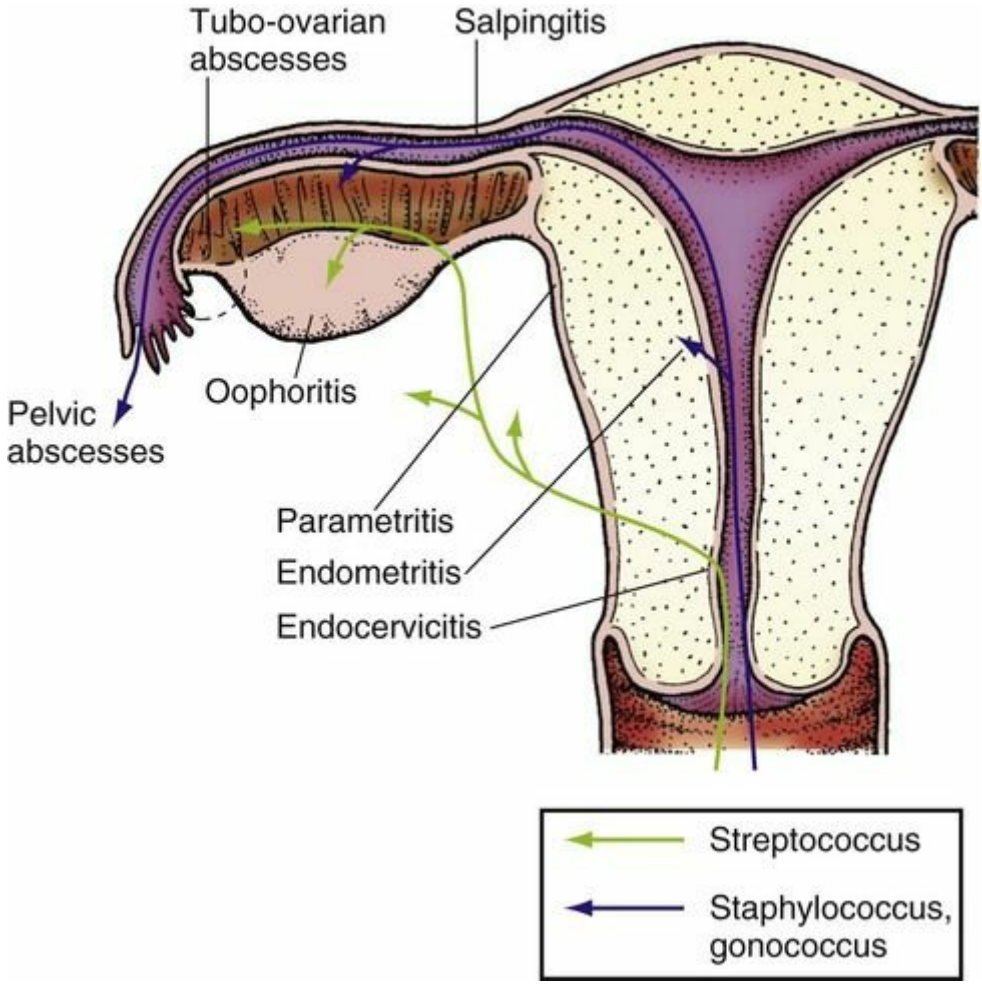

FIG. 74-4 The spread of pelvic inflammatory disease.

- Endometritis (infection of the endometrial cavity)
- Salpingitis (inflammation of the fallopian tubes)
- Oophoritis (ovarian infection)

- Parametritis (infection of the parametrium)
- Peritonitis (infection of the peritoneal cavity)
- Tubal or tubo-ovarian abscess

Usually multiple pathogens are involved in the development of PID. Sexually transmitted organisms are most often responsible, especially *C. trachomatis* and *N. gonorrhoeae.* Organisms that are part of the vaginal flora can also cause PID including *Gardnerella vaginalis, Haemophilus influenzae, Staphylococcus, Streptococcus, Mycoplasma, Escherichia coli,* and other aerobic and anaerobic organisms. There is increasing evidence that the anaerobes involved in bacterial vaginosis may have a role in the development of PID and increase the risk for infection with HIV, *N. gonorrhoeae*, *C. trachomatis*, and HSV (CDC, 2010b; Sweet, 2012).

The organisms invade the pelvis from an infection ascending from the vagina or cervix. Infections are spread during sexual intercourse, during childbirth (including the postpartum period), and after abortion. *Sepsis and death can occur, especially if treatment is delayed or inadequate.*

PID is one of the leading causes of infertility and is related to the increase in the number of ectopic pregnancies reported in the United States. It is an acute syndrome resulting in tenderness in the tubes and ovaries (adnexa) and, typically, dull pelvic pain. However, many women experience only mild discomfort or menstrual irregularity, whereas others have acute pain, which can affect their gait. Others experience no symptoms at all—so-called "silent" or "subclinical" PID. The diagnosis and treatment of this disease are challenging. Irreversible scarring or stricture, causing sterility, may occur before it is diagnosed (Sweet, 2012).

Because of variations in patient manifestations, the diagnosis is difficult because women may have subtle symptoms not typical of the disease. Delay in diagnosis and treatment may add to complications of PID in the upper genital tract. The disease is usually diagnosed on the basis of clinical signs and symptoms. The Centers for Disease Control and Prevention (CDC) (2013e) has set minimum criteria for diagnosis, but no laboratory or physical examination techniques alone are both sensitive and specific (Table 74-4).

TABLE 74-4
Diagnostic Criteria For Pelvic Inflammatory Disease

Minimum Criteria for Initiating Empiric Treatment for Pelvic Inflammatory Disease
• Sexually active woman and at risk for STDs • Pelvic or lower abdominal pain • No other cause for illness can be found (e.g., appendicitis)
and
• Uterine tenderness or • Adnexal tenderness or • Cervical motion tenderness (chandelier sign)
Additional Criteria to Increase the Specificity of the Diagnosis of PID
• Oral temperature >101° F (>38.3° C) • Abnormal cervical or vaginal mucopurulent discharge • Presence of white blood cells on saline microscopy of vaginal secretions • Elevated erythrocyte sedimentation rate • Elevated C-reactive protein • Laboratory documentation of cervical infection with *Neisseria gonorrhoeae* or *Chlamydia trachomatis*
Definitive Criteria for Diagnosing PID, Warranted in Selected Cases
• Histopathologic evidence of endometritis on endometrial biopsy • Transvaginal sonography or MRI techniques showing thickened, fluid-filled tubes with or without free pelvic fluid or tubo-ovarian complex, or Doppler studies suggesting pelvic infection • Laparoscopic abnormalities consistent with PID

PID, Pelvic inflammatory disease; *STDs*, sexually transmitted diseases.

Modified from Centers for Disease Control and Prevention (CDC). (2014). *Sexually transmitted diseases treatment guidelines, 2010: Pelvic inflammatory diseases*. Retrieved November 2014, from www.cdc.gov/std/treatment/2010/pid.htm

Patient-Centered Collaborative Care

Assessment

History.

Obtain a complete history of the symptoms with menstrual, obstetric, sexual, and family history and a history of previous episodes of pelvic inflammatory disease (PID) or other sexually transmitted diseases (see Chart 74-1). Assess for contraceptive use, a history of reproductive surgery, and other risk factors previously discussed. Ask the patient if sexual abuse has occurred. If so, encourage her to discuss what happened and whether she was seen by a health care provider.

Many of the same factors that place women at risk for STDs also place them at risk for PID. Risk factors for sexually active women include:

- Age younger than 26 years
- Multiple sexual partners
- Intrauterine device (IUD) placed within the previous 3 weeks
- Smoking
- A history of PID
- Chlamydial or gonococcal infection; bacterial vaginosis
- A history of sexually transmitted diseases (STDs)

Physical Assessment/Clinical Manifestations.

One of the most frequent symptoms of PID is lower abdominal or pelvic pain. Conduct a complete pain assessment. Other symptoms include irregular vaginal bleeding (spotting or bleeding between periods), dysuria (painful urination), an increase or change in vaginal discharge, dyspareunia (painful sexual intercourse), malaise, fever, and chills.

Observe whether the patient has discomfort with movement. Often the patient has a hunched-over gait to protect her abdomen. She may find it difficult to independently get on the examination table or stretcher. Assess for lower abdominal tenderness, possibly with rigidity or rebound tenderness. A pelvic examination by the health care provider may reveal yellow or green cervical discharge and a reddened or **friable** cervix (a cervix that bleeds easily). Criteria for accurate diagnosis of PID are listed in Table 74-4. The diagnosis of PID is usually based on health history, physical examination, and laboratory tests. Imaging studies and laparoscopy are not generally used to make the diagnosis.

Psychosocial Assessment.

The woman who has symptoms of PID is usually anxious and fearful of the examination and unknown diagnosis. She may need much reassurance and support during the physical examination because her abdomen may be very tender or painful. Explain what is taking place to help promote comfort during the examination.

Because PID is often associated with an STD, the woman may feel embarrassed or uncomfortable discussing her symptoms or history. Use a nonjudgmental approach, and encourage the patient to express her feelings and concerns. Determining the patient's ability to follow through with the treatment plan is essential in deciding whether hospitalization should be considered.

Laboratory Assessment.

The health care provider obtains specimens from the cervix, urethra, and rectum to determine the presence of *N. gonorrhoeae* or *C. trachomatis.* The white blood cell (WBC) count, erythrocyte sedimentation rate (ESR), and C-reactive protein may be elevated but are not specific for PID. A sensitive test that detects human chorionic gonadotropin (hCG) in urine or blood should be performed to determine whether the patient is pregnant. Microscopic examination of vaginal discharge should be done to evaluate for the presence of more than 10 WBCs per high-power field, which correlates with infection. Bacterial vaginosis can be found by

observing the diagnostic "clue" cells with microscopic examination of vaginal discharge.

Other Diagnostic Assessment.

Abdominal *ultrasonography* may be used to determine the presence of appendicitis and tubo-ovarian abscesses that need to be ruled out when the diagnosis of PID is made. Transvaginal ultrasound and *MRI* are used in some cases to detect tubal wall thickening, fluid-filled tubes, and free pelvic fluid or a tubo-ovarian abscess, all associated with PID. *Endometrial biopsy* also has been used to increase the accuracy of the diagnosis.

◆ Analysis

The priority collaborative problem for patients with pelvic inflammatory disease (PID) is infection related to invasion of pelvic organs by pathogens.

◆ Planning and Implementation

Managing Infection

Planning: Expected Outcomes.

The patient with PID is expected to have her infection resolved, be free of abdominal pain, and prevent re-infection.

Interventions.

Patient-centered collaborative care includes antibiotic therapy and self-management measures.

Uncomplicated PID is usually treated on an ambulatory care basis. The CDC (2010b) recommends hospitalization for PID if the patient:

- Has appendicitis, ectopic pregnancy, or other surgical emergency that has not been excluded
- Is pregnant
- Does not respond to oral antibiotic therapy
- Is unable to follow or tolerate treatment on an ambulatory care basis
- Has severe illness, nausea and vomiting, or high fever
- Has a tubo-ovarian abscess

There are no recommendations about whether HIV-infected women should be hospitalized. Assess the ability of high-risk women for self-management at home. The patient's health status and availability of support systems are important considerations for home care. If the

infection has not responded to treatment, the patient may need to be hospitalized for IV antibiotic therapy and further evaluation.

The CDC recommends oral and/or parenteral antibiotics for PID (CDC, 2010b). Drug therapy is required for 14 days. If the woman has not responded to oral antibiotics, she is hospitalized for IV antibiotic therapy and further evaluation. Inpatient therapy involves a combination of several IV antibiotics until the woman shows signs of improvement (e.g., decreased pelvic tenderness for at least 24 hours). Then oral antibiotics are continued at home until the course of treatment has lasted 14 days.

Antibiotic therapy relieves pain by destroying the pathogens and decreasing the inflammation caused by infection. Other pain-relief measures include taking mild analgesics and applying heat to the lower abdomen or back. As with any infection, encourage the patient to increase her intake of fluids and to eat nutritious foods that can promote healing. *Teach the patient to rest in a semi-Fowler's position and encourage limited ambulation to promote gravity drainage of the infection that may help relieve pain.*

Nursing Safety Priority QSEN

Action Alert

Instruct women who are being treated for PID on an ambulatory care basis to avoid sexual intercourse for the full course of treatment and until their symptoms have resolved. Ask them to check their temperature twice a day. Teach them to report an increase in temperature to their health care provider. Remind them to be seen by the health care provider within 72 hours from starting antibiotic treatment and then 1 and 2 weeks from the time of the initial diagnosis.

In a small number of patients, the pain and tenderness may not be relieved by antibiotic therapy. The surgeon may perform a laparoscopy to remove an abscess through one or more sub-umbilical incisions to provide better access to the fallopian tubes. Before surgery, provide information about hospital routines and procedures. After surgery, the care of the woman with PID is similar to that of any patient after laparoscopic abdominal surgery. One difference is that she may have a wound drain for drainage of abscess fluid that may not have been completely removed during surgery. Observe, measure, and record wound drainage every 4 to 8 hours as requested.

Community-Based Care.

If the woman is hospitalized, collaborate with the case manager or discharge planner before the woman is discharged to home. Teach the patient with PID to see her health care provider for follow-up to assess for complications and assess that the infection has resolved. The ongoing role of the nurse is to assess for any continued risk for contracting PID again, signs of persistent or recurrent infection, and education to prevent exposure to and infection with all STDs (e.g., decrease the number of partners, consistently use condoms). Establish an atmosphere of trust that encourages the woman to return frequently, if needed, for education or reassurance.

Home Care Management.

Parenteral antibiotic therapy may be given at home, but usually the health care provider changes the treatment regimen to oral antibiotics before hospital discharge.

Self-Management Education.

Patient teaching focuses on providing information about PID, identifying symptoms that suggest persistent or recurrent infection (persistent pelvic pain, dysmenorrhea, low backache, fever), and urging completion of antibiotic treatment, rest, and healthy nutrition to resolve the infection and prevent complications. Review information for oral antibiotic therapy (Chart 74-4).

Chart 74-4 Patient and Family Education: Preparing for Self-Management

Oral Antibiotic Therapy for Sexually Transmitted Diseases

- Take your medicine for the number of times a day it is prescribed and until it is completed.
- Your sexual partner must be treated if you have a sexually transmitted disease (STD). Expedited partner therapy is one way to ensure partners are treated.
- Be sure to return for your follow-up appointment after completing your antibiotic treatment.
- Call if you have any questions or concerns.
- Do not have sex until after you and your partner complete your antibiotic therapy. This should be at least 7 days, even if treatment is one dose.

- Drink at least 8 to 10 glasses of fluid a day to help heal your infection, while taking your antibiotics.
- Do not take antacids containing calcium, magnesium, or aluminum, such as Tums, Maalox, or Mylanta, with your antibiotics. They may decrease the effectiveness of the antibiotic.
- Take your antibiotics on an empty stomach unless your health care provider instructs you to take them with food.

Counsel the patient to contact her sexual partner(s) for examination and treatment. All sexual partners should be treated for gonorrhea and chlamydia infection regardless of whether they have symptoms. Remind the patient about follow-up care, and counsel her about the complications that can occur after an episode of PID. These problems include increased risk for recurrence, ectopic pregnancy, and infertility. Chronic pelvic pain may also develop.

Discuss contraception and the patient's need or desire for it. This discussion includes the use of condoms that can decrease the risk for future episodes of PID. Consider the likelihood that the patient had unprotected (from pregnancy and STDs) intercourse, which resulted in PID. Contraception that includes the use of condoms is an important health message to be communicated. Help the patient understand that having sexual intercourse with multiple partners increases the risk for recurrent episodes. Douching has also been suggested as a risky behavior for development of PID and/or infection with *Chlamydia* or *N. gonorrhoeae.*

Psychosocial concerns may require counseling. A patient who has PID may exhibit a variety of feelings (guilt, disgust, anger) about having a condition that may have been transmitted to her sexually. These feelings may affect her relationship with significant others and future sexual partners. She may also have concerns about future fertility if PID has damaged or scarred the fallopian tubes and other reproductive organs. Provide nonjudgmental emotional support, and allow time for her to discuss her feelings. The primary provider of care may refer the patient to a mental health care provider as another appropriate option.

NCLEX Examination Challenge

Physiological Integrity

A client with pelvic inflammatory disease returns to her primary care provider's office 3 days after starting treatment with oral antibiotics.

Which symptom does the nurse recognize that requires immediate intervention?
A Mild nausea
B Temperature of 101° F
C Report of two diarrheal stools daily after starting antibiotic
D Expression of anxiety that her partner will "catch" the infection

Health Care Resources.

The cost of antibiotics for patients with PID and other STDs may be a concern for those who are uninsured, underinsured, or impoverished. In collaboration with the case manager or social worker, help locate community resources for free or discounted drugs for women who cannot afford them. Ask the patient directly if she has the ability to pay for the drug and her follow-up visits, regardless of her apparent financial status.

If infertility is a result of PID, the patient may need referral to a clinic specializing in infertility treatment and counseling. She can also contact support groups for infertile couples, which exist in many local communities.

Evaluation: Outcomes

Evaluate the care of the patient with PID based on the identified priority patient problem. The expected outcomes include that the patient should:

- Show evidence that the infection has resolved
- Report or demonstrate that pain is relieved or reduced and that she feels more comfortable
- Demonstrate a plan for ensuring treatment of her partner, obtaining antibiotics, and returning for follow-up care

Vaginal Infections

Vaginal infection associated with sexual activity may produce vaginal discharge or vulvar irritation. The common causes of vaginal infection that can be but are not always sexually transmitted include:

- *Trichomonas vaginalis*
- *Candida*, primarily *Candida albicans*
- Bacteria that produce bacterial vaginosis, including *Gardnerella vaginalis*, *Mycoplasma hominis*, and anaerobes including *Prevotella* and *Mobiluncus* species

Men can also get these infections but are not always symptomatic. Trichomoniasis and candida infections are limited to the vagina. They

can be very irritating and bothersome but do not cause any long-term problems. The partner must also be treated for *trichomoniasis* for the infection to be resolved. *Candidiasis* does not usually require partner treatment. However, if the male partner is symptomatic (irritation of the genital skin), treatment is indicated. It is important to remember that *Candida* is a normal flora on the skin and vagina. Although it can be transmitted sexually, candidiasis occurs in women regardless of their sexual activity. Also, antibiotics that change the normal flora of the vagina contribute to infection.

Bacterial vaginosis (BV) has been implicated in upper genital tract infections. Women undergoing surgery of the upper genital tract should be evaluated and treated if BV is found. Chapter 71 describes the management of each of these infections.

Other Sexually Transmitted Diseases

Less common diseases in the United States that are transmitted by sexual contact are lymphogranuloma venereum, chancroid, and granuloma inguinale. Like syphilis, all of these diseases are associated with ulcers but they are seen most often in less developed countries. As newcomers migrate into the United States and international travel increases, these STDs may become more common. Ask patients suspected of these infections whether they have traveled out of the United States and whether they had sexual contact with people who live in other countries.

Nursing Concepts and Clinical Judgment Review

What might you OBSERVE if the patient has altered sexuality as a result of a sexually transmitted disease (STD)?

- Report of heavy and abnormal vaginal discharge
- Report of urinary frequency or dysuria
- Ulcers, blisters, or warts in the genital area
- Low-grade fever
- Report of malaise
- Report of vaginal, penile, or anal itching or irritation
- Report of abdominal pain (pelvic inflammatory disease [PID])
- Anxious behavior
- Depressive symptoms
- Report of disinterest in sexual activity
- Changes in relationships (e.g., ending a long-term relationship)

What should you INTERPRET and how should you RESPOND to a patient with altered sexuality as a result of STD?

Perform and interpret focused physical assessment, including:

- Vital signs
- Pain intensity and quality
- Posture and mobility
- Skin inspection (genital area)

Respond by:

- Reporting and documenting all findings
- Helping patient with abdominal pain into a semi-Fowler's position
- Providing pain-control measures

- Teaching patient about prescribed antibiotic or antiviral therapy
- Teaching patient to avoid sexual intercourse while being treated
- Teaching patient the importance of treating all sexual partners
- Teaching patient and partner(s) about safer sex practices
- Providing support and listening to the patient and partner(s) without judgment

On what should you REFLECT?

- Examine your feelings about patients who make sexual choices different from your own.
- Think about what else you could do to help patients meet their physical and emotional needs during this time.
- Determine what other health teaching may be needed for this patient.
- Monitor the patient's response to pain-control interventions.

Get Ready for the NCLEX® Examination!

Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Maintain patient and partner confidentiality and privacy at all times. **Patient-Centered Care** QSEN
- Use gloves when examining the patient's genitalia or skin lesions. **Safety** QSEN

Health Promotion and Maintenance

- Teach patients to not have sexual intercourse during their treatment for sexually transmitted disease (STD). **Safety** QSEN
- Assume that all adult patients may be sexually active, regardless of age or stage of life. Sexually transmitted diseases are still spread within the older adult population because perception of risk is lower.
- Educate young women about increased vulnerability to STDs; women's vaginal mucous membranes place them at higher risk for contracting an STD, and young women statistically have more partners and more unprotected sex, which further increases their risk. **Safety** QSEN
- Teach the patient about the availability of expedited partner therapy; be sure that both the patient and the partner take all doses of the drug.
- Encourage all patients who are sexually active to use condoms during sexual intimacy (see Chart 74-3).
- Urge sexually active people, especially those younger than 26 years (or those older than 26 years if at high risk), to have STD screenings at least annually.
- Treat all patients, regardless of diagnosis, gender identity, or sexual orientation, with respect.
- Respect the sexual choices of all patients. **Patient-Centered Care** QSEN

Psychosocial Integrity

- Provide privacy for patients undergoing examination or testing for STDs.
- Allow the patient to express fears and/or anxiety regarding a diagnosis of STD. **Patient-Centered Care** QSEN
- Refer patients newly diagnosed with an STD to local resources and support groups as needed based on their response. **Teamwork and**

Collaboration QSEN

- Encourage all patients who have an STD to inform their sexual partner(s) of their health status.

Physiological Integrity

- Assess patients with STD using the guidelines in Chart 74-1. **Evidence-Based Practice** QSEN
- Recognize that each stage of syphilis has unique symptoms and it is important to not overlook symptoms that resolve.
- Understand that patients without symptoms may still be infected with an STD.
- Encourage patients to adhere to their entire anti-infective drug regimen (see Chart 74-4), even after they begin to feel better.
- Teach patients the expected side effects and possible adverse reactions to prescribed drugs.
- Teach patients about the short-term and long-term complications of STD using the information in Table 74-2.
- Be aware that PID is diagnosed based on the criteria in Table 74-4. **Evidence-Based Practice** QSEN

Bibliography

Asterisk indicates a classic or definitive work on this subject.

Glossary

A

abdominal acute compartment syndrome (AACS) A complication after abdominal trauma that occurs when the intraabdominal pressure is sustained at greater than 200 mm Hg.

abdominoperineal (AP) resection The surgical removal of the sigmoid colon, rectum, and anus through combined abdominal and perineal incisions. This resection is performed when rectal tumors are present.

ablative The process or act of removing.

abscess A localized collection of pus caused by an inflammatory response to bacteria in tissues or organs.

absolute neutrophil count (ANC) The percentage and actual number of mature circulating neutrophils; used to measure a patient's risk for infection. The higher the numbers, the greater the resistance to infection.

absorption The uptake from the intestinal lumen of nutrients produced by digestion.

acalculia Difficulty with math calculations; caused by brain injury or disease.

acalculous cholecystitis Inflammation of the gallbladder occurring in the absence of gallstones; typically associated with biliary stasis caused by any condition that affects the regular filling or emptying of the gallbladder.

acclimatization The process of adapting to a high altitude; involves physiologic changes that help the body compensate for less available oxygen in the atmosphere.

accommodation The process of maintaining a clear visual image when the gaze is shifted from a distant object to a near object. The eye adjusts its focus by changing the curvature of the lens.

achlorhydria The absence of hydrochloric acid from gastric secretions.

acid A substance that releases hydrogen ions when dissolved in water. The strength of an acid is measured by how easily it releases hydrogen ions in solution.

acidosis An acid-base imbalance in which blood pH is below normal.

acinus The structural unit of the lower respiratory tract consisting of a respiratory bronchiole, an alveolar duct, and an alveolar sac.

Acorn cardiac support device A polyester mesh jacket that is placed over the ventricles to provide support and avoid overstretching the myocardial muscle in the patient with heart failure; reduces heart muscle hypertrophy and assists with improvement of ejection fraction.

acoustic neuroma A benign tumor of cranial nerve VIII; symptoms include damage to hearing, facial movements, and sensation. The tumor can enlarge into the brain, damaging structures in the cerebellum.

active euthanasia Purposeful action that directly causes death; not supported by most professional organizations, including the American Nurses Association.

active immunity Resistance to infection that occurs when the body responds to an invading antigen by making specific antibodies against the antigen. Immunity lasts for years and is natural by infection or artificial by stimulation (e.g., vaccine) of the body's immune defenses.

active surveillance (AS) Observation for cancer, without immediate active treatment.

activities of daily living (ADLs) The activities performed in the course of a normal day, such as bathing, dressing, feeding, and ambulating.

activity therapist See *recreational therapist.*

acute Having relatively greater intensity; marked by a sudden onset and short duration.

acute adrenal insufficiency A life-threatening event in which the need for cortisol and aldosterone is greater than the available supply. Also called “addisonian crisis.”

acute arterial occlusion The sudden blockage of an artery, typically in the lower extremity, in the patient with chronic peripheral arterial disease.

acute compartment syndrome (ACS) A complication of a fracture characterized by increased pressure within one or more compartments and causing massive compromise of circulation to the area.

Compartments are sheaths of inelastic fascia that support and partition muscles, blood vessels, and nerves in the body.

acute coronary syndrome (ACS) A disorder, including unstable angina and myocardial infarction, that results from obstruction of the coronary artery by ruptured atherosclerotic plaque and leads to platelet aggregation, thrombus formation, and vasoconstriction.

acute gastritis Inflammation of the gastric mucosa or submucosa after exposure to local irritants. Various degrees of mucosal necrosis and inflammatory reaction occur in acute disease. Complete regeneration and healing usually occur within a few days.

acute hematogenous infection An infection resulting from bacteremia, disease, or nonpenetrating trauma that is disseminated by the blood through the circulation.

acute kidney injury (AKI) A rapid decrease in kidney function, leading to the collection of metabolic wastes in the body; formerly called "acute renal failure (ARF)."

acute-on-chronic kidney disease A condition in which acute kidney injury occurs in addition to chronic kidney disease.

acute pain The unpleasant sensory and emotional experience associated with tissue damage that results from acute injury, disease, or surgery.

acute pancreatitis A serious inflammation of the pancreas characterized by a sudden onset of abdominal pain, nausea, and vomiting. It is caused by premature activation of pancreatic enzymes that destroy ductal tissue and pancreatic cells and results in autodigestion and fibrosis of the pancreas.

acute paronychia Inflammation of the skin around the nail, which usually occurs with a torn cuticle or an ingrown toenail.

acute pericarditis An inflammation or alteration of the pericardium, the membranous sac that encloses the heart; may be fibrous, serous, hemorrhagic, purulent, or neoplastic.

acute pyelonephritis Active bacterial infection in the kidney.

acute respiratory distress syndrome (ARDS) Respiratory failure marked by hypoxemia that persists even when 100% oxygen is given, as well as decreased pulmonary compliance, dyspnea, noncardiac-associated bilateral pulmonary edema, and dense pulmonary infiltrates on x-ray.

acute sialadenitis Inflammation of a salivary gland; can be caused by

infectious agents, irradiation, or immunologic disorders.

adaptive immunity The immunity that a person's body makes (or can receive) as an adaptive response to invasion by organisms or foreign proteins; occurs either naturally or artificially through lymphocyte responses and can be either active or passive.

addisonian crisis Acute adrenal insufficiency; a life-threatening event in which the need for cortisol and aldosterone is greater than the available supply.

adenocarcinoma Tumor that arises from the glandular epithelial tissue.

adenohypophysis The anterior lobe of the pituitary gland, which makes up about 70% of the gland.

adiponectin An anti-inflammatory and insulin sensitizing hormone.

adipose Fatty.

adjuvant A substance that aids another substance, such as a cancer treatment that uses chemotherapy in addition to surgery.

adjuvant therapy Chemotherapy that is used along with surgery or radiation.

adrenal crisis Acute adrenocortical insufficiency, which can be life threatening.

adrenal Cushing's disease An excess of glucocorticoids caused by a problem in the adrenal cortex, usually a benign tumor (adrenal adenoma). This usually occurs in only one adrenal gland.

advance directive (AD) A written document prepared by a competent person to specify what, if any, extraordinary actions he or she would want when no longer able to make decisions about personal health care.

adverse drug event (ADE) An unintended harmful reaction to an administered drug.

aerosolization Transmission via fine airborne droplets.

aesthetic plastic surgery Plastic surgery that is cosmetic and aims to alter a person's physical appearance.

afferent arteriole The smallest, most distal portion of the renal arterial system that supplies blood to the nephron. From the afferent arteriole, blood flows into the glomerulus, a series of specialized capillary loops.

after-drop A continued decrease in core body temperature after a victim

is removed from a cold environment; results from equilibration of core and peripheral blood temperature and counter-current cooling of the blood perfusing cold tissue.

afterload The pressure or resistance that the ventricles must overcome to eject blood through the semilunar valves and into the peripheral blood vessels; the amount of resistance is directly related to arterial blood pressure and blood vessel diameter.

agglutination A clumping action that results during the antibody-binding process when antibodies link antigens together to form large and small immune complexes.

agnosia A general term for a loss of sensory comprehension; may include an inability to write, comprehend reading material, or use an object correctly.

agraphia Loss of the ability to write; caused by brain injury or disease.

