N_1, N_2, N_3	Increasing involvement of regional lymph nodes
Distant Metastasis (M)	
M_x	Presence of distant metastasis cannot be assessed
M_0	No distant metastasis
M_1	Distant metastasis

Tumor growth is assessed in terms of **doubling time** (the amount of time it takes for a tumor to double in size) and **mitotic index** (the percentage of actively dividing cells within a tumor). The smallest detectable tumor is about 1 cm in diameter and contains 1 billion cells. To reach this size, it must undergo at least 30 doublings. A tumor with a mitotic index of less than 10% is a slow-growing tumor; a tumor with an index of 85% is fast growing. Tumors have a wide range of growth rates.

NCLEX Examination Challenge

Physiological Integrity

Which pathologic description of a client's tumor does the nurse interpret as being the "most malignant" or "high grade" cancer?
A Poorly differentiated; mitotic index = 20%, euploid
B Moderately differentiated; mitotic index = 50%, euploid
C Undifferentiated; mitotic index = 50%, aneuploid
D Highly differentiated; mitotic index = 10%, aneuploid

Cancer Etiology and Genetic Risk

Carcinogenesis takes years and depends on several tumor and patient factors (Santos et al., 2013). Three interacting factors influence cancer development: exposure to carcinogens, genetic predisposition, and immune function. These factors account for variation in cancer development from one person to another, even when each person is exposed to the same hazards.

Oncogene activation is the main mechanism of carcinogenesis regardless of the specific cause. These oncogenes are turned on (expressed) under controlled conditions for cellular regulation when cells divide for normal growth and replacement of dead or damaged tissues. At other times they are turned off, controlled, or suppressed by products of "suppressor genes."

When a normal cell is exposed to any carcinogen (initiator), the normal cell's DNA can be damaged and mutated. The mutations damage suppressor genes, preventing them from producing proteins that control cellular regulation for the expression of oncogenes. As a result, the oncogenes are overexpressed and can cause the cells to change from normal cells to cancer cells. When oncogenes are overexpressed in a cell, excessive amounts of cyclins are produced and upset the balance between cell growth enhancement and cell growth limitation. The effect of these excessive cyclins is greater than the effect of the suppressor gene products, thus losing cellular regulation and allowing uncontrolled cell division.

Oncogenes are not abnormal genes but are part of every cell's normal makeup. Oncogenes become a problem only if they are overexpressed as a result of exposure to carcinogenic agents or events with loss of cellular regulation. Both external and personal factors can activate oncogenes.

External Factors Causing Cancer

External factors, including environmental exposure, are responsible for about 80% of cancer in North America (ACS, 2014). Environmental carcinogens are chemical, physical, or viral agents that cause cancer (USDHHS, 2011).

Chemical carcinogenesis can occur from exposures to many known chemicals, drugs, and other products used in everyday life. Chemicals vary in how carcinogenic they are. For example, tobacco and alcohol appear to be only mildly carcinogenic. For these substances, chronic, long-term exposure to large amounts is required before cellular regulation is lost and a cancer develops. However, these two substances can act as *co-*

carcinogens, meaning that when they are taken together, they enhance each other's carcinogenic activity.

Not all cells are susceptible to carcinogenesis to the same degree. Normal cells that have the ability to divide are at greater risk for cancer development than are normal cells that are not capable of cell division. For example, cancers commonly arise in bone marrow, skin, lining of the GI tract, ductal cells of the breast, and lining of the lungs. All of these cells normally undergo cell division. Cancers of nerve tissue, cardiac muscle, and skeletal muscle are rare. These cells do not normally undergo cell division.

About 30% of cancers diagnosed in North America are related to tobacco use (ACS, 2014; Canadian Cancer Society, 2014). Tobacco is the single most preventable source of carcinogenesis. It contains many different carcinogens and co-carcinogens. Long-term tobacco use first initiates and then promotes cancer. The risk for cancer development from tobacco use depends on a person's immune function, genetic susceptibility, and amount and types of tobacco exposure.

Tissues with the greatest risk for tobacco-induced cancer are those that have direct contact with tobacco or tobacco smoke. Cigarette smoking and tobacco use also promote the development of other cancers. Table 21-6 lists the specific cancers that are associated with tobacco use.

TABLE 21-6

Cancer Types Associated with Tobacco Use

• Lung	• Uterine cervix
• Oral cavity	• Kidney
• Pharynx	• Bladder
• Larynx	• Liver
• Esophagus	• Stomach
• Pancreas	• Myeloid leukemia

Data from American Cancer Society. (2014). *Cancer facts and figures—2014.* Report No. 00-300M–No. 500814. Atlanta: Author.

Physical carcinogenesis from physical agents or events also causes cancer by DNA damage. Two physical agents that are known to cause cancer are radiation and chronic irritation.

Even small doses of radiation affect cells to some degree. Some effects are temporary and are self-repaired. Other effects cannot be repaired and may induce cancer in the damaged cell. The two types of radiation that cause cancer are ionizing and ultraviolet (UV). Some ionizing radiation is found naturally in such elements as radon, uranium, and radium found in rocks and soil. Other sources of ionizing radiation include x-rays for diagnosis and treatment of disease, as well as cosmic radiation. UV

radiation is a type of solar radiation, coming from the sun. Other sources of UV radiation include tanning beds and germicidal lights. UV rays do not penetrate deeply, and the most common cancer type caused by UV exposure is skin cancer.

Both ionizing and UV radiation mutate genes. Although radiation exposure induces cancers more often among cells that can divide, it can cause cancer also among nondividing cells.

Chronic irritation and tissue trauma are suspected to cause cancer. The incidence of skin cancer is higher in the scars of people with burn scars or other types of severe skin injury. Chronically irritated tissues undergo frequent cell division and thus are at an increased risk for DNA mutation.

Viral carcinogenesis occurs when viruses infect body cells and break DNA strands. Viruses then insert their own genetic material into the human DNA. Breaking the DNA, along with viral gene insertion, mutates the cell's DNA and can either activate an oncogene or damage suppressor genes. Viruses that cause cancer are **oncoviruses**. Table 21-7 lists cancers of known viral origin.

TABLE 21-7

Cancers Associated with a Known Viral Origin

VIRUS	MALIGNANCIES
Epstein-Barr virus	Burkitt's lymphoma, B-cell lymphoma, nasopharyngeal carcinoma
Hepatitis B virus	Primary liver carcinoma
Hepatitis C virus	Primary liver carcinoma, possibly B-cell lymphomas
Human papilloma virus	Cervical carcinoma, vulvar carcinoma, penile carcinoma, and other anogenital carcinomas
Human lymphotrophic virus type I	Adult T-cell leukemia
Human lymphotrophic virus type II	Hairy cell leukemia

From U.S. Department of Health and Human Services, Public Health Service, National Toxicology Program. (2011). *Report on carcinogens* (12th ed.). Retrieved January 2014, from http://ntp.niehs.nih.gov/go.roc12.

Dietary factors related to cancer development are poorly understood although dietary practices are suspected to alter cancer risk. Suspected dietary factors include low fiber intake and a high intake of red meat or animal fat. Preservatives, preparation methods, and additives (dyes, flavorings, sweeteners) may have cancer-promoting effects. Chart 21-1 lists dietary habits that may reduce cancer risk.

Chart 21-1 Patient and Family Education: Preparing for Self-Management

Dietary Habits to Reduce Cancer Risk

- Avoid excessive intake of animal fat.
- Avoid nitrites (prepared lunch meats, sausage, bacon).
- Minimize your intake of red meat.
- Keep your alcohol consumption to no more than one or two drinks per day.
- Eat more bran.
- Eat more cruciferous vegetables, such as broccoli, cauliflower, Brussels sprouts, and cabbage.
- Eat foods high in vitamin A (e.g., apricots, carrots, leafy green and yellow vegetables) and vitamin C (e.g., fresh fruits and vegetables, especially citrus fruits).

Personal Factors and Cancer Development

Personal factors, including immune function, age, and genetic risk, also affect whether a person is likely to develop cancer.

Immune function protects the body from foreign invaders and non-self cells (see Chapter 17). Non-self cells include cells that are no longer normal, such as cancer cells. Cell-mediated immunity, especially natural killer (NK) cells and helper T-cells, provides immune surveillance.

Cancer incidence increases among immunosuppressed people. Adults older than 60 years have immune systems with reduced function and a higher incidence of cancer compared with that of the general population. Organ transplant recipients taking immunosuppressive drugs to prevent organ rejection also have a higher incidence of cancer. In patients with acquired immune deficiency syndrome (AIDS), cancer incidence may be as high as 70%.

Advancing age is the single most important risk factor for cancer (ACS, 2013b). As a person ages, immune protection decreases and external exposures to carcinogens accumulate. Teach older adults to be aware of and report manifestations such as the seven warning signs of cancer (Table 21-8) to health care providers. Health care providers should investigate all manifestations suggestive of disease. Cancer assessment considerations for the older adult are listed in Chart 21-2.

Chart 21-2 Nursing Focus on the Older Adult

Cancer Assessment

CANCER TYPE	ASSESSMENT CONSIDERATION
Colorectal cancer	Ask the patient whether bowel habits have changed over the past year (e.g., in consistency, frequency, color). Is there any obvious blood in the stool? Test at least one stool specimen for occult blood during the patient's hospitalization. Encourage the patient to have a baseline colonoscopy. Encourage the patient to reduce dietary intake of animal fats, red meat, and smoked meats. Encourage the patient to increase dietary intake of bran, vegetables, and fruit.
Bladder cancer	Ask the patient about the presence of: Pain on urination Blood in the urine Cloudy urine Increased frequency or urgency
Prostate cancer	Ask the patient about: Hesitancy Change in the size of the urine stream Pain in the back or legs History of urinary tract infections
Skin cancer	Examine skin areas for moles or warts. Ask the patient about changes in moles (e.g., color, edges, sensation).
Leukemia	Observe the skin for color, petechiae, or ecchymosis. Ask the patient about: Fatigue Bruising Bleeding tendency History of infections and illnesses Night sweats Unexplained fevers
Lung cancer	Observe the skin and mucous membranes for color. How many words can the patient say between breaths? Ask the patient about: Cough Hoarseness Smoking history Exposure to inhalation irritants Exposure to asbestos Shortness of breath Activity tolerance Frothy or bloody sputum Pain in the arms or chest Difficulty swallowing

TABLE 21-8

The Seven Warning Signs of Cancer

C	**C**hanges in bowel or bladder habits
A	**A** sore that does not heal
U	**U**nusual bleeding or discharge
T	**T**hickening or lump in the breast or elsewhere
I	**I**ndigestion or difficulty swallowing
O	**O**bvious change in a wart or mole
N	**N**agging cough or hoarseness

Genetic/Genomic Considerations

Patient-Centered Care QSEN

Genetic risk for cancer occurs only in a small percent of the population; however, people who have a genetic predisposition are at very high risk for cancer development (Beery & Workman, 2012). Mutations in suppressor genes or oncogenes can be inherited when they occur in germline cells (sperm and ova) and are then passed on to one's children, in whom all cells contain the inherited mutations. Thus for some people, tight cellular regulation is compromised by a mutation in a suppressor gene, which reduces or halts its function and allows oncogene overexpression. In other people, the suppressor genes are normal and the oncogene is mutated and does not respond to suppressor gene signals, thus reducing cellular regulation and increasing the risk for cancer development. Table 21-9 lists conditions associated with an increased genetic risk for cancer development. Be sure to include questions about these conditions when performing a family history.

TABLE 21-9

Conditions Associated with a Genetic Predisposition for Cancer

CONDITION	SPECIFIC CANCER TYPE
Inherited cancers*	Breast cancer
	Prostate cancer
	Ovarian cancer
Familial clustering	Breast cancer
	Melanoma
Bloom syndrome	Leukemia
Familial polyposis	Colorectal cancer
Chromosomal aberrations	
Down syndrome (47 chromosomes)	Leukemia
Klinefelter syndrome (47,XXY)	Breast cancer
Turner's syndrome (45,XO)	Leukemia
	Gonadal carcinoma
	Meningioma
	Colorectal cancer

*Not all breast, prostate, or ovarian cancers are inherited.

Genetic testing for cancer predisposition is available to confirm or rule out

a person's genetic risk for some specific cancer types. These tests are performed on blood and are expensive, and the cost often is not covered by insurance. Genetic testing should not be performed unless a family history clearly indicates the possibility of increased genetic risk and the patient wants to have the test results. *These tests do not diagnose the presence of cancer; they only provide risk information.*

A variety of issues and potential problems exist with genetic testing for cancer risk. Correct interpretation of the results is critical. Ideally, a genetic counselor is involved in giving the patient information before, as well as after, testing is performed. *When a patient tests positive for a known cancer-causing gene mutation, his or her risk for cancer development is greatly increased; however, the cancer still may never develop.*

Other issues regarding genetic testing include who will have access to the information and whether to share the test results with family members. Genetic testing has implications for the entire family, not just the patient being tested. For more information on genetic testing, see Chapter 4.

Cultural Considerations

Patient-Centered Care QSEN

The incidence of cancer varies among races. American Cancer Society (ACS) data (2012; 2013) show that African Americans have a higher incidence of cancer than white people do and the death rate is higher for African Americans. Since 1960, the overall incidence among African Americans has increased 27% whereas for white people it has increased only 12%. Cancer sites and cancer-related mortality vary along racial lines as well. One explanation for this difference is that more African Americans have less access to health care. Thus they are more often diagnosed with later-stage cancer that is more difficult to cure or control. However, this disparity in health care access does not explain all differences.

When risks for cancer development are assessed, behavior and socioeconomic factors are assessed along with ethnicity and genetic predisposition. The American Cancer Society (2013) reports that cancer incidence and survival are often related to socioeconomic factors. These factors include the availability of health care services or the belief that seeking early health care has a positive effect on the outcome of cancer diagnosis.

Cancer Prevention

Cancer prevention activities focus on primary prevention and secondary prevention. **Primary prevention** is the use of strategies to prevent the actual occurrence of cancer. This type of cancer prevention is most effective when there is a known cause for a cancer type. **Secondary prevention** is the use of screening strategies to detect cancer early, at a time when cure or control is more likely.

Primary Prevention

Avoidance of known or potential carcinogens is an effective prevention strategy when a cause of cancer is known and avoidance is easily accomplished. For example, teach people to use skin protection during sun exposure to avoid skin cancer. Much lung cancer can be avoided by not using tobacco and by eliminating environmental asbestos exposure. Teach everyone about the dangers of cigarette smoking and other forms of tobacco use (see the *Health Promotion and Maintenance* feature in Chapter 27). Teach people who are exposed to carcinogens in the workplace to use personal protective equipment that reduces direct contact with this substance. As more cancer causes are identified, avoidance may become even more effective.

Modifying associated factors appears to have a positive influence in reducing cancer risk. Absolute causes are not known for many cancers, but some conditions appear to increase risk. Examples are the increased incidence of cancer among people who consume alcohol; the association of a diet high in fat and low in fiber with colon cancer, breast cancer, and ovarian cancer; and a greater incidence of cervical cancer among women who have multiple sexual partners. Modifying behavior to reduce the associated factor may decrease the risk for cancer development. Therefore teach all people to limit their intake of alcohol to no more than one ounce per day and to include more fruits, vegetables, and whole grains in their diets. Instruct women about the importance of limiting the number of sexual partners and to use safer sex practices to avoid exposure to viruses that can increase the risk for cervical cancer (see Table 21-7 for a listing of cancer-causing viruses).

Removal of "at risk" tissues reduces cancer risk for a person who has a known high risk for developing a specific type of cancer. Examples include removing moles to prevent conversion to skin cancer, removing colon polyps to prevent colon cancer, and removing breasts to prevent breast cancer. Not all "at risk" tissues can be removed (e.g., those that are part of essential organs).

Chemoprevention is a strategy that uses drugs, chemicals, natural nutrients, or other substances to disrupt one or more steps important to cancer development. These agents may be able to reverse existing gene damage or halt the progression of the transformation process. Currently, hundreds of agents are under investigation for chemoprevention. At this time, only a few agents have been found effective and are commonly prescribed. These include the use of aspirin and celecoxib (Celebrex) to reduce the risk for colon cancer, the use of vitamin D and tamoxifen to reduce the risk for breast cancer, and the use of lycopene to reduce the risk for prostate cancer (ACS, 2014).

Vaccination is a new method of primary cancer prevention. Although vaccines against colon cancer and others are being explored, currently the only vaccine approved for cancer prevention prevents infection from several forms of the human papilloma virus (HPV). These vaccines are Gardasil and Cervarix. As more viruses are identified as being cancer causing, it is hoped that vaccines will be developed to prevent those viral infections.

Secondary Prevention

Regular screening for cancer does not reduce cancer incidence but can greatly reduce some types of cancer deaths. Teach all adults the benefits of participating in specific routine screening techniques annually as part of health maintenance. General screening recommendations are listed in chapters discussing cancers by organ system. The age and type of participation in specific screening tests are different for people who have an identified increased risk for a specific cancer type. In addition, there is some controversy about when the age and frequency for screening has the greatest benefit. Examples of recommended screenings include (ACS, 2014):

- Yearly mammography for women older than 40 years
- Yearly clinical breast examination for women older than 40 years; every 3 years for women ages 20 to 39 years
- Colonoscopy at age 50 years and then every 10 years
- Yearly fecal occult blood for adults of all ages
- Digital rectal examination (DRE) for men older than 50 years

Because cancer development clearly involves gene changes (either inherited gene mutations or acquired damage-induced gene mutations), people can be screened for some gene mutations that increase the risk for cancer. A few examples of these known gene mutations are mutations in the *BRCA1* gene, which increases the risk for both breast and ovarian

cancer; mutations in the *BRCA2* gene, which increases the risk for breast cancer; and mutations in the *APC*, *MLH1*, and *MSH2* genes, which increase the risk for colon cancer.

When taking a patient history and the person appears to have a strong family history of either breast cancer or colon cancer, create a three-generation pedigree to more fully explore the possibility of genetic risk. If a pattern of risk emerges, inform the person about the possible benefits of genetic screening and advise him or her to talk with an oncologist or genetics professional for more information. Screening can help a person at increased genetic risk for cancer to alter lifestyle factors, participate in early detection methods, or even have at-risk tissue removed. Genetic screening has some personal risks as well as potential benefits (see Chapter 4).

NCLEX Examination Challenge

Health Promotion and Maintenance

A 65-year-old client tells the nurse she does not have mammograms because there is no history of breast cancer in her family. What is the nurse's best response?

A "You are correct. Breast cancer is an inherited type of malignancy and your family history indicates a low risk for you."

B "Performing breast self-examination monthly at home is sufficient screening for someone with your family history."

C "Because your breasts are no longer as dense as they were when you were younger, your risk for breast cancer is now decreased."

D "Breast cancer can be found more frequently in families; however, the risk for general, nonfamilial breast cancer increases with age."

Get Ready for the NCLEX® Examination!

Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

Health Promotion and Maintenance

- Teach all people to avoid tanning beds and to use sunscreen and to wear protective clothing during sun exposure. **Patient-Centered Care** QSEN
- Encourage patients to participate in the recommended cancer-screening activities for their age-group and cancer risk category. **Patient-Centered Care** QSEN
- Inform all patients who smoke that smoking increases the risk for development of many cancer types.
- Assist anyone interested in smoking cessation to find an appropriate smoking cessation program (see Chapter 27). **Patient-Centered Care** QSEN
- Assess the patient's knowledge about causes of cancer and his or her screening/prevention practices. **Patient-Centered Care** QSEN
- Assist patients who fear a cancer diagnosis to understand that finding cancer at an early stage increases the chances for cure.
- Ask all patients about their exposures to environmental agents that are known or suspected to impair cellular regulation and increase the risk for cancer.
- Obtain a detailed family history (at least three generations), and use this information to create a pedigree to assess the patient's risk for familial or inherited cancer. **Patient-Centered Care** QSEN
- Teach anyone, especially older adults, the "seven warning signs of cancer" (see Table 21-8).

Physiological Integrity

- Be aware of these facts regarding cancer risk and cancer development:
  - Cancer cells originate from normal body cells.
  - Transformation of a normal cell into a cancer cell involves mutation of the genes (DNA) of the normal cell and results in the loss of cellular regulation.
  - Oncogenes that are overexpressed can cause a cell to develop into a tumor.
  - Only one cell has to undergo malignant transformation for cancer to begin.

- Benign tumors grow by expansion, whereas malignant tumors grow by invasion.
- Most tumors arise from cells that are capable of cell division.
- A key feature of cancer cells is the loss of cellular regulation and apoptosis. These cells have an "infinite" life span.
- Primary prevention of cancer involves avoiding exposure to known causes of cancer.
- Secondary prevention of cancer involves screening for early detection.
- Tobacco use is a causative factor in 30% of all cancers.
- Tumors that metastasize from the primary site into another organ are still designated as tumors of the originating tissue.

CHAPTER 22

Care of Patients with Cancer

June Eilers

PRIORITY CONCEPTS

- Infection
- Pain
- Clotting

Learning Outcomes

Safe and Effective Care Environment

1. Modify the environment to protect patients who have neutropenia, thrombocytopenia, or peripheral neuropathy from infection and injury.
2. Protect yourself and others from cytotoxic agents and radiation.

Health Promotion and Maintenance

3. Teach patients and family members how to avoid injury and infection when blood counts are low.
4. Teach patients and family members how to manage side effects of cancer treatment.

Psychosocial Integrity

5. Reduce the psychological impact of cancer treatment for the patient and family.
6. Work with other members of the health care team to ensure that patient values, preferences, and expressed needs related to cancer and its treatment are respected.

Physiological Integrity

7. Interpret laboratory data and clinical manifestations to determine the presence of cancer treatment side effects and oncologic emergencies.
8. Ensure that the patient with cancer has his or her pain effectively managed.
9. Prioritize nursing interventions for the patient with neutropenia or thrombocytopenia.
10. Prioritize nursing care for the patient receiving radiation therapy.
11. Prioritize nursing care for the patient receiving hormonal manipulation therapy.
12. Prioritize nursing care for the patient receiving biological response modifiers and growth factors as supportive therapy in the treatment of cancer.
13. Prioritize nursing care for the patient receiving targeted therapy for cancer.
14. Prioritize care for patients who experience an oncologic emergency.

http://evolve.elsevier.com/Iggy/

Cancer is a serious common problem in all parts of the world. Most people fear cancer and associate a cancer diagnosis with pain, suffering, and death. In affluent countries, more than 68% of people diagnosed with cancer are cured and thousands of others live 5 years or longer (American Cancer Society, 2014; Canadian Cancer Society, 2014). *Regardless of treatment type, cancer always affects a person's physical and psychological functioning and stresses the family.*

Providing care to patients experiencing cancer and their families is complex and challenging. This chapter describes the general interventions for cancer and the problems associated with cancer treatment. For treatments and patient problems that occur with specific cancer types, consult the chapters in which the cancer is described. Table 22-1 lists common cancer types and the specific locations within this text where the interventions are presented.

TABLE 22-1

Text Location of Specific Cancer Content

CANCER TYPE	CHAPTER
Bladder (urothelial)	66
Brain	45
Breast	70
Cervical	71
Colorectal	56
Esophageal	54
Head and Neck	29
Leukemia	40
Lung	30
Lymphoma	40
Ovarian	71
Prostate	72
Renal cell carcinoma	67
Skin	25
Stomach (gastric)	55

General Disease-Related Consequences of Cancer

Cancer can develop in any organ or tissue and destroys normal tissue, which decreases function of that tissue or organ. Even when cancers occur in nonvital tissues or organs, they can cause death by **metastasizing** (spreading) into vital organs and disrupting critical physiologic processes (see Chapter 21). Advanced cancers often cause:

- Reduced immunity and blood-producing functions
- Altered GI structure and function
- Motor and sensory deficits
- Decreased respiratory function

Reduced Immunity and Blood-Producing Functions

Impaired immune and blood-producing functions occur most often in patients with leukemia and lymphoma but can also occur with any cancer that invades the bone marrow. Tumor cells enter the bone marrow and reduce the production of healthy white blood cells (WBCs), which are needed for normal immune function. Thus patients who have cancer, especially leukemia, are at an increased risk for infection (McCance et al., 2014).

When cancer invades the bone marrow, it also causes anemia by decreasing the number of red blood cells (RBCs) and causes thrombocytopenia by decreasing the number of platelets. These changes may be caused by the cancer itself or by cancer treatment, especially chemotherapy. The patient feels weak and fatigued and is at risk for impaired clotting with bleeding. In addition, patients with anemia may be short of breath, especially if they also have respiratory involvement related to cancer.

Altered GI Structure and Function

Abdominal tumors may obstruct or compress structures anywhere in the GI tract, reducing the ability to absorb nutrients and eliminate wastes. Tumors often also increase metabolic rate and the need for nutrients at a time when the patient has less energy for meal preparation or eating.

Tumors that invade the liver profoundly damage this organ, which has many important metabolic functions. This damage leads to malnutrition and death.

Many patients with cancer have anorexia that often interferes with their ability to meet energy needs. **Cachexia** (extreme body wasting and malnutrition) develops from an imbalance between food intake and

energy use (increased catabolism). This problem may occur even when nutritional intake appears adequate. Changes in taste resulting from the cancer or the treatment can reduce appetite and cause food aversions. Some patients experience early satiety or a sense of fullness and inability to eat even though they have eaten only a small volume of food.

Nutrition support for the patient with cancer, especially one undergoing cancer therapy, is complex. A diet high in protein and carbohydrates is often prescribed to help him or her maintain weight and to provide the nutrients needed for energy and cellular repair. Patients and families often believe cancer can be cured more easily if weight is gained or maintained. Currently no one nutrition plan meets the needs of all patients with cancer. Challenges related to food intake often become an emotional problem for family members who struggle with watching nutrition changes in their loved ones.

Motor and Sensory Deficits

Motor and sensory deficits occur when cancers invade bone or the brain or compress nerves. In patients with bone metastasis, the primary cancer started in another organ (e.g., lung, prostate, breast). Bones become thinner with an increased risk for *pathologic fractures* that can occur with minimal trauma. Bone metastasis causes pain, fractures, spinal cord compression, and hypercalcemia, each of which reduces mobility.

Patients have sensory changes if the spinal cord is damaged or if nerves are compressed. Sensory, motor, and cognitive functions are impaired when cancer spreads to the brain. Any tumor, cancer or benign, growing in the brain can destroy healthy brain tissue and cause death.

Cancer treatments also contribute to sensory and motor deficits. Certain chemotherapy agents cause peripheral neuropathy that leads to altered sensation, pain, and modified gait. "Chemo brain" is an alteration of cognitive function experienced by some patients.

The patient with cancer may also have pain, especially chronic pain. Pain does not always accompany cancer, but it can be a major problem for those with terminal cancer. Chapter 3 provides an in-depth discussion of the causes and management of cancer pain. The concept map in Chapter 3 (p. 27) presents nursing care issues related to chronic cancer pain.

Reduced Gas Exchange

Cancer can disrupt oxygenation in several ways and often results in death. Tumors in the airways cause airway obstruction. If lung tissue is involved, lung capacity is decreased, leading to hypoxemia. Tumors can

also press on blood and lymph vessels in the chest, which results in pulmonary edema and dyspnea. Tumors can thicken the alveolar membrane and damage pulmonary blood vessels, reducing gas exchange. With any lung tumor (primary or metastatic), patients are at risk for hypoxia, poor gas exchange, and poor tissue oxygenation.

Cancer Management

The purpose of cancer management is to prolong survival time and improve quality of life. Without cancer therapy, many patients with cancer would die within months of diagnosis. Cancer therapy includes surgery, radiation, chemotherapy, immunotherapy (biological response modifiers), molecularly targeted therapy, photodynamic therapy, and hormonal therapy. These therapies may be used separately or in combination to kill cancer cells. The types of therapy used depend on the specific type of cancer, whether the cancer has spread, and the health of the patient. Treatment regimens *(protocols)* have been established for most types of cancer.

Surgery

Surgery is the earliest known treatment for cancer and continues to be a cornerstone of therapy. Most cancers are diagnosed with the assistance of surgery, and it is used as part of therapy in many cancers. For cancer, surgery involves the removal of diseased or suspicious tissue. If cancer is confined to the removed tissue, surgery alone can result in a "cure" for that cancer. Even when surgery cannot result in a cancer cure, it is often a useful part of diagnosis, treatment, follow-up, and rehabilitation. Current types of cancer surgery are used for prophylaxis, diagnosis, cure, control, palliation, assessing therapy effectiveness, and reconstruction.

Prophylactic surgery removes "at-risk" tissue to prevent cancer development. It is performed when a patient has either an existing premalignant condition or a strong predisposition for development of a specific cancer. For example, removing a benign polyp from the colon before it can develop into colon cancer is a prophylactic action.

Diagnostic surgery (biopsy) is the removal of all or part of a suspected lesion for examination and testing. It provides evidence for the presence of cancer. Other forms of therapy are seldom initiated without this confirmation of cancer. The extent of a biopsy varies from a fine needle aspiration to an open incision exploratory surgery.

Curative surgery removes all cancer tissue. Surgery alone can result in a cure rate of about 30% when all visible and microscopic tumor is removed or destroyed. This number could increase with screening and early detection efforts.

Cancer control, or *cytoreductive surgery,* removes part of but not the entire tumor. It is also known as "debulking" surgery and decreases the number of cancer cells, which increases the chances that other therapies can be successful.

Palliative surgery focuses on improving the quality of life during the survival time, not on cure. Examples include removal of tumor tissue that is causing pain, obstruction, or difficulty swallowing.

Second-look surgery is a repeat examination after treatment to assess the disease status in patients who have been treated and have no symptoms of remaining tumor. The results of this surgery are used to determine whether a specific therapy should be continued or discontinued.

Reconstructive or *rehabilitative surgery* increases function, enhances appearance, or both. Examples include breast reconstruction after mastectomy, replacement of the esophagus, bowel reconstruction, revision of scars, and cosmetic reconstruction in head and neck cancer.

Side Effects of Surgical Therapy

Unlike surgery performed for many other reasons, cancer surgery often involves the loss of a body part or its function. Sometimes whole organs are removed, such as the kidney, lung, breast, testis, leg, or tongue. *Any organ loss reduces function.* Some cancer surgery results in scarring or disfigurement. Patients are anxious about surviving the cancer and want to be "rid" of it. However, they also may be grieving a change in appearance or lifestyle.

Patient-Centered Collaborative Care

The care needs of the patient having surgery for cancer are similar to those related to surgery for other reasons (see Chapters 14, 15, and 16). For cancer surgery, additional priority care needs are psychosocial support and assisting the patient to achieve maximum function.

Often cancer surgery occurs within days of the diagnosis, before the patient and family have time to adjust. Be aware that the stress of the diagnosis can significantly impact the patient's and family's ability to understand any teaching provided at this time. Assess the patient's and family's ability to cope with the uncertainty of cancer and its treatment and with the changes in body image and role. For example, surgery involving the genitals, urinary tract, colon, or rectum may permanently damage these organs, resulting in changes in the patient's means of sexual expression or control of elimination. Procedures to create a urinary or fecal diversion may damage nerves, causing erectile dysfunction in men and painful intercourse in women.

Coordinate with the health care team to support the patient. Encourage the patient and family to express their concerns. Help the patient accept changes in appearance or function by encouraging him or

her to look at the surgical site, touch it, and participate in dressing changes. Provide information about support groups such as those sponsored by the American Cancer Society (www.cancer.org) or Canadian Cancer Society (www.cancer.ca). Some cancer organizations have support groups for patients and separate support groups for patients' spouses and children. Discuss having a person who has coped with the same issues come for a visit. Such visits can help show the patient that many aspects of life can be the same after cancer treatment. For patients who have persistent depression as a result of the cancer diagnosis or appearance changes, a referral to a mental health counselor and drug therapy may be indicated.

Physical rehabilitation is often indicated after surgery. Reduced function may be an outcome for some types of cancer surgery. For example, a modified radical mastectomy for breast cancer can lead to muscle weakness and reduced arm function on that side. Performing specific exercises after surgery can reduce functional loss. Head and neck cancer surgery often requires therapy to improve swallowing and speech. Therapy can be painful and challenging. The patient needs encouragement to perform the expected activities. Teach patients about the importance of performing the exercises to regain as much function as possible and prevent complications. Coordinate with the physical therapist, occupational therapist, and family members to plan strategies individualized to each patient to regain or maintain optimal function.

The role of surgery in cancer care continues to change. Laparoscopic and other minimally invasive approaches with smaller incisions and robotic access to internal body cavities have reduced some risks (Yu et al., 2013) (see Chapters 14 and 15). Regardless of the surgical approach, nurses have a critical role in the patient's recovery after surgery. This includes reinforcing the importance of early mobility, pain management, and prevention of infection.

The use of surgery in combination with other therapies has increased. Such combinations may include intraoperative radiation therapy, the placement of a radioactive source, or the administration of chemotherapy into a body cavity. Other uses include surgical placement of internal catheters into a specific vessel and placement of electronic pumps for chemotherapy or pain drugs.

Clinical Judgment Challenge

Ethical/Legal

Mrs. W. is an 80-year-old woman who has undergone exploratory surgery for an acute bowel obstruction. She had been relatively healthy, although growing more frail in recent years, and recently began to need home oxygen intermittently for chronic lung disease. Persistent abdominal pain and vomiting brought her to the emergency department. She lives alone in an assisted-living apartment near her daughter Joan, who provides some additional assistance with grocery shopping, bill paying, etc. Mrs. W. has just been admitted to the ICU after surgery, where she is expected to remain intubated and mechanically ventilated overnight. The surgeon and Mrs. W.'s daughter are talking outside of her room. You join the conversation in time to hear the surgeon explain that a large, disseminated cancer was found as the cause of the obstruction; he removed as much as he could but was not able to resect all of the cancer. Joan responds, "I was afraid of this. Whatever you do, don't tell my mother it was cancer—she'll never be able to cope with that. Please, just tell her that it was a benign tumor and you took it out." The surgeon looks uncertain but nods and then leaves the bedside. Joan turns to you and says, "Tell the other nurses—nobody can say it was cancer."

1. What, if anything, should you say to Joan at this point?
   It is now the next day. As expected, Mrs. W. has remained stable through the night and has been successfully extubated. She is still somewhat sleepy and has not asked any questions about her surgery. When Joan comes in to visit, she pulls you aside and says, "No one told her about the cancer, right?"
2. How should you respond to Joan now?
3. Review the ethical principles in Chapter 1. What ethical principle(s) are at risk or in play with this situation?

Radiation Therapy

Radiation therapy (radiotherapy) involves the use of radionuclides, ionizing radiation beams, or discrete gamma ray sources to treat cancer. The purpose of radiation therapy for cancer is to destroy cancer cells, have minimal damaging effects on the surrounding normal cells, and maintain a safe environment. Radiation may be used to cure, control, or palliate the disease.

The effects of radiation are seen only on tissues within the radiation path; thus this type of therapy usually is a *local* treatment. For example, radiation to the chest for lung cancer causes skin changes and hair loss only on the chest area actually being irradiated. The person does *not* lose

his or her scalp hair. When total body irradiation (TBI) is used, all body areas are affected. Some effects are apparent within days or weeks, whereas other effects on deeper tissues may not be apparent for months to years after radiation therapy is completed.

Most radiation therapy for cancer is ionizing radiation. When cells are exposed to it, particles within the cell's nucleus are rearranged, resulting in a tremendous release of intracellular energy. Ionizing radiation is given off by many elements, including radium, and radioactive isotopes of specific elements.

As a radioactive element breaks down (decays), radiation energy is released as high energy particles (alpha particles and beta particles) and high energy photons (gamma rays). **X-rays** are radiation that is generated by machine. All types of radiation are identical in their effects on cells.

The energy produced by radioactive elements (gamma rays, alpha particles, beta particles) varies in its ability to penetrate tissues and damage cells (Fig. 22-1). *Gamma rays* are used most commonly for radiation therapy because of their ability to deeply penetrate tissues. *Beta particles* are weaker and must be placed within or very close to the cancer cells for cancer therapy (see discussion of brachytherapy on p. 375). *Alpha particles* are not used as cancer therapy.

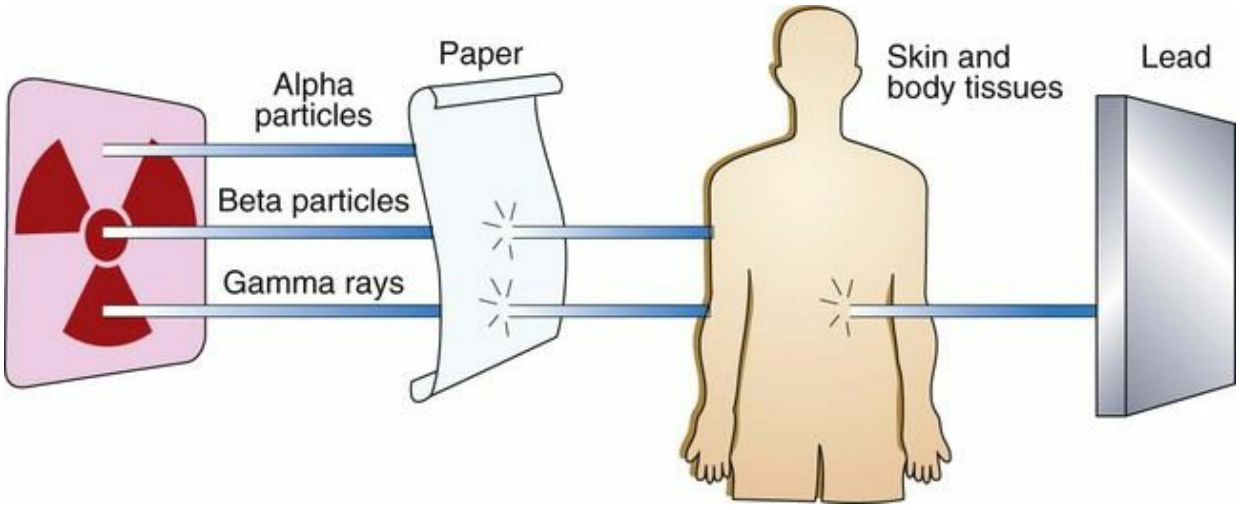

FIG. 22-1 Penetrating capacity of different types of radiation.

The amount of radiation delivered to a tissue is the **exposure;** the amount of radiation absorbed by the tissue is the **radiation dose.** The dose is always less than the exposure because some energy is lost on the way to the tissue. The three factors determining the absorbed dose are the *intensity* of exposure, the *duration* of exposure, and the *closeness* (distance) of the radiation source to the cells. Absorbed radiation doses

are described in units called **gray (gy).** One gy is equal to one joule of energy absorbed by one kg of a material. The total dose of radiation used depends on tumor size and location and on the radiation sensitivity of the tumor and nearby tissues. Some normal tissues are more sensitive than others to radiation. For example, breast tissue tolerates much higher doses of radiation than the liver does. A total dose of 50 to 60 gy might be prescribed for a breast cancer. However, only 12 gy might be prescribed for a liver tumor because a higher dose would destroy healthy liver cells as well as the tumor.

Radiation therapy usually is given as a series of divided doses because of the varying responses of all cancer cells within one tumor. Most often, small doses of radiation are given on a daily basis for a set time period to allow greater destruction of cancer cells while reducing the damage to normal tissues.

The intensity of the radiation decreases with the distance from the radiation emitting source. This factor is known as the *inverse square law.* For example, the radiation dose received at a distance of 2 meters from the radiation source is only one fourth of the dose received at a distance of 1 meter from the radiation source; the dose of radiation received at 3 meters is only one ninth of the dose received at 1 meter.

Cells damaged by radiation either die outright or become unable to divide. Radiation damage occurs anytime a cell is exposed to radiation, not just when it is dividing. However, the damage is greater to dividing cells than to non-dividing cells when exposed to radiation. Cancer radiation therapy does not immediately kill all cells within a tumor because these cells absorb the radiation dose slightly differently and their overall response to the radiation is slightly different. A few cells die immediately, and more die within the next few days. Some cells are unable to divide as a result of a single treatment. Still other cells repair the radiation-induced damage and recover.

Radiation may be used as a stand-alone treatment or may be combined with other cancer therapies. Combining therapies requires careful planning of sequencing, timing, and dose of each therapy to maximize tumor kill and limit damage to normal cells. Often, combining radiation with chemotherapy involves first giving agents that radiosensitize and actually enhance the radiation damage and result in a greater cell kill than either therapy used alone.

Radiation Delivery Methods and Devices

Radiation delivery types for cancer therapy are teletherapy and brachytherapy. The type used depends on the patient's general health

and on the shape, size, and location of the tumor. The ideal radiation dose is one that kills the cancer cells with an acceptable level of damage to normal tissues (damage to normal tissues cannot be avoided).

Teletherapy is radiation delivered from a source outside of the patient. *Because the source is external, the patient is not radioactive and is not hazardous to others.* Newer teletherapy delivery methods improve the accuracy of the dose delivered. Intensity modulated radiation therapy (IMRT) breaks the single beam into thousands of smaller beams that better focus on the tumor. Stereotactic body radiotherapy (SBRT) uses three-dimensional tumor imaging to identify the exact tumor location, which allows precise delivery of higher radiation doses and spares more of the surrounding tissue. Usually, the total dosage is delivered in one to five separate treatment sessions.

Regardless of the delivery method, the exact tumor location is first determined for therapy accuracy. Once the pattern of radiation delivery is decided, the patient must always be in exactly the same position for all treatments. Ensure that the patient can get into and maintain this position. Position-fixing devices and markings, either on the patient's body or on the devices, ensure the proper position each day of treatment. The markings may be small permanent "tattoos," ink outlines on the skin, or a marked mask laid over the skin. Position-fixing devices include customized external body molds, foam-based body molds, and fiberglass splints.

Brachytherapy means "short" (close) therapy. The radiation source comes into direct, continuous contact with the tumor for a specific time period. This method provides a high dose of radiation in the tumor and a very limited dose in surrounding normal tissues.

Brachytherapy uses radioactive isotopes either in solid form or within body fluids. Isotopes can be delivered to the tumor in several ways. *With all types of brachytherapy, the radiation source is within the patient. Therefore the patient emits radiation for a period of time and is a potential hazard to others.* When the isotopes used are unsealed and suspended in a fluid, they are given by the oral or IV routes or instilled within body cavities. An example of brachytherapy with soluble isotopes is the ingestion or injection of the radionuclide *iodine-131* (^{131}I) (an iodine base with a half-life of 8.05 days) to treat some thyroid cancers. The iodine concentrates in the thyroid gland and destroys the thyroid cancer cells. *When isotopes are unsealed, they enter body fluids and eventually are eliminated in waste products. These wastes are radioactive and should not be directly touched by anyone. They must be handled according to guidelines established by the institution. After the isotope is completely eliminated from the body, neither the*

patient nor the body wastes are radioactive.

Solid or sealed radiation sources are implanted within or near the tumor. These sources can be temporary or permanent. Most implants emit continuous, low-energy radiation to tumors. Some devices (e.g., seeds or needles) can be placed into the tumor and stay in place by themselves. Seeds are so small and the half-life of the isotope so short that this device is permanently left in place (often for prostate cancer) and, over time, completely loses its radioactivity. Other devices are removed and reused in other patients. Some sources must be held in place during therapy using special applicators. While the solid implants are in place, the patient emits radiation but excreta are not radioactive. Thus, at this time, the patient poses a hazard to others but the excreta do not.

Traditional implants deliver "low-dose rates" (LDRs) of radiation continuously, and patients are hospitalized for several days. "High-dose rate" (HDR) implant radiation is another delivery type. The patient comes into the radiation therapy department several times a week, and a stronger radiation implant is placed for only an hour or so each time. The patient is radioactive only when the implant is in place (Rupert, 2011). Chart 22-1 lists the best practices for the safety of the personnel providing care to the patient with a sealed radiation implant.

Chart 22-1 Best Practice for Patient Safety & Quality Care QSEN

Care of the Patient with Sealed Implants of Radioactive Sources

- Assign the patient to a private room with a private bath.
- Place a "Caution: Radioactive Material" sign on the door of the patient's room.
- If portable lead shields are used, place them between the patient and the door.
- Keep the door to the patient's room closed as much as possible.
- Wear a dosimeter film badge at all times while caring for patients with radioactive implants. The badge offers no protection but measures a person's exposure to radiation. Each person caring for the patient should have a separate dosimeter to calculate his or her specific radiation exposure.
- Wear a lead apron while providing care. Always keep the front of the apron facing the source of radiation (do not turn your back toward the

patient).
- If you are attempting to conceive, do not perform direct patient care regardless of whether you are male or female.
- Pregnant nurses should not care for these patients; do not allow pregnant women or children younger than 16 years to visit.
- Limit each visitor to one-half hour per day. Be sure visitors stay at least 6 feet from the source.
- Never touch the radioactive source with bare hands. In the rare instance that it is dislodged, use a long-handled forceps to retrieve it. Deposit the radioactive source in the lead container kept in the patient's room.
- Save all dressings and bed linens in the patient's room until after the radioactive source is removed. After the source is removed, dispose of dressings and linens in the usual manner. Other equipment can be removed from the room at any time without special precautions and does not pose a hazard to other people.

A newer approach of targeted therapy for liver cancers involves interventional radiology to place a catheter in the femoral artery and then position it into the liver. Yttrium-90 radioactive beads are injected into the blood vessels supplying liver tumors. These beads lodge in the tumor vessels and deliver a calculated dose of beta particles directly into the tumor(s). This dose travels only 1 to 2 centimeters, and the beads decay to near zero after about 96 hours. This method can deliver an effective therapy dose to the liver without damaging the healthy liver tissue.

Side Effects of Radiation Therapy

Side effects of radiation therapy include both acute and long-term site-specific changes (Table 22-2). These effects are limited to the tissues exposed to the radiation. Therefore the side effects vary according to the site (Ruppert, 2011). Skin changes and hair loss are local but are often permanent depending on the total absorbed dose.

TABLE 22-2

Acute and Late Site-Specific Effects of Radiation Therapy

ACUTE EFFECTS	LATE EFFECTS
Brain	**Subcutaneous and Soft Tissue**
Alopecia and radiodermatitis of the scalp	Radiation-induced fibrosis
Ear and external auditory canal irritation	**Central Nervous System**
Cerebral edema	Brain necrosis
Nausea and vomiting	Leukoencephalopathy
Somnolence syndrome	Cognitive and emotional dysfunction
Head and Neck	Pituitary and hypothalamic dysfunction
Oral mucositis	Spinal cord myelopathies
Taste changes	**Head and Neck**
Oral candidiasis	Xerostomia and dental caries
Oral herpes	Trismus
Acute xerostomia	Osteoradionecrosis
Dental caries	Hypothyroidism
Esophagitis and pharyngitis	**Lung**
Breast and Chest Wall	Pulmonary fibrosis
Skin reactions	**Heart**
Esophagitis	Pericarditis
Chest and Lung	Cardiomyopathy
Esophagitis and pharyngitis	Coronary artery disease
Taste changes	**Breast/Chest Wall**
Pneumonia	Atrophy, fibrosis of breast tissue
Abdomen and Pelvis	Lymphedema
Anorexia	**Abdomen and Pelvis**
Nausea and vomiting	Small and large bowel injury
Diarrhea and proctitis	
Cystitis	
Vaginal dryness/vaginitis	
Eye	
Conjunctival edema and tearing	

Altered taste sensations and fatigue are two common systemic side effects noted by patients during radiation, regardless of the radiation site. Taste changes are thought to be caused by metabolites released from dead cells. Many patients develop an aversion to the taste of red meats. Fatigue may be related to the increased energy demands needed to repair damaged cells. Regardless of the cause, radiation-induced fatigue can be debilitating and may last for months (Poirier, 2011). Some degree of bone marrow suppression occurs regardless of the treatment site. The intensity of the suppression is related to the dose, site, and size of the area irradiated.

Radiation damage to normal tissues during therapy can start inflammatory responses that lead to tissue fibrosis and scarring. These effects may appear years after radiation treatment. For example, women who receive HDR therapy for uterine cancer may develop radiation-induced colon changes (which also was irradiated) years later, resulting

in constipation and even obstruction. Because any form of radiation can damage and mutate normal cell DNA, radiation therapy increases the risk for development of second malignancies. This risk is lower when delivery methods involve less exposure to normal tissues.

Not all patients experience the same degree of side effects to normal tissues even when receiving the same dose of radiation therapy. Genetic differences appear to influence how sensitive a person's normal tissues are to radiation damage (Proud, 2014).

Patient-Centered Collaborative Care

Most patients and family members are anxious about radiation and look to the nurse to explain the purpose and side effects of radiation therapy. Accurate information about radiation therapy helps patients cope with the treatment (Ruppert, 2011).

Skin in the radiation path becomes dry and may break down. Teaching patients about skin care needs during radiation therapy is a priority intervention. Instruct the patient to not remove temporary ink markings when cleaning the skin until radiation therapy is completed. There are no universal evidence-based interventions for skin care during radiation therapy. It is important to teach patients to avoid skin irritation from clothing and to follow the radiation-oncology department's policy regarding the use and timing of skin care products. Use of skin care products designed to manage or protect the skin from radiation damage does reduce the degree of skin problems that develop during a full course of radiation therapy (Bergstrom, 2011). Chart 22-2 is an example of an established skin care protocol during external radiation therapy.

Chart 22-2 Patient and Family Education: Preparing for Self-Management

Skin Protection During Radiation Therapy

- Wash the irradiated area gently each day with either water or a mild soap and water as prescribed by your radiation therapy team.
- Use your hand rather than a washcloth when cleansing the therapy site to be gentler.
- Rinse soap thoroughly from your skin.
- If ink or dye markings are present to identify exactly where the beam of radiation is to be focused, take care not to remove them.
- Dry the irradiated area with patting motions rather than rubbing motions; use a clean, soft towel or cloth.

- Use only powders, ointments, lotions, or creams on your skin at the radiation site that are prescribed by the radiation oncology department.
- Wear soft clothing over the skin at the radiation site.
- Avoid wearing belts, buckles, straps, or any type of clothing that binds or rubs the skin at the radiation site.
- Avoid exposure of the irradiated area to the sun:
  - Protect this area by wearing clothing over it.
  - Try to go outdoors in the early morning or evening to avoid the more intense sun rays.
  - When outdoors, stay under awnings, umbrellas, and other forms of shade during the times when the sun's rays are most intense (10 am to 7 pm).
- Avoid heat exposure.

Nursing Safety Priority QSEN

Action Alert

Skin in the radiation path is more sensitive to sunburn and sun damage. Advise against direct skin exposure to the sun during treatment and for at least 1 year after completing radiation therapy.

The normal tissues most sensitive to external radiation are bone marrow cells, skin, mucous membranes, hair follicles, and germ cells (ova and sperm). When possible, these tissues are shielded from radiation during therapy. At times, they cannot be protected from exposure. Some changes caused by radiation are permanent. The long-term problems vary with the location and dose of radiation received (see Table 22-2). For example, radiation to the throat and upper chest can cause difficulty in swallowing and can lead to reduced nutrition. A registered dietitian is part of the radiation oncology team. Head and neck radiation may damage the salivary glands and cause dry mouth **(xerostomia),** which affects quality of life and increases the patient's lifelong risk for tooth decay. Thus teach patients that regular dental visits are essential. Bone exposed to radiation therapy is less dense and breaks more easily (the cause of pathologic fractures). Fatigue remains a common problem during and for some time after radiation therapy. Exercise and sleep interventions may be somewhat beneficial for fatigue. Teach about the symptoms that might be expected from the specific location and dose of radiation (see Table 22-1 for the location of this information for different

cancer types).