Airborne Precautions Infection control guidelines from the Centers for Disease Control and Prevention; used for patients with infections spread by the airborne transmission route, such as tuberculosis. Negative airflow rooms are required to prevent the airborne spread of microbes.

akinesia Slow or no movement, as seen in a patient with Parkinson disease. Also called "bradykinesia."

albuminuria The presence of albumin in the urine.

alcoholic hepatitis Liver inflammation caused by the toxic effect of alcohol on hepatocytes. The liver becomes enlarged, with cellular degeneration and infiltration by fat, leukocytes, and lymphocytes.

aldosterone The chief mineralocorticoid produced by the adrenal cortex. Aldosterone increases kidney reabsorption of sodium and water, thus restoring blood pressure, blood volume, and blood sodium levels. Aldosterone secretion is regulated by the renin-angiotensin system, serum potassium ion concentration, and adrenocorticotropic hormone.

alexia Complete inability to understand written language; caused by brain injury or disease.

alkaline reflux gastropathy A complication of gastric surgery in which the pylorus is bypassed or removed. Endoscopic examination reveals regurgitated bile in the stomach and mucosal hyperemia. Symptoms include early satiety, abdominal discomfort, and vomiting. Also called "bile reflux gastropathy."

alkalosis An acid-base imbalance in which blood pH is above normal.

allele An alternate form (or variation) of a gene.

allergen A foreign protein that is capable of causing a hypersensitivity response, or allergy, that ranges from uncomfortable (itchy, watery eyes or sneezing) to life threatening (allergic asthma, anaphylaxis, bronchoconstriction, or circulatory collapse); causes a release of natural chemicals, such as histamine, in the body.

allergy An increased or excessive response to the presence of a foreign protein or allergen (antigen) to which the patient has been previously exposed.

allogeneic bone marrow transplantation The transplantation of bone marrow from a sibling.

allograft A graft of tissue or bone between individuals of the same species but a different genotype; the donor may be a cadaver or a living person, either related or unrelated. Also called "homograft."

alopecia Hair loss.

alveolitis Inflammation of the alveoli.

amaurosis fugax A transient, brief episode of blindness in one eye.

ambulatory A term that refers to a patient who goes to the hospital or physician's office for treatment and returns home on the same day.

ambulatory aid Assistive device such as a cane or a walker.

ambulatory pump Infusion therapy pump generally used with a home care patient to allow a return to his or her usual activities while receiving infusion therapy.

amenorrhea The absence of menstrual periods in women.

amnesia Loss of memory.

amputation The removal of a limb or other appendage of the body.

amyotrophic lateral sclerosis (ALS) A progressive and degenerative disease of the motor system that is characterized by atrophy of the hands, forearms, and legs and results in paralysis and death. There is no known cause, no cure, no specific treatment, no standard pattern of progression, and no method of prevention. Also called "Lou Gehrig's disease."

anaerobic Lacking adequate oxygen.

anaerobic cellular metabolism Metabolism without oxygen.

anal fissure A painful ulcer at the margin of the anus.

analgesia Pain relief or pain suppression.

anaphylaxis The widespread reaction that occurs in response to contact with a substance to which the person has a severe allergy (antigen); characterized by blood vessel and bronchiolar smooth muscle involvement causing widespread blood vessel dilation, decreased cardiac output, and bronchoconstriction; results in cell damage and the release of large amounts of histamine, severe hypovolemia, vascular collapse, decreased cardiac contraction, and dysrhythmias and causes extreme whole-body hypoxia.

anasarca Generalized edema.

anastomosis Surgical reattachment. Also a general term meaning "a connection."

anatomic dead space Places in which air flows but the structures are too thick for gas exchange.

anemia A clinical sign of some abnormal condition related to a reduction in one of the following: number of red blood cells, amount of hemoglobin, or hematocrit (percentage of packed red blood cells per deciliter of blood).

anergy The inability to mount an immune response to an antigen.

anesthesia An induced state of partial or total loss of sensation with or without loss of consciousness.

aneuploid (aneuploidy) An abnormal karyotype with more or fewer than 23 pairs of chromosomes.

aneurysm A permanent localized dilation of an artery (to at least 2 times its normal diameter) that forms when the middle layer (media) of the artery is weakened, stretching the inner (intima) and outer (adventitia) layers. As the artery widens, tension in the wall increases and further widening occurs, thus enlarging the aneurysm.

aneurysmectomy A surgical procedure performed to excise an aneurysm.

angina pectoris Literally, "strangling of the chest"; a temporary imbalance between the ability of the coronary arteries to supply oxygen and the demand for oxygen by the cardiac muscle. As a result, the patient experiences chest discomfort.

angioedema Diffuse swelling resulting from a vascular reaction in the deep tissues; can occur in a patient having an anaphylactic reaction.

anion Ion that has a negative charge.

anisocoria A difference in the size of the pupils.

ankle-brachial index (ABI) A ratio derived by dividing the ankle blood pressure by the brachial blood pressure; this calculation is used to assess the vascular status of the lower extremities. To obtain the ABI, a blood pressure cuff is applied to the lower extremities just above the malleoli. The systolic pressure is measured by Doppler ultrasound at both the dorsalis pedis and posterior tibial pulses. The higher of these two pressures is then divided by the higher of the two brachial pulses.

anomia Inability to find words.

anorectal abscess A localized induration and fluctuance that is caused by inflammation of the soft tissue near the rectum or anus and is most often the result of obstruction of the ducts of glands in the anorectal region by feces, foreign bodies, or trauma.

anorectic drugs Drugs that suppress appetite, which reduces food intake and, over time, may result in weight loss; may be prescribed for obese patients in a comprehensive weight reduction program.

anorexia The loss of appetite for food.

anorexia nervosa An eating disorder of self-induced starvation resulting from a fear of fatness, even though the patient is underweight.

anorexin Neuropeptide that decreases appetite.

anoxic Completely lacking oxygen.

antalgic (gait) A term that refers to an abnormality in the stance phase of gait. When part of one leg is painful, the person shortens the stance phase on the affected side.

anterior colporrhaphy Surgery for severe symptoms of cystocele in which the pelvic muscles are tightened for better bladder support.

anterior nares The nostrils or external openings into the nasal cavities.

antibody-mediated immunity (AMI) or antibody-mediated immune system The defense response that produces antibodies directed against certain pathogens. The antibodies inactivate the pathogens and protect against future infection from that microorganism.

antidepressants A group of drugs that help manage clinical depression.

antiepileptic drugs (AEDs) A class of drugs used to control seizures. Also called "anticonvulsants."

antigen A foreign protein or allergen that is capable of causing an immune response; protein on the surface of a cell.

anuria Complete lack of urine output; usually defined as less than 100 mL/24 hr.

aortic regurgitation The flow of blood from the aorta back into the left ventricle during diastole; occurs when the aortic valve leaflets do not close properly during diastole and the annulus (the valve ring that attaches to the leaflets) is dilated or deformed.

aortic stenosis Narrowing of the aortic valve orifice and obstruction of left ventricular outflow during systole.

aphasia Inability to use or comprehend spoken or written language due to brain injury or disease.

apheresis A procedure in which whole blood is withdrawn from the patient, a blood component (e.g., stem cells) is filtered out, and the plasma is returned to the patient.

aphonia Inability to produce sound; complete but temporary loss of the voice.

aphthous stomatitis Noninfectious stomatitis.

apical impulse The pulse located at the left fifth intercostal space in the midclavicular line in the mitral area (the apex of the heart). Also called the "point of maximal impulse."

apolipoprotein E One of several regulators of lipoprotein metabolism.

appendectomy Surgical removal of the inflamed appendix.

appendicitis Acute inflammation of the vermiform appendix, which is the blind pouch attached to the cecum of the colon, usually located in the right iliac region just below the ileocecal valve.

approximated In a clean laceration or a surgical incision to be closed with sutures or staples, the act of bringing together the wound edges with the skin layers lined up in correct anatomic position so they can be held in place until healing is complete.

apraxia The loss of the ability to carry out a purposeful motor activity.

aqueous humor The clear, watery fluid that is continually produced by the ciliary processes and fills the anterior and posterior chambers of

the eye. This fluid drains through the canal of Schlemm into the blood to maintain balanced intraocular pressure (pressure within the eye).

arcus senilis An opaque ring within the outer edge of the cornea caused by fat deposits. Its presence does not affect vision.

areflexic bladder Urinary retention and overflow (dribbling) caused by injuries to the lower motor neuron at the spinal cord level of S2 to S4 (e.g., multiple sclerosis and spinal cord injury below T12). Bladder emptying may be achieved by performing a Valsalva maneuver or tightening the abdominal muscles. The effectiveness of these maneuvers should be ascertained by catheterizing the patient for residual urine after voiding. Also called "flaccid bladder."

arrhythmogenic right ventricular cardiomyopathy (dysplasia) A form of cardiomyopathy that results from the replacement of myocardial tissue with fibrous and fatty tissue.

arterial revascularization The surgical procedure most commonly used to increase arterial blood flow in the affected limb of a patient with peripheral arterial disease.

arterial ulcers A painful complication in the patient with peripheral arterial disease. Typically, the ulcer is small and round, with a "punched out" appearance and well-defined borders. Ulcers develop on the toes (often the great toe), between the toes, or on the upper aspect of the foot. With prolonged occlusion, the toes can become gangrenous.

arteriography Angiography of the arterial vessels; this invasive diagnostic procedure involves fluoroscopy and the use of a contrast medium and is performed when an arterial obstruction, narrowing, or aneurysm is suspected.

arteriosclerosis A thickening, or hardening, of the arterial wall.

arteriotomy A surgical opening into an artery.

arteriovenous malformation (AVM) An abnormality that occurs during embryonic development, resulting in a tangled mass of malformed, thin-walled, dilated vessels. The congenital absence of a capillary network in these vessels forms an abnormal communication between the arterial and venous systems and increases the risk that the vessels may rupture, causing bleeding, such as into the subarachnoid space or into the intracerebral tissue with brain AVMs. In the absence of the capillary network, the thin-walled veins are subjected to arterial

pressure.

arthralgia Pain in a joint.

arthritis Inflammation of one or more joints.

arthrodesis The surgical fusion of a joint.

arthrogram An x-ray study of a joint after contrast medium (air or solution) has been injected to enhance its visualization.

arthroscopy Procedure in which a fiberoptic tube is inserted into a joint for direct visualization of the ligaments, menisci, and articular surfaces of the joint.

articulations Joint surfaces.

artifact In the electrocardiogram, interference that is seen on the monitor or rhythm strip and may look like a wandering or fuzzy baseline; can be caused by patient movement, loose or defective electrodes, improper grounding, or faulty equipment.

ascending tracts Groups of nerves that originate in the spinal cord and end in the brain.

ascites The accumulation of free fluid within the peritoneal cavity. Increased hydrostatic pressure from portal hypertension causes this fluid to leak into the peritoneal cavity.

assistive/adaptive device Any item that enables the patient to perform all or part of an activity independently.

assistive technology Electronic equipment that increases the ability of disabled patients to care for themselves.

asterixis A coarse tremor characterized by rapid, nonrhythmic extensions and flexions in the wrists and fingers; a motor disturbance seen in portal-systemic encephalopathy. Also called a “liver flap” or “flapping tremor.”

asthma A chronic respiratory condition in which reversible airflow obstruction in the airways occurs intermittently.

astigmatism A refractive error caused by unevenly curved surfaces on or in the eye (especially of the cornea) that distort vision.

ataxia Gait disturbance or loss of balance.

atelectasis Collapse of alveoli.

atelectrauma Shear injury to alveoli from opening and closing.

atherectomy An invasive nonsurgical technique in which a high-speed, rotating metal burr uses fine abrasive bits to scrape plaque from inside an artery while minimizing damage to the vessel surface.

atherosclerosis A type of arteriosclerosis that involves the formation of plaque within the arterial wall; the leading contributor to coronary artery and cerebrovascular disease.

atrial fibrillation (AF) A cardiac dysrhythmia in which multiple rapid impulses from many atrial foci, at a rate of 350 to 600 times per minute, depolarize the atria in a totally disorganized manner, with no P waves, no atrial contractions, a loss of the atrial kick, and an irregular ventricular response.

atrial gallop An abnormal fourth heart sound that occurs as blood enters the ventricles during the active filling phase at the end of ventricular diastole; may be heard in patients with hypertension, anemia, ventricular hypertrophy, myocardial infarction, aortic or pulmonic stenosis, and pulmonary emboli.

atrioventricular (AV) junction In the cardiac conduction system, the area consisting of a transitional cell zone, the atrioventricular (AV) node itself, and the bundle of His. The AV node lies just beneath the right atrial endocardium, between the tricuspid valve and the ostium of the coronary sinus.

attenuated The quality of making a substance weaker; for example, antigens that are used to make vaccines are specially processed to make them less likely to grow in the body.

atypical angina Angina that manifests itself as indigestion, pain between the shoulders, an aching jaw, or a choking sensation that occurs with exertion. Many women experience atypical angina.

atypical migraine The least common of the three types of migraine headaches, after migraines with aura and migraines without aura; the atypical category includes menstrual and cluster migraines.

aura A sensation that signals the onset of a headache or seizure; the patient may experience visual changes, flashing lights, or double vision.

autoamputation of the distal digits A condition in which the tips of the digits fall off spontaneously; can occur in severe cases of Raynaud's phenomenon.

autoantibodies Antibodies directed against self tissues of cells.

autocontamination The occurrence of infection in which the patient's own normal flora overgrows and penetrates the internal environment.

autodigestion Self-digestion. Specifically, the process of the stomach digesting itself if there is a break in its protective mucosal barrier.

autogenous Belonging to the person, such as a person's vein being moved from one part of the body to another.

autoimmune pancreatitis A chronic inflammatory form of pancreatitis that can also affect the bile ducts, kidneys, and other major connective tissues.

autologous blood transfusion Reinfusing the patient's own blood during surgery.

autologous bone marrow transplantation A type of bone marrow transplant in which patients receive their own stem cells, which were collected before high-dose chemotherapy.

autologous donation The donation of a patient's own blood before scheduled surgery for use, if needed, during the surgery to eliminate transfusion reactions and reduce the risk of bloodborne disease.

autolysis The spontaneous disintegration of tissue by the action of the patient's own cellular enzymes.

automaticity The ability of a cell to initiate an impulse spontaneously and repetitively; in cardiac electrophysiology, the ability of primary pacemaker cells (SA node, AV junction) to generate an electrical impulse.

autonomic dysreflexia (AD) A syndrome that affects the patient with an upper spinal cord injury; characterized by severe hypertension and headache, bradycardia, nasal stuffiness, and flushing; caused by a noxious stimulus, usually a distended bladder or constipation. This is a neurologic emergency and must be promptly treated to prevent a hypertensive brain attack.

autonomic nervous system (ANS) The part of the nervous system that is not under conscious control; consists of the sympathetic nervous system and the parasympathetic nervous system.

autonomy Ethical principle that implies a person's self-determination and self-management.

autosome Any of the 22 pairs of human chromosomes containing genes that code for all the structures and regulatory proteins needed for

normal function but do not code for the sexual differentiation of a person.

axial loading A mechanism of injury that involves vertical compression. An example is a diving accident, in which the blow to the top of the head causes the vertebrae to shatter and pieces of bone enter the spinal canal and damage the cord.

azoospermia The absence of living sperm in the semen.

azotemia An excess of nitrogenous wastes (urea) in the blood.

B

B-type natriuretic peptide (BNP) A peptide produced and released by the ventricles when the patient has fluid overload as a result of heart failure (HF).

Babinski's sign Dorsiflexion of the great toe and fanning of the other toes, which is an abnormal reflex in response to testing the plantar reflex with a pointed (but not sharp) object; indicates the presence of central nervous system disease. The normal response is plantar flexion of all toes.

bacteremia The presence of bacteria in the bloodstream.

bacteriuria Bacteria in the urine.

bad death A death embodied by pain, not having one's wishes followed at the end of one's life, isolation, abandonment, and constant agonizing about losses associated with death.

Baker's cyst Enlarged popliteal bursa.

banding See *endoscopic variceal ligation.*

barbiturate coma The use of drugs such as pentobarbital sodium or sodium thiopental at dosages to maintain complete unresponsiveness; used for patients whose increased intracranial pressure cannot be controlled by other means. These drugs decrease the metabolic demands of the brain and cerebral blood flow, stabilize cell membranes, decrease the formation of vasogenic edema, and produce a more uniform blood supply. The patient in a barbiturate coma requires mechanical ventilation, sophisticated hemodynamic monitoring, and intracranial pressure monitoring.

bariatrics Branch of medicine that manages obesity and its related diseases.

baroreceptors Sensory receptors in the arch of the aorta and at the origin of the internal carotid arteries that are stimulated when the arterial walls are stretched by an increased blood pressure.

Barrett's epithelium Columnar epithelium (instead of the normal squamous cell epithelium) that develops in the lower esophagus during the process of healing from gastroesophageal reflux disease. It is considered premalignant and is associated with an increased risk of cancer in patients with prolonged disease.

Barrett's esophagus Ulceration of the lower esophagus caused by exposure to acid and pepsin, leading to the replacement of normal distal squamous mucosa with columnar epithelium as a response to tissue injury.

base A substance that binds (reduces) free hydrogen ions in solution. Strong bases bind hydrogen ions easily; weak bases bind less readily.

Basic Cardiac Life Support (BCLS) Procedure that involves ventilating the patient who has stopped breathing, as well as giving chest compressions in the absence of a carotid pulse. Also known as "cardiopulmonary resuscitation (CPR)."

Bell's palsy Acute paralysis of cranial nerve VII; characterized by a drawing sensation and paralysis of all facial muscles on the affected side. The patient cannot close the eye, wrinkle the forehead, smile, whistle, or grimace. The face appears masklike and sags. Also called "facial paralysis."

beneficence The ethical principle of preventing harm and ensuring the patient's well-being.

benign Altered cell growth that is harmless and does not require intervention.

benign tumor cells Normal cells growing in the wrong place or at the wrong time.

bereavement Grief and mourning experienced by the survivor before and after a death.

bicaval technique Surgical technique in heart transplantation in which the intact right atrium of the donor heart is preserved by anastomoses at the recipient's superior and inferior vena cavae.

bifurcation The point of division of a single structure into two branches.

bigeminy A type of premature complex that exists when normal

complexes and premature complexes occur alternately in a repetitive two-beat pattern, with a pause occurring after each premature complex so that complexes occur in pairs.

bilateral orchiectomy The surgical removal of both testes, typically performed as palliative surgery in patients with prostate cancer. It is not intended to cure the prostate cancer but to arrest its spread by removing testosterone.

bilateral salpingo-oophorectomy (BSO) Surgical removal of both fallopian tubes and both ovaries.

biliary colic Intense pain due to obstruction of the cystic duct of the gallbladder from a stone moving through or lodged within the duct. Tissue spasm occurs in an effort to mobilize the stone through the small duct.

biliary stent A plastic or metal device that is placed percutaneously to keep a duct of the biliary system open in patients experiencing biliary obstruction.

biofilm A complex group of microorganisms that functions within a "slimy" gel coating on medical devices.

biological response modifiers (BRMs) A class of immunomodulating drugs that attempt to modify the course of disease. Also called "biologics."

biologics See *biological response modifiers.*

biomedical technician Member of the health care team who maintains the safety of adaptive and electronic devices by monitoring their function and making repairs as needed.

biotrauma Inflammatory response–mediated damage to alveoli.

bivalve To cut a cast lengthwise into two equal pieces.

black box warning A governmental designation indicating that a drug has at least one serious side effect and must be used with caution.

bladder ultrasound Less invasive test to determine postvoiding residual urine volumes for the patient with a reflex (upper motor neuron) or uninhibited bladder; often used to measure residual urine in the bladder of patients with spinal cord injury.

blanch To whiten or lighten.

blast phase cell Immature cell that divides.

bloodborne metastasis The release of tumor cells into the blood; the most common cause of cancer spread.

blood pressure (BP) The force of blood exerted against the vessel walls.

blood stem cells Immature, unspecialized (undifferentiated) cells that are capable of becoming any type of blood cell, depending on the body's needs.

Blumberg's sign Pain felt on abrupt release of steady pressure (rebound tenderness) over the site of abdominal pain.

body mass index (BMI) A measure of nutritional status that does not depend on frame size; indirectly estimates total fat stores within the body by the relationship of weight to height.

bolus feeding A method of tube feeding that involves intermittent feeding of a specified amount of enteral product at specified times during a 24-hour period, typically every 4 hours.

bone biopsy Procedure in which the physician extracts a specimen of bone tissue for microscopic examination to confirm the presence of infection or neoplasm; not commonly done today.

bone mineral density (BMD) The quality of bone that determines bone strength. It peaks between 30 and 35 years of age, when both bone resorption activity and bone-building activity occur at a constant rate. When bone resorption activity exceeds bone-building activity, bone density decreases.

bone reduction Realignment of fractured bone ends for proper healing.

bone resorption Loss of bone density due to demineralization resulting from the release of calcium from storage areas in bones.

bone scan A radionuclide test in which radioactive material is injected for visualization of the entire skeleton; used to detect tumors, arthritis, osteomyelitis, osteoporosis, vertebral compression fractures, and unexplained bone pain.

borborygmus (borborygmi) Bowel sounds, especially loud gurgling sounds, resulting from hypermotility of the bowel.

boring In pain, the type of intense pain that feels like it is going through the body.

Bouchard's nodes Swelling at the proximal interphalangeal joints in osteoarthritis involving the hands.

bowel retraining A program for patients with neurologic problems that is designed to include a combination of suppository use and a consistent toileting schedule.

bradycardia Slowness of the heart rate; characterized as a pulse rate less than 50 to 60 beats/min.

bradydysrhythmia An abnormal heart rhythm characterized by a heart rate less than 60 beats/min.

bradykinesia Slow or no movement, as seen in a patient with Parkinson disease. Also called "akinesia."

brain abscess A collection of pus that forms in the extradural, subdural, or intracerebral area of the brain as a result of a purulent infection, usually due to bacteria invading the brain directly or indirectly.

brain attack Stroke; disruption in the normal blood supply to the brain, either as an interruption in blood flow (ischemic stroke) or as bleeding within or around the brain (hemorrhagic stroke). A medical emergency that occurs suddenly, a stroke should be treated immediately to prevent neurologic deficit and permanent disability. Formerly called "cerebrovascular accident," the National Stroke Association now uses the term "brain attack" to describe stroke.

brain herniation syndrome In the patient with untreated increased intracranial pressure, protrusion (herniation) of the brain downward toward the brainstem or laterally from a unilateral lesion within one cerebral hemisphere, causing irreversible brain damage and possibly death.

breakthrough pain Additional pain that "breaks through" the pain that is being managed by mainstay analgesic drugs.

breast augmentation Cosmetic surgical procedure to enhance the size, shape, or symmetry of the breasts.

breast-conserving surgery Surgical method for breast cancer that removes the bulk of the tumor rather than the entire breast.

Broca's aphasia See *expressive aphasia*.

Broca's area An important speech area of the cerebrum. It is located in the frontal lobe and is composed of neurons responsible for the formation of words, or speech.

bronchoscopy Insertion of a tube in the airway, usually as far as the secondary bronchi, for the purpose of visualizing airway structures

and obtaining tissue samples for biopsy or culture.

bruit Swishing sound in the larger arteries (carotid, aortic, femoral, and popliteal) that can be heard with a stethoscope or Doppler probe; may indicate narrowing of the artery and is usually associated with atherosclerotic disease.

bulbar Pertaining to the muscles involved in facial expression, chewing, and speech.

bulimia nervosa An eating disorder that is characterized by episodes of binge eating in which the patient ingests a large amount of food in a short time, followed by purging behavior such as self-induced vomiting or excessive use of laxatives and diuretics.

bunion Hallux valgus deformity of the foot in which lateral deviation of the great toe causes the first metatarsal head to become enlarged.

bunionectomy Surgical removal of the hallux valgus deformity (bunion) of the foot.

butterfly rash A dry, scaly, raised rash on the face; the major skin manifestation of systemic lupus erythematosus.

C

cachexia Extreme body wasting and malnutrition that develop from an imbalance between food intake and energy use.

calciphylaxis A condition of thrombosis and skin necrosis that can occur in stage 5 chronic kidney disease.

calculi Abnormal formations of a mass of mineral salts that can occur in the body; forms in the kidney when excess calcium precipitates out of solution. Also called "stones."

calculous cholecystitis Inflammation of the gallbladder usually following and created by obstruction of the cystic duct by a stone (calculus).

callus The loose, fibrous, vascular tissue that forms at the site of a fracture as the first phase of healing and is normally replaced by hard bone as healing continues.

calyx The anatomic term for a cuplike structure.

Canadian Triage Acuity Scale (CTAS) A standardized model for triage in which lists of descriptors are used to establish the triage level.

cancellous The softer tissue inside bones that contains large spaces, or

trabeculae, that are filled with red and yellow marrow.

candidiasis An infection caused by the fungus *Candida albicans.*

canthus The place where the upper and lower eyelids meet at the corner of either side of the eye.

capillary closing pressure The amount of pressure needed to occlude skin capillary blood flow.

capillary leak syndrome The response of capillaries to the presence of biologic chemicals (mediators) that change blood vessel integrity and allow fluid to shift from the blood in the vascular space into the interstitial tissues.

Caplan's syndrome The presence of pneumoconiosis and rheumatoid nodules in the lungs; noted primarily in coal miners and asbestos workers.

capsule The layer of fibrous tissue on the outer surface of the kidney, which provides protection and support. The renal capsule itself is surrounded by layers of fat and connective tissue.

carboxyhemoglobin Carbon monoxide on oxygen-binding sites of the hemoglobin molecule.

carcinoembryonic antigen (CEA) An oncofetal antigen that may be elevated in 70% of people with colorectal cancer. CEA is not specifically associated with the colorectal cancer and may be elevated in the presence of other benign or malignant diseases and in smokers. CEA is often used to monitor the effectiveness of treatment and to identify disease recurrence.

carcinogen Any substance that changes the activity of the genes in a cell so that the cell becomes a cancer cell.

carcinogenesis Cancer development.

cardiac axis In electrocardiography (ECG), the direction of electrical current flow in the heart. The relationship between the cardiac axis and the lead axis is responsible for the deflections seen on the ECG pattern.

cardiac catheterization The most definitive but most invasive test in the diagnosis of heart disease; involves passing a small catheter into the heart and injecting contrast medium.

cardiac index A calculation of cardiac output requirements to account for differences in body size; determined by dividing the cardiac output by

the body surface area.

cardiac markers Serum studies that include troponin, creatine kinase–MB, and myoglobin.

cardiac output (CO) The volume of blood ejected by the heart each minute; normal range in adults is 4 to 7 L/min.

cardiac rehabilitation The process of actively assisting the patient with cardiac disease to achieve and maintain a productive life while remaining within the limits of the heart's ability to respond to increases in activity and stress. *Phase 1* begins with the acute illness and ends with discharge from the hospital. *Phase 2* begins after discharge and continues through convalescence at home. *Phase 3* refers to long-term conditioning.

cardiac resynchronization therapy (CRT) In patients with some types of heart failure, the use of a permanent pacemaker alone or in combination with an implantable cardioverter-defibrillator to provide biventricular pacing.

cardiac tamponade Compression of the myocardium by fluid that has accumulated around the heart; this compresses the atria and ventricles, prevents them from filling adequately, and reduces cardiac output.

cardiogenic shock Post–myocardial infarction heart failure in which necrosis of more than 40% of the left ventricle has occurred. Also called "class IV heart failure."

cardiomegaly Enlarged heart.

cardiomyopathy A subacute or chronic disease of cardiac muscle; classified into four categories based on abnormalities in structure and function: dilated, hypertrophic, restrictive, and arrhythmogenic.

cardiopulmonary bypass (CPB) Diversion of the blood from the heart to a bypass machine, where it is heparinized, oxygenated, and returned to the circulation through a cannula placed in the ascending aortic arch or femoral artery to provide oxygenation, circulation, and hypothermia during induced cardiac arrest for coronary artery bypass surgery. This process ensures a motionless operative field and prevents myocardial ischemia.

cardioversion A synchronized countershock that may be performed in emergencies for hemodynamically unstable ventricular or supraventricular tachydysrhythmias or electively for stable

tachydysrhythmias that are resistant to medical therapies. The shock depolarizes a critical mass of myocardium simultaneously during intrinsic depolarization and is intended to stop the re-entry circuit and allow the sinus node to regain control of the heart.

carina The point at which the trachea branches into the right and left mainstem bronchi.

carpal tunnel syndrome (CTS) A common condition in which the median nerve in the wrist becomes compressed, causing pain and numbness.

carrier (1) A person who harbors an infectious agent without symptoms of active disease; (2) in genetics, a person who has one mutated allele for a recessive genetic disorder. A carrier does not usually have any manifestations of the disorder but can pass the mutated allele to his or her children.

case management The process of assessment, planning, implementation, evaluation, and interaction for patients who have complex health problems and incur a high cost to the health care system. Goals include promoting quality of life, decreasing fragmentation and duplication of care across health care settings, and maintaining cost-effectiveness.

caseation necrosis A type of necrosis in which tissue is turned into a granular mass.

cast A rigid device that immobilizes the affected body part while allowing other body parts to move. It is most commonly used for fractures but may also be applied to correct deformities (e.g., clubfoot) or to prevent deformities (e.g., those seen in some patients with rheumatoid arthritis).

cataract A lens opacity that distorts the image projected onto the retina.

catechol O-methyltransferases (COMTs) Enzymes that inactivate dopamine.

catecholamines Hormones (dopamine, epinephrine, and norepinephrine) released by the adrenal medulla in response to stimulation of the sympathetic nervous system.

cation Ion that has a positive charge.

cell-mediated immunity Microbial resistance that is mediated by the action of specifically sensitized T-lymphocytes.

cellulitis An acute, spreading, edematous inflammation of the deep

subcutaneous tissues; usually caused by infection of a wound or burn.

central IV therapy IV therapy in which a vascular access device (VAD) is placed in a central blood vessel, such as the superior vena cava.

cerebral angiography (arteriography) Visualization of the cerebral circulation (carotid and vertebral arteries) after injecting a contrast medium into an artery (usually the femoral).

cerebral blood flow (CBF) Useful in evaluating cerebral vasospasm; can be measured in many areas of the brain with the use of radioactive substances.

cerebral perfusion pressure (CPP) The pressure gradient over which the brain is perfused. It is influenced by oxygenation, cerebral blood volume, blood pressure, cerebral edema, and intracranial pressure (ICP) and is determined by subtracting the mean ICP from the mean arterial pressure. A cerebral perfusion pressure above 70 mm Hg is generally accepted as an appropriate goal of therapy.

cerebral salt wasting (CSW) The primary cause of hyponatremia in the neurosurgical population; characterized by hyponatremia, decreased serum osmolality, and decreased blood volume. It is thought to result from the extrarenal influence of atrial natriuretic factor.

cerumen The wax produced by glands within the external ear canal; helps protect and lubricate the ear canal.

cervical polyp Tumor that arises from the mucosa and extends to the opening of the cervical os. Polyps result from hyperplasia of the endocervical epithelium, inflammation, or an abnormal local response to hormonal stimulation or localized vascular congestion of the cervical blood vessels. Polyps are the most common benign growth of the cervix.

$CHADS_2$ scoring system Acronymn for Congestive heart failure, Hypertension, Age ≥ 75 years, Diabetes mellitus, Stroke. Determines if a patient with atrial fibrillation needs preventive anticoagulant therapy.

chalazion An inflammation of a sebaceous gland in the eyelid.

chancre The ulcer that is the first sign of syphilis. It develops at the site of entry (inoculation) of the organism, usually 3 weeks after exposure. The lesion may be found on any area of the skin or mucous membranes but occurs most often on the genitalia, lips, nipples, and hands and in the oral cavity, anus, and rectum.

chemotherapy The treatment of cancer with chemical agents that have systemic effects; used to cure and to increase survival time.

chemotherapy-induced peripheral neuropathy (CIPN) The loss of sensory or motor function of peripheral nerves associated with exposure to certain anticancer drugs.

chest tube A drain placed in the pleural space to allow closed–chest drainage, which restores intrapleural pressure and allows re-expansion of the lung after surgery in patients who have undergone thoracotomy (incision of the chest wall).

Cheyne-Stokes respirations Common sign of nearing death in which apnea alternates with periods of rapid breathing.

choked disc See *papilledema.*

cholecystectomy The surgical removal of the gallbladder.

cholecystitis Inflammation of the gallbladder.

cholecystokinin A hormone that stimulates digestive juices and may work with leptin to increase or decrease appetite.

choledochojejunostomy Surgical anastomosis of the common bile duct with the jejunum.

cholelithiasis The presence of gallstones.

cholesteatoma A benign overgrowth of squamous cell epithelium.

cholesterol Serum lipid that includes high-density lipoproteins and low-density lipoproteins.

cholinergic crisis Overmedication with cholinesterase inhibitors.

cholinesterase inhibitors Drugs that improve cholinergic neurotransmission in the central nervous system by delaying the destruction of acetylcholine by acetylcholinesterase, thus delaying the onset of cognitive decline. These are approved for symptomatic treatment of Alzheimer's disease but do not affect the course of the disease.

chondroitin A supplement that may play a role in strengthening cartilage.

choreiform movement Rapid, jerky movement.

chronic Having a slow onset and symptoms that persist for an extended period.

chronic calcifying pancreatitis (CCP) Alcohol-induced chronic pancreatitis that is characterized by protein precipitates that plug the ducts and lead to ductal obstruction, atrophy, and dilation. The epithelium of the ducts undergoes histologic changes, resulting in metaplasia (cell replacement) and ulceration. This inflammatory process causes fibrosis of the pancreatic tissue.

chronic constrictive pericarditis A fibrous thickening of the pericardium that prevents adequate filling of the ventricles and eventually results in cardiac failure; caused by chronic pericardial inflammation due to tuberculosis, radiation therapy, trauma, kidney failure, or metastatic cancer.

chronic fatigue syndrome (CFS) A chronic illness characterized by severe fatigue for 6 months or longer, usually following flu-like symptoms. At least four of the following criteria are required for diagnosis: sore throat; substantial impairment in short-term memory or concentration; tender lymph nodes; muscle pain; multiple joint pain with redness or swelling; headaches of a new type, pattern, or severity; unrefreshing sleep; and postexertional malaise lasting more than 24 hours.

chronic gastritis A patchy, diffuse inflammation of the mucosal lining of the stomach. Chronic gastritis usually heals without scarring but can progress to hemorrhage and ulcer formation.

chronic health problem A condition that has existed for at least 3 months.

chronic hepatitis Chronic liver inflammation that usually occurs as a result of hepatitis B or C. Superimposed infection with hepatitis D virus (HDV) in patients with chronic hepatitis B may also result in chronic hepatitis. Can lead to cirrhosis and liver cancer.

chronic kidney disease (CKD) A condition characterized by loss of kidney function over time.

chronic obstructive pancreatitis Pancreatitis that develops from inflammation, spasm, and obstruction of the sphincter of Oddi. Inflammatory and sclerotic lesions occur in the head of the pancreas and around the ducts, causing obstruction and backflow of pancreatic secretions.

chronic osteomyelitis Bone infection that persists over a long time due to misdiagnosis or inadequate treatment. Also called “subchronic osteomyelitis.”

chronic pain Pain that persists or recurs for indefinite periods (usually more than 3 months), often involves deep body structures, is poorly localized, and is difficult to describe. Also called "persistent pain."

chronic pancreatitis A progressive, destructive disease of the pancreas characterized by remissions and exacerbations. Inflammation and fibrosis of the tissue contribute to pancreatic insufficiency and diminished function of the organ.

chronic paronychia Inflammation of the skin around the nail that persists for months. People at risk for chronic paronychia are those with frequent exposure to water, such as homemakers, bartenders, and laundry workers.

chronic pyelonephritis A kidney disorder that results from repeated or continued upper urinary tract infections or the effects of such infections.

chronic stable angina (CSA) Type of angina characterized by chest discomfort that occurs with moderate to prolonged exertion and in a pattern that is familiar to the patient.

chyme The liquid formed when food is transformed during the digestion process in the gastrointestinal tract.

circle of Willis At the base of the brain, the ring formed by the anterior, middle, and posterior cerebral arteries where they are joined together by small communicating arteries.

circumcision The surgical removal of the prepuce or foreskin of the penis.

circumferential Referring to something that completely surrounds an extremity or the thorax.

cirrhosis Liver disease that is characterized by extensive scarring of the liver and is usually caused by a chronic irreversible reaction to hepatic inflammation and necrosis; disease typically develops insidiously and has a prolonged, destructive course.

classic heat stroke A form of heat stroke in which the body's ability to dissipate heat is significantly impaired; occurs over time as a result of long-term exposure to a hot, humid environment such as a home without air-conditioning in the high heat of the summer.

clinical practice guideline An "official recommendation" based on evidence to diagnose and/or manage a health problem (e.g., pain management).

clinical psychologist Member of the health care team who counsels patients and families on their psychological problems and on strategies to cope with disability.

clinically competent The condition of being legally competent and having decisional capacity.

clonic (rhythmic) Pertaining to a state of alternating muscle stiffness followed by rhythmic jerking motions, as in a tonic-clonic seizure.

clonus The sudden, brief, jerking contraction of a muscle or muscle group often seen in seizures. Also called "myoclonus."

closed fracture A fracture that does not extend through the skin and therefore has no visible wound. Also called "simple fracture."

closed reduction A nonsurgical method for managing a simple fracture. While applying a manual pull, or traction, on the bone, the health care provider manipulates the bone ends so they realign.

closed traumatic brain injury A type of traumatic primary brain injury that occurs as the result of blunt trauma; the integrity of the skull is not violated, and damage to brain tissue depends on the degree and mechanisms of injury.

***C. difficile*–associated disease (CDAD)** Clinical manifestations that are caused by *Clostridium difficile* as a potential result of antibiotic therapy use, especially in older adults.

clubbing Changes in the tissue beds of the fingers and toes, with the base of the nail becoming spongy; results from chronic oxygen deprivation in the tissue beds.

cluster headache A type of oculotemporal or oculofrontal headache marked by unilateral, excruciating, nonthrobbing pain that is felt deep in and around the eye and may radiate to the forehead, temple, cheek, ear, occiput, or neck. Average duration is 10 to 45 minutes. Headaches occur every 8 to 12 hours and up to 24 hours daily at the same time for about 6 to 8 weeks (hence the term "cluster"), followed by remission for 9 months to a year. Cause and mechanism are unknown but have been attributed to vasoreactivity and oxyhemoglobin desaturation.

clysis See *hypodermoclysis.*

coagulopathy Clotting abnormalities.

cognition The ability of the brain to process, store, retrieve, and manipulate information.

cognitive therapist A member of the rehabilitative health care team, usually a neuropsychologist, who works primarily with patients who have experienced head injuries and have cognitive impairments.

cohorting The practice of grouping patients who are colonized or infected with the same pathogen.

cold antibody anemia A form of immunohemolytic anemia (in which the immune system attacks a person's own red blood cells for unknown reasons) that occurs with complement protein fixation on immunoglobulin M (IgM). In this condition, the arteries in the hands and feet constrict profoundly in response to cold temperatures or stress.

cold phase A phase after peripheral nerve trauma resulting in complete denervation in which the skin appears cyanotic, mottled, or reddish blue and feels cool compared with the contralateral unaffected extremity. The cold phase follows the warm phase, which lasts 2 to 3 weeks after injury.

colectomy Surgical removal of part or all of the colon.

collaboration The planning, implementing, and evaluation of patient care using an interdisciplinary (ID) plan of care.

collateral circulation Circulation that provides blood to an area with altered tissue perfusion through smaller vessels that develop and compensate for the occluded vessels.

colon interposition A surgical procedure that may be performed in patients with an esophageal tumor when the tumor involves the stomach or the stomach is otherwise unsuitable for anastomosis. In colon interposition, a section of right or left colon is removed and brought up into the thorax to substitute for the esophagus.

colon resection Surgery performed for colorectal cancer in which the tumor and regional lymph nodes are removed.

colonoscopy The endoscopic examination of the entire large bowel.

colostomy The surgical creation of an opening between the colon and the surface of the abdomen.

colposcopy Examination of the cervix and vagina using a colposcope, which allows three-dimensional magnification and intense illumination of epithelium with suspected disease. This procedure can locate the exact site of precancerous and malignant lesions for biopsy.

command center See *emergency operations center.*

commando procedure Mnemonic for combined neck dissection, mandibulectomy, and oropharyngeal resection—a procedure in which the surgeon removes a segment of the mandible with the oral lesion and performs a radical neck dissection.

communicable The ability of an infection, such as influenza, to be transmitted from person to person.

communicating hydrocephalus Form of hydrocephalus that occurs when the flow of cerebrospinal fluid (CSF) is blocked after it exits the ventricles; this form is "communicating" because CSF can still flow between the ventricles, which remain open.

compartment syndrome A condition in which increased tissue pressure in a confined anatomic space causes decreased blood flow to the area, leading to hypoxia and pain.

compensated cirrhosis A form of cirrhosis in which the liver has significant scarring but is still able to perform essential functions without causing significant symptoms.

compensatory mechanism The means of producing compensation. Also called "adaptive mechanism."

complement activation and fixation Actions triggered by some classes of antibodies that can remove or destroy antigen.

complete spinal cord injury An injury in which the spinal cord has been severed or damaged in a way that eliminates all innervation below the level of the injury.

complex regional pain syndrome (CRPS) A complex disorder that includes debilitating pain, atrophy, autonomic dysfunction (excessive sweating, vascular changes), and motor impairment (most notably muscle paresis), probably caused by an abnormally hyperactive sympathetic nervous system. This syndrome most often results from traumatic injury and commonly occurs in the feet and hands; formerly called "reflex sympathetic dystrophy (RSD)."

compliance In respiratory physiology, a measure of elasticity within the lung. Also, a patient's fulfillment of a caregiver's prescribed course of treatment.

compound fracture See *open fracture.*

compression fracture A fracture that is produced by a loading force

applied to the long axis of cancellous bone. These fractures commonly occur in the vertebrae of patients with osteoporosis.

computed tomography coronary angiography (CTCA) 64-slice diagnostic scan used to diagnose coronary artery disease in symptomatic patients.

conductive hearing loss Hearing loss that results from any physical obstruction of sound wave transmission (e.g., a foreign body in the external canal, a retracted or bulging tympanic membrane, or fused bony ossicles).

conductivity The ability of a cell to transmit an electrical stimulus from cell membrane to cell membrane.

congestive heart failure (CHF) Former term for "left-sided heart failure." Categorized as either systolic heart failure or diastolic heart failure, which may be acute or chronic and mild to severe.

conization The removal of a cone-shaped sample of tissue from the cervix for cytologic study.

conjunctivae The mucous membranes of the eye that line the undersurface of the eyelids (palpebral conjunctiva) and cover the sclera (bulbar conjunctiva).

connective tissue disease (CTD) A group of diseases that are the major focus of rheumatology (the study of rheumatic diseases); most are musculoskeletal disorders.

consensual response In assessing pupillary reaction to light, a slight constriction of the pupil of the eye not being tested when a penlight is brought in from the side of the patient's head and shined into the eye being tested as soon as the patient opens his or her eyes.

consolidation Solidification; lack of air spaces in the lung, such as occurs in pneumonia.

constipation The passage of hard, dry stool fewer than 3 times a week (as defined by the Association of Rehabilitation Nurses).

contact laser prostatectomy (CLP) Procedure for treating benign prostatic hyperplasia that uses laser energy to coagulate excess tissue. Also called "interstitial laser coagulation (ILC)."

Contact Precautions Infection control guidelines from the Centers for Disease Control and Prevention; used for patients with infections spread by direct contact or contact with items in the patient's

environment, such as pediculosis.

contiguous Something in direct contact with, or adjacent to, another area or structure.

continence The ability to voluntarily control emptying the bladder and colon. Continence is a learned behavior whereby a person can suppress the urge to urinate until a socially appropriate location is available.

continuous feeding A method of tube feeding in which small amounts of enteral product are continuously infused (by gravity drip or by a pump or controller device) over a specified time.

continuous positive airway pressure (CPAP) A respiratory treatment that improves obstructive sleep apnea in patients with heart failure.

contractility The ability of a cell to contract in response to an impulse. In cardiac electrophysiology, the ability of atrial and ventricular muscle cells to shorten their fiber length in response to electrical stimulation, generating sufficient pressure to propel blood forward. Contractility is the mechanical activity of the heart.

contraction The closure of a wound as new collagen replaces damaged tissue, pulling the wound edges inward along the path of least resistance.

contralateral Pertaining to the opposite side.

contrecoup injury Bruising of the brain tissue, with damage occurring on the side opposite the site of impact.

control therapy drugs Drugs used every day, regardless of symptoms, to reduce airway responsiveness to prevent asthma attacks from occurring.

contusion A bruise; when referring to closed head injury, a bruising of brain tissue usually found at the site of impact (coup injury). Compare with *contrecoup injury.*

cor pulmonale Right-sided heart failure caused by pulmonary disease.

cordectomy Excision of a vocal cord in surgery for laryngeal cancer.

cornea The clear layer that forms the external coat on the front of the eye.

corneal abrasion Scrape or scratch of the cornea that disrupts its integrity.

corneal ulceration Deep disruption of the corneal epithelium that

extends into the stromal layer and is caused by bacteria, protozoa, or fungi.

coronary artery bypass graft (CABG) A surgical procedure in which occluded coronary arteries are bypassed with the patient's own venous or arterial blood vessels or synthetic grafts.

coronary artery disease (CAD) Disease affecting the arteries that provide blood, oxygen, and nutrients to the myocardium; partial or complete blockage of the blood flow through the coronary arteries, causing ischemia and infarction of the myocardium, angina pectoris, and acute coronary syndromes. Also known as "coronary heart disease" or simply "heart disease."

coronary artery vasculopathy (CAV) A form of coronary artery disease that presents as diffuse plaque in the arteries of the donor heart in patients who have received a heart transplant.

cortisol The main glucocorticoid produced by the adrenal cortex.

coryza The common cold, or acute viral rhinitis.

cough assist A technique for assisting the tetraplegic patient to cough. Place his or her hands on either side of the rib cage or upper abdomen below the diaphragm; then, as the patient inhales, push upward to help expand the lungs and cough.

craniotomy Surgical incision into the cranium.

creatine kinase (CK) An enzyme specific to cells of the brain, myocardium, and skeletal muscle. Its appearance in the blood indicates tissue necrosis or injury, with levels following a predictable rise and fall during a specified period.

Credé maneuver A technique used to assist in urination in which a patient places his or her hand in a cupped position directly over the bladder area and pushes inward and downward gently as if massaging the bladder to empty.

crepitus A continuous grating sensation caused when irregular cartilage or bone fragments rub together and which may be felt or heard as a joint is put through passive range of motion; also, a crackling sensation that can be felt on a patient's chest, indicating that air is trapped within the tissues.

CREST syndrome In patients with systemic sclerosis, the combination of **c**alcinosis (calcium deposits), **R**aynaud's phenomenon, **e**sophageal dysmotility, **s**clerodactyly (scleroderma of the digits), and

telangiectasia (spider-like hemangiomas).

cricothyroidotomy Surgical procedure in which an opening is made between the thyroid cartilage and cricoid cartilage ring and results in a tracheostomy. Also called "cricothyrotomy." The procedure is used in an emergency for access to the lower airways.

crises In the patient with sickle cell disease, periodic episodes of extensive cellular sickling that have a sudden onset and can occur as often as weekly or as seldom as once a year.

critical access hospital A small rural facility of 15 or fewer inpatient beds that provides around-the-clock emergency care services 7 days per week. Considered a necessary provider of health care to community residents who are not close to other hospitals in a given region.

cross-contamination A type of contamination in which organisms from another person or from the environment are transmitted to the patient.

cryotherapy (1) A way of decreasing muscle pain by "cooling down" the area with a local, short-acting gel or cream, such as after physical therapy; (2) in ophthalmologic surgery, use of a freezing probe to repair retinal detachment.

cryptorchidism Failure of the testes to descend into the scrotum.

culture A procedure for identifying a microorganism by cultivating and isolating it in tissue cultures or artificial media.

Curling's ulcer Acute ulcerative gastroduodenal disease, which may develop within 24 hours of a severe burn injury because of reduced gastrointestinal blood flow and mucosal damage.

Cushing's disease (Cushing's syndrome) Hypercortisolism caused by oversecretion of hormones by the adrenal cortex.

Cushing's triad A classic yet late sign of increased intracranial pressure (ICP) manifested by severe hypertension with a widened pulse pressure and bradycardia. As ICP increases, the pulse becomes thready, irregular, and rapid. Cerebral blood flow increases in response to hypertension.

Cushing's ulcer Acute ulcerative gastroduodenal disease that may develop as a result of increased intracranial pressure.

cutaneous (superficial) reflexes Superficial reflexes. Usually the plantar and abdominal reflexes are tested.

cyanosis Bluish or darkened discoloration of the skin and mucous membranes; results from an increased amount of deoxygenated hemoglobin.

cyclic feeding A method of tube feeding similar to continuous feeding (see definition of *continuous feeding*) except the infusion is stopped for a specified time in each 24-hour period ("down time"); the down time typically occurs in the morning to allow bathing, treatments, and other activities.

cystitis Inflammation of the bladder.

cystocele Herniation of the bladder into the vagina.

cytokines Small protein hormones produced by white blood cells.

cytotoxic Having cell-damaging effects.

D

dandruff An accumulation of patchy or diffuse white or gray scales on the surface of the scalp.

death When illness or trauma overwhelms the compensatory mechanisms of the body and the lungs and heart cease to function.

death rattle Loud, wet respirations caused by secretions in the respiratory tract and oral cavity of a patient who is near death.

débridement The removal of infected tissue from a healing wound.

debriefing After a mass casualty incident or disaster, (1) the provision of sessions for small groups of staff in which teams are brought in to discuss effective coping strategies (critical incident stress debriefing), and (2) the administrative review of staff and system performance during the event to determine opportunities for improvement in the emergency management plan.

debris Dead cells and tissues in a wound.

decerebrate posturing Abnormal posturing and rigidity characterized by extension of the arms and legs, pronation of the arms, plantar flexion, and opisthotonos; usually associated with dysfunction in the brainstem area. Also called "decerebration."

decerebration See *decerebrate posturing.*

decompensated cirrhosis A form of cirrhosis in which liver function is significantly impaired with obvious manifestations of liver failure.

decompressive craniectomy Removal of a section of the skull in the patient with uncontrolled intracranial pressure (ICP); allows for additional space for edema without increasing ICP.

decorticate posturing Abnormal posturing seen in the patient with lesions that interrupt the corticospinal pathways. The arms, wrists, and fingers are flexed with internal rotation and plantar flexion of the legs. Also called "decortication."

decortication See *decorticate posturing.*

deep tendon reflexes Tested as part of the neurologic assessment. An intact reflex arc is indicated when the muscle contracts in response to the tendon being struck with a reflex hammer.

deep vein thrombophlebitis Presence of a thrombus associated with inflammation in the deep veins, usually in the legs. Compared with superficial thrombophlebitis, it presents a greater risk for pulmonary embolism. Also called "deep vein thrombosis."

deep vein thrombosis (DVT) Common term for "deep vein thrombophlebitis."

defibrillation An asynchronous countershock that depolarizes a critical mass of myocardium simultaneously to stop the re-entry circuit, allowing the sinus node to regain control of the heart.

dehiscence A partial or complete separation of the outer layers of a wound, sometimes described as a "splitting open" of the wound.

dehydration Fluid intake less than what is needed to meet the body's fluid needs.

delayed union Term describing a fracture that has not healed within 6 months of injury.

delegation The process of transferring to a competent person the authority to perform a selected nursing task or activity in a selected patient care situation.

delirium An acute state of confusion, usually short-term and reversible within 3 weeks. Often seen among older adults in a hospital or other unfamiliar setting.

dementia A syndrome of slowly progressive cognitive decline with global impairment of intellectual function. The most common type is Alzheimer's disease.

demyelination Destruction of myelin between the nodes of Ranvier; a

major pathologic finding in multiple sclerosis or Guillain-Barré syndrome.

depolarization The ability of a cell to respond to a stimulus by initiating an impulse. Also called "excitability."

depression A response to multiple life stresses, a single situation, a primary disorder, or a problem associated with dementia; this response can range from mild, transient feelings of sadness to a severe sense of helplessness and hopelessness.

dermal papillae Fingerlike projections of dermal tissue that anchor the epidermis to the dermis.

dermatomes Specific areas of the skin that receive sensory input from spinal nerves.

descending tracts Groups of nerves that begin in the brain and end in the spinal cord.

desquamation The shedding or peeling of skin.

diabetic peripheral neuropathy (DPN) A progressive deterioration of nerves that results in loss of nerve function (sensory perception). A common complication of diabetes, it often involves all parts of the body.

diagnostic peritoneal lavage (DPL) Test that determines the presence of internal bleeding following abdominal trauma.

dialysate The solution used in dialysis. It is composed of water, glucose, sodium chloride, potassium, magnesium, calcium, and bicarbonate; dialysate composition may be altered according to the patient's needs for treatment of electrolyte imbalances.

dialyzer The apparatus used to perform hemodialysis. Also known as the "artificial kidney," it has four parts: a blood compartment, a dialysate compartment, a semipermeable membrane, and an enclosed structure to support the membrane.

diaphragmatic pacing A pacemaker for the phrenic nerve to cause the diaphragm to contract (leading to inhalation). Also known as "phrenic nerve pacing."

diastole The phase of the cardiac cycle that consists of relaxation and filling of the atria and ventricles; normally about two thirds of the cardiac cycle.

diastolic blood pressure The amount of pressure/force against the

arterial walls during the relaxation phase of the heart.

diastolic heart failure Heart failure that occurs when the left ventricle is unable to relax adequately during diastole, which prevents the ventricle from filling with sufficient blood to ensure adequate cardiac output.

Dietary Guidelines for Americans Recommendations made by the USDA and U.S. Department of Health and Human Services to help people maintain nutritional health; updated every 5 years.

Dietary Reference Intakes (DRIs) Nutrition guide developed by the Institute of Medicine of the National Academies that provides a scientific basis for food guidelines in the United States and Canada.

diffuse axonal injury (DAI) A type of closed head injury that is usually related to high-speed acceleration/deceleration, as with motor vehicle crashes. There is significant damage to axons in the white matter, and there are lesions in the corpus callosum, midbrain, cerebellum, and upper brainstem. Patients with severe injury may present with immediate coma, and most survivors require long-term care.

diffuse cutaneous systemic sclerosis Skin thickening on the trunk, face, and proximal and distal extremities in patients with systemic sclerosis.

diffuse light reflex A description of a light reflex that is spotty or multiple because of a changed eardrum shape from either retraction or bulging.

diffusion The spontaneous, free movement of particles (solute) across a permeable membrane down a concentration gradient; that is, from an area of higher concentration to an area of lower concentration.

digestion The mechanical and chemical process in which complex foodstuffs are broken down into simpler forms that can be used by the body.

digoxin toxicity A reaction to therapy with digitalis derivatives (digoxin) that is identified by monitoring serum digoxin and potassium levels (hypokalemia potentiates digitalis toxicity). Signs of toxicity are nonspecific (anorexia, fatigue, changes in mental status). Toxicity may cause dysrhythmia, most commonly premature ventricular contractions.

dilated cardiomyopathy (DCM) A type of cardiomyopathy that involves extensive damage to the myofibrils and interference with myocardial metabolism. There is normal ventricular wall thickness but dilation of

both ventricles and impairment of systolic function.

dilation Increase in the diameter of blood vessels.

diplopia Double vision.

direct current stimulation (DCS) The placement of an implantable device to promote bone fusion; used as an adjunct for patients for whom spinal fusion may be difficult.

direct inguinal hernia A sac formed from the peritoneum that contains a portion of the intestine and passes through a weak point in the abdominal wall.

direct response Pupil constriction in response to bringing a penlight in from the side of the patient's head and shining the light in the eye being tested as soon as the patient opens his or her eyes.

directly observed therapy (DOT) A technique in which a health care professional watches the patient swallow prescribed drugs.

disabling health problem Any physical or mental health problem that can cause disability.

disaster A mass casualty incident in which the number of casualties exceeds the resource capabilities of a particular community or hospital facility.

disaster triage tag system A system that categorizes triage priority by colored and numbered tags.

discoid lesion Round lesion in patients who have discoid lupus erythematosus; evident when exposed to sunlight or ultraviolet light.

disease-modifying antirheumatic drugs (DMARDs) Drugs prescribed to slow the progression of mild rheumatoid disease before it worsens, such as hydroxychloroquine, sulfasalazine, or minocycline.

disequilibrium A condition in which the hydrostatic pressure is not the same in the two fluid spaces on either side of a permeable membrane.

disinfection A method of infection control in which the level of disease-causing organisms is reduced but the organisms are not killed; adequate when an item is entering a body area that has resident bacteria or normal flora, such as the respiratory tract.

diskitis Disk inflammation.

dislocation of a joint Occurrence of the articulating surfaces of two or more bones moving away from each other.

dissociate The act of separating and releasing ions.

diverticula Sacs resulting from the herniation of the mucosa and submucosa of a tubular organ into surrounding tissue.

diverticulitis The inflammation of one or more diverticula.

diverticulosis The presence of many abnormal pouchlike herniations (diverticula) in the wall of the intestine.

dizziness A disturbed sense of a person's relationship to space.

DNR Do not resuscitate; order from a physician or other authorized health care provider who instructs that CPR not be attempted in the event of cardiac or respiratory arrest.

dopamine agonist A class of drugs that mimic dopamine. Dopamine agonists stimulate dopamine receptors and are typically the most effective during the first 3 to 5 years of use. Prescribed for the patient with Parkinson disease to reduce dyskinesias (problems with movement).

dose-dense chemotherapy Chemotherapy that uses higher doses more often for aggressive cancer treatment, especially breast cancer.

double-barrel stoma The least common type of colostomy, which is created by dividing the bowel and bringing both the proximal and distal portions to the abdominal surface to create two stomas.

doubling time The amount of time it takes for a tumor to double in size.

Droplet Precautions Infection control guidelines from the Centers for Disease Control and Prevention; used for patients with infections spread by the droplet transmission route, such as influenza.

drug holiday Period of time lasting up to 10 days in which the patient with Parkinson disease receives no drug therapy.

dual x-ray absorptiometry (DXA or DEXA) A type of radiographic scan that measures bone mineral density in the hip, wrist, or vertebral column; used as a screening and diagnostic tool for diagnosis and for follow-up evaluation of treatment of osteoporosis.

ductal carcinoma in situ (DCIS) An early, noninvasive form of breast cancer in which cancer cells are located within the duct and have not invaded the surrounding fatty breast tissue.

ductal ectasia A benign breast disease caused by dilation and thickening of the collecting ducts in the subareolar area. The ducts become distended and filled with cellular debris, which activates an

inflammatory response. It is usually seen in women approaching menopause.

dumping syndrome A constellation of vasomotor symptoms that typically occur within 30 minutes after eating; believed to occur as a result of the rapid emptying of gastric contents into the small intestine, which shifts fluid into the gut and causes abdominal distention. Early manifestations include vertigo, tachycardia, syncope, sweating, pallor, and palpitations.

Dupuytren's contracture A slowly progressive contracture of the palmar fascia that results in flexion of the fourth or fifth digit of the hand and occasionally affects the third digit. Although a fairly common problem, the cause is unknown. It usually occurs in older men, tends to occur in families, and can be bilateral.

durable power of attorney for health care (DPOAHC) A legal document in which a person appoints someone else to make health care decisions in the event he or she becomes incapable of making decisions.

dysarthria Slurred speech.

dysfunctional uterine bleeding (DUB) A nonspecific term to describe bleeding that is excessive or abnormal in amount or frequency without predisposing anatomic or systemic conditions. Such bleeding occurs most often at either end of the span of a woman's reproductive years, when ovulation is becoming established or when it is becoming irregular at menopause.

dyskinesia Difficulty with movement.

dyslexia Problems understanding written language; caused by brain injury or disease.

dysmetria The inability to direct or limit movement.

dyspareunia Painful sexual intercourse.

dyspepsia Indigestion or heartburn following meals.

dysphagia Difficulty in swallowing.

dysphasia Slurred speech.

dyspnea Difficulty in breathing or breathlessness.

dyspnea on exertion (DOE) Dyspnea that is associated with activity, such as climbing stairs.

dysrhythmia A disorder of the heartbeat involving a disturbance in cardiac rhythm; irregular heartbeat.

dystrophic Pertaining to or characterized by dystrophy; abnormal.

dystrophin A muscle protein that maintains muscle integrity by sending signals to coordinate smooth, synchronous muscle fiber contraction. Faulty action of this protein causes muscular dystrophy.

dysuria Painful urination.

E

Eaton-Lambert syndrome A form of myasthenia gravis that affects the muscles of the trunk and the pelvic and shoulder girdles; often observed in combination with small cell carcinoma of the lung. Although weakness increases after exertion, there may be a temporary increase in muscle strength during the first few contractions, followed by a rapid decline.

ecchymoses Large purple, blue, or yellow bruises of the skin resulting from small hemorrhages; these bruises are larger than petechiae.

ecchymotic Pertaining to a bruise.

ECG caliper A measurement tool used in analysis of an electrocardiographic (ECG) rhythm strip.

echocardiography In cardiovascular assessment, the use of ultrasound waves to assess cardiac structure and mobility, particularly of the valves; a noninvasive, risk-free test that is easily performed at the bedside or on an ambulatory care basis.

echolalia Automatic repetition of what another person says.

ectopic Out of place.

ectropion A turning outward and sagging of the eyelid, which is caused by relaxation of the orbicular muscle.

edema Tissue swelling as a result of the accumulation of excessive fluid in the interstitial spaces.

edentulous Without teeth.

efferent arterioles The extremely small blood vessels that carry the remaining blood out of the glomerulus (once the glomerulus has filtered the blood to make urine) and into one of two additional capillary systems (the peritubular capillaries or the vasa recta).

effluent Drainage.

effusion An accumulation of fluid, such as in a joint (where it may limit movement).

ejection fraction The percentage of blood ejected from the heart during systole.

electrical bone stimulation The use of an electronic device (e.g., magnetic coils applied on the skin or over a cast to deliver a pulsed magnetic field) to promote bone union after a fracture. The exact mechanism of action is unknown, but this procedure is based on research showing that bone has inherent electrical properties that are used in healing.

electrocardiogram (ECG) A graphic recording of the electrical current generated by the heart. The ECG provides information about cardiac dysrhythmias, myocardial ischemia, site and extent of myocardial infarction, cardiac hypertrophy, electrolyte imbalances, and effectiveness of cardiac drugs. It is a routine part of cardiovascular evaluation and is a valuable diagnostic test.

electroencephalography (EEG) A recording of the electrical activity of the cerebral hemispheres; it represents the voltage changes in various areas of the brain as determined by recording the difference between two electrodes.

electrolyte A substance in body fluids that carries an electrical charge. Also called an "ion."

electromyography (EMG) A recording of the electrical activity of peripheral nerves by testing muscle activity.

electrophysiologic study (EPS) In cardiovascular assessment, an invasive procedure performed in a catheterization laboratory during which programmed electrical stimulation of the heart is used to induce and evaluate lethal dysrhythmias and conduction abnormalities to permit accurate diagnosis and effective treatment. The study is used in patients who have survived cardiac arrest, have recurrent tachydysrhythmias, or experience unexplained syncopal episodes.

electrovaporization of the prostate (EVAP) Procedure for treating benign prostatic hyperplasia with high-frequency electrical current to cut and vaporize excess tissue.

embolectomy Removal of a blood clot.

embolic stroke Damage to the brain when a blood clot forms somewhere in the body (usually the heart) and travels through the bloodstream to

block one or more of the arteries supplying the brain.

embolus The occurrence of inflammation and thickening of the vein wall around a clot (thrombus).

emergence Recovery from anesthesia.

emergency medical technician (EMT) Prehospital care provider who supplies basic life-support interventions such as oxygen, basic wound care, splinting, spinal immobilization, and monitoring of vital signs.

emergency medicine physician A member of the emergency health care team with education and training in the specialty of emergency patient management.

emergency operations center (EOC) A designated location in the Hospital Incident Command System (HICS) with accessible communication technology. Also called the "command center."

emergency preparedness A goal or plan to meet the extraordinary need for hospital beds, staff, drugs, personal protective equipment, supplies, and medical devices such as mechanical ventilators.

Emergency Severity Index (ESI) A standardized model for triage that categorizes both patient acuity and resource utilization into five levels, from most urgent to least urgent.

emergent triage In a three-tiered triage scheme, the category that includes any condition or injury that poses an immediate threat to life or limb, such as crushing chest pain or active hemorrhage.

emetogenic A substance that induces nausea and vomiting.

emmetropia The state of perfect refraction of the eye; with the lens at rest, light rays from a distant source are focused into a sharp image on the retina.

emotional abuse The intentional use of threats, humiliation, intimidation, and isolation to another person.

emotional lability Having uncontrollable emotions; for example, the patient laughs and then cries unexpectedly for no apparent reason.

empyema A collection of pus in the pleural space.

encephalitis An inflammation of the brain parenchyma (brain tissue) and meninges that affects the cerebrum, brainstem, and cerebellum; usually caused by a virus.

endometrial ablation Procedure for dysfunctional uterine bleeding that

removes a built-up uterine lining using a laser, roller ball, or balloon.

endometrial cancer Cancer of the inner uterine lining.

endometriosis The abnormal occurrence of endometrial tissue outside the uterine cavity.

endometritis An infection of the endometrium.

endoscope A tube that allows viewing and manipulation of internal body areas.

endoscopic retrograde cholangiopancreatography (ERCP) The visual and radiographic examination of the liver, gallbladder, bile ducts, and pancreas by means of an endoscope and the injection of radiopaque dye to identify the cause and location of obstruction.

endoscopic variceal ligation (EVL) The application of small "0" bands around the base of the esophageal varices to cut off their blood supply. Also called "banding."

endoscopy The direct visualization of the gastrointestinal tract by means of a flexible fiberoptic endoscope.

endothelin A secretion produced by the endothelial cells when they are stretched.

endovascular stent graft The repair of an abdominal aortic aneurysm using a stent made of flexible material; the stent is inserted through a skin incision into the femoral artery by way of a catheter-based system.

end-stage kidney disease (ESKD) Acute renal failure combined with chronic renal insufficiency, resulting in the inability of the kidney to excrete waste products normally. The patient may need hemodialysis or a kidney transplant.

energy conservation Strategies to reduce the fatigue associated with chronic and disabling conditions, such as allowing rest periods and setting priorities.

engraftment The successful transplantation of cells in the patient's bone marrow.

enophthalmos Backward displacement of the eyeball into the orbit so that the eye appears sunken.

enteroscopy Visualization of the small intestine.

enterostomal feeding tube A tube used for patients who need long-term enteral feeding; the physician directly accesses the gastrointestinal

tract using surgical, endoscopic, or laparoscopic techniques.

entropion The turning inward of the eyelid, causing the eyelashes to rub against the eye.

enucleation The surgical removal of the entire eyeball.

envenomation Venom injection from a snakebite.

epididymitis Inflammation of the epididymis.

epidural Term for the space between the dura mater and vertebrae; it consists of fat, connective tissue, and blood vessels.

epidural hematoma An accumulation of clotted blood resulting from arterial bleeding into the space between the dura and the skull; a neurosurgical emergency.

epiglottis A leaf-shaped, elastic structure that is attached along one edge to the top of the larynx; it closes over the glottis during swallowing to prevent food from entering the trachea and opens during breathing and coughing.

epiglottitis Infection or inflammation of the epiglottis and supraglottic structures that results in swelling. If swelling is great enough, the airway can be obstructed.

epilepsy A chronic disorder characterized by recurrent, unprovoked seizure activity; may be caused by an abnormality in electrical neuronal activity, an imbalance of neurotransmitters, or a combination of both.

epistaxis Nosebleed.

erectile dysfunction (ED) The inability to achieve or maintain a penile erection sufficient for sexual intercourse.

ergonomics An applied science in which the workplace is designed to increase worker comfort (thus reducing injury) while increasing efficiency and productivity.

erosion Ulceration.

eructation The act of belching.

erythema Redness of the skin.

erythema migrans A round or oval flat or slightly raised rash.

erythrocyte A red blood cell (RBC). Red blood cells are the major cells in the blood and are responsible for tissue oxygenation.

erythroplakia A velvety red mucosal lesion, most often occurring in the oral cavity.

erythropoiesis The selective maturation of stem cells into mature erythrocytes.

eschar The crust of dead tissue that forms from coagulated particles of destroyed dermis in a patient with a full-thickness burn injury.

escharotomy Incision made through tight eschar to relieve pressure and allow normal blood flow and breathing.

esophageal stricture Narrowing of the esophageal opening.

esophageal varices The distention of fragile, thin-walled esophageal veins due to increased pressure; the increased pressure is a result of portal hypertension, in which the blood backs up from the liver and enters the esophageal and gastric vessels that carry it into the systemic circulation.

esophagectomy The surgical removal of all or part of the esophagus.

esophagitis Inflammation of the esophagus.

esophagogastroduodenoscopy (EGD) The visual examination of the esophagus, stomach, and duodenum by means of a fiberoptic endoscope.

esophagogastrostomy The surgical creation of a communication between the stomach and the esophagus; it involves the removal of part of the esophagus and proximal stomach.

essential hypertension Elevated blood pressure that is not caused by a specific disease. The major risk factor is a family history of hypertension. Also called "primary hypertension."

euploid Having the correct number of chromosome pairs for the species.

euploidy The normal diploid number for a cell.

eustachian tube Tube that connects the nasopharynx with the middle ear and opens during swallowing to equalize pressure within the middle ear.

euthyroid Having normal thyroid function.

euvolemia A state of balanced fluid intake and output.

evidence-based practice (EBP) A QSEN competency in which the nurse integrates best current evidence with clinical expertise and patient/family preferences and values for delivery of optimal health

care.

evisceration The total separation of all layers of a wound and the protrusion of internal organs through the open wound.

evoked potentials Tests to measure the electrical signals to the brain generated by hearing, touch, or sight. Also called "evoked response."

exacerbation An increase in severity of a disease. Also called "flare-up."

excitability The ability of a cell to respond to a stimulus by initiating an impulse. Also called "depolarization." In cardiac electrophysiology, it is the ability of non-pacemaker myocardial cells to respond to an electrical impulse generated from pacemaker cells and to depolarize.

exercise electrocardiography In cardiovascular assessment, a test that assesses cardiovascular response to an increased workload. Also called "exercise tolerance" or a "stress test." Exercise electrocardiography helps determine the functional capacity of the heart, screens for coronary artery disease, and identifies dysrhythmias that develop during exercise. It also aids in evaluating the effectiveness of antidysrhythmic drugs.

exercise tolerance See *exercise electrocardiography.*

exertional dyspnea Breathlessness or difficulty breathing that develops during activity or exertion.

exertional heat stroke A form of heat stroke with a sudden onset, typically due to strenuous physical activity in hot, humid conditions. Lack of acclimatization to hot weather and wearing clothing too heavy for the environment are common contributing factors.

exogenous Originating outside the body.

exogenous hyperthyroidism Hyperthyroidism caused by excessive use of thyroid replacement hormones.

exophthalmos Abnormal protrusion of the eyeball (proptosis).

expedited partner therapy (EPT) Therapy used to treat chlamydia in which patients are given a drug or prescription with specific instructions for administration to their partners without direct evaluation by a health care provider. Also called "patient-delivered partner therapy."

exploratory laparotomy A surgical opening of the abdominal cavity to investigate the cause of an obstruction or peritonitis.

exposure (1) The final component of the primary survey that allows for

thorough assessment of the trauma patient; (2) in radiation therapy, the amount of radiation that is delivered to a tissue.

expressed gene When a particular gene has been "turned on."

expressive aphasia A type of aphasia resulting from damage in Broca's area of the frontal lobe of the brain. A motor speech problem in which the patient understands what is said but is unable to communicate verbally and has difficulty writing; rote speech and automatic speech, such as responses to a greeting, are often intact. The patient is aware of the deficit and may become frustrated and angry. Also called "Broca's aphasia" or "motor aphasia."

expressivity In genetics, the degree of expression a person has when a specific autosomal dominant gene is present. The gene is always expressed, but some people have more severe results.

external fixation A system in which pins or wires are passed through skin and bone and connected to a rigid external frame to immobilize a fracture during healing.

external fixator See *external fixation.*

external hemorrhoid A hemorrhoid that lies below the anal sphincter and can be seen on inspection of the anal region.

external otitis A painful irritation or infection of the skin of the external ear, with resulting allergic response or inflammation. When it occurs in patients who participate in water sports, external otitis is called "swimmer's ear."

external urethral sphincter The sphincter composed of the skeletal muscle that surrounds the urethra.

extracapsular Located outside the joint capsule.

extracellular fluid (ECF) The portion of total body water (about one third) that is in the space outside the cells. This space also includes interstitial fluid, blood, lymph, bone, and connective tissue water, and the transcellular fluids.

extracranial-intracranial bypass A surgical procedure in which the surgeon performs a craniotomy and bypasses the blocked artery by making a graft (bypass) from the first artery to the second artery to establish blood flow around the blocked artery and re-establish blood flow to the involved areas.

extramedullary tumor A tumor found within the spinal dura but outside

the cord.

extrapulmonary Involving nonpulmonary tissues.

extravasation Escape of fluids or drugs into the subcutaneous tissue; a complication of intravenous infusion.

extrinsic factor In hematology, an event (e.g., trauma) that occurs outside the blood to cause platelet plugs to form.

extubation The removal of an endotracheal tube.