NCLEX Examination Challenge

Psychosocial Integrity

The client receiving brachytherapy with implanted radioactive "seeds" for prostate cancer asks the nurse when these seeds will be removed. What is the nurse's best response?

A "The half-life of radiation in these seeds is so short that it is not necessary to remove them."
B "They will be removed only if their presence is painful or leads to an enlarged prostate gland."
C "When we know for certain that all cancerous cells have been killed, the seeds will be removed."
D "The seeds are small enough to be absorbed by your body and excreted in the urine or stool."

Cytotoxic Systemic Agent Therapy

When cancer has spread beyond a localized area that can be removed with surgery or safely treated with radiation therapy, systemic therapy is indicated for optimal results. Systemic therapy has many effects on normal tissues as well as on cancerous tissue.

Genetic/Genomic Considerations

Patient-Centered Care QSEN

A newer approach to selection of cancer treatment agents to be used is checking the patient's genetic profile to determine the likelihood of experiencing dangerous side effects. This process, known as *pharmacogenomics*, allows a more individualized approach to chemotherapy selection and side effect management. In addition, checking the genetic profile of the tumor can determine its sensitivity to various chemotherapy and targeted therapy agents (Boucher et al., 2014; Santos et al., 2013). This increasingly common practice individualizes cancer therapy and improves therapy outcomes. Expected future outcomes include an economic advantage for cancer care as decisions for treatment can be based on likelihood of effectiveness for an individual rather than on a tumor type or stage of disease. Remind patients that assessing genetic sensitivity can result in a selection of therapy that

differs from that of other people with the same cancer type.

Systemic therapy with the use of antineoplastic agents is cytotoxic therapy in that the agents induce cell damaging/cell killing (cytotoxic) actions on cells, including cancer cells. Selection of agents to use as cytotoxic treatment of cancer is based on cellular kinetic concepts that include cell cycle, growth factors, and tumor burden. Most of the cytotoxic agents are not cancer cell specific and thus potentially affect all cells in the body. This effect is especially seen on rapidly dividing cells such as those in the bone marrow. The time when bone marrow activity and white blood cell counts are at their lowest levels after cytotoxic therapy is the **nadir.** It occurs at different times for different drugs. To reduce immunosuppression, combination cytotoxic therapy avoids using drugs with nadirs that occur at or near the same time.

Chemotherapy

Chemotherapy, the treatment of cancer with chemical agents, is used to cure and to increase survival time. It has some selectivity for killing cancer cells over normal cells. This killing effect on cancer cells is related to the ability of chemotherapy to damage DNA and interfere with cell division. Tumors with rapid growth are often more sensitive to chemotherapy.

As described in Chapter 21, cancer cells can separate from the original tumor, spread to new areas, and establish new cancers at distant sites **(metastasize).** Patients with metastatic cancer will die unless treatment eliminates the metastatic cancer cells along with the original cancer cells. Chemotherapy is useful in treating cancer because its effects are systemic, providing the opportunity to kill metastatic cancer cells that may have escaped local treatment. Chemotherapy used along with surgery or radiation is termed **adjuvant** therapy.

Drugs used for chemotherapy usually are given systemically and exert their cell-damaging **(cytotoxic)** effects against healthy cells as well as cancer cells. The normal cells most affected by chemotherapy are those that divide rapidly, including skin, hair, intestinal tissues, spermatocytes, and blood-forming cells. These drugs are classified by the specific types of action they exert in the cancer cell (Table 22-3).

TABLE 22-3

Categories of Chemotherapeutic Drugs

Antimetabolites
Azacitidine (Vidaza)
Capecitabine (Xeloda)
Cladribine (Leustatin)
Clofarabine (Clolar)
Cytarabine (Cytosar, ara-C)
Decitabine (Dacogen)
Floxuridine (FUDR)
5-Fluorouracil (Adrucil, Efudex, Fluoroplex)
Fludarabine (Fludara, FLAMP)
Gemcitabine (Gemzar)
6-Mercaptopurine (Purinethol)
Methotrexate (MTX, Mexate)
Nelarabine (Arranon)
Pemetrexed (Alimta)
Pentostatin (Nipent)
6-Thioguanine (Tabloid)
Antitumor Antibiotics
Bleomycin (Blenoxane)
Dactinomycin (Cosmegen)
Daunorubicin (Cerubidine, Daunomycin)
Doxorubicin (Adriamycin, Rubex)
Doxorubicin liposomal (Doxil)
Epirubicin (Ellence)
Idarubicin (Idamycin)
Mitomycin C (Mutamycin)
Mitoxantrone (Novantrone)
Valrubicin (Valstar)
Antimitotics
Cabazitaxel (Jevtana)
Docetaxel (Taxotere)
Etoposide (VP-16, VePesid)
Eribulin mesylate (Halaven)
Paclitaxel (Taxol)
Teniposide (Vumon)
Vinblastine (Velban, Velbe, Velsar)
Vincristine (Oncovin)
Vinorelbine (Navelbine)
Alkylating Agents
Altretamine (Hexalen)
Bendamustine (Treanda)
Busulfan (Busulfex)
Carboplatin (Paraplatin)
Carmustine (BiCNU, Gliadel)
Chlorambucil (Leukeran)
Cisplatin (Platinol)
Cyclophosphamide (Cytoxan, Procytox)
Dacarbazine (DTIC)
Estramustine (Emcyt, Estracyte)
Ifosfamide (Ifex)
Lomustine (CCNU, CeeNU)
Mechlorethamine (Mustargen)
Melphalan (Alkeran) (available in oral or IV form)
Oxaliplatin (Eloxatin)
Streptozocin (Zanosar)
Temozolomide (Temodar)
Thiotepa (Thioplex)
Topoisomerase Inhibitors
Irinotecan (Camptosar)
Topotecan (Hycamtin)
Miscellaneous Agents
Arsenic trioxide (Trisenox)
Asparaginase (Elspar)
Hydroxyurea (Droxia, Hydrea)
Ixabepilone (Ixempra)
Pegaspargase (Oncaspar)
Procarbazine (Matulane, Natulan)
Vorinostat (Zolinza)

Chemotherapy Drug Categories

Alkylating agents cross-link DNA, making the DNA strands bind tightly together. This action prevents proper DNA and ribonucleic acid (RNA) synthesis, which inhibits cell division.

Antimetabolites are similar to normal metabolites needed for vital cell processes. Most cell reactions require metabolites in order to begin or continue the reaction. Antimetabolites closely resemble normal metabolites and are "counterfeit" metabolites that fool cancer cells into using the antimetabolites in cellular reactions. Because antimetabolites cannot function as proper metabolites, their presence impairs cell division.

Antimitotic agents interfere with the formation and actions of microtubules so cells cannot complete mitosis during cell division. As a result, the cancer cell either does not divide at all or divides only once.

Antitumor antibiotics damage the cell's DNA and interrupt DNA or RNA synthesis. Exactly how the interruptions occur varies with each agent.

Topoisomerase inhibitors disrupt an enzyme (topoisomerase) essential for DNA synthesis and cell division. When drugs disrupt the enzyme, proper DNA maintenance is prevented, leading to DNA breakage and cell death.

Miscellaneous chemotherapy drugs are those with mechanisms of action that are either unknown or do not fit those of other drug categories.

Combination Chemotherapy

Successful cancer chemotherapy often involves giving more than one specific anticancer drug in a timed manner *(combination chemotherapy).* Using more than one drug can be more effective in killing cancer cells than using just one drug. However, the side effects and damage caused to normal tissues also increase with combination chemotherapy.

Treatment Issues

Drugs selected for use with a given patient are based on the sensitivity of cancer cells to the drug and the stage or extent of disease. Dosages for most chemotherapy drugs are calculated according to the patient's size. Often, calculations are based on milligrams per square meter of total

body surface area (TBSA), which considers the patient's height as well as weight.

Chemotherapy drugs are given on a regular basis and are timed to maximize cancer cell kill and minimize damage to normal cells. The intent is to allow normal cells time to recover from any injury but not allow adequate time for the cancer cells to recover. The schedule may vary slightly to accommodate a patient's response to therapy, but chemotherapy is usually scheduled every 3 to 4 weeks for a specified number of times. Maintaining the intended dosage and timing schedule to ensure the patient receives what was planned is a critical factor in the successful response to chemotherapy. Newer protocols of giving higher doses of chemotherapy more often, called **dose-dense chemotherapy**, may be used for aggressive cancer treatment, especially for breast cancer. This dose-dense therapy also results in more intense side effects.

Patient and family education are critical in helping patients maintain an optimal dosing schedule for best outcomes, reducing side effects, and preventing therapy complications. Many patient problems are managed in the home. Therefore comprehensive and consistent patient education efforts by knowledgeable nurses are key to patient safety (see the Quality Improvement box).

Quality Improvement QSEN

Use of Checklists Can Help Ensure Important Information is Included in Patient Education

Dalby, C., Nesbitt, M., Frechette, C., Kennerley, K., Lacoursiere, L., & Buswell, L. (2013). Standardization of initial chemotherapy teaching to improve care. *Clinical Journal of Oncology Nursing, 17*(5), 472-475.

Chemotherapy for cancer treatment uses toxic drugs with many side effects and complications, and regimens often last for many months. Patients and families require much education and support to manage side effects and reduce the ongoing risks to patient safety. The oncology nurses at a large, well-known comprehensive cancer center that has multiple satellite ambulatory care sites noted that patients continued to have concerns for how to manage problems at home and when to seek professional help even after completing an initial chemotherapy teaching session. Closer examination of teaching techniques revealed that different satellites employed different resources and that individual oncology nurses used different approaches to patient teaching. To comply with the recently updated standards put forth by the American Society of Clinical Oncology and the Oncology Nursing Society to

strengthen patient education, the nurses formed an improvement team consisting of nurse representatives from each treatment satellite, an oncology clinical nurse specialist, and a quality improvement expert. This team first agreed on what categories of patient education were critical and then reached consensus for developing category-specific appropriate checklists for teaching content to cover in each category.

Checklists were developed for content in the categories of (1) patient-specific information, (2) treatment regimen, (3) how and what to communicate (to health care providers), and (4) patient resources. Inclusion of content was determined by vote from experienced oncology nurses. In addition, a treatment-specific calendar for patient/family use was developed, as was a patient education assessment survey. The checklists and other resources were used at the initial chemotherapy visit. The survey was implemented at the third chemotherapy visit to determine checklist effectiveness, reassess patient educational needs, and reinforce key content from earlier teaching sessions.

Survey results at 4 months indicated a high degree of patient satisfaction (97%) with initial chemotherapy teaching. Patients indicated that they were confident in what to expect during chemotherapy and when to contact their providers. The nurses at the satellites involved in this project believed that the checklists helped them provide more consistent and comprehensive education.

Commentary: Implications for Practice and Research

Accurate patient and family education are critical in helping patients maintain an optimal dosing schedule for best outcomes, reducing side effects, and preventing serious therapy complications. This project demonstrated the checklists could help standardize the information and resources presented to patients at initial chemotherapy to ensure adequate patient preparation. Having input from experienced nurses at multiple sites helped ensure no critical information was omitted from teaching plans and helped obtain "buy-in" from all nurses working in these areas. This plan is now being expanded to all satellite clinics of the cancer center.

Many chemotherapy drugs are given IV, although other routes may be used. For specific cancer types, the chemotherapy may be infused or instilled into a body cavity. The *intrathecal* route delivers drugs into the spinal canal, and the *intraventricular* route delivers drugs directly into the ventricles of the brain. *Intraperitoneal* instillations place the drugs within the abdominal cavity, most often for ovarian cancer. Drugs for bladder

cancer can be instilled directly into the bladder *(intravesicular route).* In some instances, drugs may be applied as a *topical* preparation for skin lesions. *Intra-arterial* infusions may be used to deliver a higher dose locally. For examples, with liver tumors, an interventional radiologist places a catheter into the artery supplying the liver tumor. The concentrated chemotherapy drug, delivered in sponge-like beads, is infused, and the beads become trapped in the small arteries feeding the tumor. The techniques and care needs for different routes are described with the specific cancer type most commonly associated with the specific administration route.

The IV route is the most common for chemotherapy. The standard of care designated by the Oncology Nursing Society (ONS) and supported by the American Society of Clinical Oncologists (ASCO) for safe administration of IV chemotherapy is that administration of these drugs requires special education and handling (Neuss et al., 2013; Polovich & Martin, 2011). Special education for competency does not mean that only an advanced practice nurse can perform this function; however, it does mean that the person should be a registered nurse who has completed an approved chemotherapy course. Responsibility for monitoring the patient during chemotherapy administration, however, rests with all nurses providing patient care.

A serious complication of IV infusion is **extravasation,** which occurs when drug leaks into the surrounding tissues (also called *infiltration*). When the drugs given are **vesicants** (chemicals that damage tissue on direct contact), the results of extravasation can include pain, infection, and tissue loss (Fig. 22-2). Surgery is sometimes needed for severe tissue damage.

FIG. 22-2 Appearance of tissue damage and loss after chemotherapy extravasation.

The most important nursing intervention for extravasation is prevention (Gonzales, 2013; Schulmeister, 2014). Small extravasations resolve without extensive treatment if less than 0.5 mL of the drug has leaked into the tissues. If a larger amount has leaked, extensive tissue damage occurs and surgery may be needed. Careful monitoring of the access site is critical during chemotherapy administration to prevent leakage of larger volumes. Institutions should have established evidenced-based policies and procedures that are drug specific to guide extravasation management. With some drugs, cold compresses to the area are prescribed; for other agents, warm compresses are used. Antidotes may be injected into the site of extravasation. Coordinate with the oncologist and pharmacist to determine the specific antidote needed for the extravasated drug. Increasingly, when vesicants are part of therapy, the use of an implanted port or central line to decrease the risk for extravasation is recommended. Even with these devices, the nurse

must observe closely for any indication of leakage and initiate management guidelines immediately.

Most chemotherapy drugs, even oral drugs, are absorbed through the skin and mucous membranes. As a result, the health care workers who prepare or give these drugs (especially nurses and pharmacists) are at risk for absorbing them. Anyone preparing, giving, or disposing of chemotherapy drugs or handling excreta from patients within 48 hours of receiving IV chemotherapy must use extreme caution and wear personal protective equipment (PPE). Such equipment includes eye protection, masks, double gloves or "chemo" gloves, and gown. The Occupational Safety and Health Administration (OSHA) and the Oncology Nursing Society (ONS) have established these practice guidelines and protective standards (Walton et al., 2012).

About two dozen anticancer drugs are available currently as oral agents (Table 22-4). This number is expected to double within the next 10 years. Only a few are actually oral formulations of classic cytotoxic chemotherapy agents; more are classified as specific types of targeted therapy agents (discussed later). Oral drugs are more convenient for the patient, and they can be taken at home. However, there are many problems with oral anticancer drugs. One of the biggest problems is the perception by patients and non-oncology nurses that these drugs are less toxic than those given intravenously (Davey, 2013; Neuss et al., 2013), which is **not** true. *Oral anticancer drugs are just as toxic to the person taking the drug and the person handling the drug as are standard chemotherapy drugs.* The responsibility for administration of these drugs often shifts from the oncology clinic to the home or to non-oncology acute care settings, and issues of protection, correct administration, adherence, and recognition and management of side effects are major concerns. Patients need education and support to self-manage this therapy, including the accidental ingestion by another person. Not all patients are willing or able to accept the responsibility of self-management, and this must be considered during patient selection for oral chemotherapy.

TABLE 22-4

Current Oral Chemotherapeutic Drugs

AGENT	DRUG CATEGORY	CANCER TYPE
Altretamine (Hexalen)	Alkylating agent	Ovarian cancer
Capecitabine (Xeloda)	Antimetabolite	Breast cancer
		Colorectal cancer
Chlorambucil (Leukeran)	Alkylating agent	Chronic lymphocytic leukemia; Hodgkin's lymphoma
		Non-Hodgkin's lymphoma
Dasatinib (Sprycel)	Tyrosine kinase inhibitor	Chronic myelogenous leukemia; acute myelogenous leukemia that is Philadelphia chromosome positive
Erlotinib (Tarceva)	Epidermal growth factor receptor inhibitor	Non–small cell lung cancer
		Pancreatic cancer
Everolimus (Afinitor)	Angiogenesis inhibitor	Advanced renal cell carcinoma
Gefitinib (Iressa)	Epidermal growth factor receptor inhibitor	Non–small cell lung cancer
Hydroxyurea (Droxia, Hydrea)	Miscellaneous agent	Chronic myelogenous leukemia
		Head and neck cancer
		Melanoma
		Ovarian cancer
		Sickle cell disease
Imatinib (Gleevec)	Tyrosine kinase inhibitor	Chronic myelogenous leukemia that is Philadelphia chromosome positive
		Gastrointestinal stromal tumors
		Myelodysplastic syndrome
Lapatinib (Tykerb)	Tyrosine kinase inhibitor	Breast cancer
Lenalidomide (Revlimid)	Angiogenesis inhibitor	Multiple myeloma; myelodysplastic syndrome
Lomustine (CCNU, CeeNU)	Alkylating agent	Hodgkin's lymphoma
		Malignant glioma
Melphalan (Alkeran)	Alkylating agent	Multiple myeloma Ovarian cancer
Mercaptopurine (Purinethol)	Antimetabolite	Acute lymphocytic leukemia
Nilotinib (Tasigna)	Tyrosine kinase inhibitor	Chronic myelogenous leukemia that is Philadelphia chromosome positive
Pazopanib (Votrient)	Multikinase inhibitor	Advanced renal cell carcinoma
Procarbazine (Matulane, Natulan)	Miscellaneous agent	Hodgkin's lymphoma
Sorafenib (Nexavar)	Multikinase inhibitor	Advanced renal cell carcinoma; hepatocellular carcinoma
Sunitinib (Sutent)	Multikinase inhibitor	Advanced renal cell carcinoma; gastrointestinal stromal tumor
Temozolomide (Temodar)	Alkylating agent	Brain tumors (primary)
Thioguanine (Tabloid)	Antimetabolite	Acute myelogenous leukemia
Topotecan (Hycamtin)	Topoisomerase inhibitor	Small cell lung cancer
Vorinostat (Zolinza)	Histone inhibitor	Cutaneous T-cell lymphoma

Because these oral agents can be absorbed through skin and mucous membranes and exert toxic effects, the person who handles and administers them needs to use PPE in the same way as during IV chemotherapy administration. This becomes a more critical issue when non-oncology nurses are administering the drugs. The ONS practice guidelines stress nurse education for competence to administer these drugs. All nurses administering these drugs must know the indications for drug use, dosage ranges, side effects and adverse effects, schedules, and specific precautions (Yagasaki & Komatsu, 2013). In addition, these oral agents must not be crushed, split, broken, or chewed. These drugs

are biohazardous and must be discarded in accordance with agency policy.

Adherence to defined oral chemotherapy schedules and dosages is more of a problem than with IV administration (Davey, 2013). Studies have shown that even highly motivated patients with cancer consider that skipping doses or reducing doses of oral drugs has only a minor impact. As with teaching other aspects of self-care, nurses have to be certain that patients and caregivers understand the implications of the decisions they make. Disrupting the schedule or reducing dosages has a negative impact on therapy outcomes and leads to drug resistance among cancer cells, disease progression, and reduced survival.

Side Effects of Chemotherapy

Temporary and permanent damage can occur to normal tissues from chemotherapy because it is systemic and exerts its effects on all cells. Problems include hemorrhagic cystitis, cardiac muscle damage, and loss of bone density. For some cancer drugs, agents that protect specific healthy cells (cytoprotectants or chemoprotectants) are given ahead of or with chemotherapy drugs to decrease the impact of these drugs on normal tissues. For example, amifostine (Ethyol) reduces DNA damage and is used to prevent kidney damage in patients receiving cisplatin; to reduce neutropenia; and to reduce radiation-induced xerostomia for patients receiving radiation therapy for head and neck cancer. Mesna (Mesnex) binds toxic metabolites to decrease bladder toxicity from ifosfamide and high-dose cyclophosphamide use.

Serious short-term side effects occur with cytotoxic chemotherapy. The side effects on the hematopoietic (blood-producing) system can be life threatening and are the most common reason for changing the dosage or the treatment plan. The suppressive effects on the bone marrow blood-forming cells cause **anemia** (decreased numbers of red blood cells and hemoglobin), **neutropenia** (decreased numbers of white blood cells leading to immunosuppression), and **thrombocytopenia** (decreased numbers of platelets). Common distressing side effects include nausea and vomiting, **alopecia** (hair loss), **mucositis** (open sores on mucous membranes), many skin changes, anxiety, sleep disturbance, altered bowel elimination, and changes in cognitive function. The emotional impact of these side effects is referred to as *cancer therapy symptom distress,* which can vary from patient to patient.

Drug therapy is used to reduce symptom distress from some of these side effects. For other problems, such as alopecia, no evidence-based prevention strategies exist but the patient can be helped to reduce his or

her distress from its presence. Nonpharmacologic nursing interventions for many types of symptom distress experienced include distraction, massage, guided imagery, and other forms of complementary therapy (Serra et al., 2012).

Psychosocial issues can occur during chemotherapy. For many chemotherapy regimens, drugs are given over a period ranging from 2 hours to as long as 8 hours. During this time, the patient may be confined to a treatment area and constantly reminded of the disease and its treatment. Distraction methods such as virtual reality, guided imagery, reading, watching television, and talking with visitors may help reduce the sense of unpleasantness.

❖ Patient-Centered Collaborative Care

The priority care issues during chemotherapy are protecting the patient from the life-threatening side effects and managing the associated distressing symptoms. For some patients, the symptoms are so unpleasant that they want to stop treatment.

Bone Marrow Suppression

In addition to killing cancer cells, chemotherapy also destroys circulating blood cells and reduces replacement of these cells by suppressing bone marrow function, also known as *myelosuppression.* The numbers of all circulating leukocytes, erythrocytes, and platelets are decreased. Reduced leukocyte numbers, especially **neutropenia**, greatly increase the risk for infection. Decreased erythrocytes and platelets cause hypoxia, fatigue, and impaired clotting leading to an increased tendency to bleed.

Infection risk results from neutropenia, placing the patient at extreme risk for sepsis. This critical problem is the major dose-limiting side effect of cancer chemotherapy and can lead to death during treatment. Many chemotherapy drugs cause myelosuppression to some degree and decrease the patient's protective responses to infection. The severity of the risk is related to drug dosage. Impairment is temporary, and protection recovers within weeks after therapy completion. However, the seriousness of potential infections makes this problem a major treatment concern (Held-Warmkessel, 2011). The most common infections are fungal, bacterial, and viral breakthrough. Most infections during neutropenia result from overgrowth of the patient's own normal flora and entrance of these organisms into the bloodstream.

Infection risk can be managed with the use of biological response modifiers (BRMs) and growth factors to stimulate bone marrow production of immune system cells. Although not appropriate for all

types of cancer, this supportive treatment can reduce the risk for infection during chemotherapy. This treatment is discussed in the Immunotherapy section on p. 387. Actual infections are treated with anti-infective drugs, such as antibiotic, antifungal, and antiviral drugs. Just like for any other infection, anti-infective therapy is specific for the organism(s) causing the infection.

Considerations for Older Adults

Patient-Centered Care QSEN

Older adults are at even greater risk for chemotherapy-induced neutropenia because of age-related changes in bone marrow function. Using growth factors, such as filgrastim (Neupogen) and pegfilgrastim (Neulasta), before neutropenia occurs rather than later can reduce the severity of neutropenia and the risk for infectious complications. Be extra vigilant in assessing older adults for early manifestations of infection.

Nursing Safety Priority QSEN

Action Alert

The priority nursing interventions for the patient with neutropenia are protecting him or her from infection within the health care system and teaching the patient and family how to reduce infection risk in the home. Total patient assessment, including skin and mucous membrane inspection, lung sounds, mouth assessment, and inspection of venous access device insertion sites, must be performed every 8 hours by a registered nurse for hospitalized patients.

Explain to the patient the importance of reporting any change in skin and mucous membranes or other health status. Instruct him or her to report any pimple, sore, rash, or open skin area. Also teach him or her to report a cough, burning on urination, pain around the venous access site, or new drainage from any body area. Good handwashing before contact with the patient is essential for infection prevention. Use aseptic technique with any invasive procedure. Chart 22-3 lists the best practices to prevent infection in patients with neutropenia.

Chart 22-3 Best Practice for Patient Safety & Quality

Care QSEN

Care of the Patient with Myelosuppression and Neutropenia

- Place the patient in a private room whenever possible.
- Use good handwashing technique or use alcohol-based hand rubs before touching the patient or any of the patient's belongings.
- Ensure that the patient's room and bathroom are cleaned at least once each day.
- Do not use supplies from common areas for patients with myelosuppression and neutropenia. For example, keep a dedicated box of disposable gloves in his or her room and do not share this box with any other patient. Provide single-use food products, individually wrapped gauze, and other individually wrapped items.
- Limit the number of health care personnel entering the patient's room.
- Monitor vital signs every 4 hours, including temperature.
- Inspect the patient's mouth at least every 8 hours.
- Inspect the patient's skin and mucous membranes (especially the anal area) for the presence of fissures and abscesses at least every 8 hours.
- Inspect open areas, such as IV sites, every 4 hours for manifestations of infection.
- Change wound dressings daily.
- Obtain specimens of all suspicious areas for culture (as specified by the agency), and promptly notify the physician.
- Assist the patient in coughing and deep-breathing exercises.
- Encourage activity at a level appropriate for the patient's current health status.
- Change IV tubing daily or according to unit protocol.
- Keep frequently used equipment in the room for use with this patient only (e.g., blood pressure cuff, stethoscope, thermometer).
- Limit visitors to healthy adults.
- Use strict aseptic technique for all invasive procedures.
- Monitor the white blood cell count daily.
- Avoid the use of indwelling urinary catheters.
- Follow agency policy for restriction of fresh flowers and potted plants in the patient's room.