F

facial paralysis See *Bell's palsy.*

facilitated diffusion Diffusion across a cell membrane that requires the assistance of a transport system or membrane-altering system. Also called "facilitated transport."

facilitated transport See *facilitated diffusion.*

failed back surgery syndrome (FBSS) A combination of organic, psychological, and socioeconomic factors in patients for whom back surgery is not successful. Discouraged by repeated surgical procedures, these patients must continue long-term nonsurgical management of pain, including nerve blocks.

fall An unintentional change in body position that results in the patient's body coming to rest on the floor or ground.

fallophobia In some older adults, the fear of falling and sustaining a serious injury.

far point (of vision) The farthest point at which the eye can see an object.

fascia An inelastic tissue that surrounds groups of muscles, blood vessels, and nerves in the body.

fasciculation Abnormal, involuntary twitching of a muscle.

fasciotomy A surgical procedure in which an incision is made through the skin and subcutaneous tissues into the fascia of the affected compartment to relieve the pressure in and restore circulation to the affected area in the patient with acute compartment syndrome.

fat embolism syndrome (FES) A serious complication, usually resulting from a fracture, in which fat globules are released from the yellow bone marrow into the bloodstream. This syndrome usually occurs within 48 hours of the fracture and can result in respiratory failure or

death, often from pulmonary edema.

fatigue (stress) fracture A fracture that results from excessive or repeated strain and stress on a bone.

fatty liver Caused by the accumulation of fats in and around the hepatic cells. It may be caused by alcohol abuse or other factors. Also known as "steatosis."

fecal occult blood test (FOBT) A diagnostic test that measures the presence of blood in the stool from gastrointestinal bleeding; this is a common finding associated with colorectal cancer.

Felty's syndrome The combination of rheumatoid arthritis, hepatosplenomegaly (enlarged liver and spleen), and leukopenia.

femoral hernia A hernia that protrudes through the femoral ring.

fetor hepaticus The distinctive fruity or musty breath odor of chronic liver disease and portal-systemic encephalopathy.

fibrinolysis The breakdown of a clot.

fibrinolytic Drug that targets the fibrin component of the coronary thrombosis; used to dissolve thrombi in the coronary arteries and restore myocardial blood flow; examples include tissue plasminogen activator, anisoylated plasminogen-streptokinase activator complex, and reteplase.

fibroadenoma A solid, slowly enlarging, benign mass of connective tissue that is unattached to the surrounding breast tissue and is typically discovered by the patient herself. The mass is usually round, firm, easily movable, nontender, and clearly delineated from the surrounding tissue.

fibrocystic breast condition (FBC) Physiologic nodularity of the breast that is thought to be caused by an imbalance in the normal estrogen-to-progesterone ratio. It is the most common breast problem of women between 20 and 30 years of age.

fibroids See *leiomyomas.*

fibromyalgia syndrome (FMS) A chronic pain syndrome characterized by pain and tenderness at specific sites in the back of the neck, upper chest, trunk, low back, and extremities along with fatigue, sleep disturbances, and headache.

fibrosis Replacement of normal cells with connective tissue and collagen (scar tissue).

fidelity Ethical principle that refers to the agreement that nurses will keep their obligations or promises to patients to follow through with care.

filter The movement of fluid from the space with higher hydrostatic pressure through the membrane into the space with lower hydrostatic pressure.

filtration The movement of fluid through a cell or blood vessel membrane because of hydrostatic pressure differences on both sides of the membrane.

financial abuse Mismanagement or misuse of the patient's property or resources.

first heart sound (S_1) Sound created by the closure of the mitral and tricuspid valves (atrioventricular valves).

first intention Healing in which the wound can be easily closed and dead space eliminated without granulation, which thus shortens the phases of tissue repair. Inflammation resolves quickly, and connective tissue repair is minimal, resulting in a thin scar.

fistula An abnormal opening between two adjacent organs or structures.

five cardinal manifestations of inflammation Warmth, redness, swelling, pain, and decreased function.

fixed occlusion Wiring the jaws together in the mouth closed position.

flaccid bladder See *areflexic bladder.*

flaccid paralysis Paralysis of a part of the body that is characterized by loss of muscle tone due to hypotonia; may be seen in the patient who has experienced a brain attack.

flail chest Inward movement of the thorax during inspiration, with outward movement during expiration; results from multiple rib fractures caused by blunt chest trauma that leaves a segment of the chest wall loose.

flatulence The presence of an excessive amount of gas in the stomach or intestines.

fluid overload An excess of body fluid. Also called “overhydration.”

folliculitis A superficial bacterial infection involving only the upper portion of the hair follicle.

forensic nurse examiner (RN-FNE) Emergency department specialist

who is trained to recognize evidence of abuse and to intervene on the patient's behalf and who obtains patient histories, collects forensic evidence, and offers counseling and follow-up care for victims of rape, child abuse, and domestic violence.

fracture A break or disruption in the continuity of a bone.

fremitus Vibration.

frequency (1) The highness or lowness of tones (expressed in hertz). The greater the number of vibrations per second, the higher the frequency (pitch) of the sound; the fewer the number of vibrations per second, the lower the pitch; (2) an urge to urinate frequently in small amounts.

fresh frozen plasma (FFP) Plasma that is frozen immediately after donation so that the clotting factors are preserved.

friable Easily crumbled or damaged.

frostbite A cold injury characterized by the degree of tissue freezing and the resultant damage it produces. Frostbite injuries can be superficial, partial, or full thickness.

frostnip A form of superficial frostbite (typically on the face, fingers, or toes) that produces pain, numbness, and pallor but is easily remedied with the application of warmth and does not induce tissue injury.

Fulmer SPICES A framework that identifies six serious "marker conditions" that can lead to longer hospital stays for patients, higher medical costs, and deaths.

fulminant hepatitis A severe acute and often fatal form of hepatitis caused by failure of the liver cells to regenerate, with progression to necrosis.

furuncle A localized inflammation of the skin caused by bacterial infection, usually *Staphylococcus,* of a hair follicle. Also called "a boil."

G

gallium scan A test that is similar to the bone scan but uses the radioisotope *gallium citrate* and is more specific and sensitive in detecting bone problems. This substance also migrates to brain, liver, and breast tissue and therefore is used to examine these structures when disease is suspected.

gamma globulin See *immunoglobulin.*

ganglion A round, cystlike lesion, often overlying a wrist joint or tendon.

gastrectomy The surgical removal of part or all of the stomach.

gastric bypass A type of gastric restriction surgery in which gastric resection is combined with malabsorption surgery. The patient's stomach, duodenum, and part of the jejunum are bypassed so that fewer calories can be absorbed. Also known as a "Roux-en-Y gastric bypass," or "RNYGB."

gastric lavage Procedure of irrigating the stomach in which a large-bore nasogastric tube is inserted into the stomach and room-temperature solution is instilled in volumes of 200 to 300 mL. The solution and blood are repeatedly withdrawn manually until returns are clear or light pink and without clots.

gastritis An inflammation of the gastric mucosa (stomach lining).

gastroenteritis An increase in the frequency and water content of stools or vomiting as a result of inflammation of the mucous membranes of the stomach and intestinal tract. It affects primarily the small bowel and can be of either viral or bacterial origin.

gastroesophageal reflux (GER) Condition that occurs as a result of backward flow of stomach contents into the esophagus.

gastroesophageal reflux disease (GERD) An upper gastrointestinal disease caused by the backward flow (reflux) of gastrointestinal contents into the esophagus.

gastrojejunostomy Surgical anastomosis of the stomach to the jejunum.

gastroparesis Delay in gastric emptying.

gastrostomy A stoma created from the abdominal wall into the stomach.

gel phenomenon In patients with rheumatoid arthritis, morning stiffness that lasts between 45 minutes and several hours after awakening.

gender dysphoria Discomfort with one's natal sex.

gender identity A person's inner sense of maleness or femaleness not related to reproductive anatomy.

gender reassignment surgery See *sex reassignment surgery.*

gene The deoxyribonucleic acid (DNA) in the form of chromosomes within the nucleus of each cell that contains the instructions for making all the different proteins any organism makes. Every human cell with a nucleus contains the entire set of human genes.

general anesthesia A reversible loss of consciousness induced by

inhibiting neuronal impulses in the central nervous system.

generalized seizure One of the three broad categories of seizure disorders along with partial seizures and unclassified seizures. There are six types: tonic-clonic, tonic, clonic, absence, myoclonic, and atonic (akinetic).

genetics The science concerned with the general mechanisms of heredity and the variation of inherited traits.

genital herpes (GH) An acute, recurring, incurable viral disease of the genitalia caused by the herpes simplex virus and transmitted through contact with an infected person. An outbreak typically is preceded by a tingling sensation of the skin followed by the appearance of vesicles (blisters) on the penis, scrotum, vulva, perineum, vagina, cervix, or perianal region. The blisters rupture spontaneously, leaving painful erosions. After the lesions heal, the virus remains dormant, periodically reactivating with a recurrence of symptoms.

genome The complete set of human genes. Each human cell with a nucleus contains the entire set of human genes. The human genome contains about 35,000 individual genes.

genomic health care The application of known genetic variation to enhance health care to individuals and their families.

genomics The science focusing on the function of all of the human DNA, including genes and noncoding DNA regions.

genotype The actual alleles for a genetic trait, not just what can be observed.

genu valgum A deformity in which the knees are abnormally close together and the space between the ankles is increased. Also called "knock-knee."

genu varum A deformity in which the knees are abnormally separated and the lower extremities are bowed inward. Also called "bowleg."

Geriatric Depression Scale—Short Form (GDS-SF) A valid and reliable screening tool to help determine if an older patient has clinical depression.

geriatric failure to thrive (GFTT) A complex syndrome including undernutrition, impaired physical functioning, depression, and cognitive impairment.

geriatric syndromes Major health issues that are associated with late

adulthood in community and inpatient settings.

ghrelin The "hunger hormone" that is secreted in the stomach; increases in a fasting state and decreases after a meal.

Glasgow Coma Scale (GCS) An objective and widely accepted tool for neurologic assessment and documentation of level of consciousness. It establishes baseline data for eye opening, motor response, and verbal response. The patient is assessed and assigned a numeric score for each of these areas. A score of 15 represents normal neurologic functioning, and a score of 3 represents a deep coma state.

glaucoma A group of ocular diseases resulting in increased intraocular pressure, causing reduced blood flow to the optic nerve and retina and followed by tissue damage.

glomerulus A series of specialized capillary loops that receive blood from the afferent arteriole and then filter water and small particles from the blood to make urine. The remaining blood leaves the glomerulus via the efferent arteriole.

glossectomy The partial or total surgical removal of the tongue.

glossitis A smooth, beefy red tongue.

glottis The opening between the true vocal cords inside the larynx.

glucagon A hormone secreted by the pancreas that increases blood glucose levels. It is a "counterregulatory" hormone that has actions opposite those of insulin. It causes the release of glucose from cell storage sites whenever blood glucose levels are low.

gluconeogenesis The conversion of proteins and amino acids to glucose in the body.

glucosamine A supplement that may decrease inflammation.

glycemic A term referring to blood glucose.

glycogenesis The production of glycogen in the body.

glycogenolysis The breakdown of glycogen into glucose.

glycoprotein (GP) IIb/IIIa inhibitors Drugs that target the platelet component of the thrombus. They are administered intravenously to prevent fibrinogen from attaching to activated platelets at the site of a thrombus and are given to patients with acute coronary syndromes (especially unstable angina and non–Q-wave myocardial infarction). Examples include abciximab, eptifibatide, and tirofiban.

glycosylated hemoglobin (A1C) A standardized test that measures how much glucose permanently attaches to the hemoglobin molecule. A1C levels greater than 6.5% are diagnostic of diabetes mellitus.

"go bag" See *personal readiness supplies.*

goiter Enlargement of the thyroid gland.

gonadotropins Hormones that stimulate the ovaries and testes to produce sex hormones.

gonads The male and female reproductive endocrine glands. Male gonads are the testes, and female gonads are the ovaries.

goniometer An instrument for measuring angles; also refers to a tool used to measure joint range of motion.

good death A death that is free from avoidable distress and suffering for patients, families, and caregivers; in agreement with patients' and families' wishes; and consistent with clinical practice standards.

gout A systemic disease in which urate crystals deposit in the joints and other body tissues, causing inflammation.

grading System of classifying cellular aspects of a cancer tumor.

granulation The formation of scar tissue for wound healing to occur.

granuloma Growth that develops in the lungs of patients with sarcoidosis and contains lymphocytes, macrophages, epithelioid cells, and giant cells; scar tissue.

Graves' disease Toxic diffuse goiter characterized by hyperthyroidism, enlargement of the thyroid gland, abnormal protrusion of the eyes, and dry, waxy swelling of the front surfaces of the lower legs.

gray (gy) Unit of measurement for an absorbed radiation dose.

gray matter In the spinal cord, neuron cell bodies.

grief The emotional feeling related to the perception of loss.

grommet A polyethylene tube that is surgically placed through the tympanic membrane to allow continuous drainage of middle-ear fluids in the patient with otitis media.

ground substance A lubricant composed of protein and sugar groups that surrounds the dermal cells and fibers and contributes to the skin's normal suppleness and turgor.

guardian A person appointed to make health care decisions for a patient

who is determined to not be legally competent.

Guillain-Barré syndrome (GBS) An acute autoimmune disorder characterized by varying degrees of motor weakness and paralysis. It may be referred to by a variety of other names, such as "acute idiopathic polyneuritis" and "polyradiculoneuropathy."

gynecomastia Abnormal enlargement of the breasts in men.

H

H_2-receptor antagonists A group of drugs that inhibit gastric acid secretion by blocking the effects of histamine on parietal cell receptors in the stomach.

half-life Time it takes for the amount of drug in the body to be reduced by 50%.

halitosis A foul odor of the mouth.

hallux valgus A common deformity of the foot that occurs when the great toe deviates laterally at the metatarsophalangeal joint; sometimes referred to as a "bunion."

halo fixator A static traction device used for immobilization of the cervical spine. Four pins or screws are inserted into the skull, and a metal halo ring is attached to a plastic vest or cast when the spine is stable, allowing increased patient mobility.

hammertoe The dorsiflexion of any metatarsophalangeal joint with plantar flexion of the adjacent proximal interphalangeal joint. The second toe is most often affected.

hand hygiene Infection control protocol that refers to both handwashing and alcohol-based hand rubs.

health care–associated infection (HAI) Infections associated with the provision of health care; for example, microorganisms can enter the body through the genitourinary tract in patients with indwelling urinary catheters.

heart failure A general term for the inadequacy of the heart to pump blood throughout the body, causing insufficient perfusion of body tissues with vital nutrients and oxygen. Also called "pump failure."

heart rate (HR) Term referring to the number of times the ventricles contract each minute.

heart transplantation A surgical procedure in which a heart from a donor with a comparable body weight and ABO compatibility is transplanted into a recipient less than 6 hours after procurement. It is the treatment of choice for patients with severe dilated cardiomyopathy and may be considered for patients with restrictive cardiomyopathy.

heat exhaustion A syndrome primarily caused by dehydration from heavy perspiration and inadequate fluid and electrolyte consumption during heat exposure over hours to days; if left untreated, can be a precursor to heat stroke.

heat stroke A true medical emergency in which the victim's heat regulatory mechanisms fail and are unable to compensate for a critical elevation in body temperature; if uncorrected, organ dysfunction and death will ensue.

Heberden's nodes Swelling at the distal interphalangeal joints in osteoarthritis that involves the hands.

hematemesis The vomiting of blood.

hematochezia The passage of red blood via the rectum.

hematocrit The percentage of packed red blood cells per deciliter of blood.

hematogenous tuberculosis A form of tuberculosis that spreads throughout the body when a large number of organisms enter the blood. Also called “miliary tuberculosis.”

hematopoiesis The production of blood cells, which occurs in the red marrow of bones.

hematuria Blood in the urine.

hemianopsia Blindness in half of the visual field of one or both eyes. Also called “hemianopia.”

hemiarthroplasty Surgical replacement of part of the shoulder joint, typically the humeral component, as an alternative to total shoulder arthroplasty.

hemiparesis Weakness on one side of the body.

hemiplegia Paralysis on one side of the body.

hemoconcentration Elevated plasma levels of hemoglobin, hematocrit, serum osmolarity, glucose, protein, blood urea nitrogen, and electrolytes that occur when only the water is lost and other substances remain.

hemodilution Excessive water in the vascular space.

hemoglobin A (HbA) Normal adult hemoglobin. The molecule has two alpha chains and two beta chains of amino acids.

hemoglobin S (HbS) An abnormal beta chain of hemoglobin associated with sickle cell disease that is sensitive to low oxygen content of red blood cells.

hemolytic The characteristic of destroying red blood cells.

hemolytic anemia Anemia caused by the destruction of red blood cells.

hemoptysis Coughing up blood or blood-stained sputum.

hemorrhoid Unnaturally swollen or distended vein in the anorectal region.

hemorrhoidectomy The excision of a hemorrhoid.

hemostasis The multi-step process of controlled blood clotting.

heparin-induced thrombocytopenia (HIT) The aggregation of platelets into "white clots" that can cause thrombosis, usually in the form of an acute arterial occlusion; occurs with heparin administration. Also called "white clot syndrome."

hepatic encephalopathy See *portal-systemic encephalopathy.*

hepatitis The widespread inflammation of liver cells.

hepatitis A Hepatitis that is caused by the hepatitis A virus (HAV) and is characterized by a mild course similar to that of a typical viral syndrome and often goes unrecognized. It is spread via the fecal-oral route by oral ingestion of fecal contaminants. Sources of infection include contaminated water, shellfish caught in contaminated water, and food contaminated by infected food handlers. The virus may also be spread by oral-anal sexual activity. The incubation period is usually 15 to 50 days. The disease is usually not life threatening but may be more severe in people older than 40 years. It can also complicate pre-existing liver disease.

hepatitis B A form of hepatitis that is caused by the hepatitis B virus (HBV), which is shed in the body fluids of infected people and asymptomatic carriers. It is spread through unprotected sexual intercourse with an infected partner, needle sharing, blood transfusions, and other modes. Symptoms usually occur within 25 to 180 days of exposure and include nausea, fever, fatigue, joint pain, and jaundice. Most adults who get hepatitis B recover, clear the virus from

their body, and develop immunity; however, up to 10% of patients with the disease do not develop immunity and become carriers.

hepatitis C Hepatitis that is caused by the hepatitis C virus (HCV). Transmission is blood to blood, most commonly by needle sharing or needle stick injury with contaminated blood. The rate of sexual transmission is very low; it is not spread by casual contact and is rarely transmitted from mother to fetus. The average incubation period is 7 weeks. Most people are asymptomatic and are not diagnosed until long after the initial exposure when an abnormality is detected during a routine laboratory evaluation or when symptoms of liver impairment appear. Hepatitis C causes chronic inflammation in the liver that eventually causes the hepatocytes to scar and may progress to cirrhosis.

hepatitis carrier Person who has had hepatitis B but has not developed immunity. Hepatitis carriers can infect others even though they are not sick and demonstrate no obvious signs of disease. Chronic carriers are at high risk for cirrhosis and liver cancer.

hepatitis D The hepatitis D virus (HDV) co-infects with hepatitis B virus (HBV) and needs the presence of HBV for viral replication. HDV can co-infect a patient with HBV or can occur as a superinfection in a patient with chronic HBV. Superinfection usually develops into chronic HDV infection. The incubation period is 14 to 56 days. As with HBV, the disease is transmitted primarily by parenteral routes.

hepatitis E Hepatitis E virus (HEV) was originally identified by its association with waterborne epidemics of hepatitis in the Indian subcontinent. Since then, it has occurred in epidemics in Asia, Africa, the Middle East, Mexico, and Central and South America, typically after heavy rains and flooding. In the United States, hepatitis E has been found only in travelers returning from endemic areas. The virus is transmitted via the fecal-oral route, and the clinical course resembles that of hepatitis A. HEV has an incubation period of 15 to 64 days. There is no evidence at this time of a chronic form of hepatitis E.

hepatocyte Liver cell.

hepatomegaly Enlargement of the liver.

hepatorenal syndrome (HRS) A state of progressive oliguric renal failure associated with hepatic failure, resulting in functional impairment of kidneys with normal anatomic and morphologic features. It indicates a

poor prognosis for the patient with hepatic failure and is often the cause of death in patients with cirrhosis.

hereditary chronic pancreatitis Pancreatitis that may be associated with *SPINK1* and *CFTR* gene mutations.

heritability The risk that a disorder can be transmitted to one's children in a recognizable pattern.

hernia A weakness in the abdominal muscle wall through which a segment of the bowel or other abdominal structure protrudes.

herniated nucleus pulposus (HNP) The protrusion (herniation) of the pulpy material from the center of a vertebral disk; herniated disks occur most often between the fourth and fifth lumbar vertebrae (L4-5) but may occur at other levels. A herniation in the lumbosacral area can press on the adjacent spinal nerve (usually the sciatic nerve), causing severe burning or stabbing pain into the leg or foot, or it may press on the spinal cord itself, causing leg weakness and bowel and bladder dysfunction. The specific area of pain depends on the level of herniation.

hernioplasty Surgical repair of a hernia in which the surgeon reinforces the weakened outside muscle wall with a mesh patch.

herniorrhaphy The surgical repair of a hernia.

heterotopic ossification Abnormal bony overgrowth, often into muscle; seen as a complication of prolonged immobility in patients with spinal cord injury.

hiatal hernia Protrusion of the stomach through the esophageal hiatus of the diaphragm and into the thorax. Also called "diaphragmatic hernia."

high-alert drug A drug that has an increased risk for causing patient harm if given in error.

high altitude disease (HAD) See *high altitude illnesses.*

high altitude illnesses Pathophysiologic responses in the body caused by exposure to low partial pressure of oxygen at high elevations.

high altitude pulmonary edema (HAPE) A form of acute mountain sickness often seen with high altitude cerebral edema. Clinical indicators include persistent dry cough, cyanosis of the lips and nail beds, tachycardia and tachypnea at rest, and rales auscultated in one or both lungs. Pink, frothy sputum is a late sign.

high-density lipoproteins (HDLs) Part of the total cholesterol value that should be more than 45 mg/dL for men and more than 55 mg/dL for women; "good" cholesterol.

highly sensitive C-reactive protein (hsCRP) A serum marker of inflammation and a common and critical component to the development of atherothrombosis.

high-output heart failure Heart failure that occurs when cardiac output remains normal or above normal. It is usually caused by increased metabolic needs or hyperkinetic conditions such as septicemia (fever), anemia, and hyperthyroidism. This type of heart failure is different from left- and right-sided heart failure, which are typically low-output states, and is not as common as other types.

hilum The area of the kidney in which the renal artery and nerve plexus enter and the renal vein and ureter exit. This area is not covered by the renal capsule.

hirsutism Abnormal growth of body hair, especially on the face, chest, and the linea alba of the abdomen of women.

homeostasis The narrow range of normal conditions (e.g., body temperature, blood electrolyte values, blood pH, blood volume) in the human body; the tendency to maintain a constant balance in normal body states.

homeostatic mechanism A safeguard or control mechanism within the human body that prevents dangerous changes.

homocysteine An essential sulfur-containing amino acid that is produced when dietary protein breaks down; elevated values (greater than 15 mmol/L) may be a risk factor for the development of cardiovascular disease.

homonymous hemianopsia Condition in which there is blindness in the same side of both eyes.

hordeolum An infection of the sweat glands in the eyelid.

hormone Chemical produced in the body that exerts its effects on specific tissues known as "target tissues."

hospice An interdisciplinary approach to facilitate quality of life and a "good" death for patients near the end of their lives, with care provided in a variety of settings.

Hospital Incident Command System (HICS) An organizational model

for disaster management in which roles are formally structured under the hospital or long-term care facility incident commander, with clear lines of authority and accountability for specific resources.

hospital incident commander As defined in a hospital's emergency response plan, the person (either an emergency physician or administrator) who assumes overall leadership for implementing the institutional plan at the onset of a mass casualty incident. The hospital incident commander has a global view of the entire situation, facilitates patient movement through the system, and brings in resources to meet patient needs.

hospitalist Family practitioner or internist employed by a hospital.

human leukocyte antigen (HLA) Antigen that is present on the surfaces of nearly all body cells as a normal part of the person and acts as an antigen only if it enters another person's body.

human papilloma virus (HPV) test A test that can identify many high-risk types of HPV associated with the development of cervical cancer.

humoral immunity A type of immunity provided by antibodies circulating in body fluids.

Huntington disease (HD) A hereditary disorder transmitted as an autosomal dominant trait at the time of conception (formerly called "Huntington chorea"). Men and women between 35 and 50 years of age are affected; clinical onset is gradual. The two main symptoms are progressive mental status changes (leading to dementia) and choreiform movements (rapid, jerky movements) in the limbs, trunk, and facial muscles.

hydrocephalus The abnormal accumulation of cerebrospinal fluid within the skull.

hydronephrosis Abnormal enlargement of the kidney caused by a blockage of urine lower in the tract and filling of the kidney with urine.

hydrophilic Tending to absorb water readily.

hydrophobic Not readily absorbing water; waterproof.

hydrostatic pressure The force of the weight of water molecules pressing against the confining walls of a space.

hydrotherapy The application of water for treatment of injury or disease.

hydroureter Abnormal distention of the ureter.

hyperacusis An intolerance for sound levels that do not bother other people.

hyperaldosteronism Excessive mineralocorticoid production.

hypercalcemia A total serum calcium level above 10.5 mg/dL or 2.75 mmol/L, which can cause fatigue, anorexia, nausea and vomiting, constipation, polyuria, and serious damage to the urinary system.

hypercapnia Increased arterial carbon dioxide levels.

hypercarbia Increased partial pressure of arterial carbon dioxide ($Paco_2$) levels.

hypercellularity An abnormal number of cells.

hyperemia Increased blood flow to an area.

hyperesthesia Abnormally increased sensation.

hyperextension A mechanism of injury that occurs when a part of the body is suddenly accelerated and then decelerated, causing extreme extension.

hyperflexion A mechanism of injury that occurs when a part of the body is suddenly and forcefully accelerated forward, causing extreme flexion.

hyperglycemia Abnormally high levels of blood glucose.

hyperinsulinemia Chronic high blood insulin levels.

hyperkalemia An elevated level of potassium in the blood.

hyperlipidemia An elevation of serum lipid (fat) levels in the blood.

hypermagnesemia A serum magnesium level above 2.1 mEq/L.

hypernatremia An excessive amount of sodium in the blood.

hyperopia An error of refraction that occurs when the eye does not refract light enough, causing images to fall (converge) behind the retina and resulting in poor near vision. Also called "farsightedness."

hyperosmotic Describes fluids with osmolarities (solute concentrations) greater than 300 mOsm/L; hyperosmotic fluids have a greater osmotic pressure than do isosmotic fluids and tend to pull water from the isosmotic fluid space into the hyperosmotic fluid space until an osmotic balance occurs. Also called "hypertonic."

hyperpharmacy See *polypharmacy.*

hyperphosphatemia A serum phosphorus level above 4.5 mg/dL.

hyperpituitarism Hormone oversecretion that occurs with pituitary tumors or hyperplasia.

hyperplasia Growth that causes tissue to increase in size by increasing the number of cells; abnormal overgrowth of tissue.

hyperpnea An abnormal increase in the depth of respiratory movements.

hypersensitivity An overreaction to a foreign substance.

hypertension A cardiovascular condition pertaining to people who have a systolic blood pressure of 140 mm Hg or higher or a diastolic blood pressure of 90 mm Hg or higher or who take medication to control blood pressure; approximately 1 of every 5 Americans has hypertension.

hypertensive crisis A severe elevation in blood pressure (greater than 180/120 mm Hg) that can cause damage to organs such as the kidneys or heart.

hyperthermia Elevated body temperature; fever.

hyperthyroidism A condition caused by excessive production of thyroid hormone.

hypertonia A condition of excessive muscle tone, which tends to cause fixed positions or contractures of the involved extremities and restricted range of motion of the joints.

hypertonic See *hyperosmotic.*

hypertriglyceridemia Elevated levels (150 mg/dL or above) of triglyceride in the blood.

hypertrophic cardiomyopathy (HCM) A type of cardiomyopathy that involves disarray of the myocardial fibers and asymmetric ventricular hypertrophy; leads to a stiff left ventricle that results in diastolic filling abnormalities.

hypertrophy The enlargement or overgrowth of an organ; tissue increases in size by the enlargement of each cell.

hyperuricemia An excess of uric acid in the blood.

hyperventilation A state of increased rate and depth of breathing.

hyperviscous The quality of being thicker than normal.

hypervolemia Increased plasma volume; or fluid excess.

hypocalcemia A total serum calcium level below 9.0 mg/dL or

2.25 mmol/L.

hypocapnia Decreased arterial carbon dioxide levels.

hypodermoclysis The slow infusion of isotonic fluids into subcutaneous tissue.

hypoesthesia Abnormally decreased sensation.

hypoglycemia Abnormally low levels of glucose in the blood.

hypokalemia A decreased serum potassium level; a common electrolyte imbalance.

hyponatremia A serum sodium level below 136 mEq/L (mmol/L).

hypo-osmotic Describes fluids with osmolarities of less than 270 mOsm/L. Hypo-osmolar fluids have a lower osmotic pressure than isosmotic fluids, and water tends to be pulled from the hypo-osmotic fluid space into the isosmotic fluid space until an osmotic balance occurs. Also called "hypotonic."

hypophonia Soft voice.

hypophosphatemia Inadequate levels of phosphate in the blood (below 3.0 mg/dL).

hypophysectomy Surgical removal of the pituitary gland.

hypoproteinemia A decrease in serum proteins.

hypothalamic-hypophysial portal system The small, closed circulatory system that the hypothalamus shares with the anterior pituitary gland, which allows hormones produced in the hypothalamus to travel directly to the anterior pituitary gland.

hypothalamus A structure within the brain; an integral part of autonomic nervous system control (controlling temperature and other functions) that is essential in intellectual function.

hypothermia A core body temperature less than 95° F (35° C).

hypotonia An abnormal condition of inadequate muscle tone, with an inability to maintain balance.

hypotonic See *hypo-osmotic.*

hypoventilation A state in which gas exchange at the alveolar-capillary membrane is inadequate so that too little oxygen reaches the blood and carbon dioxide is retained.

hypovolemia Abnormally decreased volume of circulating fluid in the

body; fluid deficit.

hypoxemia (hypoxemic) Decreased blood oxygen levels; hypoxia.

hypoxia A reduction of oxygen supply to the tissues.

hysterosalpingogram An x-ray of the cervix, uterus, and fallopian tubes that is performed after injection of a contrast medium. This test is used in infertility workups to evaluate tubal anatomy and patency and uterine problems such as fibroids, tumors, and fistulas.

hysteroscopy Examination of the interior of the uterus and cervical canal using an endoscope.

I

icterus Yellow discoloration of the sclerae.

idiopathic chronic pancreatitis Pancreatitis that may be associated with *SPINK1* and *CFTR* gene mutations.

idiopathic seizure See *unclassified seizure.*

ileostomy The surgical creation of an opening into the ileum, usually by bringing the end of the terminal ileum through the abdominal wall and forming a stoma, or ostomy.

immediate memory Short-term or new memory. Test by asking the patient to repeat two or three unrelated words to make sure they were heard; after about 5 minutes, while continuing the examination, ask the patient to repeat the words.

immunity Resistance to infection; usually associated with the presence of antibodies or cells that act on specific microorganisms.

immunocompetent Having proper functioning of the body's ability to maintain itself and defend against disease.

immunoglobulin Antibody. Also called “gamma globulin.”

impermeable Not porous.

implanted port A device used for long-term or frequent infusion therapy; consists of a portal body, a dense septum over a reservoir, and a catheter that is surgically implanted on the upper chest or upper extremity.

inactivation The process of binding an antibody to an antigen to cover the antigen's active site and to make the antigen harmless without destroying it. Also called “neutralization.”

incisional hernia Protrusion of the intestine at the site of a previous surgical incision resulting from inadequate healing. Most often caused by postoperative wound infections, inadequate nutrition, and obesity. Also called "ventral hernia."

incomplete spinal cord injury An injury in which the spinal cord has been damaged in a way that allows some function or movement below the level of the injury.

incontinence Involuntary loss of urine or stool severe enough to cause social or hygienic problems.

independent living skills See *instrumental activities of daily living (IADLs).*

indirect inguinal hernia A sac formed from the peritoneum that contains a portion of the intestine or omentum. The hernia pushes downward at an angle into the inguinal canal. In males, indirect inguinal hernias can become large and often descend into the scrotum.

indolent Slow-growing.

induration Hardening.

infarction Necrosis, or cell death.

infective endocarditis A microbial infection (e.g., viruses, bacteria, fungi) involving the endocardium; previously called "bacterial endocarditis."

inferior vena cava filtration Surgical procedure in which the surgeon inserts a filter device percutaneously into the inferior vena cava of a patient with recurrent deep vein thrombosis (to prevent pulmonary emboli) or pulmonary emboli that do not respond to medical treatment. The device is meant to trap emboli in the inferior vena cava before they progress to the lungs. Holes in the device allow blood to pass through, thus not significantly interfering with the return of blood to the heart.

inferior wall myocardial infarction A type of myocardial infarction that occurs in patients with obstruction of the right coronary artery, causing significant damage to the right ventricle.

infiltrating ductal carcinoma The most common type of breast cancer; it originates in the mammary ducts and grows in the epithelial cells lining these ducts.

infiltration The leakage of IV solution into the tissues around the vein.

inflammatory breast cancer A rare but highly aggressive form of invasive breast cancer. Symptoms include swelling, skin redness, and pain in

the breasts.

inflammatory cytokines Proteins produced primarily by white blood cells that assist in the inflammatory and immune responses of the body (e.g., tumor necrosis factor, interleukins).

inflow disease Chronic peripheral arterial disease with obstruction at or above the common iliac artery, abdominal aorta, or profunda femoris artery. The patient experiences discomfort in the lower back, buttocks, or thighs after walking a certain distance. The pain usually subsides with rest.

informatics A QSEN competency in which the nurse uses information and technology to communicate, manage knowledge, mitigate error, and support decision making.

infratentorial Located below the tentorium of the cerebellum.

infusate A solution that is infused into the body.

infusion therapy The delivery of parenteral medications and fluids through a variety of catheter types and locations using multiple techniques and procedures, such as intravenous and intra-arterial therapy to deliver solutions into the vascular system.

inpatient A patient who is admitted to a hospital.

inpatient rehabilitation facilities (IRFs) Freestanding rehabilitation hospitals, rehabilitation or skilled units within hospitals (e.g., transitional care units), and skilled nursing facilities to which the patient is typically admitted for 1 to 3 weeks or longer.

insensible water loss Water loss from the skin, lungs, and stool that cannot be controlled.

instrumental activities of daily living (IADLs) Special activities performed in the course of a day such as using the telephone, shopping, preparing food, and housekeeping. Also called "independent living skills."

insufflation The practice of injecting gas or air into a cavity before surgery to separate organs and improve visualization.

intensity A quality of sound that is expressed in decibels; generally, having a high degree of energy or activity.

intensivist A physician who specializes in critical care.

intention tremor A tremor that occurs when performing an activity.

interbody cage fusion Cagelike spinal device that is implanted into the space where a disk was removed. Bone graft tissue grows into and around the cage and creates a stable spine at that level.

intercostally Located between the ribs.

intermittent claudication A characteristic leg pain experienced by patients with chronic peripheral arterial disease. Typically, patients can walk only a certain distance before a cramping muscle pain forces them to stop. As the disease progresses, the patient can walk only shorter and shorter distances before pain recurs. Ultimately, pain may occur even at rest.

internal derangement A broad term for disturbances of an injured knee joint.

internal fixation The use of metal pins, screws, rods, plates, or prostheses to immobilize a fracture during healing. The surgeon makes an incision (open reduction) to gain access to the broken bone and implants one or more devices.

internal hemorrhoid A hemorrhoid that is located above the anal sphincter and cannot be seen on inspection of the perineal area.

internal urethral sphincter The smooth detrusor muscle that lines the interior of the bladder neck.

interstitial cystitis A bladder inflammation of unknown etiology that occurs predominantly in women and is characterized by urinary frequency and pain on bladder filling.

interstitial fluid A portion of the extracellular fluid that is between cells, sometimes called the "third space."

interstitial laser coagulation (ILC) Procedure for treating benign prostatic hyperplasia that uses laser energy to coagulate excess tissue. Also called "contact laser prostatectomy (CLP)."

intra-abdominal hypertension (IAH) Condition of sustained or repeated intra-abdominal pressure of 12 mm Hg or higher.

intra-abdominal pressure Pressure contained within the abdominal cavity.

intra-aortic balloon pump (IABP) An intra-aortic counterpulsation device. It may be used as an invasive intervention to improve myocardial perfusion during an acute myocardial infarction, reduce preload and afterload, and facilitate left ventricular ejection. It is also

used when patients do not respond to drug therapy with improved tissue perfusion, decreased workload of the heart, and increased cardiac contractility.

intra-arterial infusion therapy The use of catheters placed into arteries to obtain repeated arterial blood samples, to monitor various hemodynamic pressures continuously, and to infuse chemotherapy agents or fibrinolytics.

intracapsular Located within the joint capsule.

intracellular fluid (ICF) The portion of total body water (about two thirds) that is found inside the cells.

intracerebral hemorrhage Bleeding within the brain tissue caused by the tearing of small arteries and veins in the subcortical white matter.

intracorporeal Situated or occurring inside the body.

intramedullary tumor Tumor originating within the spinal cord in the central gray matter and anterior commissure. It is often malignant.

intraocular pressure (IOP) Pressure of the fluid within the eye; may be measured by methods that involve direct contact with the eye or by noncontact techniques.

intraoperative During surgery.

intraosseous (IO) therapy Infusion therapy that is delivered to the vascular network in the long bones.

intraperitoneal (IP) infusion therapy The administration of antineoplastic agents into the peritoneal cavity.

intrapulmonary Within the respiratory tract.

intrarenal/intrinsic renal failure Decreased renal function resulting from damage to the glomeruli, interstitial tissue, or tubules. It can contribute to acute renal failure.

intrathecal Referring to the spine.

intravascular ultrasonography (IVUS) In cardiac catheterization, the use of a flexible catheter with a miniature transducer that emits sound waves. Sound waves are reflected off the plaque and the arterial wall, creating an image of the blood vessel; used as an alternative to injecting a contrast medium into the coronary arteries.

intravenous (systemic) fibrinolytic therapy The intravenous administration of thrombolytic agents to dissolve a thrombus.

intravesical Situated inside the bladder.

intrinsic factor A substance normally secreted by the gastric mucosa and needed for intestinal absorption of vitamin B_{12}. A deficiency of intrinsic factor and the resulting failure to absorb vitamin B_{12} lead to pernicious anemia.

intussusception The telescoping of a segment of the intestine within itself.

invasive hemodynamic monitoring System used in critical care areas to provide quantitative information about vascular capacity, blood volume, pump effectiveness, and tissue perfusion. It directly measures pressures in the heart and great vessels.

ion A substance found in body fluids that carries an electrical charge. Also called "electrolyte."

iontophoresis A treatment for lower back pain in which a small electrical current and dexamethasone are typically used.

ipsilateral Occurring on the same side.

iris The colored portion of the external eye; its center opening is the pupil. Muscles of the iris contract and relax to control pupil size and the amount of light entering the eye.

irreducible hernia A hernia that cannot be reduced or placed back into the abdominal cavity; requires immediate surgical evaluation.

irritability An overresponse to stimuli.

irritable bowel syndrome (IBS) A chronic gastrointestinal disorder characterized by chronic or recurrent diarrhea, constipation, and/or abdominal pain and bloating. Also called "spastic colon," "mucous colon," or "nervous colon."

ischemia Blockage of blood flow through a blood vessel resulting in a lack of oxygen. Prolonged severe ischemia can cause irreversible damage to tissue.

ischemic Cell dysfunction or death from a lack of oxygen resulting from decreased blood flow in a body part.

ischemic stroke A type of brain attack caused by occlusion of a cerebral artery by either a thrombus or an embolus. About 80% of all brain attacks are ischemic.

isoelectric Having equal electric potentials, such as in the heart.

isosmotic Having the same osmotic pressures. Also called “isotonic” or “normotonic.”

isotonic See *isosmotic.*

J

jaundice A syndrome characterized by excessive circulating bilirubin levels. Liver cells cannot effectively excrete bilirubin, and skin and mucous membranes become characterized by a yellow coloration.

jejunostomy The surgical creation of an opening between the jejunum and the surface of the abdominal wall.

joint The place at which two or more bones come together. Also referred to as "articulation" of the joint. The primary function is to provide movement and flexibility in the body.

jugular venous distention (JVD) Enlargement of the jugular vein of the neck; caused by an increase in jugular venous pressure.

juxtaglomerular complex Specialized cells that produce and store renin in the afferent arteriole, efferent arteriole, and distal collecting tubule; taken together, the juxtaglomerular cells and the macula densa.

K

karyotype Technique used to make an organized arrangement of all the chromosomes within one cell during the metaphase section of mitosis.

keratin The protein produced by keratinocytes; makes the outermost skin layer waterproof.

keratinocytes Basal skin cells attached to the basement membrane of the epidermis that undergo cell division and differentiation to continuously renew skin tissue integrity and maintain optimal barrier function. As basal cells divide, keratinocytes are pushed upward and flattened to form the stratified layers of the epithelium (malpighian layers).

keratoconjunctivitis sicca A condition of the eyes that results from changes in tear composition, lacrimal gland malfunction, or altered tear distribution. Also called "dry eye syndrome."

keratoconus The degeneration of the corneal tissue resulting in abnormal corneal shape.

keratoplasty Corneal transplant. The surgical removal of diseased corneal tissue and replacement with tissue from a human donor cornea.

ketogenesis The conversion of fats to acids in the body.

ketone bodies Substances, including acetone, that are produced as by-products of the incomplete metabolism of fatty acids. When insulin is not available (as in uncontrolled diabetes mellitus), they accumulate in the blood and cause metabolic acidosis. Also called "ketones."

knee height caliper Device that uses the distance between the patella and heel to estimate height.

Kupffer cells Phagocytic cells that are part of the body's reticuloendothelial system and are involved in the protective function of the liver. Kupffer cells engulf harmful bacteria and anemic red blood cells.

Kussmaul respiration A type of breathing that occurs when excess acids caused by the absence of insulin increase hydrogen ion and carbon dioxide levels in the blood. This state triggers an increase in the rate and depth of respiration in an attempt to excrete more carbon dioxide and acid.

kwashiorkor Lack of protein quantity and quality in the presence of adequate calories. Body weight is somewhat normal, and serum proteins are low.

kyphoplasty A minimally invasive surgery for managing vertebral fractures in patients with osteoporosis. Bone cement is injected into the fracture site to provide pain relief, and an inflated balloon is used to restore height to the vertebra.

L

labyrinthectomy Surgical removal of the labyrinth; used as a radical treatment of Ménière's disease when medical therapy is ineffective and the patient already has significant hearing loss.

labyrinthitis An infection of the labyrinth of the ear; may occur as a complication of acute or chronic otitis media.

laceration A type of wound characterized by tearing or mangling and usually caused by sharp objects and projectiles.

lacrimal gland A small gland that produces tears; located in the upper outer part of each ocular orbit.

lacto-ovo-vegetarian A vegetarian diet pattern in which milk, cheese, eggs, and dairy foods are eaten but meat, fish, and poultry are avoided.

lactose intolerance The inability to convert lactose (found in milk and

dairy products) to glucose and galactose in the body.

lacto-vegetarian A vegetarian diet pattern in which milk, cheese, and dairy foods are eaten but meat, fish, poultry, and eggs are avoided.

laparoscopy A minimally invasive procedure in which the surgeon makes several small incisions near the umbilicus through which a small endoscope is placed to examine the abdomen; direct examination of the pelvic cavity through an endoscope.

laparotomy An open surgical approach in which a large abdominal incision is made.

laryngectomee A person who has had a laryngectomy.

laryngopharynx The area behind the larynx that extends from the base of the tongue to the esophagus. It is the critical dividing point at which solid foods and fluids are separated from air.

larynx The "voice box"; it is composed of several cartilages and is located above the trachea and just below the throat at the base of the tongue; part of the upper respiratory tract.

laser An acronym for light amplification by stimulated emission of radiation. As a surgical tool, a laser emits a high-powered beam of light that cuts tissue more cleanly than do scalpel blades. A laser creates intense heat, rapidly clots blood vessels or tissue, and turns target tissue (e.g., a tumor) into vapor.

latency period The time between the initiation of a cell and the development of an overt tumor.

latex allergy Reactions to exposure to latex in gloves and other medical products; reactions include rashes, nasal or eye symptoms, and asthma.

latrodectism A syndrome caused by the venom of a black widow spider bite in which neurotransmitter releases from nerve terminals to cause severe abdominal pain, muscle rigidity and spasm, hypertension, and nausea and vomiting.

lead In an ECG, the provider of one view of the heart's electrical activity.

lead axis In electrocardiography, the imaginary line that joins the positive and negative poles of the lead systems.

left shift An increase in the band cells (immature neutrophils) in the white blood cell differential count; an early indication of infection.

left-sided heart (ventricular) failure Inadequacy of the left ventricle of

the heart to pump adequately; results in decreased tissue perfusion from poor cardiac output and pulmonary congestion from increased pressure in the pulmonary vessels; typical causes include hypertensive, coronary artery, or valvular disease involving the mitral or aortic valve. Most heart failure begins with failure of the left ventricle and progresses to failure of both ventricles.

legally competent A person 18 years of age or older, a pregnant or a married minor, a legally emancipated (free) minor who is self-supporting, or a person not declared incompetent by a court of law.

leiomyomas Benign, slow-growing solid tumors of the uterine myometrium (muscle layer). These are the most commonly occurring pelvic tumors. Also called "myomas" and "fibroids."

lens The circular, convex structure of the eye that lies behind the iris and in front of the vitreous body. Normally transparent, the lens bends the rays of light entering through the pupil so they focus on the retina. The curve of the lens changes to focus on near or distant objects.

leptin A hormone that is released by fat cells and possibly by gastric cells; it also acts on the hypothalamus to control appetite.

leukemia A type of cancer with uncontrolled production of immature white blood cells in the bone marrow; the bone marrow becomes overcrowded with immature, nonfunctional cells, and the production of normal blood cells is greatly decreased.

leukocyte White blood cell (WBC); this immune system cell protects the body from the effects of invasion by organisms.

leukopenia A reduction in the number of white blood cells.

leukoplakia White, patchy lesions on a mucous membrane.

levels of evidence Term used to refer to the status, rank, or strength of evidence.

LGBTQ Acronym for "lesbian, gay, bisexual, transgender, and queer/questioning" culture.

libido Sexual desire.

lichenified An abnormal thickening of the skin to a leathery appearance; can occur in patients with chronic dermatitis because of their continual rubbing of the area to relieve itching.

Lichtenberg figures Branching or ferning marks that appear on the skin as a result of a lightning strike. Also called "keraunographic

markings" or "erythematous arborization."

life review A structured process of reflecting on one's life that is often facilitated by an interviewer.

light reflex The reflection of the otoscope's light off the eardrum in the form of a clearly demarcated triangle of light in the normal ear.

limited cutaneous systemic sclerosis Thick skin that is usually limited to sites distal to the elbow and knee but also involves the face and neck.

lipid Fat, including cholesterol and triglycerides, that can be measured in the blood.

lipolysis The decomposition or splitting up of fat to provide fuel for energy when liver glucose is unavailable.

liposuction A cosmetic procedure to reduce the amount of adipose tissue in selected areas of the body.

lithotripsy The use of sound, laser, or dry shock wave energy to break a kidney stone into small fragments. Also called "extracorporeal shock wave lithotripsy."

living will A legal document that instructs physicians and family members about what life-sustaining treatment is wanted (or not wanted) if the patient becomes unable to make decisions.

lobectomy Surgical removal of an entire lung lobe.

lobular carcinoma in situ (LCIS) A noninvasive form of breast cancer that does not show up as a calcified cluster on a mammogram and is therefore most often diagnosed incidentally during a biopsy for another problem.

local anesthesia Anesthesia that is delivered by applying it to the skin or mucous membranes of the area to be anesthetized or by injecting it directly into the tissue around an incision, wound, or lesion.

locus The specific chromosome location for a gene.

log rolling Turning technique in which the patient turns all at once while his or her back is kept as straight as possible.

loop electrosurgical excision procedure (LEEP) Diagnostic procedure/treatment in which a thin loop-wire electrode that transmits a painless electrical current is used to cut away affected cervical cancer tissue.

lordosis The anterior concavity in the curvature of the lumbar and

cervical spine when viewed from the side; a common finding in pregnancy and abdominal obesity.

Lou Gehrig's disease See *amyotrophic lateral sclerosis (ALS).*

low back pain (LBP) Pain in the lumbosacral region of the back caused by muscle strain or spasm, ligament sprain, disk degeneration, or herniation of the nucleus pulposus from the center of the disk. Herniated disks occur most often between the fourth and fifth lumbar vertebrae (L4-5) but may occur at other levels.

low-density lipoproteins (LDLs) Part of the total cholesterol value that should be less than 130 mg/dL; "bad" cholesterol.

lower esophageal sphincter (LES) The portion of the esophagus proximal to the gastroesophageal junction; when at rest, the sphincter is closed to prevent reflux of gastric contents into the esophagus.

low-intensity pulsed ultrasound A method using ultrasonic waves to promote bone union in slow-healing fractures or for new fractures as an alternative to surgery.

low-profile gastrostomy device (LPGD) A gastrostomy device that uses a firm or balloon-style internal bumper or retention disk; an antireflux valve keeps gastric contents from leaking onto the skin.

loxoscelism Systemic effects from the injected toxin of a spider bite.

lumbar puncture (spinal tap) The insertion of a spinal needle into the subarachnoid space between the third and fourth (sometimes the fourth and fifth) lumbar vertebrae to withdraw spinal fluid for analysis.

lumen The inside cavity of a tube or tubular organ, such as a blood vessel or airway.

lung compliance The quality of elasticity of the lungs.

lunula The white crescent-shaped portion of the nail at the lower end of the nail plate.

lurch An abnormality in the swing phase of gait; occurs when the muscles in the buttocks or legs are too weak to allow the person to change weight from one foot to the other.

Lyme disease A systemic infectious disease that is caused by the spirochete *Borrelia burgdorferi* and results from the bite of an infected deer tick. Signs and symptoms include a large "bull's-eye" circular rash, malaise, fever, headache, and muscle or joint aches.

lymphadenopathy Persistently enlarged lymph nodes.

lymphedema Abnormal accumulation of protein fluid in the subcutaneous tissue of the affected limb after a mastectomy.

lymphoblastic Pertaining to abnormal leukemic cells that come from the lymphoid pathways and develop into lymphocytes.

lymphocytic Pertaining to abnormal leukemic cells that come from the lymphoid pathways.

lymphokine Cytokine produced by T-cells.

lysis Breakage, for example, of a cell membrane.

M

macrocytic anemia A form of vitamin B_{12} deficiency anemia characterized by abnormally large precursor cells.

macrovascular Referring to large blood vessels.

macular Referring to a macula, a discolored spot on the skin that is not raised above the surface.

macular degeneration The deterioration of the macula, the area of central vision.

magnesium (Mg^{2+}) A mineral that forms a cation when dissolved in water.

magnetoencephalography (MEG) A noninvasive imaging technique that measures the magnetic fields produced by electrical activity in the brain via extremely sensitive devices such as superconducting quantum interference devices (SQUIDs).

malabsorption A syndrome associated with a variety of disorders and intestinal surgical procedures and characterized by impaired intestinal absorption of nutrients.

malignant Referring to cancer.

malignant cell growth Altered cell growth that is serious and, without intervention, leads to death; cancer.

malignant hypertension A severe type of elevated blood pressure that rapidly progresses, with systolic blood pressure greater than 200 mm Hg and diastolic blood pressure greater than 150 mm Hg (greater than 130 mm Hg when there are pre-existing complications).

malignant transformation The process of changing a normal cell into a cancer cell.

mammography An x-ray of the soft tissue of the breast.

mandibulectomy Surgical removal of the jaw.

marasmic-kwashiorkor A combined protein and energy malnutrition that often presents clinically when metabolic stress is imposed on a chronically starved patient.

marasmus A calorie malnutrition in which body fat and protein are wasted but serum proteins are often preserved.

marsupialization Surgical formation of a pouch that is a new duct opening.

mass casualty event A situation affecting the public health that is defined based on the resource availability of a particular community or hospital facility. When the number of casualties exceeds the resource capabilities, a disaster situation is recognized to exist.

mastication The process of chewing.

mastoiditis An acute or chronic infection of the mastoid air cells caused by untreated or inadequately treated otitis media.

maze procedure An open chest surgical technique often performed with coronary artery bypass grafting for patients in atrial fibrillation with decompensation.

mean arterial pressure (MAP) The arterial blood pressure (between 60 and 70 mm Hg) necessary to maintain perfusion of major body organs, such as the kidneys and brain.

mechanical débridement Method of débriding a wound by mechanical entrapment and detachment of dead tissue.

mechanical obstruction The physical obstruction of the bowel by disorders outside the intestine (e.g., adhesions or hernias) or by blockages in the lumen of the intestine (e.g., tumors, inflammation, strictures, or fecal impactions).

mediastinal shift A shift of central thoracic structures toward one side; seen on chest x-ray.

mediastinitis Infection of the mediastinum.

medical command physician As defined in a hospital's emergency response plan, the person responsible for determining the number,

acuity, and medical resource needs of victims arriving from the incident scene and for organizing the emergency health care team response to injured or ill patients.

medical harm Physician incidents and all errors caused by members of the health care team or system that lead to patient injury or death.

medical nutrition supplements (MNSs) Enteral products taken by patients who cannot consume enough nutrients in their usual diet (e.g., Ensure, Boost).

medication overuse headache See *rebound headache.*

medulla A general term for the most interior portion of an organ or structure.

melena Blood in the stool, with the appearance of black tarry stools.

memory cell A type of B-lymphocyte that remains sensitized but does not start to produce antibodies until the next exposure to the same antigen.

Ménière's disease Tinnitus, one-sided sensorineural hearing loss, and vertigo that is related to overproduction or decreased reabsorption of endolymphatic fluid and causes a distortion of the entire inner canal system.

meninges The immediate protective covering of the brain and the spinal cord.

meningioma A type of benign brain tumor that arises from the coverings of the brain (the meninges) and causes compression and displacement of adjacent brain tissue.

meningitis Inflammation, usually bacterial or viral, of the arachnoid and pia mater of the brain and spinal cord and the cerebrospinal fluid. May be caused by bacteria or viruses; symptoms are the same regardless of the causative organism.

meniscectomy Surgical excision of a meniscus, as in a knee joint.

menses The monthly flow of blood from the genital tract of women.

metabolic syndrome A collection of related health problems with insulin resistance as a main feature. Other features include obesity, low levels of physical activity, hypertension, high blood levels of cholesterol, and elevated triglyceride levels. Metabolic syndrome increases the risk for coronary heart disease. Also called “syndrome X.”

metastasis The growth and spread of cancer.

metastasize To spread cancer from the main tumor site to many other body sites.

metastatic Referring to disease, such as cancer, that transfers from one organ to another organ or part not directly connected; pertains to additional tumors that form after cancer cells move from the primary location by breaking off from the original group and establishing remote colonies.

methemoglobinemia The conversion of normal hemoglobin to methemoglobin.

microalbuminuria The presence of very small amounts of albumin in the urine that are not measurable by a urine dipstick or usual urinalysis procedures. Specialized assays are used to analyze a freshly voided urine specimen for microscopic levels of albumin.

microcytic Abnormally small in size, such as an abnormally small red blood cell.

microvascular Referring to small blood vessels.

microvascular decompression A surgical procedure to relieve the pain of trigeminal neuralgia by relocating a small artery that compresses the trigeminal nerve as it enters the pons. The surgeon carefully lifts the loop of the artery off the nerve and places a small silicone sponge between the vessel and the nerve.

midline catheter A type of catheter that is 6 to 8 inches long and inserted through the veins of the antecubital fossa; used in therapies lasting from 1 to 4 weeks.

migraine headache An episodic familial disorder manifested by a unilateral, frontotemporal, throbbing pain that is often worse behind one eye or ear. It is often accompanied by a sensitive scalp, anorexia, photophobia, and nausea with or without vomiting. Three categories of migraine headache are migraines with aura, migraines without aura, and atypical migraines.

migratory arthritis In the early stage of rheumatoid arthritis, symptoms that are migrating or involve more joints.

miliary tuberculosis See *hematogenous tuberculosis.*

minimally invasive direct coronary artery bypass (MIDCAB) Surgical procedure that does not require cardiopulmonary bypass and may be used for patients with a lesion of the left anterior descending artery. Also known as “keyhole” surgery.

minimally invasive esophagectomy (MIE) A laparoscopic surgical procedure to remove part of the esophagus; may be performed in patients with early-stage cancer.

minimally invasive inguinal hernia repair (MIIHR) Surgical repair of an inguinal hernia through a laparoscope, which is the treatment of choice.

minimally invasive surgery (MIS) A general term for any surgery performed using laparoscopic technique.

Minimum Data Set (MDS) 3.0 Interdisciplinary tool required by the U.S. Centers for Medicare and Medicaid Services (CMS) to assess patients (residents) in nursing homes.

miosis Constriction of the pupil of the eye.

mitosis Cell division.

mitotic index The percentage of actively dividing cells within a tumor.

mitral regurgitation Inability of the mitral valve to close completely during systole, which allows the backflow of blood into the left atrium when the left ventricle contracts; usually due to fibrosis and calcification caused by rheumatic disease. Also called "mitral insufficiency."

mitral stenosis Thickening of the mitral valve due to fibrosis and calcification and usually caused by rheumatic fever. The valve leaflets fuse and become stiff, the chordae tendineae contract, and the valve opening narrows, preventing normal blood flow from the left atrium to the left ventricle. As a result, left atrial pressure rises, the left atrium dilates, pulmonary artery pressures increase, and the right ventricle hypertrophies.

mitral valve prolapse (MVP) Dysfunction of the mitral valve that occurs because the valvular leaflets enlarge and prolapse into the left atrium during systole; usually benign but may progress to pronounced mitral regurgitation.

mixed conductive-sensorineural hearing loss A profound hearing loss that results from a combination of both conductive and sensorineural types of hearing loss.

modifiable risk factor A factor in disease development that can be altered or controlled by the patient. Examples include elevated serum cholesterol levels, cigarette smoking, hypertension, impaired glucose tolerance, obesity, physical inactivity, and stress.

monokine Cytokine made by macrophages, neutrophils, eosinophils, and monocytes.

morbid obesity A weight that has a severely negative effect on health; usually more than 100% above ideal body weight or a body mass index greater than 40.

morbidity An illness or an abnormal condition or quality.

mortality Death.

Morton's neuroma Plantar digital neuritis, a condition in which a small tumor grows in a digital nerve of the foot. The patient usually describes the pain as an acute, burning sensation in the web space that involves the entire surface of the third and fourth toes.

motor Facilitating movement.

motor aphasia See *expressive aphasia.*

motor cortex Area in the frontal lobe of the brain that controls voluntary movement.

mourning The outward social expression of loss.

mucositis Open sores on mucous membranes.

multi-casualty event A disaster event in which a limited number of victims or casualties are involved and can be managed by a hospital using local resources.

multigated blood pool scanning In nuclear cardiology, cardiac blood pool imaging is a noninvasive test to evaluate cardiac motion and calculate ejection fraction by using a computer to synchronize the patient's electrocardiogram with pictures obtained by a gamma-scintillation camera. In multigated blood pool scanning, the computer breaks the time between R waves into fractions of a second, called “gates.” The camera records blood flow through the heart during each gate. By analyzing information from multiple gates, the computer can evaluate ventricular wall motion and calculate ejection fraction (percentage of the left ventricular volume that is ejected with each contraction) and ejection velocity.

multiple organ dysfunction syndrome (MODS) The sequence of inadequate blood flow to body tissues, which deprives cells of oxygen and leads to anaerobic metabolism with acidosis, hyperkalemia, and tissue ischemia; this is followed by dramatic changes in vital organs and leads to the release of toxic metabolites and destructive enzymes.

multiple sclerosis (MS) A chronic autoimmune disease that affects the myelin sheath and conduction pathway of the central nervous system. It is one of the leading causes of neurologic disability in persons 20 to 40 years of age.

murmur Abnormal heart sound that reflects turbulent blood flow through normal or abnormal valves; murmurs are classified according to their timing in the cardiac cycle (systolic or diastolic) and their intensity depending on their level of loudness.

muscle biopsy The extraction of a muscle specimen for the diagnosis of atrophy (as in muscular dystrophy) and inflammation (as in polymyositis).

muscular dystrophy (MD) A group of degenerative myopathies characterized by weakness and atrophy of muscle without nervous system involvement. At least nine types have been clinically identified and can be broadly categorized as slowly progressive or rapidly progressive.

mutation A change in deoxyribonucleic acid (DNA) that is passed from one generation to another.

myalgia Muscle aches/muscle pain.

myasthenia gravis (MG) A chronic autoimmune disease of the neuromuscular junction. It is characterized by remissions and exacerbations, with fatigue and weakness primarily in the muscles innervated by the cranial nerves and in the skeletal and respiratory muscles. It ranges from mild disturbances of the ocular muscles to a rapidly developing, generalized weakness that may lead to death from respiratory failure.

myasthenic crisis Undermedication with cholinesterase inhibitors.

mydriasis Dilation of the pupil of the eye.

myelin sheath A white, lipid covering of the axon.

myelocytic Pertaining to leukemias in which the abnormal cells come from the myeloid pathways.

myelogenous Pertaining to leukemias in which the abnormal cells come from the myeloid pathways.

myelography Radiography of the spine after injection of contrast medium into the subarachnoid space of the spine; used to visualize the vertebral column, intervertebral disks, spinal nerve roots, and

blood vessels.

myocardial hypertrophy Enlargement of the myocardium.

myocardial infarction (MI) Injury and necrosis of myocardial tissue that occurs when the tissue is abruptly and severely deprived of oxygen; usually caused by atherosclerosis of a coronary artery, rupture of the plaque, subsequent thrombosis, and occlusion of blood flow.

myocardial nuclear perfusion imaging (MNPI) The use of radionuclide techniques in which radioactive tracer substances are used to view, record, and evaluate cardiovascular abnormalities; useful for detecting myocardial infarction and decreased myocardial blood flow and for evaluating left ventricular ejection.

myocardium The heart muscle.

myoglobin A low–molecular-weight heme protein found in cardiac and skeletal muscle; an early marker of myocardial infarction.

myoglobinuria The release of muscle myoglobulin into the urine.

myomas See *leiomyomas.*

myomectomy The surgical removal of leiomyomas with preservation of the uterus.

myopathy A problem in muscle tissue.

myopia An error of refraction that occurs when the eye over-refracts or over-bends the light and focuses images in front of the retina; this results in normal near vision but poor distance vision. Also called "nearsightedness."

myositis Inflammation of a muscle.

myosplint Electrical stimulation of tension splints in the heart to help the ventricle change to a more normal shape in the patient with heart failure; under investigation in Europe and the United States.

myringoplasty Surgical reconstruction of the eardrum.

myringotomy The surgical creation of a hole in the eardrum; performed to drain middle-ear fluids and relieve pain in the patient with otitis media (middle-ear infection).

myxedema Dry, waxy swelling of the skin that is accompanied by nonpitting edema (especially around the eyes, in the hands and feet, and between the shoulder blades) and is associated with primary hypothyroidism.

myxedema coma A rare, serious complication of untreated or poorly treated hypothyroidism in which decreased metabolism causes the heart muscle to become flabby and the chamber size to increase, resulting in decreased cardiac output and decreased perfusion to the brain and other vital organs.