When delegating any nursing care activity to unlicensed assistive personnel (UAP), teach them the importance of protecting the neutropenic patient from infection. Stress the ways that cross-contamination can occur and how to avoid this source of infection. Also ensure that UAP understand that even when the neutropenic patient is

very tired and does not feel well, certain aspects of personal hygiene cannot be deferred. *Teach the importance of mouth care and washing of the axillary and perianal regions at least every 12 hours.*

Monitoring for manifestations of infection is critical for the hospitalized patient with neutropenia. The reduced numbers of neutrophils can limit the presence of common infection manifestations. Often the patient with neutropenia does not develop a high fever or have purulent drainage even when a severe infection is present. Hospital units specializing in care of neutropenic patients often have standard protocols that nurses initiate as soon as infection is suspected, *before* a physician examines the patient, because treatment delay can result in sepsis and death. These protocols specify what types of cultures to obtain (e.g., blood, urine, sputum, central line, wound), what diagnostic tests to obtain (e.g., chest x-ray), and what antibiotics to start immediately.

Nursing Safety Priority QSEN

Critical Rescue

Consider any temperature elevation in a patient with neutropenia an indication of infection. Report it to the health care provider immediately, and implement standard infection protocols.

Many patients remain at home during periods of neutropenia and are at continuing risk for infection. The focus remains on keeping the patient's own normal flora under control and preventing transmission of organisms from other people to him or her. *The patient with neutropenia but no other manifestations of communicable disease is NOT an infection hazard to other people; however, other people can be an infection hazard to the patient.* Teach patients and families self-care actions to reduce the risk for infection (Chart 22-4), especially handwashing.

Chart 22-4 Patient and Family Education: Preparing for Self-Management

Prevention of Infection

During the times your white blood cell counts are low:

- Avoid crowds and other large gatherings of people who might be ill.
- Do not share personal toilet articles, such as toothbrushes, toothpaste, washcloths, or deodorant sticks, with others.
- If possible, bathe daily, using an antimicrobial soap. If total bathing is

not possible, wash the armpits, groin, genitals, and anal area twice a day with an antimicrobial soap.
- Clean your toothbrush at least weekly by either running it through the dishwasher or rinsing it in liquid laundry bleach (and then rinsing the bleach out with hot running water).
- Wash your hands thoroughly with an antimicrobial soap before you eat and drink, after touching a pet, after shaking hands with anyone, as soon as you come home from any outing, and after using the toilet.
- Follow the cancer center's instructions for eating fresh salads; raw fruits and vegetables; meat, fish and eggs; and pepper and paprika.
- Wash dishes between use with hot, sudsy water, or use a dishwasher.
- Do not drink water, milk, juice, or other cold liquids that have been standing at room temperature for longer than an hour.
- Do not reuse cups and glasses without washing.
- Do not change pet litter boxes.
- Take your temperature at least once a day and whenever you do not feel well.
- Report any of these indications of infection to your physician immediately:
  - Temperature greater than 100° F (37.8° C)
  - Persistent cough (with or without sputum)
  - Pus or foul-smelling drainage from any open skin area or normal body opening
  - Presence of a boil or abscess
  - Urine that is cloudy or foul smelling or that causes burning on urination
- Take all prescribed drugs.
- Wear clean disposable gloves underneath gardening gloves when working in the garden or with houseplants.
- Wear a condom (if you are a man) when having sex. If you are a woman having sex with a male partner, ensure that he wears a condom.

Anemia and *thrombocytopenia* also result from the bone marrow suppression caused by some chemotherapy drugs. Anemia causes patients to feel fatigued from a lack of adequate red blood cells to transport oxygen, and some tissues are hypoxic. Thrombocytopenia increases the risk for excessive bleeding from impaired clotting. When the platelet count is less than 50,000/mm^3, small trauma can lead to prolonged bleeding. With a count lower than 20,000 platelets/mm^3, spontaneous and uncontrollable bleeding may occur. Both anemia and

thrombocytopenia may require transfusion therapy.

The use of growth factors to stimulate production of red blood cells and platelets to improve clotting is common. Erythropoiesis-stimulating agents (ESAs) such as darbepoetin alfa (Aranesp) and epoetin alfa (Epogen and Procrit) can prevent or improve anemia associated with chemotherapy and can reduce the need for transfusions. These drugs increase the production of many blood cell types, not just erythrocytes, increasing the patient's risk for hypertension, blood clots, strokes, and heart attacks, especially among older adults. Also, certain types of cancer cells grow faster in the presence of these ESAs, such as head and neck cancer cells, leukemias, and some lymphomas, and their use may be restricted. Dosing is based on each patient's hemoglobin levels to ensure that just enough red blood cells are produced to avoid the need for transfusion but not necessarily to bring hemoglobin or hematocrit levels up to normal.

An example of growth factor therapy for thrombocytopenia is the use of oprelvekin (Neumega). This drug increases the production of platelets. The drug may cause fluid retention and increase the risk for heart failure and pulmonary edema. Other side effects include conjunctival bleeding, hypotension, and tachycardia. Check whether patients have a working scale, and teach them to weigh themselves daily and keep a record. Remind them to immediately report sudden weight gain or dyspnea to the health care provider.

The priority for nursing care for the patient with thrombocytopenia is to provide a safe environment. Chart 22-5 lists the best practices for Bleeding Precautions for impaired clotting. Teach UAP the importance of using Bleeding Precautions and the need to report any evidence of bleeding immediately. Caregivers at home also need to know these practices.

Chart 22-5 Best Practice for Patient Safety & Quality Care QSEN

Prevention of Injury for the Patient with Thrombocytopenia

- Handle the patient gently.
- Use and teach unlicensed assistive personnel (UAP) to use a lift sheet when moving and positioning the patient in bed.
- Avoid IM injections and venipunctures.
- When injections or venipunctures are necessary, use the smallest-gauge needle for the task.

- Apply firm pressure to the needle stick site for 10 minutes or until the site no longer oozes blood.
- Apply ice to areas of trauma.
- Test all urine and stool for the presence of occult blood.
- Observe IV sites every 4 hours for bleeding.
- Instruct patients to notify nursing personnel immediately if any trauma occurs and if bleeding or bruising is noticed.
- Avoid trauma to rectal tissues:
  - Do not administer enemas.
  - If suppositories are prescribed, lubricate liberally and administer with caution.
- Instruct the patient and UAP that the patient should use an electric shaver rather than a razor.
- When providing mouth care or supervising others in providing mouth care:
  - Use a soft-bristled toothbrush or tooth sponges.
  - Do not use water pressure gum cleaners.
  - Make certain that dentures and other dental devices fit and do not irritate.
- Instruct the patient not to blow the nose or insert objects into the nose.
- Instruct UAP and the patient that the patient should wear shoes with firm soles whenever ambulating.
- Practice fall prevention strategies according to the agency's policies.
- Keep pathways and walkways clear and uncluttered.

Teach patients with thrombocytopenia and their families to avoid injury and excessive bleeding when discharge occurs before the platelet count has returned to normal. Chart 22-6 reviews precautions to teach patients to prevent bleeding and what to do if bleeding occurs.

Chart 22-6 Patient and Family Education: Preparing for Self-Management

Preventing Injury or Bleeding

During the time your platelet count is low:

- Use an electric shaver.
- Use a soft-bristled toothbrush.
- Do not have dental work performed without consulting your cancer health care provider.
- Do not take aspirin or any aspirin-containing products. Read the label

to be sure that the product does not contain aspirin or salicylates.
- Do not participate in contact sports or any activity likely to result in your being bumped, scratched, or scraped.
- If you are bumped, apply ice to the site for at least 1 hour.
- Avoid hard foods that would scrape the inside of your mouth.
- Eat only warm, cool, or cold foods to avoid burning your mouth. Be especially cautious with cheese topping on pizza.
- Check your skin and mouth daily for bruises, swelling, or areas with small reddish purple marks that may indicate bleeding.
- Notify your cancer health care provider if you:
  - Are injured and persistent bleeding results
  - Have excessive menstrual bleeding
  - See blood in your vomit, urine, or bowel movement
- Avoid trauma with intercourse.
- Avoid anal intercourse.
- Take a stool softener to prevent straining during a bowel movement.
- Do not use enemas or rectal suppositories.
- Avoid bending over at the waist, which increases pressure in the brain.
- Do not wear clothing or shoes that are tight or that rub.
- Avoid blowing your nose or placing objects in your nose. If you must blow your nose, do so gently without blocking either nasal passage.
- Avoid playing musical instruments that raise the pressure inside your head, such as brass wind instruments and woodwinds or reed instruments.

NCLEX Examination Challenge

Physiological Integrity

The client receiving high-dose chemotherapy who has neutropenia asks the nurse whether he and his wife can have sexual intercourse while he is receiving chemotherapy. What is the nurse's best response?
A "No, this activity will increase the side effects of the chemotherapy."
B "No, the danger of impregnating your wife is too great."
C "Yes, as long as you feel like it and use a condom."
D "Yes, if you do not have an infection."

Chemotherapy-Induced Nausea and Vomiting

Chemotherapy-induced nausea and vomiting (CINV) arises from a variety of GI and neural mechanisms. It may manifest as *anticipatory* (before receiving the chemotherapy, often triggered by thoughts, sights,

and sounds related to the anticipated chemotherapy), *acute* (within the first 24 hours after chemotherapy), *delayed* (occurring after the first 24 hours), *breakthrough* (occurring intermittently during therapy for CINV), or a combination of these. Many cancer drugs are **emetogenic** (vomiting inducing) to some degree, depending on the dose. Although evidence-based advances in prevention and control of CINV are helpful, it remains a common and distressing issue (Cherwin, 2012). Nausea often persists even when vomiting is controlled.

Acute CINV is more common than other types. It may persist for 1 to 2 days after chemotherapy is given. A few drugs, such as dacarbazine (DTIC), may trigger CINV almost as soon as the drug is started. Other drugs, such as cisplatin (Platinol), induce delayed nausea and vomiting that can continue as long as 5 to 7 days after receiving it. Patients who have CINV during one round of chemotherapy may begin to have the same manifestations before the next round as a result of sheer anticipation. Once considered the single most distressing side effect of chemotherapy, CINV often can be well controlled with appropriate evidence-based antiemetic therapy, especially with serotonin (5-HT3) antagonist drugs and the use of standardized protocols for its prevention and management.

Drug Therapy.

Many antiemetics are available to relieve nausea and vomiting. These drugs vary in the side effects they produce and how well they control CINV. One or more antiemetics are usually given before, during, and after chemotherapy. Drugs commonly used short-term to control CINV are listed in Chart 22-7. *Patient response to antiemetic therapy is variable, and the drug combinations are individualized for best effect (Barak et al., 2013).*

Chart 22-7 Common Examples of Drug Therapy

Chemotherapy-Induced Nausea and Vomiting

DRUG/USUAL DOSAGE	PHYSIOLOGIC PURPOSE	NURSING INTERVENTIONS	RATIONALE
Serotonin Antagonists			
Ondansetron (Zofran) 8 mg IV or orally every 8 hr Granisetron (Kytril) 1 mg IV or orally every 12 hr Granisetron transdermal (Sancuso) 1 patch per day starting 24 to 48 hrs before chemotherapy administration and continuing for up to 7 days after chemotherapy administration Dolasetron (Anzemet) 100 mg IV or orally 30 minutes before chemotherapy administration Palonosetron (Aloxi) 0.25 mg IV as a single dose 30 minutes before chemotherapy administration	Prevent CINV by blocking the 5-HT3 receptors in the brain (chemotrigger zone) and in the intestines. This action prevents serotonin from binding to the receptors and activating the nausea and vomiting centers.	Teach patient to change positions slowly to avoid falls.	These drugs may induce bradycardia, hypotension, and vertigo.
		Assess the patient for headache.	Headache is a common side effect of drugs from this class.
Neurokinin Receptor Antagonists			
Aprepitant (Emend) *3-day oral regimen:* Day 1, 125 mg 1 hour before chemotherapy administration Days 2 and 3, 80 mg in the morning (no chemotherapy these days) *IV regimen:* Day 1, 115 mg 30 minutes before chemotherapy, followed by oral regimen on Days 2 and 3	Reduce CINV by blocking the substance P neurokinin receptor. When used together with a serotonin antagonist and a corticosteroid, both acute and delayed nausea and vomiting are controlled.	Teach patients who are also taking warfarin (Coumadin) to have their INRs checked before and after the 3 days of this therapy.	This drug interferes with the effectiveness of warfarin.
		Teach women who are using oral contraceptives to use an additional form of birth control while on this drug.	The drug reduces the effectiveness of oral contraceptives, increasing the risk for an unplanned pregnancy.
Corticosteroids			
Dexamethasone (Decadron) 5-10 mg IV or orally daily	Reduce CINV by decreasing swelling in the brain's chemotrigger zone.	Teach patients to reduce salt intake to about 4 g daily.	Drug causes fluid retention and hypertension.
Prokinetic Agents			
Metoclopramide (Reglan) 20-40 mg IM or IV twice or three times daily	Reduce CINV by blocking dopamine receptors in the brain's chemotrigger zone.	Teach the patient to avoid driving or operating heavy machinery.	Increased drowsiness is common.
Benzodiazepines			
Lorazepam (Ativan) 1-3 mg orally or IV twice or three times daily	Reduce CINV by enhancing cholinergic effects and by decreasing the person's awareness.	Teach the patient and family that the patient should avoid driving, operating heavy machinery, making legal decisions, and going up and down staircases unassisted.	The drug induces amnesia and profound drowsiness.

CINV, Chemotherapy-induced nausea and vomiting; *INR,* international normalized ratio.

Nursing Safety Priority QSEN

Drug Alert

Do not confuse the antiemetic drug *Anzemet* (dolasetron) with the diabetes drug *Avandamet* (a combination of metformin and rosiglitazone). The drugs have similar sounding names but totally different actions.

Regardless of which drugs are being used to prevent or reduce CINV, they are most effective when used in an evidence-based approach for prevention and management on a scheduled basis (Davidson et al., 2012). Drug therapy for CINV works best when given before the nausea and vomiting are out of control. *The nursing priority is to coordinate with the patient and health care provider to ensure adequate control of CINV. Ensure that antiemetics are given before chemotherapy and are repeated based on the response and duration of CINV.* When patients are receiving dose-dense

chemotherapy, the intensity of CINV also increases and more aggressive antiemetic therapy is needed. Teach patients to continue the therapy, even when CINV appears controlled. *When the patient stops taking the drug(s), teach him or her to start retaking the drug at the first sign of nausea to prevent it from becoming uncontrollable.*

Considerations for Older Adults

Patient-Centered Care QSEN

The older adult can become dehydrated more quickly than a younger adult if CINV is not controlled. Teach older adults to be proactive with taking their prescribed antiemetics and to contact their health care provider if the CINV either does not resolve within 12 hours or becomes worse.

Mucositis

Mucositis (sores in mucous membranes) often develops in the entire GI tract, especially in the mouth (**stomatitis** refers to reactions that involve the other tissues and structures in the oral cavity). Mucositis is believed to be a complex, multiphase process at the cellular level started in response to cytotoxic chemotherapy. Mouth sores cause pain and interfere with eating and quality of life. Chart 22-8 lists the patient education for self-management of mucositis.

Chart 22-8 Patient and Family Education: Preparing for Self-Management

Mouth Care for Patients with Mucositis

- Examine your mouth (including the roof, under the tongue, and between the teeth and cheek) every 4 hours for fissures, blisters, sores, or drainage.
- If sores or drainage is present, contact your health care provider to determine whether these areas need to be cultured.
- Brush the teeth and tongue with a soft-bristled brush or sponges every 8 hours and after meals.
- Avoid the use of mouthwashes that contain alcohol or glycerin.
- "Swish and spit" room-temperature tap water, normal saline, or salt and soda water on a regular basis (at least 4 times a day) and as needed according to changes in the oral cavity.
- Drink 2 or more liters of water per day if another health problem does

not require limiting fluid intake.
- Take antimicrobial drugs as prescribed.
- Use topical analgesic drugs as prescribed.
- Take pain medications on schedule as needed.
- Apply a water-based moisturizer to your lips after each episode of mouth care and as needed.
- Use prescribed "artificial saliva" or mouth moisturizers as needed.
- Avoid using tobacco or drinking alcoholic beverages.
- Avoid spicy, salty, acidic, dry, rough, or hard food.
- Cool liquids to prevent burns or irritation.
- If you wear dentures, use them only during meals. When not in place, soak dentures in an antimicrobial solution. Rinse thoroughly before placing them in your mouth.

Frequent mouth assessment and oral hygiene are key in managing mucositis. Stress the importance of good and frequent oral hygiene, including teeth cleaning and mouth rinsing. Because most patients with mucositis also have bone marrow suppression and are at risk for impaired clotting with bleeding, they must take care to avoid traumatizing the oral mucosa. Instruct them to use a soft-bristled toothbrush or disposable mouth sponges. Recommendations include *gentle* flossing once daily. Encourage them to rinse the mouth with plain water or saline at frequent intervals during the day and night when awake. Frequency is guided by the intensity of the mucositis. Initially, the rinses start after meals and at bedtime, then every 2 hours, and then progressing to hourly if needed for comfort. Teach patients to avoid mouthwashes that contain alcohol or other drying agents that may further irritate the mucosa.

Oral hygiene equipment must be kept clean. Remind patients not to share toothbrushes. Toothbrushes can be cleaned weekly by using a home dishwasher or by rinsing them with a solution of liquid bleach or hydrogen peroxide and then rinsing with hot water.

Many compounds are available for pain relief from mucositis as "swish and spit" mixtures that contain a local anesthetic combined with anti-inflammatory agents, although their use is not evidence-based. Remind the patient that these mixtures are not to be swallowed. For multiple mouth lesions, most patients require systemic pain medications.

Alopecia

Alopecia, hair loss, may occur as whole-body hair loss or may be as mild as only a thinning of the scalp hair. When body hair loss includes pubic hair, patients may struggle with their sexual identity and may not discuss

this problem. Reassure patients that hair loss is temporary. Regrowth usually begins about 1 month after completion of chemotherapy; however, the new hair may differ from the original hair in color, texture, and thickness. No known evidence-based treatment safely prevents alopecia. *The priority nursing actions are to teach patients how to avoid scalp injury and to assist them in coping with this body image change.*

The hairless scalp is at risk for injury. Teach the patient to avoid direct sunlight on the scalp by wearing a hat or other head covering. Sunscreen use is essential to prevent sunburn because many drugs increase sun sensitivity, regardless of skin darkness. This skin can be damaged by helmets, headphones, headsets, wigs, and other items that rub the head. Teach the patient to wear some head covering underneath these items. Head coverings also are needed during cold weather and in cool environments to reduce body heat loss and prevent hypothermia.

Assist patients in selecting a type of head covering that suits their income and lifestyle. One recommendation is to coordinate wig purchases with the patient's hairdresser or barber. Having very short hair or a shaved head now is common and socially acceptable for men, and many men choose not to wear a wig during chemotherapy. Cutting the hair very short before chemotherapy begins allows a better wig fit.

Suggest that patients purchase a wig before therapy begins and have their hairdresser shape it to mimic their usual hairstyle to reduce appearance changes. High-quality wigs are expensive but can look very much like the patient's own hair. Many local units of the American Cancer Society (ACS) offer the loan of wigs that other patients have donated to be lent to others with cancer. Patients also can disguise hair loss with caps, scarves, and turbans. The ACS also provides instruction (Look Good-Feel Better) regarding makeup and the use of scarves, for example, to improve appearance and how patients feel about themselves. Patients in control of their appearance may improve their quality of life during therapy (Borsellino & Young, 2011).

Changes in Cognitive Function

Some patients receiving chemotherapy have reported changes in cognitive function—most commonly reduced ability to concentrate, memory loss, and difficulty learning new information during treatment and for months to years after treatment. Although most types of chemotherapy drugs do not cross the blood-brain barrier and were thought not to affect any part of brain function, the drugs can induce inflammation and general biochemical changes that could reduce cognitive function, at least temporarily (Kanaskie, 2012; Myers, 2012).

This problem, termed "chemo brain," is reported most often in women undergoing chemotherapy for breast cancer, although it is not limited either to women or to breast cancer treatment. The fact that it is reported more in this population reflects that breast cancer is very common, it is often treated with high-dose chemotherapy, and most patients with breast cancer survive a long time after therapy.

Comparisons of brain structure and cognitive function before, during, and after high-dose chemotherapy show some anatomic changes in brain white matter and gray matter. These changes are not usually present at 3 years after completion of therapy. It is not known why all patients receiving high-dose chemotherapy do not develop the problem; however, genetic differences may be partly responsible. Not only is the exact cause of this side effect unclear, so are the personal risk factors.

The priority for nursing care is to support the patient who reports this side effect. Listen to the patient's concerns, and tell him or her that other patients have also reported such problems. Providing absolute reassurance is difficult, but the results of early studies indicate that recovery is likely with time. A common sense approach includes that patients should be warned against participating in other behaviors that could alter cognitive functioning, such as excessive alcohol intake, recreational drug use, and activities that increase the risk for head injury. Research about reducing the effects of chemo brain is ongoing.

Chemotherapy-Induced Peripheral Neuropathy

Chemotherapy-induced peripheral neuropathy (CIPN) is the loss of sensory or motor function of peripheral nerves associated with exposure to certain anticancer drugs (Binner et al., 2011; Tofthagen et al., 2011). Some patients undergoing chemotherapy with nerve-damaging drugs (e.g., antimitotics and platinum-based drugs) have rapid onset of severe CIPN. The degree of CIPN is related to the dosage of the nerve-damaging drugs; higher doses lead to greater neuropathy. The results of CIPN on function are widespread, with the most common problems including loss of sensation in the hands and feet, orthostatic hypotension, erectile dysfunction, neuropathic pain, loss of taste discrimination, and severe constipation. CIPN is a long-term consequence and may be permanent in some people. No known interventions prevent CIPN.

The priority for nursing care of patients experiencing CIPN is teaching them to prevent injury. Loss of sensation increases the patient's risk for injury because he or she may not be aware of excessive heat, cold, or pressure. The risk for injury to the feet is very high. Falls are more likely because

the patient cannot feel changes in terrain and because of orthostatic hypotension. Chart 22-9 lists teaching priorities for the patient with CIPN.

Chart 22-9 Patient and Family Education: Preparing for Self-Management

Chemotherapy-Induced Peripheral Neuropathy

- Protect feet and other body areas where sensation is reduced (e.g., do not walk around in bare feet or stocking feet; always wear shoes with a protective sole).
- Be sure shoes are long enough and wide enough to prevent creating sores or blisters.
- Buy shoes in the afternoon or evening to accommodate any size change needed for foot swelling.
- Provide a long break-in period for new shoes; do not wear new shoes for longer than 2 hours at a time.
- Avoid pointed-toe shoes and shoes with heels higher than 2 inches.
- Inspect your feet daily (with a mirror) for open areas or redness.
- Avoid extremes of temperature; wear warm clothing in the winter, especially over hands, feet, and ears.
- Test water temperature with a thermometer when washing dishes or bathing. Use warm water rather than hot water (less than 105° F or 40.6° C).
- Use potholders when cooking.
- Use gloves when washing dishes or gardening.
- Do not eat foods that are "steaming hot"; allow them to cool before placing them in your mouth.
- Eat foods that are high in fiber (e.g., fruit, whole grain cereals, vegetables).
- Drink 2 to 3 liters of fluid (nonalcoholic) daily unless your health care provider has told you to restrict fluid intake.
- Use the actions for "Falls Prevention" supplied by the cancer center during all activities.
- Get up slowly from a lying or sitting position. If you feel dizzy, sit back down until the dizziness fades before standing; then stand in place for a few seconds before walking or using the stairs.
- To prevent tripping or falling, look at your feet and the floor or ground where you are walking to assess how the ground, floor, or step changes.
- Avoid using area rugs, especially those that slide easily.

- Keep floors free of clutter that could lead to a fall.
- Use handrails when going up or down steps.

Some issues, such as erectile dysfunction, may be helped with devices or drug therapy (see Chapter 72 for options for erectile dysfunction). Other issues are not correctable and affect many aspects of quality of life. The loss of hand sensation may make some activities that require very fine motor skills difficult or impossible. Assess the patient's ability to cope with these changes. Coordinate with an occupational therapist to help the patient adjust for sensory deficits in performing activities. Patients who have an altered gait are at increased risk for falls and injury.

NCLEX Examination Challenge

Health Promotion and Maintenance

Which precaution is most important for the nurse to teach the client who has chemotherapy-induced peripheral neuropathy?
A Avoid taking aspirin or any aspirin-containing products.
B Use a bath thermometer to check bath water temperature.
C Do not use mouthwashes that contain alcohol or glycerin.
D Bathe daily using an antimicrobial soap or gel.

Immunotherapy: Biological Response Modifiers

Biological response modifiers (BRMs) modify the patient's biologic responses to tumor cells. BRMs can influence cancer cells in a variety of ways. Some have direct antitumor activity, helping the body recognize cancer cells as foreign so that the immune system destroys them. BRMs also can improve immune function and enhance the body's ability to repair or replace cells damaged by cancer treatment.