N

nadir In cancer treatment therapy, the period of greatest bone marrow suppression, when the patient's platelet count may be very low.

nasoduodenal tube (NDT) A tube that is inserted through a nostril and into the small intestine.

nasoenteric tube (NET) Any feeding tube that is inserted nasally and then advanced into the gastrointestinal tract.

nasogastric (NG) tube A tube that is inserted through a nostril and into the stomach for liquid feeding or for withdrawing gastric contents.

nasotracheal The route for inserting a tube into the trachea via the nose.

natal sex A person's genital anatomy present at birth. Also known as "biological sex."

National Patient Safety Goals (NPSGs) Goals published by The Joint Commission that require health care organizations to focus on specific priority safety practices.

natural chemical débridement Method of débriding a wound by creating an environment that promotes self-digestion of dead tissues by bacterial enzymes.

near point of vision The closest distance at which the eye can see an object clearly.

near-drowning Recovery after submersion in a liquid medium (usually water); this term is no longer used because language that describes drowning incidents has been standardized.

near-syncope Dizziness with an inability to remain in an upright position.

necrotizing hemorrhagic pancreatitis (NHP) Inflammation of the pancreas that is characterized by diffusely bleeding pancreatic tissue with fibrosis and tissue death. This form affects about 20% of patients with pancreatitis.

needle thoracostomy A quick, temporary method of chest decompression

in which a large-bore needle is used to vent trapped air pending chest tube insertion.

negative deflection In electrocardiography, the flow of electrical current in the heart (cardiac axis) away from the positive pole and toward the negative pole.

negative feedback control mechanism The condition of maintaining a constant output of a system by exerting an inhibitory control on a key step by a product of that system. Used in a series of reactions that control hormone secretion and cellular activity based on responses to correct any movement away from normal function. An example of a simple negative feedback hormone response is the control of insulin secretion in which the action of insulin (decreasing blood glucose levels) is the opposite of the condition that stimulated insulin secretion (elevated blood glucose levels).

negative nitrogen balance A net loss of protein that occurs when the breakdown (degradation) of protein exceeds buildup (synthesis).

neglect In nursing, failure to provide for a patient's basic needs.

neoadjuvant therapy Treatment of a cancerous tumor with chemotherapy to shrink the tumor before it is surgically removed.

neoplasia Any new or continued cell growth not needed for normal development or replacement of dead and damaged tissues.

nephrectomy The surgical removal of the kidney.

nephrolithiasis The formation of stones in the kidney.

nephron The "working" unit of the kidney where urine is formed from blood. Each kidney consists of about 1 million nephrons, and each nephron separately makes urine. There are two types of nephrons: cortical and juxtamedullary.

nephropathy Pathologic change in the kidney that reduces kidney function and leads to renal failure.

nephrosclerosis Thickening in the nephron blood vessels that results in narrowing of the vessel lumen, with decreased renal blood flow and chronically hypoxic kidney tissue.

nephrostomy The surgical creation of an opening directly into the kidney; performed to divert urine externally and prevent further damage to the kidney when a stricture is causing hydronephrosis and cannot be corrected with urologic procedures.

nephrotic syndrome (NS) A condition of increased glomerular permeability that allows larger molecules to pass through the membrane into the urine and be removed from the blood. This process causes massive loss of protein into the urine, edema formation, and decreased plasma albumin levels.

neuraxial Referring to the epidural or spinal area.

neuritic plaques Degenerating nerve terminals found particularly in the hippocampus, an important part of the limbic system, and marked by increased amounts of an abnormal protein called "beta amyloid"; a characteristic change of the brain found in patients with Alzheimer's disease.

neurofibrillary tangles Tangled masses of fibrous elements throughout the neurons; a classic finding at autopsy in the brains of patients with Alzheimer's disease.

neurogenic shock Hypotension and bradycardia associated with cervical spinal injuries and caused by a loss of autonomic function. The patient is at greatest risk in the first 24 hours after injury.

neuroglia cells Cells of varying size and shape that provide protection, structure, and nutrition for the neurons.

neurohypophysis The posterior lobe of the pituitary gland that stores hormones produced in the hypothalamus.

neuroma A sensitive tumor consisting of nerve cells and nerve fibers.

neuron Excitable nerve cell that processes and transmits information through electrical and chemical signals.

neuropathic pain A type of chronic non-cancer pain that results from a nerve injury. Examples of causes include diabetic neuropathy, postherpetic neuralgia, radiculopathy (spinal nerve damage), and trigeminal neuralgia. Neuropathic pain is described as burning, shooting, stabbing, and the sensation of "pins and needles."

neurotransmitter Regulatory chemical that exerts inhibitory (slowing down) or excitatory (speeding up) activity at postsynaptic nerve cell membranes. Acetylcholine, norepinephrine, epinephrine, dopamine, and serotonin are neurotransmitters.

neurovascular assessment Assessment of the neuromuscular system that includes inspection of skin color, temperature, and capillary refill distal to an injury, surgical procedure, or cast. Palpation of pulses in the extremities below level of injury and assessment of sensation,

movement, and pain in the injured part give a complete assessment.

neutralization See *inactivation.*

neutropenia Decreased numbers of leukocytes, especially neutrophils, which causes immunosuppression.

neutrophilia Increased number of circulating neutrophils.

nevus A mole; a benign skin growth of the pigment-forming cells.

new-onset angina Cardiac chest pain that occurs for the first time.

nitroglycerin (NTG) A drug prescribed for patients with angina. It increases collateral blood flow, redistributes blood flow toward the subendocardium, and causes dilation of the coronary arteries.

nits Lice eggs.

***N*-methyl-d-aspartate (NMDA) receptor antagonist** A group of drugs that block excess amounts of glutamate, which damages nerve cells in the brain; used to treat Alzheimer's disease.

nociception Term used to describe how pain becomes a conscious experience.

nociceptive pain Pain related to the skin, musculoskeletal structures, or body organs.

nociceptors Sensory neurons that respond to pain or other noxious stimuli.

nocturia The need to urinate excessively at night. Also called "nocturnal polyuria."

nocturnal polyuria See *nocturia.*

nonadherence In health care, accidental failure by a patient to take medication.

noncompliance In health care, deliberate failure by a patient to take medication.

nonmaleficence Ethical principle that emphasizes the importance of preventing harm and ensuring the patient's well-being.

nonmechanical obstruction Intestinal obstruction that does not involve a physical obstruction in or outside the intestine. Instead, decreased or absent peristalsis results in a slowing of the movement or a backup of intestinal contents. This is also known as "paralytic ileus" or "adynamic ileus" because it is a result of neuromuscular disturbance.

nonmodifiable risk factor Factor in disease development that cannot be altered or controlled by the patient. Examples include age, gender, family history, and ethnic background.

non–ST-segment elevation myocardial infarction (NSTEMI) Myocardial infarction in which the patient typically has ST and T-wave changes on a 12-lead ECG; this indicates myocardial ischemia.

nonsustained ventricular tachycardia (NSVT) Occurrence of three or more successive premature ventricular complexes.

nontunneled percutaneous central venous catheter (CVC) A type of catheter, usually 15 to 20 cm long and with dual or triple lumens, that is inserted through the subclavian vein in the upper chest or through the jugular veins in the neck using sterile technique.

nonurgent In a three-tiered triage scheme, the category that includes patients who can generally tolerate waiting several hours for health care services without a significant risk of clinical deterioration, such as those with sprains, strains, or simple fractures.

normal flora The microorganisms living in or on the human host without causing disease; the bacteria that are characteristic of each body location. Normal flora often compete with and prevent infection from unfamiliar microorganisms attempting to invade a body site.

normal sinus rhythm (NSR) The rhythm originating from the sinoatrial node (dominant pacemaker), with atrial and ventricular rates of 60 to 100 beats/min and regular atrial and ventricular rhythms.

normotonic See *isosmotic.*

North American pit vipers The Crotalidae, one of two families of indigenous poisonous snakes in North America; named for the characteristic depression between each eye and nostril. They include rattlesnakes, copperheads, and water moccasins and account for most poisonous snakebites in the United States.

nosocomial (infection) Acquired in an inpatient health care setting; for example, infections that were not present at hospital admission. Also called "hospital-acquired infections" and "health care–associated infections."

nothing by mouth (NPO) No eating, drinking (including water), or smoking.

nuchal rigidity Stiff neck, which can be a sign of cerebrospinal fluid leak; nuchal rigidity is not checked until a spinal cord injury has been ruled

out.

nucleotide The final form of a base that actually gets put into the strand of deoxyribonucleic acid. A nucleoside becomes a complete nucleotide by the attachment of phosphate groups.

nursing assistant A member of the rehabilitative health care team who assists the registered nurse in the care of patients.

nursing technician See *nursing assistant.*

nutritional screening A screening by the health care provider that includes visual inspection, measured height and weight, weight history, usual eating habits, ability to chew and swallow, and any recent changes in appetite or food intake. The screening is a way to determine which patients need more extensive nutritional assessment.

nutritional status Reflects the balance between nutrient requirements and intake.

nystagmus Involuntary, rapid eye movements.

O

obesity An increase in body weight at least 20% above the upper limit of the normal range for ideal body weight, with an excess amount of body fat; in an adult, a body mass index greater than 30.

obligatory urine output The minimum amount of urine per day needed to dissolve and excrete toxic waste products.

obstipation The inability to pass stool; intractable constipation.

obstruction Blockage.

obstructive jaundice Jaundice caused by an impediment to the flow of bile from the liver to the duodenum; may be caused by edema of the ducts or gallstones.

obstructive sleep apnea A breathing disruption during sleep that lasts at least 10 seconds and occurs a minimum of 5 times in an hour.

Occupational Safety and Health Administration (OSHA) A federal agency that protects workers from injury or illness at their place of employment.

occupational therapist (OT, OTR) A member of the rehabilitation health care team who works to develop the patient's fine motor skills used for activities of daily living and the skills related to coordination and

cognitive retraining.

odynophagia Pain on swallowing.

oligomenorrhea Scant or infrequent menses.

oligospermia Low sperm count.

oliguria Decreased excretion of urine in relation to amount of fluid intake; usually defined as urine output less than 400 mL/day.

oncogene Proto-oncogene that has been "turned on" and can cause cells to change from normal cells to cancer cells.

oncogenesis Cancer development.

oncovirus Virus that causes cancer.

oophorectomy Surgical removal of the ovary.

open fracture A fracture in which the skin surface over the broken bone is disrupted, causing an external wound. Also called "compound fracture."

open reduction The reduction of a fracture after surgical incision into the site to allow direct visualization of the fracture. See *internal fixation*.

open traumatic brain injury A type of traumatic primary brain injury that occurs with a skull fracture or when the skull is pierced by a penetrating object. The integrity of the brain and the dura is violated and there is exposure to outside contaminants, with damage to the underlying vessels, dural sinus, brain, and cranial nerves.

opportunistic infection Infection caused by organisms that are present as part of the normal environment and would be kept in check by normal immune function.

optic disc The point at the inside back of the eye where the optic nerve enters the eyeball. It appears as a creamy pink to white depressed area in the retina and contains only nerve fibers and no photoreceptor cells.

optic fundus The area at the inside back of the eye that can be seen with an ophthalmoscope.

optic nerve The nerve of sight; connects the optic disc to the brain.

orbit The bony socket of the skull that surrounds and protects the eye along with the attached muscles, nerves, vessels, and tear-producing glands.

orchiectomy The surgical removal of one or both testes.

orchitis An acute testicular inflammation resulting from trauma or infection.

orexin Neuropeptide that is an appetite stimulant.

orotracheal The route for inserting a tube into the trachea via the mouth.

orthopnea Shortness of breath that occurs when lying down but is relieved by sitting up.

orthostatic Pertaining to or caused by standing erect.

orthostatic hypotension A decrease in blood pressure (20 mm Hg systolic and/or 10 mm Hg diastolic) that occurs during the first few seconds to minutes after changing from a sitting or lying position to a standing position. Also called "postural hypotension."

orthotopic The most common type of transplantation procedure in which a diseased organ is removed and a donor organ is grafted in its place. For example, during heart transplantation, the surgeon removes the diseased heart and leaves the posterior walls of the patient's atria, which serve as the anchor for the donor heart; anastomoses are made between the recipient and donor atria, aorta, and pulmonary arteries.

osmolality The number of milliosmoles in a kilogram of solution.

osmolarity The number of milliosmoles in a liter of solution.

osmosis The movement of a solvent across a semipermeable membrane (a membrane that allows the solvent but not the solute to pass through) from a lesser to a greater concentration.

ossiculoplasty Replacement of the ossicles within the middle ear.

osteitis deformans See *Paget's disease.*

osteoarthritis Noninflammatory form of arthritis characterized by the progressive deterioration and loss of cartilage in one or more joints; most common form of arthritis.

osteoblast Cell associated with formation of bone.

osteoclast Cell associated with destruction or resorption of bone.

osteocyte Bone cell.

osteomalacia Abnormal softening of the bone tissue characterized by inadequate mineralization of osteoid. It is the adult equivalent of rickets (vitamin D deficiency) in children.

osteomyelitis An inflammation of bone tissue caused by pathogenic

microorganisms; produces an increased vascularity and edema often involving the surrounding soft tissues.

osteonecrosis The death of bone tissue, usually because the blood supply to the bone is disrupted. Usually a complication of a hip fracture or any fracture in which there is displacement of bone.

osteopenia A condition of low bone mass that occurs when there is a disruption in the bone remodeling process.

osteophyte Bone spur.

osteoporosis A metabolic disease in which bone demineralization results in decreased density and subsequent fractures.

osteotomy Surgical resection of bone.

ostomate A patient with an ostomy.

ostomy The surgical creation of an opening, usually referring to an opening in the abdominal wall; stoma.

otorrhea Ear discharge.

otosclerosis Irregular bone growth around the ossicles.

otoscope An instrument used to examine the ear; consists of a light, a handle, a magnifying lens, and a pneumatic bulb for injecting air into the external canal to test mobility of the eardrum.

ototoxic Having a toxic effect on the inner ear structures.

outflow disease Chronic peripheral arterial disease with obstruction at or below the superficial femoral or popliteal artery. The patient experiences burning or cramping in the calves, ankles, feet, and toes after walking a certain distance; the pain usually subsides with rest.

outpatient A patient who goes to the hospital for treatment and returns home on the same day.

overflow urinary incontinence The involuntary loss of urine when the bladder is overdistended.

overweight An increase in body weight for height compared with a reference standard (e.g., the Metropolitan Life height and weight tables) or 10% greater than ideal body weight. However, this weight may not reflect excess body fat, which in an adult is a body mass index of 25 to 30.

ovoid pupil In evaluating pupils for size and reaction to light, the midstage between a normal-size pupil and a dilated pupil; indicates

the development of increased intracranial pressure.

oxygen concentrator A machine that removes nitrogen, water vapor, and hydrocarbons from room air. Also known as “oxygen extractor.”

oxygen dissociation The transfer of oxygen from hemoglobin to tissues.

P

P wave In the electrocardiogram, the deflection representing atrial depolarization.

pack-years The number of packs of cigarettes per day multiplied by the number of years the patient has smoked; used in recording the patient's smoking history.

Paget's disease A metabolic disorder of bone remodeling, or turnover, in which increased resorption or loss results in bone deposits that are weak, enlarged, and disorganized. Also known as “osteitis deformans.”

pain An unpleasant sensory and emotional experience associated with actual or potential tissue damage; the most reliable indication of pain is the patient's self-report.

palliation Relieving symptoms.

palliative care A compassionate and supportive approach to patients and families who are living with life-threatening illnesses; involves a holistic approach that provides relief of symptoms experienced by the dying patient.

palpitations A feeling of fluttering in the chest, an unpleasant awareness of the heartbeat, and an irregular heartbeat; may result from a change in heart rate or rhythm or from an increase in the force of heart contractions.

pancreatic abscess A collection of purulent material that results from extensive inflammatory necrosis of the pancreas after infection by organisms such as *Escherichia coli;* the most serious complication of pancreatitis. It is fatal if left untreated.

pancreatic pseudocyst A false cyst, so named because, unlike a true cyst, it does not have an epithelial lining. It is an encapsulated saclike structure that forms on or surrounds the pancreas and develops as a complication of acute or chronic pancreatitis. It may contain up to several liters of straw-colored or dark-brown viscous fluid, the

enzymatic exudate of the pancreas.

pancreaticojejunostomy Surgical anastomosis of the pancreatic duct with the jejunum.

pancytopenia A deficiency of all three cell types (red blood cells, white blood cells, and platelets) of the blood.

pandemic A general epidemic spread over a wide geographic area and affecting a large proportion of the population.

panniculectomy The surgical removal of any panniculus, most often the abdominal apron; usually done as a follow-up to bariatric surgery in an obese patient.

panniculitis Infection of the panniculus.

panniculus A layer of membrane; also used to refer to skinfold areas in the obese patient.

pannus Vascular granulation tissue composed of inflammatory cells that forms in a joint space; erodes articular cartilage and eventually destroys bone.

Papanicolaou test (Pap smear) A cytologic study that is effective in detecting precancerous and cancerous cells obtained from the cervix.

papilla The anatomic term for a small, nipple-shaped projection or structure.

papilledema Edema and hyperemia of the optic disc; a sign of increased intracranial pressure found on ophthalmoscopic examination. Also called a "choked disc."

papilloma A pedunculated outgrowth of tissue.

papillotomy An incision of a papilla, a small nipple-shaped projection or structure.

papular Referring to a papule, a small, solid elevation of the skin.

paracentesis A procedure in which the physician inserts a trocar catheter into the abdomen to remove and drain ascitic fluid from the peritoneal cavity.

paradoxical blood pressure An exaggerated decrease in systolic pressure by more than 10 mm Hg during the inspiratory phase of the respiratory cycle (normal is 3 to 10 mm Hg); clinical conditions that may produce a paradoxical blood pressure include pericardial tamponade, constrictive pericarditis, and pulmonary hypertension.

Also known as "paradoxical pulse" and "pulsus paradoxus."

paradoxical chest wall movement The "sucking inward" of the loose chest area during inspiration and a "puffing out" of the same area during expiration in a patient with a flail chest.

paradoxical pulse See *paradoxical blood pressure.*

paradoxical splitting Abnormal splitting of the S_2 heart sound heard in patients with severe myocardial depression; causes early closure of the pulmonic valve or a delay in aortic valve closure.

paralysis Absence of movement.

paralytic ileus Absence of peristalsis.

paramedic Prehospital care provider for patients who require care that exceeds basic life support resources. Advanced life support (ALS) may include cardiac monitoring, advanced airway management and intubation, establishing IV access, and administering drugs en route to the emergency department.

paranasal sinuses The air-filled cavities within the bones that surround the nasal passages. Lined with ciliated membrane, the sinuses provide resonance during speech and decrease the weight of the skull.

paraparesis Weakness that involves only the lower extremities, as seen in lower thoracic and lumbosacral injuries or lesions.

paraplegia Paralysis that involves only the lower extremities, as seen in lower thoracic and lumbosacral injuries or lesions.

paresis Weakness.

paresthesia Abnormal or unusual nerve sensations of touch, such as tingling and burning.

parietal cells Cells lining the wall of the stomach that secrete hydrochloric acid and produce intrinsic factor.

Parkinson disease (PD) A debilitating neurologic disease that affects motor ability and is characterized by four cardinal symptoms: tremor, rigidity, akinesia (slow movement), and postural instability. It is the third most common neurologic disorder of older adults. Also called "paralysis agitans."

parotidectomy The surgical removal of the parotid glands.

paroxysmal nocturnal dyspnea (PND) In the patient with heart disease, difficulty breathing that develops after lying down for several hours

and causes the patient to awaken abruptly with a feeling of suffocation and panic. Occurs because the heart is unable to compensate for the increased volume when blood from the lower extremities is redistributed to the venous system, which increases venous return to the heart. A diseased heart is ineffective in pumping the additional fluid into the circulatory system, and pulmonary congestion results.

paroxysmal supraventricular tachycardia (PSVT) A form of supraventricular tachycardia that occurs when the rhythm is intermittent, initiated suddenly by a premature complex such as a premature atrial complex, and terminated suddenly with or without intervention.

partial left ventriculectomy (PLV) A ventricular reconstructive procedure that involves removing a triangle-shaped section of the weakened heart in the left lateral ventricle to reduce the ventricle's diameter and decrease wall tension. Also known as “heart reduction surgery” and “Batista procedure.”

partial seizure One of the three broad categories of seizure disorders along with generalized seizure and unclassified seizure. Partial seizures are of two types: complex and simple. Partial seizures begin in a part of one cerebral hemisphere; some can evolve into generalized tonic-clonic, tonic, or clonic seizures. They are most often seen in adults and in general are less responsive to medical treatment. Also called “focal seizures” or “local seizures.”

passive euthanasia See *withdrawing or withholding life-sustaining therapy.*

passive immunity Resistance to infection that is of short duration (days or months) and either natural by transplacental transfer from the mother or artificial by injection of antibodies (e.g., immunoglobulin).

patellofemoral pain syndrome (PFPS) A health problem that occurs most often in people who are runners or who overuse their knee joints. For that reason, it is sometimes referred to as “runner's knee.” These patients describe pain as being behind or around their patella (knee cap) in one or both knees.

pathogen Any microorganism capable of producing disease.

pathogenicity The ability to cause disease.

pathologic (spontaneous) fracture A fracture that occurs after minimal trauma to a bone that has been weakened by a disease such as bone cancer or osteoporosis.

patient-centered care A QSEN competency in which the nurse recognizes the patient or designee as the source of control and full partner in providing compassionate and coordinated care based on respect for the patient's preferences, values, and needs.

patient-controlled analgesia A method that allows the patient to control the dosage of opioid analgesic received by using an infusion pump to deliver the desired amount of medication through a conventional IV route.

PDSA Acronym for plan, do, study, act, which is one of the steps of the evidence-based practice improvement (EBPI) model.

pedal Pertaining to the feet.

pediculosis An infestation by human lice.

pedigree A graph of a family history for a specific trait or health problem over several generations.

pelvic inflammatory disease (PID) Any infection of the pelvis involving the upper genital tract beyond the cervix in women. It occurs when organisms from the lower genital tract migrate from the endocervix upward through the uterine cavity into the fallopian tubes.

pelvic organ prolapse (POP) Condition in which the sling of muscles and tendons that support the pelvic organs becomes weak and is no longer able to hold them in place.

penetrance In genetics, how often or how well a gene is expressed when it is present within a population.

penetrating trauma Injuries caused by piercing; classified by the velocity of the vehicle (e.g., knife or bullet) causing the injury. Low-velocity injuries from knife wounds cause damage directly at the site; high-velocity injuries from gunshot wounds cause both direct and indirect damage. Also called “penetrating injury.”

peptic ulcer A mucosal lesion of the stomach or duodenum.

peptic ulcer disease (PUD) The impairment of gastric mucosal defenses so they no longer protect the epithelium from the effects of acid and pepsin.

percutaneous Performed through the skin and other tissues.

percutaneous alcohol septal ablation Surgical procedure for hypertrophic cardiomyopathy (HCM) in which alcohol is injected into a target septal branch of the left anterior descending coronary artery to produce a

small septal infarction. This procedure also widens the left ventricular outflow tract.

percutaneous coronary intervention (PCI) See *percutaneous transluminal coronary angioplasty (PTCA).*

percutaneous endoscopic gastrostomy (PEG) A stoma created from the abdominal wall into the stomach for insertion of a short feeding tube.

percutaneous stereotactic rhizotomy (PSR) Procedure performed under general anesthesia to treat trigeminal neuralgia; a hollow needle is passed through the inside of the patient's cheek into the trigeminal nerve fibers, and a heating current (radiofrequency thermocoagulation) goes through the needle to destroy some of the fibers.

percutaneous transhepatic cholangiography (PTC) The radiographic study of the biliary duct system using an iodinated dye instilled via a percutaneous needle inserted through the liver into the intrahepatic ducts. It may be performed when a patient has jaundice or persistent upper abdominal pain, even after cholecystectomy, but it is rarely performed as a diagnostic procedure.

percutaneous transluminal coronary angioplasty (PTCA) A nonsurgical method of improving arterial flow by opening the vessel lumen and creating a smooth inner vessel surface. One or more arteries are dilated with a balloon catheter advanced through a cannula, which is inserted into or above an occluded or stenosed artery. Also called "percutaneous vascular intervention" and "percutaneous coronary intervention (PCI)."

percutaneous vascular intervention See *percutaneous transluminal coronary angioplasty.*

pericardial effusion Complication of pericarditis that occurs when the space between the parietal and visceral layers of the pericardium fills with fluid.

pericardial friction rub An abnormal sound that originates from the pericardial sac and occurs with the movements of the heart during the cardiac cycle; usually transient and a sign of inflammation, infection, or infiltration; may be heard in patients with pericarditis resulting from myocardial infarction, cardiac tamponade, or post-thoracotomy.

pericardiectomy Surgical excision of the pericardium (the sac around the heart).

pericardiocentesis Withdrawal of pericardial fluid through a catheter inserted into the pericardial space to relieve the pressure on the heart.

pericarditis An inflammation of the tissue (pericardium) surrounding the heart.

perichondrium A tough, fibrous tissue layer that surrounds the ear cartilage and gives shape to the pinna.

periodontal disease Gum disease in which mandibular bone loss has occurred.

perioperative The operative experience consisting of the preoperative, intraoperative, and postoperative time periods.

peripheral blood stem cells (PBSCs) Stem cells that are collected from peripheral blood for transplantation into the patient.

peripheral chemoreceptors Several 1- to 2-mm collections of tissue identified in the carotid arteries and along the aortic arch.

peripheral IV therapy IV therapy in which a vascular access device (VAD) is placed in a peripheral vein, usually in the arm.

peripheral vascular disease (PVD) Any disorder that alters the natural flow of blood through the arteries and veins of the peripheral circulation.

peripherally inserted central catheter (PICC) A long catheter inserted through a vein of the antecubital fossa (inner aspect of the bend of the arm) or the middle of the upper arm.

peritonitis Acute inflammation of the visceral/parietal peritoneum and endothelial lining of the abdominal cavity, or peritoneum.

peritonsillar abscess (PTA) A complication of acute tonsillitis. The infection spreads from the tonsil to the surrounding tissue, which forms an abscess.

periungual lesion Skin lesion around the nail bed.

permeable The quality of being porous.

pernicious anemia A form of megaloblastic anemia caused by failure to absorb vitamin B_{12} because of a deficiency of intrinsic factor (normally secreted by the gastric mucosa) needed for intestinal absorption of vitamin B_{12}.

PERRLA An acronym that stands for the phrase “Pupils should be equal in size, round and regular in shape, and react to light and

accommodation."

personal emergency preparedness plan An individual plan that outlines specific arrangements in the event of disaster, such as childcare, pet care, and older adult care.

personal protective equipment (PPE) Infection control protocol that refers to the use of gloves, isolation gowns, face protection, and respirators with N95 or higher filtration.

personal readiness supplies A preassembled disaster supply kit for the home and/or automobile that contains clothing and basic survival supplies. Also called a "go bag."

petechiae Pinpoint red spots on the mucous membranes, palate, conjunctivae, or skin.

pH A measure of the free hydrogen ion level in body fluid.

pH monitoring examination The most accurate testing method of diagnosing GERD, accomplished by placing a small catheter into the distal esophagus or esophageal wall (depending on the specific technique). The patient then records a diary of activities and symptoms over a 24- to 48-hour period while pH is continuously monitored.

phagocytosis The process of engulfing, ingesting, killing, and disposing of an invading organism by neutrophils and macrophages; a key process of inflammation.

Phalen's maneuver Test to determine the presence of carpal tunnel syndrome (CTS); a positive test for CTS causes paresthesia in the medial nerve distribution of the palm of the hand in 60 seconds.

phantom limb pain (PLP) A frequent complication of amputation in which the patient perceives sensation in the absent (amputated) foot or hand. This sensation usually diminishes over time.

pharmacist Member of the health care team who oversees the prescription and preparation of medications and provides the team with essential information regarding drug safety.

pharmacologic stress echocardiogram A form of echocardiography in which either dobutamine (increases heart's contractility) or adenosine (dilates coronary arteries) is given to the patient; usually used when patients cannot tolerate exercise.

phenotype Any genetic characteristic that can actually be observed or, in

some cases, determined by laboratory test.

pheochromocytoma A tumor of the adrenal medulla, which can cause excessive secretion of catecholamines.

phlebitis Inflammation of a vein, which can predispose patients to thrombosis.

phlebothrombosis Presence of a thrombus in a vein without inflammation.

phonophobia Abnormal sensitivity to sound.

phonophoresis Treatment for back pain in which a topical drug (e.g., lidocaine, hydrocortisone) is applied followed by continuous ultrasound for 10 minutes.

photophobia Abnormal sensitivity to light.

photopsia The appearance of bright flashes of light due to the onset of retinal detachment.

physiatrist A physician who specializes in rehabilitative medicine.

physical abuse The use of a physical force, such as hitting, burning, pushing, and molesting the patient, that results in bodily injury.

physical therapist (PT, RPT) A member of the rehabilitation health care team who helps the patient achieve mobility and who teaches techniques for performing certain activities of daily living.

piggyback set See *secondary administration set.*

pitting Indentation of the skin; often occurs with edema.

pituitary Cushing's disease Oversecretion of ACTH by the anterior pituitary gland, which causes hyperplasia of the adrenal cortex in both adrenal glands and an excess of most hormones secreted by the adrenal cortex.

plantar fasciitis An inflammation of the plantar fascia, which is located in the area of the arch of the foot. It is often seen in athletes, especially runners.

plasma cell A short-lived B-lymphocyte that begins functioning immediately to produce antibodies against sensitizing antigens.

plasmapheresis The separation of plasma from whole blood, after which the blood cells are returned to the patient without the plasma to eliminate antibodies.

plethoric A flushed appearance of the skin.

pleura The continuous smooth membrane composed of two surfaces that totally enclose the lungs.

pleural effusion Fluid in the pleural space.

pleuritic chest pain A stabbing pain on taking a deep breath.

plexus Cluster of nerves.

ploidy The number and appearance of chromosomes; used to describe cancer cells.

pluripotent stem cell The precursor cell involved in the production of red blood cells.

pneumonectomy Removal of an entire lung, including all blood vessels.

pneumonia Excess fluid in the lungs resulting from an inflammatory process that can include infection.

pneumothorax Air in the pleural (chest) cavity.

podagra Inflammation of the metatarsophalangeal joint of the great toe.

point of maximal impulse (PMI) See *apical impulse.*

polycystic kidney disease (PKD) An inherited disorder in which fluid-filled cysts develop in the kidneys.

polycythemia vera (PV) A disease that involves massive production of red blood cells, leukocytes, and platelets.

polydipsia Excessive intake of water.

polymorphism A variation in form.

polyp An abnormal outgrowth from a mucous membrane.

polyphagia Excessive eating.

polypharmacy The use of many drugs to treat multiple health problems for older adults. Also known as "hyperpharmacy."

polyuria Frequent and excessive urination.

pores Openings or spaces.

portal hypertension An abnormal persistent increase in pressure within the portal vein; a major complication of cirrhosis.

portal hypertensive gastropathy A complication that can occur in patients with portal hypertension, with or without esophageal varices. Slow gastric mucosal bleeding may result in chronic slow blood loss, occult positive stools, and anemia.

portal-systemic encephalopathy (PSE) A clinical disorder seen in hepatic failure and cirrhosis; it is manifested by neurologic symptoms and is characterized by an altered level of consciousness, impaired thinking processes, and neuromuscular disturbances. Also called "hepatic encephalopathy" and "hepatic coma."

positive deflection In electrocardiography, the flow of electrical current in the heart (cardiac axis) toward the positive pole.

positive inotropic agents Drugs that increase myocardial contractility and are prescribed to improve cardiac output.

postanesthesia care unit (PACU) Recovery room.

postcholecystectomy syndrome (PCS) The occurrence of the clinical manifestations of biliary tract disease following cholecystectomy; caused by residual or recurring calculi, inflammation, or stricture of the common bile duct.

post-concussion syndrome A group of clinical manifestations following a concussion that consist of personality changes, irritability, headaches, dizziness, restlessness, nervousness, insomnia, memory loss, and depression. The prolonged pattern is classified as post-trauma syndrome.

posterior colporrhaphy The surgical procedure to repair a rectocele by strengthening pelvic supports and reducing the bulging.

posteroanterior Back to front; position for standard chest x-rays.

postherpetic neuralgia Pain that persists after herpes zoster lesions have resolved.

postictal stage Referring to the time immediately after a seizure.

postoperative period After surgery.

postpericardiotomy syndrome Symptoms, including pericardial and pleural pain, pericarditis, friction rub, elevated temperature and white blood cell count, and dysrhythmias, that occur in patients after cardiac surgery; may occur days to weeks after surgery and seems to be associated with blood that remains in the pericardial sac.

postrenal failure Decrease in renal function related to an obstruction in the flow of urine. It can progress to acute renal failure.

postural hypotension See *orthostatic hypotension.*

posture A person's body build and alignment when standing and walking.

post-void residual (PVR) The amount of urine remaining in the bladder within 20 minutes after voiding.

power air purifying respirator (PAPR) Device with a high efficiency particulate air (HEPA) filter and battery to promote positive pressure air flow; more effective than an N95 respirator.

PQRST A mnemonic (memory device) that may help in the current problem assessment of patients with gastrointestinal tract disorders. The letters represent these areas: P, precipitating or palliative (What brings it on? What makes it better or worse?); Q, quality or quantity (How does it look, feel, or sound?); R, region or radiation (Where is it? Does it spread anywhere?); S, severity scale (How bad is it [on a scale of 0 to 10]? Is it getting better, worse, or staying the same?); T, timing (Onset, duration, and frequency?).

PR interval In the electrocardiogram, the interval measured from the beginning of the P wave to the end of the PR segment; represents the time required for atrial depolarization as well as impulse delay in the atrioventricular node and travel time to the Purkinje fibers.

PR segment In the electrocardiogram, the isoelectric line from the end of the P wave to the beginning of the QRS complex, when the electrical impulse is traveling through the atrioventricular node, where it is delayed.

Prader-Willi syndrome (PWS) A complex neurodevelopmental genetic disorder that results from a hypothalamic-pituitary dysfunction that prevents appetite control. Patients with this syndrome are typically morbidly obese.

prandial (insulin secretion) The increased levels of insulin that are secreted after eating. Within 10 minutes of eating, an early burst of insulin secretion occurs, which is followed by an increasing insulin release that lasts as long as hyperglycemia is present.

prealbumin (PAB) A protein secreted by the liver that binds thyroxine.

precipitation The formation of large, insoluble antigen-antibody complexes during the antibody-binding process.

prediabetes An impaired fasting glucose (IFG) or impaired glucose tolerance (IGT).

prehospital care provider Typically, any of the first caregivers encountered by the patient if he or she is transported to the emergency department by an ambulance or helicopter.

preictal phase Referring to events that a patient experiences before a seizure, such as the presence of an aura.

pre-infarction angina Chest pain that occurs in the days or weeks before a myocardial infarction.

preload The degree of myocardial fiber stretch at the end of diastole and just before contraction; determined by the amount of blood returning to the heart from both the venous system (right heart) and the pulmonary system (left heart).

premature atrial complex (contraction) (PAC) In the electrocardiogram, an early complex that occurs when atrial tissue becomes irritable. This ectopic focus fires an impulse before the next sinus impulse is due, thus usurping the sinus pacemaker. The premature P wave from the atrial focus is early and has a shape different from that of the P wave generated from the sinus node.

premature complex In the electrocardiogram, an early complex that occurs when a cardiac cell or cell group other than the sinoatrial node becomes irritable and fires an impulse before the next sinus impulse is generated. After the premature complex, there is a pause before the next normal complex, which creates an irregularity in the rhythm.

premature ventricular complex (PVC) In the electrocardiogram, an early ventricular complex is followed by a pause that results from increased irritability of ventricular cells. The QRS complexes may be unifocal or uniform (of the same shape), or multifocal or multiform (of different shapes).

preoperative Before surgery.

prerenal failure Condition that causes inadequate kidney perfusion; can progress to acute renal failure.

presbycusis The loss of hearing, especially for high-pitched sounds; occurs as a result of aging.

presbyopia An age-related impairment of vision characterized by a loss of lens elasticity and the ability of the eye to accommodate. The near point of vision increases, and near objects must be placed farther from the eye to be seen clearly.

presence A type of communication that consists of listening and acknowledging the legitimacy of the patient's and/or family's pain.

pressure ulcer Tissue damage caused when the skin and underlying soft tissue are compressed between a bony prominence and an external

surface for an extended period; commonly occurs over the sacrum, hips, and ankles.

pretibial Pertaining to the front of the leg below the knee.

pretibial myxedema Dry, waxy swelling of the front surfaces of the lower legs.

primary angle-closure glaucoma A form of glaucoma characterized by a narrowed angle and forward displacement of the iris so that movement of the iris against the cornea narrows or closes the chamber angle, obstructing the outflow of aqueous humor. It can have a sudden onset and is an emergency. Also called "closed-angle glaucoma," "narrow-angle glaucoma," or "acute glaucoma."

primary arthroplasty A total joint arthroplasty procedure that has been performed for the first time.

primary gout The most common type of gout; results from one of several inborn errors of purine metabolism.

primary lesions In describing skin disease, the initial reaction to a problem that alters one of the structural components of the skin.

primary open-angle glaucoma (POAG) The most common form of primary glaucoma; characterized by reduced outflow of aqueous humor through the chamber angle. Because the fluid cannot leave the eye at the same rate it is produced, intraocular pressure gradually increases.

primary prevention Strategies used to avoid or delay the actual occurrence of a specific disease.

primary progressive multiple sclerosis (PPMS) A type of multiple sclerosis (MS) that involves a steady and gradual neurologic deterioration without remission of symptoms. Patients with this type of MS are usually between 40 and 60 years of age at onset of the disease and experience progressive disability with no acute attacks.

primary survey Priorities of care addressed in order of immediate threats to life as part of the initial assessment in the emergency department. Survey is based on an "ABC" mnemonic with "D" and "E" added for trauma patients: airway/cervical spine (A), breathing (B), circulation (C), disability (D), and exposure (E).

primary tumor The original tumor, usually identified by the tissue from which it arose (parent tissue), such as in breast cancer or lung cancer.

progressive multifocal leukoencephalopathy (PML) Rare disease affecting the white matter of the brain caused by a virus that attacks the cells that make myelin; occurs most often in patients who are immunosuppressed.

progressive-relapsing multiple sclerosis (PRMS) A type of multiple sclerosis (MS) that occurs in only 5% of patients with MS. It is characterized by the absence of periods of remission, and the patient's condition does not return to baseline. Progressive cumulative symptoms and deterioration occur over several years.

proliferative diabetic retinopathy A form of retinopathy associated with diabetes mellitus in which a network of fragile new blood vessels develops, leaking blood and protein into surrounding tissue. The new blood vessels are stimulated by retinal hypoxia that results from poor capillary perfusion of the retinal tissues. New blood vessels grow in the retina, onto the iris, and into the back of the vitreous. The vitreous contracts and pulls away from the retina, causing blood vessels to break and bleed into the vitreous.

promoter In oncology, a substance that promotes or enhances growth of the initiated cancer cell; may be a hormone, drug, or chemical.

pronator drift Occurs in a patient with muscle weakness due to cerebral or brainstem reasons. The arm on the weak side tends to fall, or "drift," with the palm pronating (turning inward) after the patient has closed his or her eyes and held the arms perpendicular to the body with the palms up for 15 to 30 seconds; part of the neurologic assessment.

prophylactic mastectomy Highly controversial practice of surgically removing the breast in order to reduce the risk of breast cancer.

proportionate palliative sedation A care management approach involving the administration of drugs such as benzodiazepines for the purpose of lowering patient consciousness.

proprioception (proprioceptive) Awareness of body position and movement.

prosopagnosia The inability to recognize oneself and other familiar faces; occurs in patients in the later stages of Alzheimer's disease.

prostaglandins Chemicals that are produced in the cells and cause inflammation and swelling.

prostate-specific antigen (PSA) A glycoprotein produced solely by the

prostate. The normal blood level of PSA is less than 4 ng/mL; levels are higher in patients with increased prostatic tissue as a result of benign prostatic hyperplasia, prostatic infarction, prostatitis, and prostate cancer. Levels associated with prostate cancer are usually much higher than those occurring with other prostate tissue enlargement.

prostatitis Inflammation of the prostate.

protein-calorie malnutrition (PCM) A disorder of nutrition that may present in three forms: marasmus, kwashiorkor, and marasmic-kwashiorkor. Also called "protein-energy malnutrition."

protein-energy malnutrition (PEM) See *protein-calorie malnutrition.*

protein synthesis The process by which genes are used to make the proteins needed for physiologic function.

proteinuria The presence of protein in the urine.

proteolysis The breakdown of proteins to provide fuel for energy when liver glucose is unavailable.

proton pump inhibitor (PPI) A group of drugs that inhibit the proton pump in the stomach to decrease gastric acid production.

pruritus An unpleasant itching sensation.

psoriasis A chronic, autoimmune disorder of the skin with exacerbations and remissions. It results from overstimulation of the immune system (Langerhans' cells) in the skin that activates T-lymphocytes. The features include increased skin cell division in patchy areas forming scaly plaques.

psoriatic arthritis (PsA) A syndrome of inflammatory arthritis associated with psoriasis, the skin condition characterized by a scaly, itchy rash.

psychiatric crisis nurse team An emergency department specialty team whose nurses interact with patients and families in crisis.

psychotropic drugs Antipsychotic and neuroleptic drugs. These are appropriately given to patients with emotional and behavioral health problems (e.g., hallucinations and delusions) that accompany dementia but are sometimes inappropriately used for agitation, combativeness, or restlessness. They are considered chemical restraints because they decrease mobility and patients' ability to care for themselves.

ptosis Drooping of the eyelid.

pulmonary artery occlusive pressure (PAOP) See *pulmonary artery wedge*

pressure.

pulmonary artery wedge pressure (PAWP) Measurement of pressure in the left atrium using a balloon-tipped catheter introduced into the pulmonary artery. When the balloon at the catheter tip is inflated, the catheter advances and wedges in a branch of the pulmonary artery. The tip of the catheter is able to sense pressures transmitted from the left atrium, which reflect left ventricular end-diastolic pressure. Also called "pulmonary artery occlusive pressure."

pulmonary autograph The relocation of the patient's own pulmonary valve to the aortic position for aortic valve replacement (Ross procedure).

pulmonary embolism (PE) A collection of particulate matter, most commonly a blood clot, that enters venous circulation and lodges in the pulmonary vessels, obstructing pulmonary blood flow and leading to decreased systemic oxygenation, pulmonary tissue hypoxia, and potential death.

pulmonary empyema A collection of pus in the pleural space most commonly caused by a pulmonary infection.

pulse deficit The difference between the apical and peripheral pulses.

pulse pressure The difference between the systolic and diastolic pressures.

pulse therapy Any therapy given at a high dose for a short duration.

pulsus alternans A type of pulse in which a weak pulse alternates with a strong pulse despite a regular heart rhythm; seen in patients with severely depressed cardiac function.

punctum The opening through which tears drain; located at the nasal side of the eyelid edges.

pupil The opening through which light enters the eye; located in the center of the iris of the eye.

Purkinje cells In the cardiac conduction system, the cells that make up the bundle of His, bundle branches, and terminal Purkinje fibers. These cells are responsible for the rapid conduction of electrical impulses throughout the ventricles, leading to ventricular depolarization and subsequent ventricular muscle contraction.

purpura Purple patches on the skin that may be caused by blood disorders, vascular abnormalities, or trauma.

pyelolithotomy The surgical removal of a stone from the kidney.

pyelonephritis A bacterial infection in the kidney and renal pelvis (the upper urinary tract).

pyloromyotomy An incision through the serosa and muscularis of the pylorus, down to the mucosa; created to prevent gastric motility disturbances in patients who have undergone esophagectomy.

pyuria The presence of white blood cells (pus) in the urine.

Q

QRS complex In the electrocardiogram, the portion consisting of the Q, R, and S waves, representing ventricular depolarization.

QRS duration In the electrocardiogram, the time required for depolarization of both ventricles; measured from the beginning of the QRS complex to the J point (the junction where the QRS complex ends and the ST segment begins).

QT interval In the electrocardiogram, the time from the beginning of the QRS complex to the end of the T wave. It represents the total time required for ventricular depolarization and repolarization.

quadriceps-setting exercise Postoperative leg exercise performed by straightening the legs and pushing the back of the knees into the bed.

quadrigeminy A type of premature complex consisting of a repetitive four-beat pattern; usually occurs as three sequential normal complexes followed by a premature complex and a pause, with the same pattern repeating itself in a four-beat pattern.

quadriparesis Weakness that involves all four extremities; seen with cervical spinal cord injury.

qualitative question A clinical question that focuses on the meanings and interpretations of human phenomena or experience of people and usually analyzes the content of what a person says during an interview or what a researcher observes.

quality improvement A QSEN competency in which the nurse uses data to monitor the outcomes of care processes and uses improvement methods to design and test changes to continuously improve the quality and safety of health care systems.

quantitative question A clinical question that asks about the relationship between or among defined, measurable phenomena and includes

statistical analysis of information that is collected to answer a question.

R

radiation dose The amount of radiation absorbed by the tissue.

radiation proctitis Rectal mucosa inflammation that results from external beam radiation therapy.

radical cystectomy Removal of the bladder and surrounding tissue with urinary diversion.

radicular Referring to a nerve root.

radiculopathy Referring to radicular pain; spinal nerve root involvement.

radiofrequency catheter ablation An invasive procedure that uses radiofrequency waves to abolish an irritable focus that is causing a supraventricular or ventricular tachydysrhythmia.

Rapid Response Team Team of critical care experts who save lives and decrease the risk for harm by providing care to patients before a respiratory or cardiac arrest occurs. Also called “Medical Emergency Team.”

RBC Red blood cell.

rebound headache Headache that occurs as a side effect of a drug that has relieved an initial migraine headache. Also called “medication overuse headache.”

recall memory Recent memory, which can be tested during the history taking by asking about items such as the dates of clinic or physician appointments.

receptive aphasia A type of aphasia caused by injury to Wernicke's area in the temporoparietal area of the brain and characterized by an inability to understand the spoken and written word; both reading and writing ability are equally affected. Although the patient can talk, the language is often meaningless and neologisms (made-up words) are common parts of speech. Also called “Wernicke's aphasia” or “sensory aphasia.”

reconstructive plastic surgery Type of plastic surgery that corrects or improves functional defects that have occurred as a result of congenital problems, trauma and scarring, or other types of therapy.

recreational therapist A member of the health care team who works to

help patients continue or develop hobbies or interests. Also called "activity therapist."

rectocele A protrusion of the rectum through a weakened vaginal wall.

red reflex A reflection of light on the retina seen as a red glare during ophthalmoscopic examination. An absent red reflex may indicate a lens opacity or cloudiness of the vitreous.

redirection An intervention to help with communication problems in patients with dementia; consists of attracting the patient's attention before conversing, keeping the environment as free of distractions as possible, and speaking directly to the patient in a distinct manner using clear and short sentences.

reducible hernia A hernia that can be placed back into the abdominal cavity by gentle pressure.

reduction mammoplasty Breast reduction surgery in which the surgeon removes excess breast tissue and then repositions the nipple and remaining skin flaps to produce an optimal cosmetic effect.

Reed-Sternberg cell A specific cancer cell type, found in lymph nodes, that is a marker for Hodgkin's lymphoma.

re-epithelialization In partial-thickness (superficial) wounds involving damage to the epidermis and upper layers of the dermis, a form of healing by means of the production of new skin cells by undamaged epidermal cells in the basal layer of the dermis.

refeeding syndrome Life-threatening metabolic complication that can occur when nutrition is restarted for a patient who is in a starvation state.

reflex arc A closed circuit of spinal and peripheral nerves that requires no control by the brain.

reflex sympathetic dystrophy (RSD) See *complex regional pain syndrome.*

reflux Reverse or backward flow.

reflux esophagitis Damage to the esophageal mucosa, often with erosion and ulceration, in patients with gastroesophageal reflux disease.

refraction The bending of light rays.

refractory hypoxemia Low blood oxygen levels that persist even when 100% oxygen is given.

regional anesthesia A type of local anesthesia that blocks multiple

peripheral nerves in a specific body region.

registered dietitian (RD) Member of the health care team who ensures patients meet their nutritional needs. Also called “nutritionist.”

regurgitation Flowing in the opposite direction from normal, as the occurrence of warm fluid traveling up the throat, unaccompanied by nausea, in the patient with gastroesophageal reflux disease.

rehabilitation The process of learning to live with chronic and disabling conditions by returning the patient to the fullest possible physical, mental, social, vocational, and economic capacity.

rehabilitation case manager Nurse or other health care professional who coordinates health care for patients undergoing rehabilitation in home or acute care settings.

rehabilitation nurse Nurse who coordinates the efforts of health care team members for patients undergoing rehabilitation in the inpatient setting; may be designated as the patient's case manager.

relapsing-remitting multiple sclerosis (RRMS) A type of multiple sclerosis that occurs in 85% of cases and is characterized by a mild or moderate course, depending on the degree of disability. Relapses develop over 1 to 2 weeks and resolve over 4 to 8 months, after which the patient returns to baseline.

reliever drugs Drugs used in asthma therapy to stop an asthma attack once it has started.

religions Formal belief systems that provide a framework for making sense of life, death, and suffering and responding to universal spiritual questions; a formal expression of spirituality.

relocation stress syndrome Physiologic or psychosocial distress following transfer from one environment to another, such as after admission to a hospital or nursing home. Also called “relocation trauma.”

reminiscence The process of randomly reflecting on memories of events in one's life.

remote memory Long-term memory of events; can be tested by asking patients about their birth date, schools attended, city of birth, or anything from the past that can be verified.

renal colic Severe pain associated with distention or spasm of the ureter, such as with an obstruction or the passing of a stone; the pain radiates into the perineal area, groin, scrotum, or labia. Pain may be

intermittent or continuous and may be accompanied by pallor, diaphoresis, and hypotension.

renal columns Cortical tissue that dips into the interior of the kidney and separates the pyramids in the medulla. Also called "columns of Bertin."

renal cortex The outermost layer of functional kidney tissue lying beneath the renal capsule.

renal osteodystrophy The problems in bone metabolism and structure caused by renal failure–induced hypocalcemia and hyperphosphatemia.

renal pelvis The expansion from the upper end of the ureter into which the calices of the kidney open.

renal threshold The limit to the amount of glucose that the kidney can reabsorb as glucose is filtered from the blood. Also called the "transport maximum."

renin A hormone that is produced in the juxtaglomerular complex of the kidney and helps regulate blood flow, glomerular filtration rate, and blood pressure. Renin is secreted when sensing cells (macula densa) in the distal convoluted tubule sense changes in blood volume and pressure.

repetitive stress injury (RSI) Injury caused by repeated movements of the same part of the body (e.g., carpal tunnel syndrome).

replicate The reproduction of DNA that occurs each time a cell divides.

resident An individual who lives in an inpatient facility and has all the rights of anyone living in his or her home.

residuals Amount of feeding that remains in the stomach after enteral nutrition.

resistin A hormone produced by fat cells that creates resistance to insulin activity.

resorption In referring to bone, the loss of bone minerals and density; the release of free calcium from bone storage sites directly into the extracellular fluid.

restorative aide A member of the health care team, often with the nursing department, who assists the therapists, especially in the long-term care setting.

restraint Any device (physical restraint) or drug (chemical restraint) that

prevents the patient from moving freely.

restrictive cardiomyopathy A form of cardiomyopathy that restricts the filling of the ventricles; a type of lung disease that prevents good expansion and recoil of the gas exchange unit.

restrictive (lung disorder) Any lung disorder that prevents good expansion and recoil of the gas exchange unit.

resurfacing Regrowth of new skin cells across the open area of a wound as it heals.

resuscitation phase The first phase of a burn injury, beginning at the onset of injury and continuing to about 48 hours.

rete pegs The fingers of epidermal tissue that project into the dermis.

reticular activating system (RAS) Special cells throughout the brainstem that constitute the system that controls awareness and alertness.

retina The innermost layer of the eye, made up of sensory receptors that transmit impulses to the optic nerve. It contains blood vessels and two types of photoreceptors called "rods" and "cones." Rods work at low light levels and provide peripheral vision; cones are active at bright light levels and provide color and central vision.

retinal detachment Separation of the retina from the epithelium.

retinal hole A break in the retina; can be caused by trauma or can occur with aging.

retinal tear Jagged and irregularly shaped break in the retina resulting from traction on the retina.

retinopathy Inflammation of the retina. Also used as a general term for vision problems.

retrograde Going against the normal direction of flow.

retroviruses The family of viruses that includes the human immune deficiency virus.

revision arthroplasty Surgical replacement of a prosthesis that has loosened and is causing pain.

rhabdomyolysis The breakdown or disintegration of muscle tissue; associated with excretion of myoglobin in the urine.

rheumatic carditis Inflammatory lesions in the heart due to a sensitivity response that develops after an upper respiratory tract infection with group A beta-hemolytic streptococci, which occurs in about 40% of

patients with rheumatic fever. Inflammation results in impaired contractile function of the myocardium, thickening of the pericardium, and valvular damage. Also called "rheumatic endocarditis."

rheumatic disease Any disease or condition involving the musculoskeletal system.

rheumatoid arthritis (RA) A chronic, progressive, systemic, inflammatory autoimmune disease process that primarily affects the synovial joints; one of the most common connective tissue diseases and the most destructive to the joints.

rhinitis An inflammation of the nasal mucosa.

rhinoplasty A surgical reconstruction of the nose done for cosmetic purposes and improvement of airflow.

rhinorrhea Watery drainage from the nose; a "runny" nose.

rickets Vitamin D deficiency in children.

right-sided heart (ventricular) failure The inability of the right ventricle to empty completely, resulting in increased volume and pressure in the systemic veins and systemic venous congestion with peripheral edema.

robotic technology Technology that provides mechanical parts for extremities when they are not functional or have been amputated.

Romberg sign Swaying or falling when the patient is standing with arms at the sides, feet and knees close together, and eyes closed; a test of equilibrium in neurologic assessment.

rotation A mechanism of injury in which the head is turned excessively beyond the normal range.

rubor Dusky red discoloration of the skin.

rugae Folds, as of a mucous membrane.

S

S_3 gallop The third heart sound; an early diastolic filling sound that indicates an increase in left ventricular pressure and may be heard on auscultation in patients with heart failure.

safety A QSEN competency in which the nurse minimizes risk of harm to patients and providers through both system effectiveness and individual performance.

Salem sump tube Tube inserted through the nose and placed into the stomach that is attached to low continuous suction. It has a vent ("pigtail") that prevents the stomach mucosa from being pulled away during suctioning.

salpingitis Infection of the fallopian tube.

sanguineous Having a bloody appearance.

sarcoidosis A granulomatous disorder of unknown cause that can affect any organ but most often involves the lung.

SBAR Acronym for a formal method of communication between two or more members of the health care team. It is used most often when there is an unmet patient need or problem but can also be used to communicate continuing care issues when a patient is discharged from one agency to another. It consists of four steps: **S**ituation, **B**ackground, **A**ssessment, **R**ecommendation.

scabies A contagious skin disease caused by mite infestations.

sclera The external white layer of the eye.

scleroderma See *systemic sclerosis.*

sclerotherapy The injection of a sclerosing agent via a catheter, usually in an endoscopic procedure, to stop variceal bleeding.

sclerotic Hard, or hardening.

scoliosis An abnormal lateral curve in the spine, which normally should be a straight vertical line.

scotomas Changes in peripheral vision.

sebum A mildly bacteriostatic, fat-containing substance produced by the sebaceous glands. Sebum lubricates the skin and reduces water loss from the skin surface.

second intention Healing of deep tissue injuries or wounds with tissue loss in which a cavity-like defect requires gradual filling of the dead space with connective tissue, which prolongs the repair process.

secondary administration set A short conduit that is attached to the primary administration set at a Y-injection site and is used to deliver intermittent medications. Also called a "piggyback set."

secondary gout Gout involving hyperuricemia.

secondary hypertension Elevated blood pressure that is related to a specific disease (e.g., kidney disease) or medication (e.g., estrogen).

secondary lesion Describing skin disease in terms of changes in the appearance of the primary lesion. These changes occur with progression of an underlying disease or in response to a topical or systemic therapeutic intervention.

secondary prevention Early detection of a disease or condition, sometimes before signs and symptoms are evident, to prevent or limit permanent disability or death.

secondary progressive multiple sclerosis (SPMS) A type of multiple sclerosis that begins with a relapsing-remitting course and later becomes steadily progressive. Attacks and partial recoveries may continue to occur.

secondary survey In the emergency department, a more comprehensive head-to-toe assessment performed to identify other injuries or medical issues that need to be managed or that might impact the course of treatment.

secondary tumor Additional tumor that is established when cancer cells move from the primary location to another area in the body. Also called "metastatic tumor."

seizure An abnormal, sudden, excessive, uncontrolled electrical discharge of neurons within the brain that may result in an alteration in consciousness, motor or sensory ability, and/or behavior. A single seizure may occur for no known reason; however, seizures may be due to a pathologic condition of the brain, such as a tumor.

self-tolerance In immunology, the ability to recognize self cells versus non-self cells, which is necessary to prevent healthy body cells from being destroyed along with invading cells.

Sengstaken-Blakemore tube Tube similar to a nasogastric tube that is placed through the nose and into the stomach in which an attached balloon is inflated to apply pressure to bleeding variceal areas of the esophagus.

sensitivity The likelihood that infecting bacterial organisms will be killed or stopped by a particular antibiotic drug. Sensitivity is determined by testing different antibiotics against the organisms. Organisms are "sensitive" if the antibiotic is effective in stopping their growth; organisms are "resistant" if the antibiotic is not effective.

sensorineural hearing loss Hearing loss that results from a defect in the cochlea, the eighth cranial nerve, or the brain itself. Exposure to loud

noises and music may cause this type of hearing loss as a result of damage to the cochlear hair cells.

sensory Facilitating sensation.

sensory aphasia See *receptive aphasia*.

sentinel event As defined by The Joint Commission, an unexpected occurrence involving serious physical or psychological injury or the risk thereof and requiring an intense analysis of the contributing factors and corrective action.

sepsis Systemic infection.

septic shock The type of shock that occurs when large amounts of toxins and endotoxins produced by bacteria are released into the blood, causing a whole-body inflammatory reaction.

septicemia Systemic disease associated with sepsis; the presence of pathogens in the blood.

sequestrum A piece of necrotic bone that has separated from surrounding bone tissue; a common complication of osteomyelitis.

serologic testing Laboratory testing that is performed to identify pathogens by detecting antibodies to the organism.

serositis Inflammation of a serous membrane, such as the pleura or peritoneum.

serous Having a serum-like appearance, or yellow color.

serum sickness A type III hypersensitivity reaction that develops first as a skin rash and occurs within 3 to 21 days of the administration of antivenin (Crotalidae) polyvalent. This allergic response is often accompanied by other manifestations such as fever, arthralgias (joint pains), and pruritus (itching).

severe acute respiratory syndrome (SARS) An easily spread respiratory infection first identified in China in November 2002. At first appearing as an atypical pneumonia, it is caused by a new, more virulent form of coronavirus, and there is no known effective treatment.

severe sepsis The progression of sepsis with an amplified inflammatory response.

sex chromosomes The pair of chromosomes containing the genes for sexual differentiation in humans. In males, the sex chromosomes are an X and a Y; in females, the sex chromosomes are two Xs.

sex reassignment surgery (SRS) Surgery, particularly procedures that affect the external or internal genitalia, that transitions an individual from one's natal sex to one's inner gender identity. Also known as "gender reassignment surgery."

sexually transmitted infections (STIs) Any of a group of diseases caused by infectious organisms that have been passed from one person to another through intimate contact. Some organisms that cause these diseases are transmitted only through sexual contact. Other organisms are transmitted by parenteral exposure to infected blood, fecal-oral transmission, intrauterine transmission to the fetus, and perinatal transmission from mother to neonate. Also known as "sexually transmitted diseases (STDs)."

SHARE Acronym standing for **S**tandardize critical content, **H**ardwire within your system, **A**llow opportunity to ask questions, **R**einforce quality and measurement, **E**ducate and coach.

shift to the left An increased number of immature neutrophils found on a differential count in patients with infections; can be characterized by changes in percentages of different types of leukocytes. Also known as "left shift."

shock The whole-body response to poor tissue oxygenation. Any problem that impairs oxygen delivery to tissues and organs can start the syndrome of shock and lead to a life-threatening emergency.

short peripheral catheter A catheter that consists of a plastic cannula built around a sharp stylet for venipuncture, which extends slightly beyond the cannula and is advanced into the vein.

sialagogue An agent that stimulates the flow of saliva.

simple fracture See *closed fracture.*

single-photon emission computed tomography (SPECT) A diagnostic tool using a radiopharmaceutical (agent that enables radioisotopes to cross the blood-brain barrier) that is administered by IV injection, after which the patient is scanned.

sinoatrial (SA) node In the cardiac conduction system, the primary pacemaker of the heart; located close to the epicardial surface of the right atrium near its junction with the superior vena cava. It can spontaneously and rhythmically generate electrical impulses at a rate of 60 to 100 beats/min. Also called the "sinus node."

sinus arrhythmia A variant of normal sinus rhythm that results from

changes in intrathoracic pressure during breathing; heart rate increases slightly during inspiration and decreases slightly during exhalation. Atrial and ventricular rates are between 60 and 100 beats/min, and atrial and ventricular rhythms are irregular.

sinus bradycardia A cardiac dysrhythmia caused by a decreased rate of sinus node discharge, with a heart rate that is less than 60 beats/min.

sinus tachycardia A cardiac dysrhythmia caused by an increased rate of sinus node discharge, with a heart rate that is more than 100 beats/min.

sinusitis An inflammation of the mucous membranes of the sinuses.

SIRS Acronym for systemic inflammatory response syndrome, an inflammatory state affecting the whole body.

Sjögren's syndrome In patients with advanced rheumatoid arthritis, the triad of dry eyes, dry mouth, and dry vagina caused by the obstruction of secretory ducts and glands by inflammatory cells and immune complexes.

skilled nursing facility (SNF) Part of either a hospital or long-term care (nursing home) setting in which care is reimbursed through Medicare Part A for the first 21 days after admission.

skinfold measurement Measurement that estimates body fat.

smart pump An infusion pump with dosage calculation software.

social justice Ethical principle that refers to equality and fairness—that all patients should be treated equally and fairly, regardless of age, gender, religion, race, ethnicity, or education.

social worker Member of the health care team who helps patients identify support services and resources and who coordinates transfers to or discharges from the rehabilitation setting.

sodium (Na^+) A mineral that is the major cation in the extracellular fluid and maintains extracellular fluid (ECF) osmolarity.

solute A particle dissolved or suspended in the water portion (solvent) of body fluids; a solution consists of a solute and a solvent.

solvent The water portion of fluids.

spastic bladder Incontinence characterized by sudden, gushing voids, usually without completely emptying the bladder; caused by neurologic problems affecting the upper motor neuron, such as with spinal cord injuries above the twelfth thoracic vertebra.

spastic paralysis Paralysis of a part of the body that is characterized by spasticity of muscles due to hypertonia; may be seen in the patient who has experienced a brain attack.

specialized nutrition support (SNS) Total nutritional intake orally or intravenously with commercially prepared products (either total enteral nutrition or total parenteral nutrition).

speech-language pathologist (SLP) A member of the rehabilitation health care team who evaluates and retrains patients with speech, language, or swallowing problems.

sphincter of Oddi The sheath of muscle fibers surrounding the papillary opening of the duodenum.

sphincterotomy A procedure for opening a sphincter.

spider angiomas See *telangiectasias.*

spinal fusion (arthrodesis) A surgical procedure to stabilize the spine after repeated laminectomies have been unsuccessful. Chips of bone are removed (typically from the iliac crest) or are obtained from donor bone; the chips are grafted between the vertebrae for support and to strengthen the back.

spinal shock See *spinal shock syndrome.*

spinal shock syndrome Loss of reflex activity below the level of a spinal lesion; occurs immediately after injury as a result of disruption in the communication pathways between the upper motor neurons and the lower motor neurons. Also called "spinal shock."

spinal stenosis Narrowing of the spinal canal; typically seen in people older than 60 years.

spirituality The connection to self, others, the environment, and a "higher power."

spiritual counselor Counselor who specializes in spiritual assessments and care, usually a member of the clergy.

splenectomy Surgical removal of the spleen.

splenomegaly Enlargement of the spleen.

splint Any object or device that extends to the joints above and below a fracture to immobilize it.

splinter hemorrhage Black longitudinal line or small red streak on the distal third of the nail bed; seen in patients with infective endocarditis.

spondee Two-syllable words in which there is generally equal stress on each syllable, such as *airplane, railroad,* and *cowboy;* used in testing speech reception threshold.

spondylolisthesis Condition in which one vertebra slips forward on the one below it, often as a result of spondylolysis. This problem causes pressure on the nerve roots, leading to pain in the lower back and into the buttocks.

spondylolysis A defect in one of the vertebrae; usually found in the lumbar spine.

spontaneous bacterial peritonitis (SBP) Bacterial infection of the abdominal peritoneum caused by ascites; often seen in patients with cirrhosis of the liver.

spore An encapsulated, inactive organism.

sprain Excessive stretching of a ligament.