As discussed in Chapter 17, cytokines released from immune system cells are not usually cytotoxic alone but influence how immune system cells function. The cytokines include the interferons, interleukins, tumor necrosis factors, and colony-stimulating factors. Some cytokines enhance immune function, which plays an important role in cancer prevention (see Chapters 17 and 21). Cytokines and other BRMs work by stimulating the immune system to recognize cancer cells and take actions to eliminate or destroy them. Some BRMs stimulate faster recovery of bone marrow function after treatment-induced suppression. Additional BRMs include the monoclonal antibodies and vaccines.

BRMs as Cancer Therapy

Two common types of BRMs used as cancer therapy are the interleukins and interferons. Some agents can stimulate specific immune system cells to attack and destroy cancer cells; other agents block cancer cell access to an essential function or nutrient.

Interleukins (ILs) are a large group of substances the body makes to help regulate inflammation and immunity. Some are now synthesized as anticancer drugs. In particular, ILs have been useful for renal cell carcinoma and melanoma. ILs help different immune system cells recognize and destroy abnormal body cells. In particular, IL-1, IL-2, and IL-6 appear to "charge up" the immune system and enhance attacks on cancer cells by macrophages, natural killer (NK) cells, and tumor-infiltrating lymphocytes (Abbas et al., 2012).

Interferons (IFNs) are cell-produced proteins that have been effective to some degree in the treatment of melanoma, hairy cell leukemia, renal cell carcinoma, ovarian cancer, and cutaneous T-cell lymphoma. They assist in cancer therapy by:

- Slowing tumor cell division
- Stimulating the growth and activation of NK cells
- Inducing cancer cells to resume a more normal appearance and function
- Inhibiting the expression of oncogenes

One drug classified as a BRM that has a different action is thalidomide (Thalomid), which reduces the level of tumor-secreted vascular endothelial growth factor (VEGF). VEGF is needed to maintain blood supply to the tumor. When VEGF is reduced, the tumor is poorly nourished and cancer cells die. This drug is approved for treatment of multiple myeloma.

BRMs as Supportive Therapy

BRMs used for supportive therapy during cancer treatment are the colony-stimulating factors or "growth factors" (Table 22-5). These factors induce more rapid recovery of the bone marrow after suppression by chemotherapy. This effect has two benefits. First, when bone marrow suppression is shortened or less severe, patients are less at risk for life-threatening infections, anemia, and impaired clotting with bleeding. Second, because the growth factors allow more rapid bone marrow recovery, patients can receive their chemotherapy as scheduled and may even be able to tolerate higher doses, potentially increasing the chance for cure.

TABLE 22-5

Common Biological Response Modifiers Used As Supportive Cancer Therapy

AGENT	CELL TYPE AFFECTED	INDICATIONS
Sargramostim (Leukine, Prokine)	All granulocytes Neutrophils Eosinophils Monocytes Macrophages	Chemotherapy-induced leukopenia
Filgrastim (Neupogen) Pegfilgrastim (Neulasta)	Neutrophils	Chemotherapy-induced neutropenia
Epoetin alfa (Epogen, Procrit) Darbepoetin alfa (Aranesp)	Erythrocytes	Chemotherapy-induced anemia Chemotherapy-induced fatigue Anemia induced by renal failure
Oprelvekin (Neumega)	Platelets	Chemotherapy-induced thrombocytopenia
Sipuleucel-T (Provenge) (product is a vaccine)	T-cells; antigen-processing cells (macrophages)	Hormone-refractory prostate cancer

Side Effects of BRM Therapy

Patients receiving interleukins have generalized and often severe inflammatory reactions. Fluid shifts and capillary leak syndrome (CLS) are widespread with edema formation. Tissue swelling affects the function of all organs and can be life threatening. Patients receiving high-dose BRM therapy should receive care in an intensive care or monitoring unit. These effects occur during the period of acute drug infusion and resolve after therapy completion.

Many BRMs and growth factors induce manifestations of inflammation during and just after receiving the drug, including fever, chills, rigors, and flu-like symptoms (general malaise). Problems are worse when higher doses are given, but they seem to become less severe over time. The nursing priorities for patients receiving BRMs include assessing for complications of systemic inflammation and making patients as comfortable as possible. Fever is treated with acetaminophen. Patients with severe rigors are managed with meperidine (Demerol). Patients may also experience nausea, vomiting, diarrhea, and anorexia. Antiemetics are helpful in the management of nausea and vomiting.

Neurologic manifestations associated with BRM use can be significant. These include confusion, fatigue, somnolence, irritation or agitation, hallucinations, vivid dreams, anxiety, and sleep disturbances. Some

patients have psychosocial issues of fear, tearfulness, depression, and mood swings. Early identification of these manifestations is an important nursing care activity.

Interferon therapy causes peripheral neuropathy. It is not known whether the neuropathy is temporary or permanent. (See the Chemotherapy-Induced Peripheral Neuropathy section on p. 386.)

Skin dryness, itching, and peeling occur with many types of BRM therapy. The skin problems are more severe with higher doses and when more than one type of BRM is used at the same time. Reactions are temporary but cause much discomfort and distress. Advise patients to apply moisturizers (unscented) to the skin and to use mild soap to clean the skin. Involved areas should be protected from the sun with clothing or the use of sunscreen agents. Teach patients to avoid swimming and to not use topical steroid creams on affected areas.

Monoclonal Antibodies

Monoclonal antibody therapy combines actions from immunotherapy and targeted therapy to help treat specific cancers. The body normally responds to foreign substances with the production of antibodies. These proteins are then able to target the antigen when present in the body, attacking and destroying the foreign antigen (nonself cells). In cancer therapy, human, mouse, and rabbit hybrid cells can produce antibodies against given targets known to be present in or on certain types of cancer cells.

Monoclonal antibodies bind to their target antigens, which are often specific cell surface membrane proteins. Binding prevents the protein from performing its functions. Some cancer cells express cell membrane surface proteins that are unique to cancer cells and have a role in cancer cell division. So, by binding these proteins, monoclonal antibodies prevent cell division. Some monoclonal antibodies actually make tumor cells more sensitive to chemotherapy and increase the effectiveness of immune system attacks on the cancer cells. The most well known monoclonal antibody for targeted therapy is rituximab (Rituxan). It binds to the protein *CD20*, which is often overexpressed on the surface of non-Hodgkin's lymphoma cell membranes. This protein activates an early step of the cell cycle division process. Binding *CD20* with rituximab prevents it from stimulating cell division in the non-Hodgkin's lymphoma cells.

Allergic reactions can be an issue in patients receiving monoclonal antibodies because of the incorporation of non-human proteins. Most of these antibodies initially were developed in mice and express some

mouse proteins. Now many of these antibodies have been "humanized," reducing the risk for allergic reactions. Nursing assessment is key for early recognition of a potentially life-threatening allergic reaction.

The monoclonal antibodies to the epidermal growth factor receptor (EGFR) bind to those specific receptors on normal and cancerous cells. Thus side effects also occur in the skin, mucous membranes, and lining of the GI tract.

Molecularly Targeted Therapy

Molecularly targeted therapies are technically biologic agents. However, their unique actions and roles in cancer therapy warrant separate discussion. These agents use molecular flaws in some cancer cells to specifically target cancer cells and have less of an impact on normal cells. Generally, molecularly targeted therapies block the growth and spread of cancer by interfering with the specific signals or molecules involved in the growth and progression of cancer cells (Beatty et al., 2011). These agents are providing patients with cancer a new sense of hope against a challenging disease.

As discussed in Chapter 21, normal cells have tightly controlled regulation over when and to what extent a cell divides; cancer cells have escaped this tight control. External events can indicate to a cell that cell division is needed. However, these external events must be communicated to the cell's nucleus to activate the genes that promote cell division (oncogenes) and turn off the genes that normally suppress cell division (suppressor genes). The key to communicating the need for cell division is the presence and activation of signal transduction pathways. Fig. 22-3 shows a segment of a cell with one signal transduction pathway. When this pathway is activated at the cell surface by binding growth factors to their receptors, having certain drugs interact with the cell's plasma membrane, binding of certain adhesion molecules (CAMs), changing movement of calcium and sodium across the membrane, or other cell-to-cell interactions, the first result is an increase in the cell's production of a family of enzymes known as *tyrosine kinases (TKs).* With increased TKs present, the pro–cell division signal activates many substances, known as *transcription factors,* within the pathway. When the pro–cell division transcription factors reach the cell's nucleus, oncogenes are activated, suppressor genes are inactivated, and a variety of proteins are produced to make cell division occur.

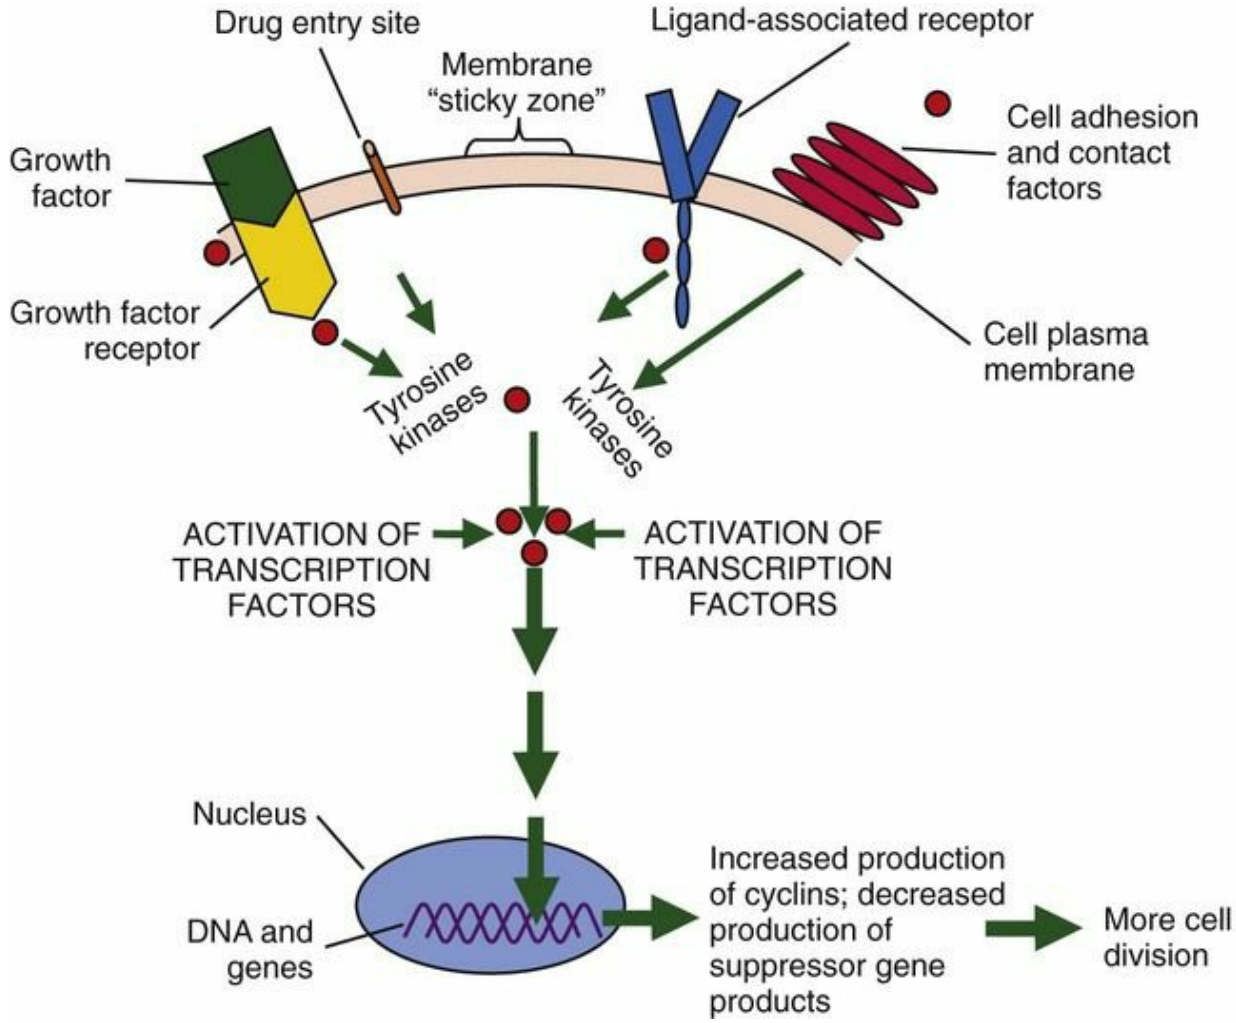

FIG. 22-3 Pro–cell division signal transduction pathway.

When cell division is not needed, external signals, such as growth factor inhibitors and the surrounding of a cell's plasma membrane with other cells, send signals that inhibit activation of TKs and the signal transduction pathway. As a result, fewer transcription factors are produced, suppressor genes are expressed, and oncogenes are suppressed. The proteins needed for cell division are not produced, and cell division does not occur.

Overall, cancer cells have more active signal transduction pathways and transcription factors that ultimately lead to excessive division of the cancer cells. Targeted therapies take advantage of differences in one or more parts of the signal transduction pathway to block it. Often these parts are overexpressed in cancer cells. Agents used as targeted therapies can disrupt the pathway and slow or stop cell division. They may work by blocking a growth factor receptor, by preventing the activation of tyrosine kinases, by limiting the production of transcription factors, and by other mechanisms that are not yet fully understood. Regardless of how a targeted therapy works, it will work only with those cancer cells that have the actual target. The result is that the signal for turning on cell division

genes (oncogenes) does not get through to the cell's nucleus (Fig. 22-4) (Byar & Workman, 2012; Santos et al., 2013).

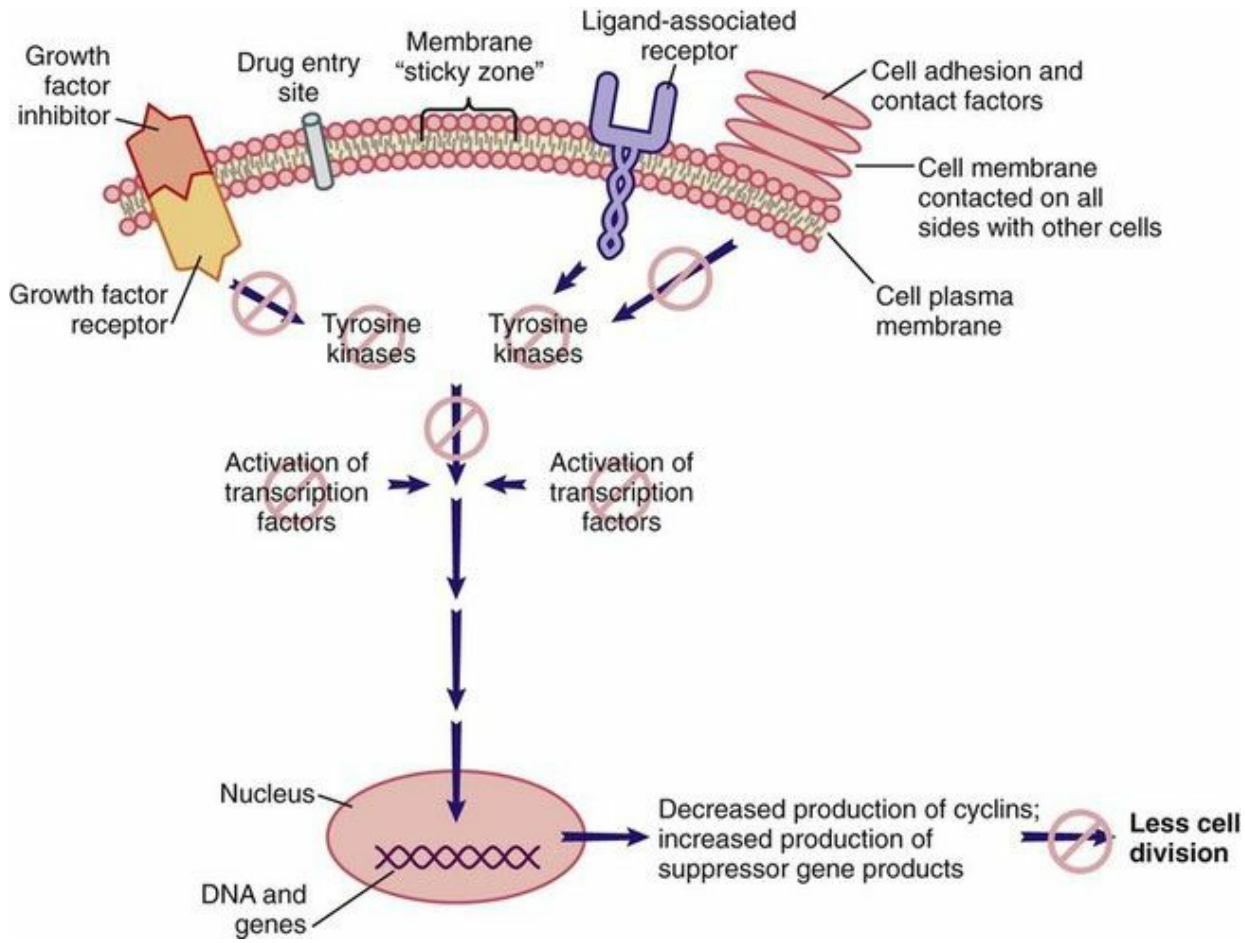

FIG. 22-4 Sites of action for targeted therapies that inhibit a signal transduction pathway and greatly reduce cell division.

Drugs for targeted therapy have been approved as treatment for certain cancers. These drugs are classified based on the mechanism of action, and some have more than one action (Table 22-6). Because of the varying mechanisms of action and the relative newness of these therapies, the priority nursing action is careful assessment for adverse reactions to therapy.

TABLE 22-6

Common Targeted Therapy Agents

CLASSIFICATION	AGENT
Tyrosine kinase inhibitors	Dasatinib (Sprycel) Imatinib mesylate (Gleevec) Lapatinib (Tykerb) Nilotinib (Tasigna)
Epidermal growth factor receptor inhibitors (EGFRIs)	Cetuximab (Erbitux) Erlotinib (Tarceva) Gefitinib (Iressa) Panitumumab (Vectibix) Trastuzumab (Herceptin)
Vascular endothelial growth factor receptor inhibitors (VEGFRIs)	Bevacizumab (Avastin)
Multikinase inhibitors	Sorafenib (Nexavar) Sunitinib (Sutent) Pazopanib (Votrient)
Proteasome inhibitors	Bortezomib (Velcade)
Angiogenesis inhibitors	Everolimus (Afinitor) Lenalidomide (Revlimid) Temsirolimus (Torisel)
Monoclonal antibodies	Alemtuzumab (Campath) Ibritumomab (Zevalin) Rituximab (Rituxan) ^{131}I tositumomab (Bexxar)

It is important to remember that these drugs will not work unless the cancer cell overexpresses the actual target substance. Thus not all patients with the same cancer type would benefit from the use of targeted therapy. Each person's cancer cells are evaluated to determine whether the cells have enough of a target to be affected by targeted therapy.

The targeted therapy agents are classified based on their action. The first application of these agents was against estrogen in breast cancer (discussed in the Hormonal Manipulation section on p. 391). There now are a group of selective estrogen receptor modulators (SERMs). Aromatase inhibitors (AIs) have been developed to interfere with estrogen's ability to promote the growth of estrogen receptor positive breast cancers. Discussion in this section will focus on the tyrosine kinase inhibitors (TKIs), epidermal growth factor/receptor inhibitors (EGFRIs), vascular endothelial growth factor/receptor inhibitors (VEGFRIs), multikinase inhibitors (MKIs), proteasome inhibitors, and angiogenesis inhibitors.

Tyrosine Kinase Inhibitors

Drugs with the main action of inhibiting activation of tyrosine kinases (TKs) are **tyrosine kinase inhibitors (TKIs)**. There are many different

TKs. Some are unique to the cell type; others may be present only in cancer cells that express a specific gene mutation. As a result, the different TKI drugs are effective in disrupting the growth of some cancer cell types and not others. An example of a TKI is imatinib mesylate (Gleevec). This drug binds to the energy site of the enzyme *tyrosine kinase* and prevents its activation. The drug is most useful in cancers that overexpress the *ABL1* oncogene, such as Philadelphia chromosome–positive chronic myeloid leukemia and metastatic gastrointestinal stromal tumors (GISTs).

Side effects common to most TKIs include fluid retention, electrolyte imbalances, and bone marrow suppression. This suppression can be severe enough to cause neutropenia, anemia, and thrombocytopenia. The problems associated with bone marrow suppression are increased when the patient also receives traditional chemotherapy with drugs that suppress bone marrow.

Epidermal Growth Factor/Receptor Inhibitors

The epidermal growth factor/receptor inhibitors (EGFRIs) block epidermal growth factor from binding to its cell surface receptor. As shown in Fig. 22-4, when this receptor is blocked, it cannot activate tyrosine kinase. As a result, the signal transduction pathway for promotion of cell division is inhibited.

An example of an EGFRI drug is trastuzumab (Herceptin), which binds the excessive amounts of a certain type of EGFR produced by some breast cancer, ovarian, and colon cancer cells in response to the activation of the *HER2/neu* gene. Binding this receptor prevents cancer cell division and increases the sensitivity to chemotherapy and immune system actions.

The most common side effects of EGFRIs include a variety of skin reactions. These may be as mild as a rash or result in excessive skin peeling and fissures. Trastuzumab has been available longer than the other EGFRIs and has been found to have adverse effects on the heart. It is not known if the cardiac effects also are common to other EGFRIs.

Vascular Endothelial Growth Factor/Receptor Inhibitors

An example of a vascular endothelial growth factor/receptor inhibitor drug is bevacizumab (Avastin). It binds to vascular endothelial growth factor (VEGF) and prevents the binding of VEGF with its receptors on the surfaces of endothelial cells present in blood vessels. This inhibits formation of new blood vessels within a tumor. As a result, tumor cells are poorly nourished and metastasis is inhibited. This drug is used with standard chemotherapy for many cancers that overexpress the receptor.

The most common side effects are hypertension and impaired wound healing. Bone marrow suppression with neutropenia and thrombocytopenia also occur, especially when the drug is used in combination with chemotherapy drugs that cause bone marrow suppression.

Multikinase Inhibitors

The multikinase inhibitors (MKIs) are drugs that inhibit the activity of specific kinases in cancer cells and in tumor blood vessels. An example of an MKI is sunitinib (Sutent). These drugs are most effective in preventing the activation of tyrosine kinases that have a specific gene mutation found most often in some renal cell carcinomas, GI stromal tumors, and pancreatic, colon, and non–small cell lung cancer cells.

A common side effect of this class of drugs is hypertension. Others include nausea and vomiting, diarrhea, constipation, mucositis, and mild neutropenia and thrombocytopenia.

Proteasome Inhibitors

Proteasome inhibitors work by preventing the formation of a large complex of proteins (a proteasome) in cells. The proteasome helps regulate the expression of genes that promote cell division and prevent cell death. Proteasome inhibitors limit the amount of proteasome present, making the cell less likely to divide and more likely to respond to signals for cell death. An example of a proteasome inhibitor is bortezomib (Velcade). Proteasomes are present in normal and cancer cells, but cancer cells are much more sensitive to the effects of proteasome inhibition than are normal cells.

The most common side effects of bortezomib are nausea, vomiting, anorexia, abdominal pain, bowel changes, and decreased taste sensation. Peripheral neuropathy is also common. Other side effects include headache, rash, pruritus, back and bone pain, and muscle aches.

Angiogenesis Inhibitors

Angiogenesis inhibitors target a specific protein kinase known as the *mammalian target of rapamycin (mTOR).* An example of an angiogenesis inhibitor is temsirolimus (Torisel). When the drug binds to an intracellular protein, a protein-drug complex forms that inhibits the activity of mTOR. When mTOR is inhibited, the concentrations of vascular endothelial growth factor (VEGF) are greatly reduced and many pro–cell division signal transduction pathways are disrupted. This drug is especially useful in suppressing the growth of renal cell carcinomas.

Hypersensitivity reactions to these drugs are common and so is hyperglycemia. Bone marrow suppression is moderate to severe with anemia, neutropenia, and thrombocytopenia. Other general side effects include headache, nausea and vomiting, back pain, muscle and joint pain, mucositis, diarrhea, and skin problems.

Photodynamic Therapy

Photodynamic therapy (PDT) is the selective destruction of cancer cells through a chemical reaction triggered by types of laser light. It can be used to destroy some cancers, reduce the size of tumors and then allow more complete tumor removal by surgery, and shrink tumors in airways or the esophagus to relieve obstruction. PDT is used most often for non-melanoma skin cancers, ocular tumors, GI tumors, and lung cancers located in the upper airways.

An agent that sensitizes cells to light is injected IV along with a dye. The intent is to sensitize cancer cells to destruction by specific wavelengths of laser light administered later. These agents enter all cells but leave normal cells more rapidly than cancer cells. Usually, within 48 to 72 hours, most of the drug has collected in high concentrations in cancer cells. At this time, a laser light is focused on the tumor. The light activates a chemical reaction in those cells retaining the sensitizing drug that induces irreversible cell damage. Some cells die and slough immediately; others continue to slough for several days. Some lesions require only one exposure to the laser, and others must be re-exposed several days after the first treatment (Agostinis et al., 2011).

Patient-Centered Collaborative Care

Use of first-generation photosensitizers in PDT was limited by an intense general sensitivity to light for up to 12 weeks. This light sensitivity required strict protection from all light sources for weeks. Newer photosensitizers and laser technologies have less general sensitivity, allowing greater use of this therapy with less need for intense protection.

Hormonal Manipulation

Hormonal manipulation involves changing usual hormone responses. Hormones are natural chemicals secreted by endocrine glands and picked up by capillaries where they circulate to all body areas. Hormones exert their effects only on their specific target tissues. Some hormones make hormone-sensitive tumors grow more rapidly. Thus decreasing the amount of these hormones available to hormone-sensitive tumors can

slow the cancer growth rate.