ST segment In the electrocardiogram, the line (normally isoelectric) representing early ventricular repolarization. It occurs from the J point to the beginning of the T wave.

ST-elevation myocardial infarction (STEMI) Myocardial infarction in which the patient typically has ST elevation in two contiguous leads on a 12-lead ECG; this indicates myocardial infarction/necrosis.

staging System of classifying clinical aspects of a cancer tumor.

Standard Precautions Infection control guidelines from the Centers for Disease Control and Prevention stating that all body excretions, secretions, and moist membranes and tissues are potentially infectious; combines protective measures from Universal Precautions and Body Substance Isolation.

stasis dermatitis In patients with venous insufficiency, discoloration of the skin along the ankles, which extends up to the calf.

stasis ulcer In patients with long-term venous insufficiency, ulcer formed as a result of edema or minor injury to the limb; typically occurs over the malleolus.

status epilepticus Prolonged seizures lasting more than 5 minutes or repeated seizures over the course of 30 minutes; a potential complication of all types of seizures.

steatorrhea An excessive amount of fat in the stool.

stem cell An immature, undifferentiated cell produced by the bone marrow.

stent A small tube that is placed in a tubular structure to dilate it; a wirelike device that may be used along with percutaneous transluminal angioplasty to help keep the vessel open.

stereotactic pallidotomy A surgical treatment for the patient with Parkinson disease when drugs are ineffective in symptom management. An electrode is used to create a lesion in a targeted area within the pallidum, with the goal of reducing tremor and rigidity.

sterilization A method of infection control in which all living organisms and bacterial spores are destroyed; used on items that invade human tissue where bacteria are not commonly found.

stoma The surgical creation of an opening; usually refers to an opening in the abdominal wall.

stomatitis Inflammation of the oral mucosa; characterized by painful single or multiple ulcerations that impair the protective lining of the mouth. The ulcerations are commonly referred to as "canker sores."

strain Excessive stretching of a muscle or tendon when it is weak or unstable; sometimes referred to as "muscle pulls."

strangulated hernia A tightly constricted hernia that compromises the blood supply to the herniated segment of the bowel as a result of pressure from the hernial ring (the band of muscle around the hernia); leads to ischemia and obstruction of the bowel loop, with necrosis of the bowel and possibly bowel perforation.

strangulated obstruction Intestinal obstruction with compromised blood flow.

stratum corneum The outermost layer of the skin.

stress test See *exercise electrocardiography.*

stress ulcers Multiple shallow erosions of the proximal stomach and occasionally the duodenum.

stress urinary incontinence (SUI) Loss of urine during activities that increase intra-abdominal pressure, such as laughing, coughing, sneezing, or lifting heavy objects.

striae Reddish purple streaks on the skin. Also called "stretch marks."

stricture Narrowing.

stridor A high-pitched crowing sound caused by laryngospasm or edema above or below the glottis; heard during respiration.

stroke See *brain attack.*

stroke volume (SV) The amount of blood ejected by the left ventricle during each heartbeat.

subarachnoid space Term for the space between the arachnoid mater and pia mater of the spinal cord. Also called "subarachnoid."

subcutaneous emphysema The presence of bubbles under the skin because of air trapping; an uncommon late complication of fracture.

subcutaneous infusion therapy Infusion therapy that is delivered under the skin when patients cannot tolerate oral medications, when intramuscular injections are too painful, or when vascular access is not available.

subcutaneous nodule Characteristic round, movable, nontender swelling under the skin of the arm or fingers in patients with severe rheumatoid arthritis.

subdural hematoma (SDH) The collection of clotted blood that typically results from venous bleeding into the space beneath the dura and above the arachnoid.

subdural space Term for the space between the dura mater and the middle layer (arachnoid).

subluxation Partial joint dislocation.

submucous resection (SMR) Surgical procedure to straighten a deviated septum when chronic symptoms or discomfort occur. Also called "nasoseptoplasty."

substernally Located below the ribs.

subtotal thyroidectomy The surgical removal of part of the thyroid tissue.

sundowning In patients with Alzheimer's disease, increased confusion at night or when excessively fatigued.

superinfection Reinfection or a second infection of the same type.

supervision Guidance or direction, evaluation, and follow-up by the nurse to ensure that the task or activity is performed appropriately.

supratentorial Located within the cerebral hemispheres, in the area above the tentorium of the cerebellum; the tentlike fold of dura that

surrounds the cerebellar hemisphere and supports the occipital lobe.

supraventricular tachycardia (SVT) A form of tachycardia that involves the rapid stimulation of atrial tissue at a rate of 100 to 280 beats/min. It is most often due to a re-entry mechanism in which one impulse circulates repeatedly throughout the atrial pathway, re-stimulating the atrial tissue at a rapid rate.

surfactant A fatty protein secreted by type II pneumocytes to reduce surface tension in the alveoli.

surveillance Term used to describe the tracking of infections by health care agencies.

susceptibility The risk of the host to infection; may be increased by the breakdown of host defenses against pathogens.

swimmer's ear See *external otitis.*

sympathectomy Surgical cutting of the sympathetic nerve branches via endoscopy through a small axillary incision.

sympathetic tone A state of partial blood vessel constriction caused when nerves from the sympathetic division of the autonomic nervous system continuously stimulate vascular smooth muscle.

synapse The area through which impulses are transmitted to their eventual destination.

syncope Transient loss of consciousness (blackouts), most commonly caused by decreased perfusion to the brain.

syndrome of inappropriate antidiuretic hormone (SIADH) Persistent hyponatremia, hypovolemia, and inappropriately elevated urine osmolality that occurs when vasopressin (antidiuretic hormone) is secreted even when plasma osmolarity is low or normal.

synovectomy The surgical removal of synovium.

synovial joint Type of joint lined with synovium, a membrane that secretes synovial fluid for lubrication and shock absorption.

synovitis Inflammation of synovial membrane.

syphilis A complex sexually transmitted disease that can become systemic and cause serious complications and even death. It is caused by the spirochete *Treponema pallidum,* which is found in the mouth, intestinal tract, and genital areas of people and animals. The infection is usually transmitted by sexual contact, but transmission can occur through close body contact and kissing.

syringe pump Pump for infusion therapy that uses a battery-powered piston to push the plunger continuously at a selected mL/hr rate; limited to small-volume continuous or intermittent infusions.

systemic Affecting the body system as a whole.

systemic lupus erythematosus (SLE) A chronic, progressive, inflammatory connective tissue disorder that can cause major body organs and systems to fail; characterized by spontaneous remissions and exacerbations.

systemic sclerosis (SSc) A chronic connective tissue disease characterized by inflammation, fibrosis, and sclerosis of the skin and vital organs. Also called "scleroderma" and formerly called "progressive systemic sclerosis."

systole The phase of the cardiac cycle that consists of the contraction and emptying of the atria and ventricles.

systolic blood pressure The amount of pressure/force generated by the left ventricle to distribute blood into the aorta with each contraction of the heart.

systolic heart failure (systolic ventricular dysfunction) Heart failure that results when the heart is unable to contract forcefully enough during systole to eject adequate amounts of blood into the circulation.

T

T wave In the electrocardiogram, the deflection that follows the ST segment and represents ventricular repolarization.

tachycardia An excessively fast heart rate; characterized as a pulse rate greater than 100 beats/min.

tachydysrhythmia An abnormal heart rhythm with a rate greater than 100 beats/min.

tactile (vocal) fremitus A vibration of the chest wall produced when the patient speaks; can be palpated on the chest wall.

target tissues The tissues that respond specifically to a given hormone.

taut Tightly stretched.

teamwork and collaboration A QSEN competency in which the nurse functions effectively within nursing and interprofessional teams, fostering open communication, mutual respect, and shared decision making to achieve quality patient care.

telangiectasias Vascular lesions with a red center and radiating branches. Also called "spider angiomas," "spider nevi," or "vascular spiders."

telemetry In electrocardiography (ECG), the use of a battery-powered transmitter system for monitoring an ambulatory patient; allows freedom of movement within a certain radius without losing transmission of the ECG.

temporal field blindness A decrease in lateral peripheral vision.

temporary pacing A nonsurgical intervention for cardiac dysrhythmia that provides a timed electrical stimulus to the heart when either the impulse initiation or the intrinsic conduction system of the heart is defective.

tendon Any one of many bands of tough, fibrous tissue that attach muscles to bones.

tendon transplant Removal of a tendon from one part of the body and transplantation into the affected area to replace a ruptured tendon that cannot be repaired surgically.

tenesmus Straining, especially painful straining to defecate.

teratogenic Tending to produce birth defects.

tetany Continuous contractions of muscle groups; hyperexcitability of nerves and muscles.

tetraplegia Another term for *quadriplegia* (paralysis that involves all four extremities).

thalamotomy An alternative to stereotactic pallidotomy as a surgical treatment for the patient with Parkinson disease; uses thermocoagulation of brain cells to reduce tremor. Usually only unilateral surgery is performed to benefit the side of the body most affected by the disease.

thalamus A structure within the brain; functions as the "central switchboard" for the central nervous system.

thallium scan A test that is similar to the bone scan but uses the radioisotope *thallium* and is more sensitive in diagnosing the extent of disease in patients with osteosarcoma.

The Joint Commission An organization that offers peer evaluation for accreditation every 3 years for all types of health care agencies that meet their standards. Formerly known as the *Joint Commission for Accreditation of Healthcare Organizations (JCAHO).*

therapeutic hypothermia Treatment that lowers the body core temperature to reduce the risk of cell, tissue, and organ damage from a low or absent blood flow. Usually follows cardiac arrest.

thermotherapy Technique for treating benign prostatic hyperplasia that uses a variety of heat methods to destroy excess prostate tissue.

third intention Delayed primary closure of a wound with a high risk for infection. The wound is intentionally left open for several days until inflammation has subsided and is then closed by first intention.

thoracentesis The aspiration of pleural fluid or air from the pleural space.

threshold In evaluating hearing, the lowest level of intensity at which pure tones and speech are heard by a patient; in general, the lowest level at which a stimulus is perceived.

thrombectomy Removal of a clot (thrombus) from a blood vessel.

thrombocytopenia A reduction in the number of blood platelets below the level needed for normal coagulation, resulting in an increased tendency to bleed.

thrombophlebitis The presence of a thrombus associated with inflammation; usually occurs in the deep veins of the lower extremities.

thrombosis The formation of a blood clot (thrombus) within a blood vessel.

thrombotic stroke Damage to the brain when blood flow is impaired from a clot, resulting in blockage to one or more of the arteries supplying blood to the brain.

thrombus A blood clot believed to result from an endothelial injury, venous stasis, or hypercoagulability.

thymectomy Removal of the thymus gland.

thymoma An encapsulated tumor of the thymus gland.

thyrocalcitonin (TCT) A hormone produced and secreted by the parafollicular cells of the thyroid gland to help regulate serum calcium levels; secreted in response to excess plasma calcium.

thyroiditis Inflammation of the thyroid gland.

thyroid storm (thyroid crisis) A life-threatening event that occurs in patients with uncontrolled hyperthyroidism and is usually caused by

Graves' disease. Key manifestations include fever, tachycardia, and systolic hypertension.

thyrotoxicosis The condition caused by excessive amounts of thyroid hormones.

thyroxine (T_4) A hormone that is produced by the follicular cells of the thyroid gland and increases metabolism.

Tinel's sign Test that confirms a diagnosis of carpal tunnel syndrome; a positive test causes palmar paresthesias when the area of the median nerve is tapped lightly.

tinnitus A continuous ringing or noise perception in the ears.

titration Adjustment of IV fluid rate on the basis of the patient's urine output plus serum electrolyte values.

TNM (tumor, node, metastasis) System developed by the American Joint Committee on Cancer to describe the anatomic extent of cancers.

toe brachial pressure index (TBPI) Toe systolic pressure divided by brachial (arm) systolic pressure; may be performed instead of or in addition to ankle-brachial index to determine arterial perfusion in the feet and toes.

tonic phase Pertaining to a state of stiffening or rigidity of the muscles, particularly of the arms and legs, and immediate loss of consciousness of a tonic-clonic seizure.

tonsillitis An inflammation and infection of the tonsils and lymphatic tissues located on each side of the throat.

tophi A collection of uric acid crystals that form hard, irregular, painless nodules on the ears, arms, and fingers of patients with gout.

topical chemical débridement Method of débriding a wound by applying topical enzyme preparations to loosen necrotic tissue.

torn meniscus Tear of the knee meniscus (medial or lateral) in which the patient typically has pain, swelling, and tenderness in the knee.

torsades de pointes A type of ventricular tachycardia that is related to a prolonged QT interval.

total hysterectomy Removal of the uterus and cervix; the procedure may be vaginal or abdominal.

total joint arthroplasty (TJA) Surgical creation of a joint, or total joint replacement; commonly performed in patients with osteoarthritis.

Also called "total joint replacement (TJR)."

total joint replacement (TJR) See *total joint arthroplasty.*

total parenteral nutrition (TPN) Provision of intensive nutritional support for an extended time; delivered to the patient through access to central veins, usually the subclavian or internal jugular veins.

total thyroidectomy The surgical removal of all of the thyroid tissue.

touch discrimination Part of the neurologic examination. The patient closes his or her eyes while the practitioner touches the patient with a finger and asks that the patient point to the area touched.

toxic and drug-induced hepatitis Liver inflammation resulting from exposure to hepatotoxins (e.g., industrial toxins, alcohol, and medications).

toxic epidermal necrolysis (TEN) A rare acute drug reaction of the skin that results in diffuse erythema and blister formation, with mucous membrane involvement and systemic toxicity.

toxic megacolon Acute enlargement of the colon along with fever, leukocytosis, and tachycardia; usually associated with ulcerative colitis.

toxic multinodular goiter Hyperthyroidism caused by multiple thyroid nodules, which may be enlarged thyroid tissues or adenomas, and a goiter that has been present for several years.

toxic shock syndrome (TSS) A severe illness caused by a toxin produced by certain strains of *Staphylococcus aureus*. It was first recognized in 1980 as related to menstruation and tampon use. It is characterized by abrupt onset of a high fever and headache, sore throat, vomiting, diarrhea, generalized rash, and hypotension. The most common manifestations are skin changes (initially a rash that resembles a severe sunburn and changes to a macular erythema similar to a drug-related rash).

toxidrome A syndrome related to drug toxicity.

toxin Protein molecule released by bacteria that affects host cell at a distant site. Continued multiplication of a pathogen is sometimes accompanied by toxin production.

trabeculation An abnormal thickening of the bladder wall caused by urinary retention and obstruction.

tracheostomy The (tracheal) stoma, or opening, that results from a

tracheotomy.

tracheotomy The surgical incision into the trachea for the purpose of establishing an airway.

trachoma A chronic conjunctivitis caused by *Chlamydia trachomatis.*

traction The application of a pulling force to a part of the body to provide reduction, alignment, and rest.

transcellular fluid Any of the fluids in special body spaces, including cerebrospinal fluid, synovial fluid, peritoneal fluid, and pleural fluid.

transcutaneous pacing Temporary pacing that is accomplished through the application of two large external electrodes.

transesophageal echocardiography (TEE) A form of echocardiography performed transesophageally (through the esophagus); an ultrasound transducer is placed immediately behind the heart in the esophagus or stomach to examine cardiac structure and function.

transferrin An iron-transport protein that can be measured directly or calculated as an indirect measurement of total iron-binding capacity.

transgender Patients who self-identify as the opposite gender or a gender that does not match their natal sex.

transient ischemic attack (TIA) A brief attack (lasting a few minutes to less than 24 hours) of focal neurologic dysfunction caused by a brief interruption in cerebral blood flow, possibly resulting from cerebral vasospasm or transient systemic arterial hypertension. Repeated attacks may damage brain tissue; multiple attacks indicate significant increased risk for brain attack.

transmyocardial laser revascularization A new surgical procedure for patients with unstable angina and inoperable coronary artery disease with areas of reversible myocardial ischemia. After a single-lung intubation, a left anterior thoracotomy is performed and the heart is visualized. A laser is used to create 20 to 24 long, narrow channels through the left ventricular muscle to the left ventricle. The channels eventually allow oxygenated blood to flow from the left ventricle during diastole to nourish the muscle.

transport maximum See *renal threshold.*

transsexual A person who has modified his or her natal body to match the appropriate gender identity, either through cosmetic, hormonal, or surgical means.

transurethral microwave therapy (TUMT) Procedure for treating benign prostatic hyperplasia using high temperatures to heat and destroy excess tissue.

transurethral needle ablation (TUNA) Procedure for treating benign prostatic hyperplasia using low radiofrequency energy to shrink the prostate.

transurethral resection of the prostate (TURP) The traditional "closed" surgical procedure for removal of the prostate. In this procedure, the surgeon inserts a resectoscope (an instrument similar to a cystoscope, but with a cutting and cauterizing loop) through the urethra. The enlarged portion of the prostate gland is then resected in small pieces.

trauma Bodily injury.

trauma center Specialty care facility that provides competent and timely trauma services to patients depending on its designated level of capability.

trauma system An organized and integrated approach to trauma care designed to ensure that all critical elements of trauma care delivery are aligned to meet the injured patient's needs.

triage In the emergency department, sorting or classifying patients into priority levels depending on illness or injury severity, with the highest acuity needs receiving the quickest evaluation and treatment.

triage officer In a hospital's emergency response plan, the person who rapidly evaluates each patient who arrives at the hospital. In a large hospital, this person is generally a physician who is assisted by triage nurses; however, a nurse may assume this role when physician resources are limited.

trigeminy A type of premature complex consisting of a repetitive three-beat pattern; usually occurs as two sequential normal complexes followed by a premature complex and a pause, with the same pattern repeating itself in triplets.

trigger points In patients with fibromyalgia syndrome, tender areas that can typically be palpated to elicit pain in a predictable, reproducible pattern.

triglycerides Serum lipid profile that includes the measurement of cholesterol and lipoproteins.

triiodothyronine (T_3) A hormone produced by the follicular cells of the

thyroid gland.

troponin A myocardial muscle protein released into the bloodstream after injury to myocardial muscle. Because it is not found in healthy patients, any rise in values indicates cardiac necrosis or acute myocardial infarction.

truss A device, usually a pad made with firm material, that is held in place over the hernia with a belt to keep the abdominal contents from protruding into the hernial sac.

tuberculosis (TB) A highly communicable disease caused by *Mycobacterium tuberculosis.* It is the most common bacterial infection worldwide.

tumescence The condition of being swollen.

tunneled central venous catheter A type of catheter used for long-term infusion therapy in which a portion of the catheter lies in a subcutaneous tunnel, separating the points where the catheter enters the vein from where it exits the skin.

turbidity Cloudiness of a solution.

turbinates Three bony projections that protrude into the nasal cavities from the walls of the internal portion of the nose.

turgor The condition of being swollen and congested; indicates the amount of skin elasticity; the normal resiliency of a pinched fold of skin.

tyrosine kinase inhibitors (TKIs) Drugs with the main action of inhibiting activation of tyrosine kinases. There are many different TKIs. Some are unique to the cell type; others may be present only in cancer cells that express a specific gene mutation. As a result, the different TKI drugs are effective in disrupting the growth of some cancer cell types and not others.

U

U wave In the electrocardiogram, the deflection that follows the T wave and may result from slow repolarization of ventricular Purkinje fibers. When present, it is of the same polarity as the T wave, although generally smaller. Abnormal prominence of the U wave suggests an electrolyte abnormality or other disturbance.

ulcerative colitis (UC) A chronic inflammatory process that affects the

mucosal lining of the colon or rectum; one of a group of bowel diseases of unknown etiology characterized by remissions and exacerbations. It can result in loose stools containing blood and mucus, poor absorption of vital nutrients, and thickening of the colon wall.

umbilical hernia Protrusion of the intestine at the umbilicus; can be congenital or acquired. Congenital umbilical hernias appear in infancy. Acquired umbilical hernias directly result from increased intra-abdominal pressure and are most commonly seen in obese people.

unclassified seizure One of the three broad categories of seizure disorders along with partial seizure and generalized seizure. They occur for no known reason, do not fit into the generalized or partial classifications, and account for about half of all seizure activity. Also called "idiopathic seizures."

uncus The inner part of the temporal lobe of the brain that can move downward and cause pressure on the brainstem; the vital sign center.

undermining Separation of the skin layers at the wound margins from the underlying granulation tissue.

unilateral body neglect syndrome In the patient who has had a brain attack, an unawareness of the existence of the paralyzed side. For example, the patient may believe he or she is sitting up straight when actually he or she is leaning to one side. Another typical example is the patient who washes or dresses only one side of the body.

Unna boot A wound dressing constructed of gauze moistened with zinc oxide; used to promote venous return in the ambulatory patient with a stasis ulcer and to form a sterile environment for the ulcer. The boot is applied to the affected limb, from the toes to the knee, after the ulcer has been cleaned with normal saline solution and covered with an elastic wrap. The dressing hardens like a cast.

upper endoscopy See *esophagogastroduodenoscopy.*

upper esophageal sphincter (UES) The ringlike band of muscle fibers at the upper end of the esophagus. When at rest, the sphincter is closed to prevent air from entering into the esophagus during respiration.

upper GI (gastrointestinal) radiographic series The radiographic visualization of the gastrointestinal tract from the oral part of the pharynx to the duodenojejunal junction; used to detect disorders of structure or function of the esophagus (barium swallow), stomach, or

duodenum.

uremia The accumulation of nitrogenous wastes in the blood (azotemia); a result of renal failure, with clinical symptoms including nausea and vomiting.

uremic frost A layer of urea crystals from evaporated sweat; may appear on the face, eyebrows, axilla, and groin in patients with advanced uremic syndrome.

uremic syndrome The systemic clinical and laboratory manifestations of end-stage kidney disease.

ureterolithiasis Formation of stones in the ureter.

ureteropelvic junction (UPJ) The narrow area in the upper third of the ureter at the point at which the renal pelvis becomes the ureter.

ureteroplasty Surgical repair of the ureter.

ureterovesical junction (UVJ) The point at which each ureter becomes narrow as it enters the bladder.

urethral meatus The opening at the endpoint of the urethra.

urethral stricture An obstruction that occurs low in the urinary tract due to decreased diameter of the urethra, causing bladder distention before hydroureter and hydronephrosis.

urethritis An inflammation of the urethra that causes symptoms similar to urinary tract infection.

urethroplasty Surgical treatment of the urethral stricture to remove the affected area with or without grafting to create a larger opening.

urgency The feeling that urination will occur immediately.

urgent triage In a three-tiered triage scheme, the category that includes patients who should be treated quickly but in whom an immediate threat to life does not currently exist, such as those with abdominal pain or displaced fractures or dislocations.

urinary tract infection (UTI) An infection in the normally sterile urinary system. The unobstructed and complete passage of urine from the renal and urinary systems is critical in maintaining a sterile urinary tract. When any structural abnormality is present, the risk for damage as a result of infection is greatly increased.

urolithiasis The presence of calculi (stones) in the urinary tract.

urosepsis The spread of an infection from the urinary tract to the

bloodstream, resulting in systemic infection accompanied by fever, chills, hypotension, and altered mental status.

urticaria A transient vascular reaction of the skin marked by the development of wheals (hives).

uterine artery embolization Treatment for leiomyomas in which a radiologist uses a percutaneous catheter inserted through the femoral artery to inject polyvinyl alcohol pellets into the uterine artery. The resulting blockage starves the tumor of circulation, allowing it (or them) to shrink.

uterine prolapse Downward displacement of the uterus into the vagina.

uvea The middle layer of the eye, which consists of the choroid, ciliary body, and iris. The choroid has many blood vessels that supply nutrients to the retina.

V

vagal maneuver Nonsurgical management of cardiac dysrhythmias that is intended to induce vagal stimulation of the cardiac conduction system, specifically the sinoatrial and atrioventricular nodes. Vagal maneuvers may be attempted to terminate supraventricular tachydysrhythmia.

vaginoplasty The construction of a new vagina in a male-to-female patient, usually with inverted penile tissue or a colon graft, and the creation of a clitoris and labia using scrotal or penile tissue and skin grafts.

validation therapy For the patient with moderate or severe Alzheimer's disease, the process of recognizing and acknowledging the patient's feelings and concerns without reinforcing an erroneous belief (e.g., if the patient is looking for his or her deceased mother).

Valsalva maneuver A form of vagal stimulation of the cardiac conduction system in which the health care provider instructs the patient to bear down as if straining to have a bowel movement.

valvular regurgitation Regurgitation of any heart valve. See also *mitral regurgitation*.

variant (Prinzmetal's) angina A type of angina caused by coronary vasospasm (vessel spasm); usually associated with elevation of the ST segment on an electrocardiogram obtained during anginal attacks.

varicose veins Distended, protruding veins that appear darkened and tortuous; common in patients older than 30 years whose occupations require prolonged standing. As the vein wall weakens and dilates, venous pressure increases and the valves become incompetent (defective). The incompetent valves enhance the vessel dilation, and the veins become tortuous and distended.

vascular access device (VAD) A catheter; a plastic tube placed in a blood vessel to deliver fluids and medications.

vasculitis Blood vessel inflammation.

vasoconstriction Decrease in diameter of blood vessels.

vasopressin Secretion of the posterior pituitary gland. Also known as "antidiuretic hormone" or "ADH."

vasospasm A sudden and transient constriction of a blood vessel.

Vaughn-Williams classification System used to categorize antidysrhythmic agents according to their effects on the action potential of cardiac cells.

vegan A vegetarian diet pattern in which only foods of plant origin are eaten.

venous beading A complication of diabetes; the abnormal appearance of retinal veins in which areas of swelling and constriction along a segment of vein resemble links of sausage. Such bleeding occurs in areas of retinal ischemia and is a predictor of proliferative diabetic retinopathy.

venous insufficiency Alteration of venous efficiency by thrombosis or defective valves; caused by prolonged venous hypertension, which stretches the veins and damages the valves, resulting in further venous hypertension, edema, and, eventually, venous stasis ulcers, swelling, and cellulitis.

venous thromboembolism (VTE) A term that refers to both deep vein thrombosis and pulmonary embolism; obstruction by a thrombus.

ventilator-associated lung injury (VALI) Damage from prolonged ventilation causing loss of surfactant, increased inflammation, fluid leakage, and noncardiac pulmonary edema. Also known as "ventilator-induced lung injury."

ventilator-induced lung injury (VILI) See *ventilator-associated lung injury.*

ventral hernia See *incisional hernia.*

ventricular asystole The complete absence of any ventricular rhythm. There are no electrical impulses in the ventricles and therefore no ventricular depolarization, no QRS complex, no contraction, no cardiac output, and no pulse, respirations, or blood pressure. The patient is in full cardiac arrest.

ventricular fibrillation (VF) A cardiac dysrhythmia that results from electrical chaos in the ventricles; impulses from many irritable foci fire in a totally disorganized manner so that ventricular contraction cannot occur; there is no cardiac output or pulse and therefore no cerebral, myocardial, or systemic perfusion. This rhythm is rapidly fatal if not successfully terminated within 3 to 5 minutes.

ventricular gallop An abnormal third heart sound that arises from vibrations of the valves and supporting structures and is produced during the rapid passive filling phase of ventricular diastole when blood flows from the atrium to a noncompliant ventricle. In patients older than 35 years, it is an early sign of heart failure or ventricular septal defect.

ventricular remodeling (1) Progressive myocyte (myocardial cell) contractile dysfunction over time; results from activation of the renin-angiotensin system caused by reduced blood flow to the kidneys, a common occurrence in low-output states; (2) after a myocardial infarction, permanent changes in the size and shape of the left ventricle due to scar tissue; such remodeling may decrease left ventricular function, cause heart failure, and increase morbidity and mortality.

ventricular tachycardia (VT) An abnormal heart rhythm that occurs with repetitive firing of an irritable ventricular ectopic focus, usually at a rate of 140 to 180 beats/min or more.

ventriculomyomectomy The surgical excision of a portion of the hypertrophied ventricular septum to create a widened outflow tract in patients with obstructive hypertrophic cardiomyopathy. Also called "ventricular septal myectomy."

veracity Ethical principle that requires that the nurse is obligated to tell the truth to the best of his or her knowledge.

vertebroplasty A minimally invasive surgery for managing vertebral fractures in patients with osteoporosis. Bone cement is injected directly into the fracture site to provide immediate pain relief.

vertigo A sense of spinning movement that may result from diseases of

the inner ear.

vesicants Chemicals or drugs that cause tissue damage on direct contact or extravasation.

vesicle In health care, a small bladder or blister.

vestibule A longitudinal area between the labia minora, the clitoris, and the vagina that contains Bartholin glands and the openings of the urethra, Skene's glands (paraurethral glands), and vagina.

viral hepatitis Inflammation of the liver that results from an infection caused by one of five major categories of viruses (hepatitis A, B, C, D, or E). Viral hepatitis is the most common type and can be either acute or chronic.

viral load testing Test that measures the presence of human immune deficiency virus genetic material (ribonucleic acid) or other viral proteins in the patient's blood.

Virchow's triad The occurrence of stasis of blood flow, endothelial injury, or hypercoagulability; often associated with thrombus formation.

viremia The presence of viruses in the blood.

virilization The presence of male secondary sex characteristics.

virtual colonoscopy A noninvasive alternative to the colonoscopy procedure. A scanner is used to view the colon.

virulence A term used to describe the frequency with which a pathogen causes disease (degree of communicability) and its ability to invade and damage a host. Virulence can also indicate the severity of the disease; often used as a synonym for *pathogenicity.*

visceral proteins Proteins such as albumin that circulate in the bloodstream and may be produced by the liver.

vitiligo An abnormality of the skin characterized by patchy areas of pigment loss with increased pigmentation at the edges. It is seen with primary hypofunction of the adrenal glands and is due to autoimmune destruction of melanocytes in the skin.

vitreous body The clear, thick gel that fills the vitreous chamber of the eye (the space between the lens and the retina). This gel transmits light and shapes the eye.

vocational counselor A member of the rehabilitative health care team who assists the patient with job placement, training, or further education.

volutrauma Damage to the lung by excess volume delivered to one lung over the other.

volvulus Obstruction of the bowel caused by twisting of the bowel.

vulvovaginitis Inflammation of the lower genital tract resulting from a disturbance of the balance of hormones and flora in the vagina and vulva.

W

warm antibody anemia A form of immunohemolytic anemia (in which the immune system attacks a person's own red blood cells for unknown reasons) that occurs with immunoglobulin G antibody excess and may be triggered by drugs, chemicals, or other autoimmune problems.

warm phase A phase lasting 2 to 3 weeks after peripheral nerve trauma resulting in complete denervation; the extremity is warm, and the skin appears flushed or rosy. The warm phase is gradually superseded by a cold phase.

water brash Reflex salivary hypersecretion that occurs in response to reflux in the patient with gastroesophageal reflux disease.

WBC White blood cell.

weaning The process of going from ventilatory dependence to spontaneous breathing.

wedge resection Removal of small, localized areas of disease.

Wernicke's aphasia See *receptive aphasia*.

Wernicke's area An important speech area of the cerebrum. It is located in the temporal lobe and plays a significant role in higher-level brain function. It enables the processing of words into coherent thought and recognition of the idea behind written or printed words (language).

Whipple procedure (radical pancreaticoduodenectomy) A surgical treatment for cancer of the head of the pancreas. The procedure entails removal of the proximal head of the pancreas, the duodenum, a portion of the jejunum, the stomach (partial or total gastrectomy), and the gallbladder, with anastomosis of the pancreatic duct (pancreaticojejunostomy), the common bile duct (choledochojejunostomy), and the stomach (gastrojejunostomy) to the jejunum.

white matter In the spinal cord, myelinated axons that surround the gray matter (neuron cell bodies).

Williams position A position in which the patient lies in the semi-Fowler's position and flexes the knees to relax the muscles of the lower back and relieve pressure on the spinal nerve root. This is typically more comfortable and therapeutic for the patient with low back pain.

withdrawing or withholding life-sustaining therapy The withdrawal or withholding of one or more therapies that might prolong the life of a person who cannot be cured by the therapy; the withdrawal of therapy does not directly cause death. Formerly called "passive euthanasia."

work-related musculoskeletal disorders (MSDs) Disorders caused by heavy lifting and dependent transfers by staff members.

X

xenograft Tissue transplanted (grafted) from another species; for example, a heart valve transplanted from a pig to a human.

xerostomia Abnormal dryness of the mouth caused by a severe reduction in the flow of saliva.

x-ray Radiation that is generated by machine.