Hormonal manipulation includes steroids, steroid analogues, and enzyme inhibitors (aromatase inhibitors, gonadotropin-releasing hormone analogues, antiandrogens, and antiestrogens). Many of these agents are used to block receptors and thus prevent the cancer cells from receiving normal hormonal growth stimulation.

Hormonal manipulation can help control some types of cancer for many years but does not cure the disease. If a tumor depends on hormone A for growth and a large quantity of hormone B (similar to A) is given to the patient, hormone B will interfere with the tumor's uptake of hormone A or will limit the amount produced. As a result, tumor growth is slowed and survival time increases. Table 22-7 lists drugs used in hormonal manipulation for cancer therapy.

TABLE 22-7

Common Agents Used for Hormonal Manipulation of Cancer

TYPE OF AGENT	EXAMPLE
Hormone Agonists	
Androgen	Fluoxymesterone (Halotestin) Testolactone (Teslac)
Estrogen	Chlorotrianisene (Tace) Conjugated equine estrogen (Premarin) Diethylstilbestrol (DES, Stilphostrol) Ethinyl estradiol (Estinyl)
Progestin	Medroxyprogesterone (Amen, Provera) Megestrol (Megace)
Luteinizing hormone–releasing hormone (LHRH)	Leuprolide (Eligard, Lupron, Viadur) Goserelin (Zoladex)
Hormone Antagonists	
Antiandrogens	Bicalutamide (Casodex) Flutamide (Eulexin)
Antiestrogens	Fulvestrant (Faslodex) Tamoxifen (Nolvadex) Toremifene (Fareston)
Hormone Inhibitors	
	Aminoglutethimide (Cytadren, Elipten) Anastrozole (Arimidex) Exemestane (Aromasin) Letrozole (Femara)

Some drugs are *hormone antagonists* that compete with natural hormones at the receptors. When hormone antagonists are given, they bind to the specific hormone receptor on or in the tumor cell and prevent the needed hormone from binding to the receptor. If a tumor needs a

certain hormone to grow and the hormone can enter or activate the cell only through a receptor, hormone antagonists can slow tumor growth.

The hormone inhibitors also are used for hormonal therapy. These drugs inhibit the normal organ production of some specific hormones. For example, the aromatase inhibitor *anastrozole* (Arimidex) prevents the production of estrogen in the adrenal gland and reduces the blood level of estrogen, which results in slower growth of some breast cancers.

Side effects of hormonal manipulation are different from those of other types of chemotherapy. Androgens and the antiestrogen receptor drugs cause masculinizing effects in women. Chest and facial hair may develop, menstrual periods stop, and breast tissue shrinks. Patients may have some fluid retention. For men and women receiving androgens, acne may develop, hypercalcemia is common, and liver dysfunction may occur with prolonged therapy. Women receiving estrogens or progestins have irregular menses, fluid retention, and breast tenderness. All patients who take estrogen or progestins are at increased risk for venous thromboembolism.

Feminine manifestations appear in men who take estrogens, progestins, or antiandrogen receptor drugs. Facial hair thins, facial skin is smoother, body fat is redistributed, and breast development **(gynecomastia)** can occur. Bone loss is common, which increases the risk for osteoporosis and pathologic bone fractures (Limburg et al., 2014). Testicular and penile atrophy also occur to some degree. Teach patients and families about expected side effects. Encourage them to express their feelings about body changes. Refer them for counseling if needed.

Oncologic Emergencies

Cancer is a chronic disease. However, a number of acute complications from the cancer and its treatment can occur. There is some controversy regarding which complications are considered oncologic emergencies (Denshar et al., 2011). This chapter includes sepsis and disseminated intravascular coagulation, syndrome of inappropriate antidiuretic hormone, spinal cord compression, hypercalcemia, superior vena cava syndrome, and tumor lysis syndrome as emergencies. Early diagnosis and immediate intervention of these emergency conditions are essential to avoid life-threatening situations. The role of the nurse is to implement interventions to prevent and detect these complications early for immediate treatment.

Sepsis and Disseminated Intravascular Coagulation

Sepsis, or *septicemia,* is a condition in which organisms enter the bloodstream (bloodstream infection [BSI]) and can result in septic shock, a life-threatening condition. Patients with cancer are at risk for infection and sepsis because their white blood cell counts are often low and immune function is impaired. Chapter 37 describes the pathophysiology of sepsis and septic shock.

Disseminated intravascular coagulation (DIC) is a problem with the blood-clotting process. DIC is triggered by many severe illnesses, including cancer. In patients with cancer, DIC often is caused by gram-negative sepsis, although viral and other bacterial infections can trigger it. A patient's normal flora can enter the bloodstream through any site of skin breakdown and cause a severe infection, especially when neutropenia is present. Additional causes of sepsis include liver disease, intravascular hemolysis, prosthetic devices, or metabolic acidosis.

Extensive, abnormal clotting occurs throughout the small blood vessels of patients with DIC. This widespread clotting depletes the existing clotting factors and platelets. As this happens, extensive bleeding occurs. Bleeding from many sites is the most common problem and ranges from minimal to fatal hemorrhage. Clots block blood vessels and decrease blood flow to major body organs and result in pain, strokelike manifestations, dyspnea, tachycardia, reduced kidney function, and bowel necrosis.

DIC is a life-threatening problem with a high mortality rate even when proper therapies are instituted. *Thus the best management of sepsis and DIC is prevention. Identify patients at greatest risk for sepsis and DIC. Practice strict adherence to aseptic technique during invasive procedures and during*

contact with nonintact skin and mucous membranes. Teach patients and families the early manifestations of infection and when to seek assistance.

When sepsis is present and DIC is likely, management focuses on reducing the infection and halting the DIC process. IV antibiotic therapy is initiated. During the early phase of DIC, anticoagulants (especially heparin) are given to limit clotting and prevent the rapid consumption of circulating clotting factors. When DIC has progressed and hemorrhage is the primary problem, clotting factors are given. See Chapter 37 for a more detailed discussion of the management of DIC.

Syndrome of Inappropriate Antidiuretic Hormone

In healthy people, antidiuretic hormone (ADH) is secreted by the posterior pituitary gland only when more fluid (water) is needed in the body, such as when plasma volume is decreased. Certain conditions induce ADH secretion when not needed by the body, which leads to syndrome of inappropriate antidiuretic hormone (SIADH).

Cancer is a common cause of SIADH, especially small cell lung cancer. SIADH also may occur with other cancers, including head and neck, melanoma, gastrointestinal, prostate, and hematologic malignancies, especially when tumors are present in the brain. Some tumors make and secrete ADH, whereas others stimulate the posterior pituitary to secrete ADH. Drugs often used in patients with cancer also can cause SIADH (e.g., morphine sulfate, cyclophosphamide).

In SIADH, water is reabsorbed in excess by the kidney and put into systemic circulation. The retained water dilutes blood sodium levels. Mild manifestations include weakness, muscle cramps, loss of appetite, and fatigue. Serum sodium levels range from 115 to 120 mEq/L or lower (normal range is 135 to 145 mEq/L). With greater fluid retention, weight gain, nervous system changes, personality changes, confusion, and extreme muscle weakness occur. As the sodium level drops toward 110 mEq/L, seizures, coma, and death may follow depending on how rapidly the sodium value is lowered.

SIADH is managed by treating the condition and the cause. Nursing priorities focus on patient safety, restoring normal fluid balance, and providing supportive care. Management includes fluid restriction, increased sodium intake, and drug therapy. One drug, demeclocycline (Declomycin), works in opposition to ADH. Immediate cancer therapy with radiation or chemotherapy may cause enough tumor regression that ADH production returns to normal. Effective treatment of the cancer triggering the syndrome is the only cure for SIADH.

Patient safety includes preventing fluid overload from becoming worse, leading to pulmonary edema and heart failure. The older adult and those with coexisting cardiac problems, kidney problems, lung problems, or liver problems are at greater risk for complications with SIADH. See Chapter 62 for a detailed discussion of SIADH management.

Nursing Safety Priority QSEN

Action Alert

Monitor for increasing fluid overload (bounding pulse, increasing neck vein distention (jugular venous distention [JVD]), presence of crackles in lungs, increasing peripheral edema, reduced urine output) at least every 2 hours. *Pulmonary edema can occur very quickly and can lead to death.* Notify the health care provider of any change that indicates the fluid overload from SIADH either is not responding to therapy or is becoming worse.

Spinal Cord Compression

Spinal cord compression (SCC) and damage occur either when a tumor directly enters the spinal cord or the spinal column or when the vertebrae collapse from tumor degradation of the bone. It is a common cause of neurologic complications of cancer. Tumors may begin in the spinal cord but more often spread from the lung, prostate, breast, and colon. SCC may cause back pain or other problems before nerve deficits occur. Neurologic problems are specific to the level of spinal compression and can lead to paralysis, which is usually permanent if the compression is not alleviated promptly. Loss of neurologic function has a tremendous negative impact on quality of life for the patient and family.

Early recognition and treatment of spinal cord compression are key to a positive outcome. Assess for neurologic changes, including back pain, muscle weakness or a sensation of heaviness in the arms or legs, numbness or tingling in the hands or feet, inability to distinguish hot and cold, and an unsteady gait. Depending on how low the compression occurs, constipation, incontinence, and difficulty starting or stopping urination also may be present. Consider the possibility of SCC with new onset of any of these problems. Teach patients and families the manifestations of early SCC, and instruct them to seek help as soon as problems occur.

Treatment is often palliative with high-dose corticosteroids given first to reduce swelling around the spinal cord and relieve manifestations.

High-dose radiation may be used to reduce the size of the tumor in the area and relieve compression. Surgery may be performed to remove the tumor and rearrange the bony tissue so less pressure is placed on the spinal cord. External back or neck braces may be used to reduce the weight borne by the spinal column and to reduce pressure on the spinal cord or spinal nerves.

Hypercalcemia

Hypercalcemia (increased serum calcium level) occurs in up to a third of patients with cancer. At high levels it is regarded an emergency and can lead to death. Breast, lung, and renal cell carcinomas; multiple myeloma; and adult T-cell leukemia and lymphoma are the most common causes among cancer patients. These cancers can secrete parathyroid hormone, causing bone to release calcium. In addition, systemic secretion of vitamin D analogues by the tumor can also cause elevated calcium levels in the bloodstream. Decreased mobility and dehydration worsen hypercalcemia.

Early manifestations of hypercalcemia are nonspecific and lead to delayed recognition, thus worsening the impact of the problem. Common manifestations include skeletal pain, kidney stones, abdominal discomfort, and altered cognition. Additional manifestations include fatigue, loss of appetite, nausea, vomiting, constipation, and increased urine output. More serious problems include severe muscle weakness, loss of deep tendon reflexes, paralytic ileus, dehydration, and electrocardiographic (ECG) changes. Severity of manifestations depends on how high the calcium level is and how quickly it rose (see Chapter 11).

Cancer-induced hypercalcemia often develops slowly for many patients, which allows the body time to adapt to this electrolyte change. As a result, manifestations of hypercalcemia may not be evident until the serum calcium level is greatly elevated. Serum ionized calcium levels are the most reliable laboratory test for this complication.

Oral hydration may be enough to reduce calcium levels and relieve manifestations. Normal saline is used when IV hydration is needed. Loop diuretics can promote calcium loss in urine. Many drugs such as bisphosphonates, which block bone resorption of calcium, calcitonin, and oral glucocorticoids, can temporarily lower serum calcium levels. Treatment of the cancer is needed for long-term calcium control. When cancer-induced hypercalcemia is life threatening or occurs with kidney disease, dialysis can temporarily reduce serum calcium levels.

Superior Vena Cava Syndrome

The superior vena cava (SVC), which returns all blood from the cranial, neck, and upper extremity vasculature to the heart, has thin walls, and compression or obstruction by tumor growth or by clots in the vessel leads to congestion of the blood (Fig. 22-5). This is known as *superior vena cava (SVC) syndrome* and can occur quickly or develop gradually over time. With gradual development, increased collateral circulation to handle the blood flow can occur. SVC compression causes pain and is life threatening. It occurs most often in patients with lymphomas (especially with tumors in the mediastinum), thymoma, lung cancer, and breast cancer.

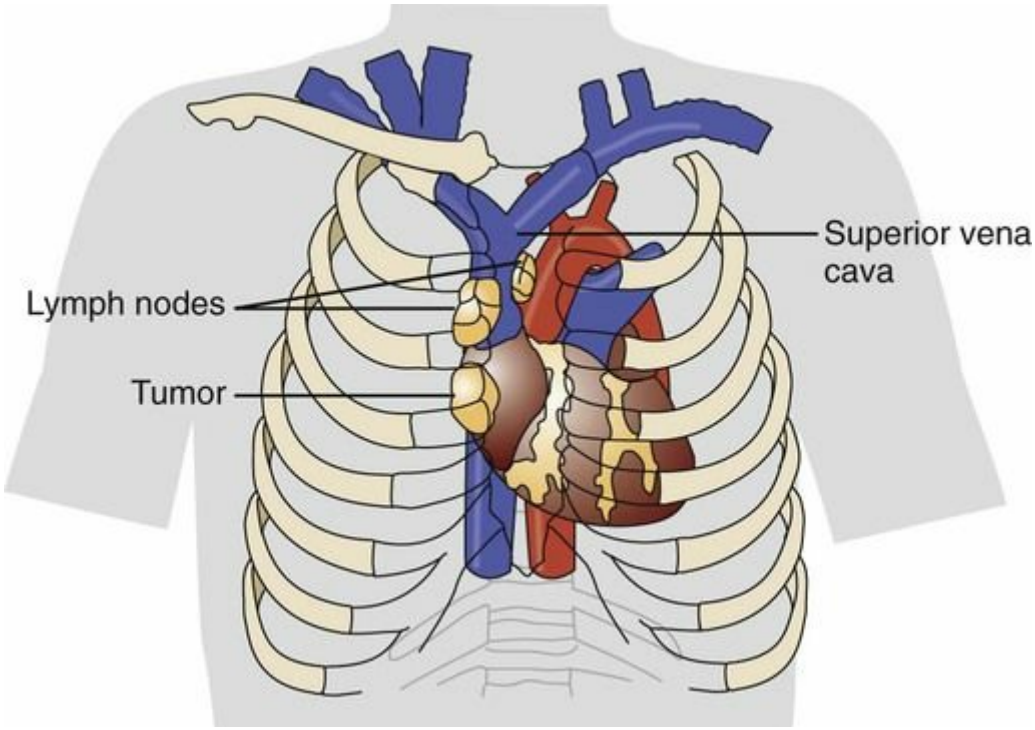

FIG. 22-5 Compression of the superior vena cava by lymph nodes and tumors in superior vena cava syndrome.

The manifestations result from the blockage of venous return from the head, neck, and upper trunk. Early manifestations occur when the patient arises after a night's sleep and include edema of the face, especially around the eyes, and tightness of the shirt or blouse collar. As the compression worsens, the patient develops engorged blood vessels and erythema of the upper body (Fig. 22-6), edema in the arms and hands, dyspnea, and epistaxis. Late manifestations include hemorrhage, cyanosis, mental status changes, decreased cardiac output, and hypotension. Radiographic imaging is essential for diagnosis and

treatment planning. Death results if compression is not relieved.

FIG. 22-6 Appearance of the face, neck, upper arms, and chest in a patient with superior vena cava syndrome.

SVC syndrome is often a late-stage manifestation; the tumor is usually widespread. High-dose radiation therapy to the upper chest area may be used to provide temporary relief. Chemotherapy may be the only option for long-term control of the cancer causing the compression. Surgery is rarely performed for this condition. A metal stent can be placed in the vena cava in an interventional radiology department to relieve swelling. Follow-up angioplasty can keep this stent open for a longer period.

NCLEX Examination Challenge

Safe and Effective Care Environment

Which change in health status indicates to the nurse that the client's superior vena cava syndrome is worsening?

A The client's systolic blood pressure is rising, and the diastolic pressure is decreasing.
B The client's severe nausea and vomiting no longer respond to antiemetics.
C The client has experienced four nosebleeds in the past 2 days.
D Pedal edema is now present.

Tumor Lysis Syndrome

In tumor lysis syndrome (TLS), large numbers of tumor cells are destroyed rapidly (Maloney & Denno, 2011). Their intracellular contents, including potassium and purines (DNA components), are released into the bloodstream faster than the body can eliminate them (Fig. 22-7). Unlike other oncologic emergencies, TLS is a positive sign that cancer treatment is effective.

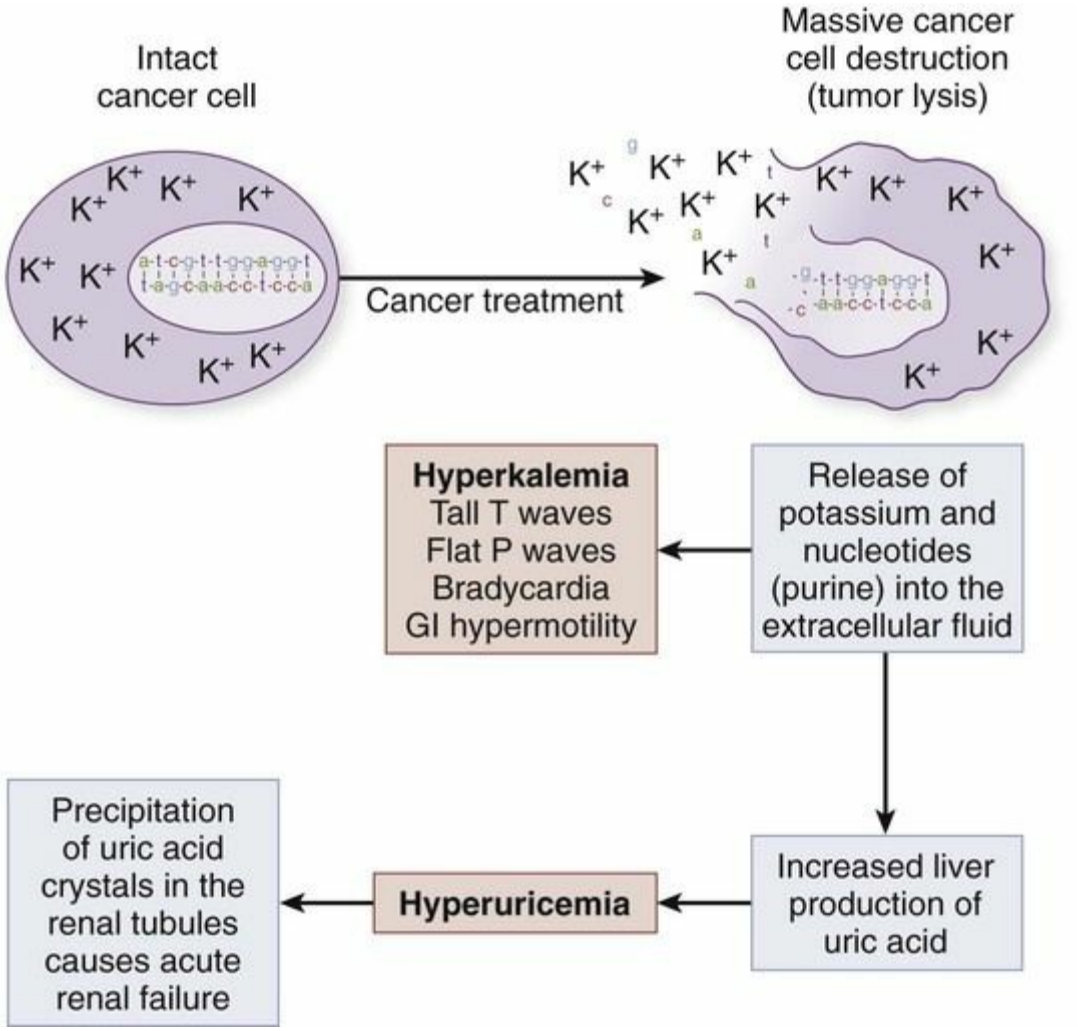

FIG. 22-7 Pathology of tumor lysis syndrome. *K*, Potassium.

Severe or untreated TLS can cause tissue damage, acute kidney injury (AKI), and death. Serum potassium levels can increase to the point of hyperkalemia, causing cardiac dysfunction (see Chapter 11). The large amounts of purines form uric acid, causing hyperuricemia. These uric acid crystals precipitate in the kidney, blocking kidney tubules and leading to AKI. The sudden development of hyperkalemia, hyperuricemia, and hyperphosphatemia has life-threatening effects on the heart muscle, kidneys, and central nervous system.

TLS is usually seen in patients receiving radiation or chemotherapy for

cancers that are very sensitive to these therapies, including leukemia, lymphoma, small cell lung cancer, germ cell tumors, inflammatory breast cancer, melanoma, and multiple myeloma. Early manifestations include lethargy, nausea, vomiting, anorexia, diarrhea, cloudy urine, flank pain, muscle weakness, and cramps.

Hydration prevents and manages TLS by diluting the serum potassium level and increasing the kidney flow rates. These actions prevent the precipitation of uric acid crystals, increase the excretion of potassium, and flush any kidney precipitate.

With tumors known to be very sensitive to cancer therapy, instruct patients to drink at least 3000 mL (5000 mL is more desirable) of fluid the day before, the day of, and for 3 days after treatment. Some fluids should be alkaline (sodium bicarbonate) to help prevent uric acid precipitation. Stress the importance of keeping fluid intake consistent throughout the 24-hour day, and help patients draw up a schedule of fluid intake.

Because some patients have nausea and vomiting after cancer therapy and may not feel like drinking fluids, stress the importance of following the antiemetic regimen. Instruct patients to contact the cancer care provider immediately if nausea prevents adequate fluid intake so parenteral fluids can be started.

Prophylaxis is essential for high-risk patients receiving treatment that is expected to reduce tumor burden quickly. Management becomes more aggressive for patients who become hyperkalemic or hyperuricemic. In addition to fluids, diuretics (especially osmotic types) are given to increase urine flow through the kidney. These agents are used cautiously to avoid dehydration. Drugs that promote purine excretion, such as allopurinol (Aloprim, Zyloprim), rasburicase (Elitek), or febuxostat (Uloric), are given (Mackiewicz, 2012). To reduce serum potassium levels for mild to moderate hyperkalemia, sodium polystyrene sulfonate can be given orally or as a retention enema. For more severe hyperkalemia, IV infusions containing glucose and insulin may be given. Patients who have severe hyperkalemia and hyperuricemia may need dialysis.

Nursing Concepts and Clinical Judgment Review

What might you NOTICE if the patient has impaired protection and increased infection risk as a result of cancer therapy?

- Recurring infections
- Presence of opportunistic infections
- Diarrhea
- Skin lesions

- Headache
- Fever

What should you INTERPRET and how should you RESPOND to a patient who has impaired protection and increased infection risk as a result cancer therapy?

Perform and interpret focused physical assessment findings including:

- Assess cardiovascular and respiratory status:
  - Vital signs
  - Presence of acute chest pain or dyspnea
  - Presence of cough
  - Presence of fever above 100° F (37.8° C)
  - Activity tolerance
- Assess urinary status:
  - Color and clarity of urine
  - Pain or burning on urination
- Assess gastrointestinal status:
  - Mouth, oropharynx, and perineal area for manifestations of infection
  - Presence of dysphagia
  - Presence of nausea, vomiting, diarrhea

Respond by:

- Collaborating with members of the health care team to protect the patient from infection
- Monitoring laboratory test results to determine indications of infection
- Teaching the patient and family about reporting changes indicating infection immediately
- Teaching the patient and family how to avoid infection in the home environment
- Continuing to assess for changes in the patient's condition, especially indications of infection in any body area

On what should you REFLECT?

- Evaluate the patient's and family's knowledge of neutropenia and its management.
- Evaluate the patient's and family's stress levels, use of coping strategies, and knowledge about community resources.
- Assess the knowledge and proficiency of unlicensed assistive personnel (UAP) in carrying out infection control measures.

Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Use aseptic technique during care for open skin areas or any invasive procedure to prevent infection. **Safety** QSEN
- Perform good handwashing before providing any care to patients with neutropenia.
- Use Bleeding Precautions for any patient with thrombocytopenia and impaired clotting (see Chart 22-5). **Safety** QSEN
- Use appropriate personal protective equipment (gowns, gloves, masks, eye protection) when mixing or administering IV or oral chemotherapeutic drugs and when handling the excreta of a patient receiving chemotherapy and for 48 hours afterward. **Safety** QSEN
- Position shields properly when patients in inpatient settings are receiving brachytherapy. **Safety** QSEN

Health Promotion and Maintenance

- Teach patients receiving radiation therapy how to care for the skin in the radiation path (see Chart 22-2). **Patient-Centered Care** QSEN
- Teach the patient and family about the manifestations of infection and when to seek medical advice. **Patient-Centered Care** QSEN
- Teach patients at risk for bleeding from impaired clotting the precautions to avoid injury (see Chart 22-6). **Patient-Centered Care** QSEN
- Instruct patients to use prescribed antiemetic drugs on a schedule for maximum relief of nausea and vomiting. **Patient-Centered Care** QSEN

Psychosocial Integrity

- Allow the patient and family the opportunity to express concerns regarding the diagnosis of cancer or the treatment regimen. **Patient-Centered Care** QSEN
- Encourage the patient to verbalize feelings about changes in appearance resulting from cancer therapy. **Patient-Centered Care** QSEN
- Explain all procedures, restrictions, drugs, and follow-up care to the patient and family.
- Encourage patients to use strategies to improve their appearance when

alopecia occurs. **Patient-Centered Care** QSEN

- Refer patients and family members to local cancer resources and support groups.
- Ensure that patient preferences are honored whenever possible. **Patient-Centered Care** QSEN

Physiological Integrity

- Perform a total assessment each time the patient with cancer is seen to determine the level of cancer treatment side effects and whether an oncologic emergency exists. **Patient-Centered Care** QSEN
- Assess the patient's pain level on a regular basis. **Patient-Centered Care** QSEN
- Use pharmacologic and nonpharmacologic therapies to reduce pain for the patient with cancer. **Patient-Centered Care** QSEN
- Work with other members of the health care team to ensure the implementation of a personalized pain management regimen. **Teamwork and Collaboration** QSEN
- Assess the venous access device at least every 30 to 60 minutes during chemotherapy administration. **Safety** QSEN
- Assess the patient receiving chemotherapy for infection at least every 8 hours. **Safety** QSEN
- Inspect the oral mucosa of patients with neutropenia at least every 8 hours. **Evidence-Based Practice** QSEN
- Report any temperature over 100° F (37.8° C) in a patient with neutropenia. **Evidence-Based Practice** QSEN
- Assess the patient with thrombocytopenia and impaired clotting for bleeding. **Safety** QSEN
- Instruct the patient and family caring for skin in the path of radiation therapy.
- Assess the patient receiving hormonal therapy for evidence of blood clot formation. **Safety** QSEN
- Closely monitor patients receiving any type of targeted therapy for manifestations of severe side effects or adverse drug reactions. **Safety** QSEN
- Teach patients and families the manifestations of oncologic emergencies and when to notify the health care provider. **Patient-Centered Care** QSEN
- Assist patients and families experiencing cancer to find appropriate community resources for support, supplies, care, and other assistance.

CHAPTER 23

Care of Patients with Infection

Donna D. Ignatavicius

PRIORITY CONCEPTS

- Infection
- Immunity

Learning Outcomes

Safe and Effective Care Environment

1. Describe infection control methods, such as hand hygiene and Transmission-Based Precautions.
2. Apply current principles of infection prevention and control.

Health Promotion and Maintenance

3. Specify health teaching for patients, families, and staff about infection control measures.

Psychosocial Integrity

4. Plan ways to help patients cope with Transmission-Based Precautions.

Physiological Integrity

5. Identify patients most at risk for infection, including older adults.
6. Provide information to patient and family about drug therapy for infections.
7. Identify common clinical manifestations of infections and infectious diseases.
8. Interpret laboratory test findings related to infections and infectious

diseases.

9. Evaluate nursing interventions for management of the patient with an infection.
10. Explain why multidrug-resistant organisms are increasing.
11. Identify basic clinical management for common emerging diseases.

http://evolve.elsevier.com/Iggy/

The human body has many *protective* systems that promote homeostasis. Physiologic mechanisms are the structural and functional defenses that protect people from stressors such as infection. When these mechanisms fail to work properly or are overcome with microbes, infection can result.

Infections and infectious diseases have been the major cause of millions of deaths worldwide for centuries. Threats of bioterrorism have been added to the concerns about multidrug-resistant and emerging infections. Global travel and migration have increased exposure to a wider variety of infectious agents than in the past.

Advancing technology and invasive procedures also introduce microorganisms into the body, often resulting in infection. In other environments these microorganisms are harmless. This chapter provides an overview of infection and general principles for prevention and management. Specific infections and their management are described elsewhere in this text.

Overview of the Infectious Process

A **pathogen** is any microorganism (also called an *agent*) capable of producing disease. Infections can be **communicable** (transmitted from person to person [e.g., influenza]) or not communicable (e.g., peritonitis). Microorganisms with differing levels of **pathogenicity** (ability to cause disease) surround everyone. **Virulence** is a term for pathogenicity. However, virulence is related more to the frequency with which a pathogen causes disease (degree of communicability) and its ability to invade and damage a host. It can also indicate the severity of the disease.

Many microorganisms live in or on the human host without causing disease. Some microbes are beneficial. Each body location harbors its own characteristic bacteria, or **normal flora.** Normal flora often functions to compete with and prevent infection from unfamiliar agents attempting to invade a body site. In some instances, microorganisms that are often pathogenic may be present in the tissues of the host and yet not cause symptomatic disease because of normal flora; this process is called *colonization*.

In the United States, the Centers for Disease Control and Prevention (CDC) collects information about the occurrence and nature of infections and infectious diseases. It then recommends guidelines to health care agencies for infection control and prevention. Certain diseases, such as tuberculosis, must be reported to health departments and the CDC. The infection control practitioner (ICP) for each health care agency is responsible for tracking infections **(surveillance)** and ensuring compliance with federal and local requirements and accreditation standards.

Transmission of Infectious Agents

Transmission of infection requires three factors:

- Reservoir (or source) of infectious agents
- Susceptible host with a portal of entry
- Mode of transmission

Reservoirs (sources of infectious agents) are numerous. Animate reservoirs include people, animals, and insects. Inanimate reservoirs include soil, water, other environmental sources, and medical equipment (e.g., IV solutions, urine collection devices). Stethoscopes used for auscultation by many health care providers carry *Staphylococcus aureus* from the skin of one patient to another. These devices should be cleaned with an antibacterial solution between patients (Alspach, 2014). The host's body can be a reservoir; pathogens colonize skin and body

substances (e.g., feces, sputum, saliva, wound drainage). A person with an active infection or an asymptomatic **carrier** (one who harbors an infectious agent without active disease) is a reservoir. Examples of *community* reservoirs include sewage, stagnant or contaminated water, and improperly handled foods.

Bacteria like *Neisseria meningitidis* can exist in the respiratory tract while causing no illness. If the bacteria invade the bloodstream or cerebrospinal fluid, they become extremely pathogenic. Another example is *Enterococcus,* which lives as normal flora in the GI system, where it is nonpathogenic and assists in the digestive process. If it enters the bloodstream, *Enterococcus* can cause disease.

Continued multiplication of a pathogen is sometimes accompanied by toxin production. **Toxins** are protein molecules released by bacteria to affect host cells at a distant site. *Exotoxins* are produced and released by certain bacteria into the surrounding environment. Botulism, tetanus, diphtheria, and *Escherichia coli* 0157:H7–related systemic diseases are attributed to exotoxins. *Endotoxins* are produced in the cell walls of certain bacteria and released only with cell lysis. For example, typhoid and meningococcal diseases are caused by endotoxins.

Host factors influence the development of infection (Table 23-1). Host defenses provide the body with an efficient system for *protection* against pathogens. Breakdown of these defense mechanisms may increase the **susceptibility** (risk) of the host for infection.

TABLE 23-1

Host Factors That Influence the Development of Infection

HOST FACTOR	INCREASED RISK FOR INFECTION
Natural immunity	Congenital or acquired immune deficiencies
Normal flora	Alteration of normal flora by antibiotic therapy
Age	Infants and older adults
Hormonal factors	Diabetes mellitus, corticosteroid therapy, and adrenal insufficiency
Phagocytosis	Defective phagocytic function, circulatory disturbances, and neutropenia
Skin/mucous membranes/normal excretory secretions	Break in skin or mucous membrane integrity; interference with flow of urine, tears, or saliva; interference with cough reflex or ciliary action; changes in gastric secretions
Nutrition	Malnutrition or dehydration
Environmental factors	Tobacco and alcohol consumption and inhalation of toxic chemicals
Medical interventions	Invasive therapy such as endoscopy, urinary catheters, IVs; chemotherapy, radiation therapy, and steroid therapy (suppress immune system); surgery

The patient's *immune status* plays a large role in determining risk for infection. Congenital abnormalities, as well as acquired health problems

(e.g., renal failure, steroid dependence, cancer, acquired immune deficiency syndrome [AIDS]), can result in numerous immunologic deficiencies. Depression of immunity may make the host more susceptible to infection or impair the ability to combat organisms that have gained entry.

Immunity is resistance to infection; it is usually associated with the presence of antibodies or cells that act on specific microorganisms. **Passive immunity** is of short duration (days or months) and either natural by transplacental transfer from the mother or artificial by injection of antibodies (e.g., immunoglobulin). **Active immunity** lasts for years and is natural by infection or artificial by stimulation of the body's immune defenses (e.g., vaccination). Chapter 17 discusses the immune system and immunity in detail.

Environmental factors can also influence patients' immune status and thus their susceptibility to or ability to fight infection. Examples include alcohol consumption, nicotine use, inhalation of bone marrow–suppressing toxic chemicals, and certain vitamin deficiencies. Malnutrition, especially protein-calorie malnutrition, places patients at increased risk for infection. Diseases such as diabetes mellitus also predispose a patient to infection. Older adults have decreased immunity, as well as other physiologic changes that make them very susceptible to infection (Chart 23-1).

Chart 23-1 Nursing Focus on the Older Adult

Factors That May Increase Risk for Infection in the Older Patient

FACTOR	AGING-ASSOCIATED CHANGES OR CONDITIONS
• Immune system	• Decreased antibody production, lymphocytes, and fever response
• Integumentary system	• Thinning skin, decreased subcutaneous tissue, decreased vascularity, slower wound healing
• Respiratory system	• Decreased cough and gag reflexes
• Gastrointestinal system	• Decreased gastric acid and intestinal motility
• Chronic illness	• Diabetes mellitus, chronic obstructive pulmonary disease, neurologic impairments
• Functional/cognitive impairments	• Immobility, incontinence, dementia
• Invasive devices	• Urinary catheters, feeding tubes, IV devices, tracheostomy tubes
• Institutionalization	• Increased person-to-person contact and transmission

Medical and surgical interventions may impair normal immune response. Steroid therapy, chemotherapy, and anti-rejection drugs increase the risk for infection. Medical devices (e.g., intravascular or urinary

catheters, endotracheal tubes, synthetic implants) may also interfere with normal host defense mechanisms. Surgery, trauma, radiation therapy, and burns result in nonintact skin. *The body's skin is one of the best barriers or defenses against infection.* When this barrier is broken, infection often results. Microorganisms may enter the body in a variety of ways, including the respiratory tract, GI tract, genitourinary tract, skin and mucous membranes, and bloodstream.

Routes of Transmission

Pathogens may enter the body through the *respiratory tract.* Microbes in droplets are sprayed into the air when people with infected oral or nasal tissues talk, cough, or sneeze. A susceptible host then inhales droplets, and pathogens localize in the lungs or are distributed via the lymphatic system or bloodstream to other areas of the body. Microorganisms that enter the body by the respiratory tract and produce distant infection include influenza virus, *Mycobacterium tuberculosis,* and *Streptococcus pneumoniae.*

Other pathogens enter the body through the *GI tract*. Some stay there and produce disease (e.g., *Shigella* causing self-limited disease). Others invade the GI tract to produce local and distant infection (e.g., *Salmonella enteritidis*). Some produce limited GI symptoms, causing systemic infection (e.g., *Salmonella typhi*) or profound involvement of other organs (e.g., hepatitis A virus). Millions of foodborne illness cases occur each year in the United States. This type of illness results in many hospitalizations and deaths.

Microorganisms also enter through the *genitourinary tract. Urinary tract infection (UTI) is one of the most common health care–associated infections (HAIs).* More than half of patients in adult intensive care units (ICUs) have urinary catheters in place. Indwelling urinary catheters are a primary cause of *catheter-associated urinary tract infections (CAUTIs),* especially in older adults. CAUTIs can increase hospital costs by prolonging the patient's length of stay and complicating the patient's recovery. In many settings, nurse-driven protocols have helped decrease the use of urinary catheters and associated infections (see the Quality Improvement box).

Quality Improvement QSEN

Reducing Catheter-Associated Urinary Tract Infections

Mori, C. (2014). A-voiding catastrophe: Implementing a nurse-driven

protocol. *MEDSURG Nursing*, *23*(1), 15-21, 28.

In spite of the move to decrease the use of indwelling urinary catheters (e.g., Foley catheters), catheter-associated urinary tract infections (CAUTIs) remain a major cause of sepsis and increased hospital costs. The Centers for Medicare and Medicaid Services (CMS) recently began to link health care reimbursement to quality improvement efforts to prevent CAUTIs.

An interdisciplinary team led by a clinical nurse specialist in a Midwestern community hospital implemented a protocol that decreased the use of urinary catheters and ensured best practices for patients for whom the catheters were indicated. Using a screening checklist, each patient was assessed to determine the need for a Foley catheter. If certain criteria were not met, the catheter was removed by a nurse using a specific protocol during and after removal. For patients who had to have a Foley catheter, the nurse provided care to minimize the chance for urinary infection, including checking that the:

- Catheter was secure
- Tamper-evident seal was intact
- Catheter tubing was not twisted or had a dependent loop
- Catheter bag was positioned lower than the bladder level
- Drainage bag did not touch the floor or was overfilled.

Commentary: Implications for Practice and Research

Research demonstrates that decreasing the use of indwelling urinary catheters is the most important intervention to prevent hospital-acquired CAUTIs. This project used this research and showed how an interdisciplinary team led by a CNS in a community hospital could improve the quality of care by decreasing urinary tract infections. In addition, nurses provided evidence-based care for patients who needed urinary catheters to ensure adequate urinary flow.

A limitation of the project was that incremental changes or strategies to maintain the positive changes were not discussed. More quality improvement activities at a unit or health care agency are needed to use current research, sustain a change in nursing practice, and achieve positive patient outcomes.

Although intact skin is the best barrier to prevent most infections, some pathogens such as *Treponema pallidum* can enter the body through intact *skin* or *mucous membranes*. Most enter through breaks in these normally effective surface barriers. Sometimes a medical procedure creates a break in cutaneous or mucocutaneous barriers, as in catheter-

acquired **bacteremia** (bacteria in the bloodstream) and surgical-site infections (SSIs). *Fragile skin of older patients and of those receiving prolonged steroid therapy increases infection risk.*

Microorganisms can gain direct access to the *bloodstream,* especially when invasive devices or tubes are used. The incidence of bloodstream infections (BSIs) continues to increase in hospitals throughout the United States. Central venous catheters (CVCs) are a primary cause of these infections (see Chapter 13 for more discussion of CVC-related BSIs). In the community setting, biting insects can inject organisms into the bloodstream, causing infection (e.g., Lyme disease, West Nile viral encephalitis).

Methods of Transmission

For infection to be transmitted from an infected source to a susceptible host, a transport mechanism is required. Microorganisms are transmitted by several routes:

- Contact transmission (indirect and direct)
- Droplet transmission
- Airborne transmission

Contact transmission is the usual mode of transmission of most infections. Many infections are spread by direct or indirect contact. With *direct contact,* the source and host have physical contact. Microorganisms are transferred directly from skin to skin or from mucous membrane to mucous membrane. Often called *person-to-person transmission,* direct contact is best illustrated by the spread of the "common cold."

Indirect contact transmission involves the transfer of microorganisms from a source to a host by passive transfer from a contaminated object. Contaminated articles or hands may be sources of infection. For example, patient-care devices like glucometers and electronic thermometers may transmit pathogens if they are contaminated with blood or body fluids. Uniforms, laboratory coats, and isolation gowns used as part of personal protective equipment (PPE) may be contaminated as well.

Indirect transmission may involve contact with infected secretions or *droplets.* Droplets are produced when a person talks or sneezes; the droplets travel short distances. Susceptible hosts may acquire infection by contact with droplets deposited on the nasal, oral, or conjunctival membranes. Therefore the CDC recommends that staff stay at least 3 feet (1 m) away from a patient with droplet infection. An example of droplet-spread infection is influenza.

Airborne transmission occurs when small airborne particles containing

pathogens leave the infected source and enter a susceptible host. These pathogens can be suspended in the air for a prolonged time. The particles carrying pathogens are usually contained in droplet nuclei or dust; they are usually propelled from the respiratory tract by coughing or sneezing. A susceptible person then inhales the particles directly into the respiratory tract. For example, tuberculosis is spread via airborne transmission.

Preventing the spread of microbes that are transmitted by the airborne route requires the use of special air handling and ventilation systems in an airborne infection isolation room (AIIR). *M. tuberculosis* and the varicella-zoster virus (chickenpox) are examples of airborne agents that require one of these systems. In addition to the AIIR, respiratory protection using a certified **powered air purifying respirator (PAPR)** is recommended for health care personnel entering the patient's room. This device has a high efficiency particulate air (HEPA) filter and battery to promote positive-pressure airflow and is more effective than N95 respirators.

Other sources of infectious agents include the environment, such as contaminated food, water, or vectors. Vectors are insects that carry pathogens between two or more hosts, such as the deer tick that causes Lyme disease.

The *portal of exit* completes the chain of infection. Exit of the microbe from the host often occurs through the portal of entry. An organism, such as *M. tuberculosis,* enters the respiratory tract and then exits the same tract as the infected host coughs. Some organisms can exit from the infected host by several routes. For example, varicella-zoster virus can spread through direct contact with infective fluid in vesicles and by airborne transmission.

Physiologic Defenses for Infection

Strong and intact host defenses can prevent microbes from entering the body or can destroy a pathogen that has entered. Impaired host defenses may be unable to defend against microbial invasion, allowing entry of organisms that can destroy cells and cause infection. Common defense mechanisms include:

- Body tissues
- Phagocytosis
- Inflammation
- Immune systems

Intact skin forms the first and most important physical barrier to the entry of

microorganisms. In addition to providing a mechanical barrier, the skin's slightly acidic pH (resulting from breakdown of lipids into fatty acids), together with normal skin flora, creates an unfriendly environment for many bacteria.

Mucous membranes' mucociliary action provides some mechanical protection against pathogenic invasion. More important, however, mucous membranes are bathed in secretions that inactivate many microorganisms. Lysozymes, which dissolve the cell walls of some bacteria, are present in large quantities in many body secretions, particularly in tears and nasal mucus.

Other body systems provide natural barriers to infection. For instance, the healthy respiratory tract clears most of all inhaled material by upper airway filtration, humidification, mucociliary transport, and coughing. Peristaltic action mechanically empties the GI tract of pathogenic organisms. Stomach acid, intestinal secretions, pancreatic enzymes, and bile, together with the competition from normal bowel flora, provide an environment that protects the GI tract from invasion by harmful organisms. In the genitourinary tract, the flushing action of urine eliminates pathogenic organisms. The low pH of urine also maintains a sterile environment, although some microorganisms, such as *E. coli,* can thrive in an acid medium.

Phagocytosis occurs when a foreign substance evades the first-line mechanical barriers and enters the body. Various leukocyte types function differently in the immune reaction, but neutrophils bear primary responsibility for phagocytosis. This process of engulfing, ingesting, killing, and disposing of an invading organism is an essential mechanism in host defense. Phagocytic dysfunction dramatically increases a patient's risk for infection.

Inflammation is another important nonspecific defense mechanism for preventing the spread of infection. It occurs when tissue becomes damaged. Damaged cells release enzymes, and polymorphonuclear (PMN) leukocytes (neutrophils) are attracted to the infected site from the bloodstream. One important substance, histamine, increases the permeability of the capillaries in inflamed tissues, thus allowing fluid, proteins, and white blood cells to enter an inflamed area. Other enzymes activate fibrinogen, which causes leaked fluid to clot and prevents its flow away from the damaged site into unaffected tissue, essentially "walling off" the inflamed tissue. The process of phagocytosis disposes of the invading microorganism and often dead tissue. If inflammation is caused by infection, the end products of inflammation form pus, which is then absorbed or exits the body through a break in the skin. Chapter 17

discusses the process of inflammation in more detail.

Specific defense responses to specific microorganisms are provided by the antibody- and cell-mediated immune systems. The **antibody-mediated immune system** produces antibodies directed against certain pathogens. These antibodies inactivate or destroy invading microorganisms as well as protect against future infection from that microorganism. Resistance to other microorganisms is mediated by the action of specifically sensitized T-lymphocytes and is called **cell-mediated immunity.** The components of the immune system work both independently and together to protect against infection. Chapter 17 describes the function of the immune system in detail.

Health Promotion and Maintenance

Infections occur most often in high-risk patients, such as older adults and those who have inadequate immune systems (immunocompromised). Implement interventions to prevent infection and detect signs and symptoms as early as possible. Chart 23-2 summarizes nursing interventions for infection prevention and control.

Chart 23-2 Best Practices for Patient Safety & Quality Care QSEN

Nursing Interventions for the Patient at Risk for Infection

- Assess patients for risk for infections.
- Monitor for signs and symptoms of infection.
- Monitor laboratory tests results, such as cultures and white blood cell (WBC) count and differential.
- Screen all visitors for infections or infectious disease.
- Inspect skin and mucous membranes for redness, heat, pain, swelling, and drainage.
- Promote sufficient nutritional intake, especially protein for healing.
- Encourage fluid intake to treat fever.
- Teach the patient and family the signs and symptoms of infections and when to report them to the health care provider.
- Teach the patient and family how to avoid infections in health care agencies and the community.

Infection Control in Health Care Settings

infection acquired in the inpatient health care setting (not present or incubating at admission) is termed a **health care–associated infection (HAI).** When occurring in a hospital setting, they are sometimes referred to as *hospital-acquired infections,* but the former term is more accurate. HAIs can be *endogenous* (from a patient's flora) or *exogenous* (from outside the patient, often from the hands of health care workers, tubes, or implants). HAIs, including surgical site infections (SSIs), cause increased health care costs and many deaths (see discussion in Chapter 16). These infections tend to occur most often because health care workers do not follow basic infection control principles.

Infection control within a health care facility is designed to reduce the risk for HAIs and thus reduce morbidity and mortality, as recommended in The Joint Commission's National Patient Safety Goals (NPSGs). This

expected outcome is consistent with the desire for health care facilities to create a *culture of safety* within their environments (see Chapter 1). Infection control and prevention is an interdisciplinary effort and includes:

- Facility- and department-specific infection control policies and procedures
- Surveillance and analysis
- Patient and staff education
- Community and interdisciplinary collaboration
- Product evaluation with an emphasis on quality and cost savings
- Bioengineering for designing health care facilities that help control the spread of infections

The infection control program of a hospital is coordinated and implemented by a health care professional certified in infection control (CIC) who has clinical and administrative experience. The Centers for Disease Control and Prevention (CDC) recommends one person with CIC credentials for every 100 occupied acute care beds. Long-term care facilities may not have a practitioner who specializes in infection control. However, every facility must designate a health care professional to be responsible for coordinating and implementing an infection prevention and control program.

Long-term care facilities are unique in that they have a large group of older adults who are together in one setting for weeks to years. Nursing homes, in particular, are required to provide a homelike environment in which residents can move and interact freely. Therefore infection control in these settings can be challenging. As a result, many infectious outbreaks may occur, such as pneumonia, *Clostridium difficile,* and multidrug-resistant organisms (discussed in the Multidrug-Resistant Organism Infections and Colonizations section on p. 405).

Ambulatory and home health care are the fastest growing segments of the health care system. Infection remains a common cause of death for dialysis patients. Little information is available about acquired infections in home health settings because data are not systematically collected, surveillance programs are not established, and best practices for infection prevention and control do not yet exist.

Methods of Infection Control and Prevention

All health care workers who come in contact with patients or care areas are involved in some aspect of the infection control program of the agency. According to the CDC, infections can be prevented or controlled in several ways:

- Hand hygiene
- Disinfection/sterilization
- Standard Precautions
- Transmission-Based Precautions
- Staff and patient placement and cohorting

Hand Hygiene

Health care workers' hands are the primary way in which infection is transmitted from patient to patient or staff to patient. **Hand hygiene** refers to both handwashing and alcohol-based hand rubs (ABHRs) ("hand sanitizers").

In 2002, the U.S. CDC released a document entitled "CDC Hand Hygiene Recommendations." These recommendations are summarized in Chart 23-3. *Handwashing is still an important part of hand hygiene, but it is recognized that in some health care settings, sinks may not be readily available.* Despite years of education, health care workers do not wash their hands or perform hand hygiene on a consistent basis (Upshaw-Owens & Bailey, 2012). The Quality Improvement box describes one hospital unit's project to improve the percentage of health care workers who perform hand hygiene.

Chart 23-3 Best Practice for Patient Safety & Quality Care QSEN

Hand Hygiene

- When hands are visibly soiled or contaminated with proteinaceous material or are visibly soiled with blood or other body fluids, wash hands with soap and water.
- If hands are not visibly soiled, use an alcohol-based hand rub (ABHR) for decontaminating hands or wash hands with soap and water.
- Use either ABHR or wash with soap and water (decontaminate hands) before having direct contact with patients.
- Decontaminate hands before donning sterile gloves to perform a procedure, such as inserting an invasive device (e.g., indwelling urinary catheter).
- Decontaminate hands after contact with a patient's intact skin (e.g., taking a pulse) or with body fluids or excretions/secretions.
- Decontaminate hands after removing gloves.
- Decontaminate hands after contact with inanimate objects (including medical equipment) in the immediate vicinity of the patient.

Quality Improvement QSEN

Improving Nursing Staff Compliance with Proper Hand Hygiene

Foulk, K.C., Tocydlowski, P., Snow, T.M., McCloud, K., Cuevas, M., Bishop, D., et al. (2012). Infusing fun into quality and safety initiatives. *Nursing2012, 42*(11), 14-16.

Proper hand hygiene is essential for patient safety to prevent the spread of infection. Nurses on a medical-surgical unit in a large mid-Atlantic hospital recognized that their unit's compliance with using proper hand hygiene was only 71%, lower than the rate for the rest of the hospital. As a result, the unit had a total of 12 *Clostridium difficile* infections over a one-year period. The quality and safety (QI) council of the unit set a goal of achieving 90% compliance with proper hand hygiene and implemented a project to change practice over the next year.

Interventions used to increase compliance included reminders in monthly staff meetings and newsletters, e-mails, and bulletin board postings. A hand hygiene game and music video (entitled "Get Your Clean On") were developed and used by the nursing staff. Each shift's charge nurse gave red laminated hands to any staff member who was not performing proper hand hygiene. The member who collected the most "hot hands" at the end of the shift was considered the most noncompliant. As a result of these interventions, the data for the following year revealed a 98% compliance with proper hand hygiene and a total of only 6 *C. difficile* infections. These data suggest that increased compliance with hand hygiene resulted in a decrease in hospital-acquired infections.

Commentary: Implications for Practice and Research

Research demonstrates that proper hand hygiene is the most important intervention to prevent hospital-acquired infections. This project utilized this research and showed how one group of nurses on a hospital unit could improve the quality of care by decreasing unit infections. The staff took a unit view to develop a variety of approaches to change behaviors. They reported that the project was fun as well as informative.

A limitation of the project was that incremental changes or strategies to maintain the positive changes were not discussed. More quality improvement activities at a unit or health care agency are needed to utilize current research, sustain a change in nursing practice, and achieve positive patient outcomes.

Effective handwashing includes wetting, soaping, lathering, applying friction under running water for at least 15 seconds, rinsing, and adequate drying. Friction is essential to remove skin oils and to disperse transient bacteria and soil from hand surfaces. Performing adequate handwashing takes time that health care workers (HCWs) may not feel they have. Handwashing can also cause dry skin, and therefore hand moisturizers are essential to maintain good hand health and hygiene.

Alcohol-based hand rubs (ABHRs) allow care providers to spend less time seeking out sinks and more time delivering care. However, these hand rubs have their limitations.

Nursing Safety Priority QSEN

Action Alert

If your hands are visibly dirty or soiled or feel sticky or if you have just toileted, *wash your hands instead of using ABHRs.* Keep in mind that ABHRs are also ineffective against spore-forming organisms such as *Clostridium difficile,* a common cause of health care–associated diarrhea, especially in older adults. Do not use an ABHR before inserting eye drops, ointments, or contact lenses because alcohol can irritate the patient's eyes, causing burning and redness. The Joint Commission's National Patient Safety Goals require that health care agencies monitor handwashing practices and the use of ABHRs to make sure that HCWs are performing hand hygiene on a regular basis.

The CDC recommends using antiseptic solutions such as chlorhexidine for handwashing in caring for patients who are at high risk for infection (e.g., those who are immunocompromised).

The classic CDC guidelines (Centers for Disease Control and Prevention [CDC], 2002) also address the issue of artificial fingernails, which have been linked to a number of outbreaks due to poor fingernail health and hygiene. The guidelines recommend that artificial fingernails and extenders not be worn while caring for patients at high risk for infections, such as those in ICUs or operating suites. Most health care agencies have banned artificial nails for all health care workers providing direct patient care and require that natural nails be short. Some agencies also ban the use of nail polish.

Sterilization and Disinfection

Sterilization and disinfection have helped invasive procedures become

much more common and safe. **Sterilization** means destroying all living organisms and bacterial spores. Many invasive procedures, such as inserting vascular access devices (VADs) and urinary catheters, require sterile technique. Sterile technique in the operating suite is discussed in detail in Chapter 15.

All items that invade human tissue where bacteria are not commonly found should be sterilized. **Disinfection** does not kill spores and only ensures a reduction in the level of disease-causing organisms. High-level disinfection is adequate when an item is going inside the body where the patient has resident bacteria or normal flora (e.g., GI and respiratory tracts). As with sterilization, no high-level disinfection can occur without first cleaning the item. This can be especially difficult with items that have narrow lumens in which organic debris can become trapped and is not easily visible. For example, endoscopes have been especially challenging to clean and have been linked to a number of infectious outbreaks.

Standard Precautions

The 2007 guidelines from the CDC focus on transmission mechanisms and the precautions needed to prevent the spread of infection. Included in these guidelines are Standard Precautions and Transmission-Based Precautions, including Airborne, Droplet, and Contact Precautions (Tables 23-2 and 23-3).

TABLE 23-2

Recommendations for Application of Standard Precautions for the Care of All Patients in All Health Care Settings

COMPONENT	RECOMMENDATIONS
Hand hygiene	Perform hand hygiene after touching blood, body fluids, secretions, excretions, contaminated items; immediately after removing gloves; between patient contacts
Personal protective equipment (PPE)	Use appropriate PPE, including:
• Gloves	For touching blood, body fluids, secretions, excretions, contaminated items; for touching mucous membranes and nonintact skin
• Gown	During procedures and patient-care activities when contact of clothing/exposed skin with blood/body fluids, secretions, and excretions is anticipated
• Mask, eye protection (goggles), face shield*	During procedures and patient-care activities likely to generate splashes or sprays of blood, body fluids, secretions, especially suctioning, endotracheal intubation
Soiled patient-care equipment	Handle in a manner that prevents transfer of microorganisms to others and to the environment; wear gloves if visibly contaminated; perform hand hygiene
Environmental control	Develop procedures for routine care, cleaning, and disinfection of environmental surfaces, especially frequently touched surfaces in patient-care areas
Textiles and laundry	Handle in a manner that prevents transfer of microorganisms to others and to the environment
Needles and other sharps	Do not recap, bend, break, or hand-manipulate used needles; use safety features such as needleless systems when available; place used sharps in puncture-resistant container
Patient resuscitation	Use mouthpiece, resuscitation bag, other ventilation devices to prevent contact with mouth and oral secretions
Patient placement	Prioritize for single-patient room if patient is at increased risk for transmission, is likely to contaminate the environment, does not maintain appropriate hygiene, or is at increased risk for acquiring infection or developing adverse outcome following infection
Respiratory hygiene/cough etiquette (source containment of infectious respiratory secretions in symptomatic patients, beginning at initial point of encounter [e.g., triage and reception areas in emergency departments and physician offices])	Instruct symptomatic persons to cover mouth/nose when sneezing/coughing; use tissues and dispose in no-touch receptacle; observe hand hygiene after soiling of hands with respiratory secretions; wear surgical mask if tolerated or maintain spatial separation, >3 feet if possible

*During aerosol-generating procedures on patients with suspected or proven infections transmitted by respiratory aerosols, wear a powered air purifying respirator (PAPR) (most effective) or N95 mask in addition to gloves, gown, and face/eye protection.

TABLE 23-3

Transmission-Based Infection Control Precautions

PRECAUTIONS (IN ADDITION TO STANDARD PRECAUTIONS)	EXAMPLES OF DISEASES IN CATEGORY
Airborne Precautions	
1. Private room required with monitored negative airflow (with appropriate number of air exchanges and air discharge to outside or through HEPA filter); keep door(s) closed 2. Special respiratory protection: • Wear PAPR for known or suspected TB • Susceptible persons not to enter room of patient with known or suspected measles or varicella unless immune caregivers are not available • Susceptible persons who must enter room must wear PAPR or N95 HEPA filter* 3. Transport: patient to leave room only for essential clinical reasons, wearing surgical mask	Diseases that are known or suspected to be transmitted by air: Measles (rubeola) *Mycobacterium tuberculosis*, including multidrug-resistant TB (MDRTB) Varicella (chickenpox)†; disseminated zoster (shingles)†
Droplet Precautions	
1. Private room preferred: if not available, may cohort with patient with same active infection with same microorganisms if no other infection present; maintain distance of at least 3 feet from other patients if private room not available 2. Mask: required when working within 3 feet of patient 3. Transport: as above	Diseases that are known or suspected to be transmitted by droplets: Diphtheria (pharyngeal) Streptococcal pharyngitis Pneumonia Influenza Rubella Invasive disease (meningitis, pneumonia, sepsis) caused by *Haemophilus influenzae* type B or *Neisseria meningitidis* Mumps Pertussis
Contact Precautions	
1. Private room preferred: if not available, may cohort with patient with same active infection with same microorganisms if no other infection present 2. Wear gloves when entering room 3. Wash hands with antimicrobial soap before leaving patient's room 4. Wear gown to prevent contact with patient or contaminated items or if patient has uncontrolled body fluids; remove gown before leaving room 5. Transport: patient to leave room only for essential clinical reasons; during transport, use needed precautions to prevent disease transmission 6. Dedicated equipment for this patient only (or disinfect after use before taking from room)	Diseases that are known or suspected to be transmitted by direct contact: *Clostridium difficile* Colonization or infection caused by multidrug-resistant organisms (e.g., MRSA, VRE) Pediculosis Respiratory syncytial virus Scabies

HEPA, High-efficiency particulate air; *MRSA*, methicillin-resistant *Staphylococcus aureus; PAPR*, powered air purifying respirator; *TB*, tuberculosis; *VRE*, vancomycin-resistant *Enterococcus*.

*Before use: training and fit testing required for personnel.

†Add Contact Precautions for draining lesions.

Standard Precautions are based on the belief that all body excretions, secretions, and moist membranes and tissues, excluding perspiration, are potentially infectious. As barriers to potential or actual infections, **personal protective equipment (PPE)** is used. PPE refers to gloves, isolation gowns, face protection (masks, goggles, face shields), and powered air purifying respirators (PAPRs) or N95 respirators (Fig. 23-1).

FIG. 23-1 **A,** Nurse in personal protective equipment (PPE) caring for a patient in a private room. **B,** Powered air purifying respirator (PAPR).

Nursing Safety Priority QSEN

Action Alert

Remember that gloves are an essential part of infection control and should always be worn as part of Standard Precautions. Either handwashing or use of alcohol-based hand rubs should be done before donning and after removing gloves. The combination of hand hygiene and wearing gloves is the most effective strategy for preventing infection transmission!

Health care settings in the United States and Canada have switched from latex to non-latex gloves. The U.S. National Institute for Occupational Safety and Health (NIOSH) issued a public warning about potential allergic reactions to those exposed to latex in gloves and other medical products. Reactions include rashes, nasal or eye symptoms, asthma, and (rarely) shock. People with **latex allergy** usually have an allergy to foods such as bananas, kiwis, and avocados. Health care workers (HCWs) have not been as strict with wearing gloves as they should because of poor fit or skin dryness, irritation, and dermatitis. One possible solution to dry skin is the use of aloe vera–coated gloves or moisturizers such as Eucerin or AmLactin products.

The respiratory hygiene/cough etiquette (RH/CE) requirement is directed at patients and visitors with signs of respiratory illness, such as sinus or chest congestion, cough, or rhinorrhea (“runny nose”). The elements for RH/CE include:

- Patient, staff, and visitor education
- Posted signs

- Hand hygiene
- Covering the nose and mouth with a tissue and prompt tissue disposal or using surgical masks (or sneezing/coughing into a shirt sleeve rather than the hand)
- Separation from the person with respiratory infection by more than 3 feet (1 m)

Transmission-Based Precautions

Transmission-Based Precautions may also be referred to as *Isolation Precautions.* But, the word *isolation* implies that the patient is physically separated from everyone, which is not always the case.

Airborne Precautions are used for patients known or suspected to have infections transmitted by the airborne transmission route. These infections are caused by organisms that can be suspended in air for prolonged periods. Negative airflow rooms are required to prevent airborne spread of microbes. Enclosed booths with high-efficiency particulate air (HEPA) filtration or ultraviolet light may be used for sputum induction procedures. Tuberculosis, measles (rubeola), and chickenpox (varicella) are examples of airborne diseases.

Droplet Precautions are used for patients known or suspected to have infections transmitted by the droplet transmission route. Such infections are caused by organisms in droplets that may travel 3 feet but are not suspended for long periods. Examples of infectious conditions requiring Droplet Precautions include influenza, mumps, pertussis, and meningitis caused by either *N. meningitidis* or *Haemophilus influenzae* type B.

Contact Precautions are used for patients known or suspected to have infections transmitted by direct contact or contact with items in the environment. Patients with significant multidrug-resistant organism (MDRO) infection or colonization, such as methicillin-resistant *Staphylococcus aureus* (MRSA) or vancomycin-resistant *Enterococcus* (VRE), are placed on Contact Precautions. Other infections requiring Contact Precautions include pediculosis (lice), scabies, respiratory syncytial virus (RSV), and *C. difficile*.

Staff and Patient Placement and Cohorting

Adequate staffing of nurses is an essential method for preventing infection. In addition to a ratio of one infection control practitioner to 100 occupied acute care beds, nurse staffing is critical. When possible, bedside nurse staffing should consist of full-time nurses assigned regularly to the unit to ensure consistent practices (Upshaw-Owens & Bailey, 2012).

Patient placement has been used as a way to reduce the spread of infection. The CDC does not mandate that all patients with infections have a private room. It does recommend that private rooms always be used for patients on Airborne Precautions and those in a protective environment (PE). A PE is architecturally designed and structured to prevent infection from occurring in patients who are at extremely high risk, such as those having stem cell therapy. The CDC also prefers private rooms for patients who are on Contact and Droplet Precautions. If private rooms are not available, keep these patients at least 3 feet apart. Many hospitals are becoming totally private-room facilities. Large health care systems have biomedical engineers to assist in designing the best environment to reduce the spread of infection, including ventilation systems and physical layout.

Cohorting is another method of patient placement. **Cohorting** is the practice of grouping patients who are colonized or infected with the same pathogen. This method has been used the most with patients who have an outbreak of a multidrug-resistant organism like methicillin-resistant *Staphylococcus aureus* (MRSA). It is particularly effective in long-term care settings.

Infection control principles for *patient transport* include limiting movement to other areas of the facility, using appropriate barriers like covering infected wounds, and notifying other departments or agencies who are receiving the patient about the necessary precautions. Accurate hand-off communication between agencies is also very important to prevent the spread of infection, according to The Joint Commission's NPSGs.

NCLEX Examination Challenge

Safe and Effective Care Environment

Which statement by a nursing student indicates a need for further teaching by the nurse regarding infection control for a client who has an open, draining wound?

A "I will wear an isolation gown when providing direct care."
B "I will wear gloves when changing the client's dressing."
C "I will wear a mask each time I enter the client's room."
D "I will use a hand sanitizer when I can't wash my hands."

Multidrug-Resistant Organism Infections and Colonizations

Antibiotics have been available for many years. Unfortunately, these drugs were commonly prescribed for conditions that did not need them or were given at higher doses and for longer periods of time than were necessary. As a result, a number of microorganisms have become resistant to certain antibiotics; that is, drugs that were once useful no longer control these infectious agents (multidrug-resistant organisms [MDROs]). For this reason, a culture of safety related to infection control has been mandated by the CDC, the Institute for Healthcare Improvement (IHI), and The Joint Commission: Standard Precautions must be strictly followed today in all health care settings to prevent more of these difficult and deadly infections.

One of the newest discoveries to explain the increase in health care–acquired infections (HCAIs), especially the rise in drug-resistant infections, is the formation of biofilms. A **biofilm,** also called *glycocalyx,* is a complex group of microorganisms that functions within a "slimy" gel coating on medical devices such as urinary catheters, orthopedic implants, and enteral feeding tubes; on parts of the body like the teeth (plaque) and tonsils; and in chronic wounds. These reservoirs become sources of infection for which antibiotics and disinfection are not effective. Antibiotic therapy may increase the growth of microbes within biofilms.

Biofilms are extremely difficult to treat, and mechanical disruption strategies are the mainstay of management and research (Ramage et al., 2010). Studies on biofilms that cause the most common HCAIs, such as catheter-associated urinary tract infections (CAUTIs) and wound infections, continue to be conducted. Many specific biofilms have been identified, and methods to remove or disrupt them are being researched.

Patients with *indwelling urinary catheters* are at high risk for pyelonephritis (kidney infection) and septicemia. Current evidence shows that urease-producing bacteria, especially *Proteus mirabilis,* cause crystalline biofilms that create a crust that can block the catheter (Stickler & Feneley, 2010). Therefore indwelling urinary catheters are used only when absolutely necessary. Antimicrobial catheters, either silver-alloy or antimicrobial-coated, are recommended for short-term urinary catheter use to decrease encrustation (Parker et al., 2009). Little evidence is available to demonstrate methods to reduce CAUTIs in long-term indwelling catheters except for frequent catheter changes. In postoperative patients, Palese et al. (2010) found that the regular use of ultrasound bladder scanners reduces urinary tract infections by

preventing the inappropriate use of urinary catheters. Nurses can use this information to provide the most current assessment interventions for reducing CAUTIs. Chapter 66 describes evidence-based interventions to prevent urinary tract infections.

Traditional débridement alone is not successful to prevent or manage *chronic wound* infections, often caused by *S. aureus*. A systematic review by Lo et al. (2008) found that silver-releasing dressings were very effective. Biofilms can be disrupted by using dry gauze to mechanically disrupt them after débridement. Antibacterial enzymes may also be used.

The most common MDROs are methicillin-resistant *Staphylococcus aureus,* vancomycin-resistant *Enterococcus*, and carbapenem-resistant *Enterococcus.* Other infections, such as vancomycin-intermediate *S. aureus* (VISA) and vancomycin-resistant *S. aureus* (VRSA), may also occur, which may be effectively treated with antibiotics such as linezolid (Zyvox) and quinupristin-dalfopristin (Synercid).

Methicillin-Resistant *Staphylococcus aureus* (MRSA)

Staphylococcus aureus (S. aureus) is a common bacterium found *on* the skin and perineum and in the nose of many people. It is usually not infectious when in these areas because the number of bacteria is controlled by good hygiene measures. However, when skin or mucous membranes are not intact, minor infections, like boils or conjunctivitis, may occur. If the organism enters into deep wounds, surgical incisions, the lungs, or bloodstream, more serious infections occur that require strong antibiotics like methicillin.

Within the past 40 years, more and more *S. aureus* infections have not responded to methicillin or other penicillin-based drugs. Known as *MRSA,* these infections are one of the fastest growing and most common in health care today. In its *5 Million Lives Campaign,* the IHI included reducing MRSA infections as one of its six new goals (see Chapter 1). This type of infection is called *health care–associated MRSA,* or *HA-MRSA.* Patients who have HA-MRSA have increased hospital stays at a very high cost. To add to this problem, about 25% of patients may be colonized with the organism. Health care staff members may also colonize. Patients who develop HA-MRSA pneumonia, abscesses, or bacteremia (bloodstream infection [BSI]) can quickly progress to sepsis and death.

MRSA is spread by direct contact and invades hospitalized patients through indwelling urinary catheters, vascular access devices, and endotracheal tubes. It is susceptible to only a few antibiotics, such as

vancomycin (Lyphocin, Vancocin) and linezolid (Zyvox). A newer IV antibiotic, ceftaroline fosamil (Teflaro), is the first cephalosporin approved to treat MRSA.

Current evidence shows that bathing hospitalized patients with pre-moistened cloths or warm water containing chlorhexidine gluconate (CHG) solution can significantly reduce MRSA infection by 23% to 32% (Kassakian, et al., 2011; Powers, et al., 2012). In 2013, the American Association of Critical Care published a recommendation that nurses use CHG to bathe patients in critical care settings as a way to reduce MRSA and other multi-drug–resistant organisms.

Nursing Safety Priority QSEN

Action Alert

Patients most at risk for HA-MRSA are older adults and those who have suppressed immunity, have a long history of antibiotic therapy, or have invasive tubes or lines. ICU patients are especially at risk. Check with your agency policy regarding specific MRSA preventive measures. Examples include bathing patients with chlorhexidine wipes and administering nasal mupirocin ointment.

Although controversial, some health care facilities have a MRSA-surveillance program in which each patient's nose is swabbed and cultured for MRSA. Staff may also be cultured. All patients with HA-MRSA infection or colonization should be placed on Contact Precautions.

Community-associated MRSA, or CA-MRSA, causes infections in healthy, nonhospitalized people, especially those living in college housing and prisons. It is easily transmitted among family members and can cause serious skin and soft-tissue infections, including abscesses, boils, and blisters. The best way to decrease the incidence of this growing problem is health teaching, including:

- Performing frequent hand hygiene, including using hand sanitizers
- Avoiding close contact with people who have infectious wounds
- Avoiding large crowds
- Avoiding contaminated surfaces
- Using good overall hygiene

Minocycline (Minocin, Apo-Minocycline) and doxycycline (Doryx, Apo-Doxy) are usually effective in treating CA-MRSA.

NCLEX Examination Challenge

Safe and Effective Care Environment

A client is admitted with a catheter-associated methicillin-resistant *Staphylococcus aureus* (MRSA) infection. Which personal protective equipment is appropriate when providing client care? **Select all that apply.**

A Mask
B Gloves
C Shoe covers
D Goggles
E Gown

Vancomycin-Resistant *Enterococcus* (VRE)

Enterococci are bacteria that live in the intestinal tract and are important for digestion. When they move to another area of the body, such as during surgery, they can cause an infection, usually treatable with vancomycin. However, in recent years, many of these infections have become resistant to the drug, and VRE results. Risk factors for this infection include prolonged hospital stays, severe illness, abdominal surgery, enteral nutrition, and immunosuppression. Place patients with VRE infections on Contact Precautions to prevent contamination from body fluids.

Unfortunately, VRE can live on almost any surface for days or weeks and still be able to cause an infection. Contamination of toilet seats, door handles, and other objects is very likely for a lengthy period.

Carbapenem-Resistant *Enterobacteriaceae* (CRE)

Carbapenem antibiotics, most often given for abdominal infections such as peritonitis, have been used extensively for the past 15 years. Examples of this class of antibiotics include imipenem (Cilastin) and meropenem (Merrum IV).

Klebsiella and *Escherichia coli* (*E. coli*) are types of *Enterobacteriaceae* that are located within the intestinal tract. Carbapenem-resistant *Enterobacteriaceae* (CRE) is a family of pathogens that are difficult to treat because they have a high level of resistance to carbapenems due to enzymes that break down the antibiotics. *Klebsiella pneumoniae* (KPC) and New Delhi mettalo-beta-lactamase are examples of these enzymes. Patients who are high risk for CRE include those in intensive care units

or nursing homes and patients who are immunosuppressed, including older adults.

To prevent the transmission of this infection, place patients that are high-risk on Contact Precautions. The CDC (2013) also recommends chlorhexidine (2% dilution) bathing to prevent CRE or decrease colonization and other types of infections from MDROs.

Occupational and Environmental Exposure to Sources of Infection

The U.S. **Occupational Safety and Health Administration (OSHA)** is a federal agency that protects workers from injury or illness at their place of employment. Unlike the voluntary guidelines developed by the CDC, OSHA regulations are law. Employers can be fined or disciplined for noncompliance with OSHA regulations. The regulation for prevention of exposure to bloodborne pathogens, such as hepatitis B and hepatitis C or the human immune deficiency virus (HIV), is one example of an OSHA regulation.

Reduction of skin and soft-tissue injuries (e.g., needle sticks) is essential to reduce bloodborne pathogen transmission to health care personnel. *OSHA mandates that sharp objects ("sharps") and needles be handled with care.* Many contaminated sharp-object exposures involve nurses. Needleless devices have helped decrease these exposures, especially when caring for patients receiving infusion therapy (see Chapter 13).

Other infection control concerns that nurses and other HCWs have are the possibilities of pandemic influenza or biologic agent exposure. A large outbreak of one of the MDROs is also worrisome, especially if no drug is sensitive enough for successful management. Nurses may fear that they will accidentally bring the infectious agent to their homes and families.

Nursing Safety Priority QSEN

Action Alert

To help prevent the transmission of an MDRO, wear scrubs and change clothes before leaving work. Keep work clothes separate from personal clothes. Take a shower when you get home, if possible, to rid your body of any unwanted pathogens. Be careful not to contaminate equipment that is commonly used, such as your stethoscope.

Another environmental source for infection is animals or insects. For example, *hantaviruses* are caused by exposure to rodent-infected areas such as old sheds or cabins. Lyme disease can be caused by deer ticks (see Chapter 18).

Saliva and excrement from deer mice and rats living in the southwestern part of the United States are the primary sources of

hantaviruses. While not a common infection, patients can die from complications such as *hantavirus pulmonary syndrome,* a severe and potentially lethal respiratory disease. Teach patients to avoid exposure to potential hantaviruses by avoiding rodent-infested areas. If infested areas need to be cleaned, teach patients to wear rubber or latex gloves and either a tight-seal negative-pressure respirator or a positive pressure powered air purifying respirator equipped with N100 or P100 filters (Ly, 2013).

Problems From Inadequate Antimicrobial Therapy

Inadequate antimicrobial therapy may range from an incorrect choice of drug to poor patient adherence. Drug regimen **noncompliance** (deliberate failure to take the drug) or **nonadherence** (accidental failure to take the drug) also contributes to resistant-organism development.

Some diseases such as tuberculosis (TB) have legal sanctions that require that a patient complete treatment. Patients who are at risk for noncompliance or nonadherence with an anti-TB drug regimen may be placed on *directly observed therapy (DOT).* This means that a health care worker must observe and validate patient compliance with the drug regimen. DOT has been very effective at reducing the spread of multidrug-resistant TB.

Serious complications of infection may also result from incomplete or inadequate antibiotic therapy. Local infections that could be cured without complications, such as cellulitis and pneumonia, may progress to abscess formation if appropriate drug therapy is not continued. Although drug therapy does not always prevent abscess, early therapy may prevent or limit the size of an abscess.

In addition to abscess formation, inadequate therapy may lead to systemic spread. If the infection is not resolved or if it is treated with drugs that are ineffective for the offending microorganism, the pathogen may enter the bloodstream (septicemia or bloodstream infection [BSI]). Inadequately treated local infections may also lead to BSI with leukocytosis (increased white blood cell count). In severe or advanced cases, leukopenia (decreased white blood cell count) and life-threatening disseminated intravascular coagulation (DIC) may occur. After pathogens invade the bloodstream, no site is protected from invasion.

BSI may progress to **septic shock,** more accurately called *sepsis-induced distributive shock.* In septic shock, insufficient cardiac output is compounded by hypovolemia. Inadequate blood supply to vital organs leads to hypoxia (lack of oxygen) and organ failure. Chapter 37 describes this type of shock and its management in detail.

❖ Patient-Centered Collaborative Care

◆ Assessment

History.

The patient's age, history of tobacco or alcohol use, current illness or

disease (e.g., diabetes), past and current drug use (e.g., steroids), and poor nutritional status may place him or her at increased risk for infection. Patients who are immunocompromised as a result of disease or therapies such as chemotherapy and radiation are also at a high risk for infection. Ask the patient about previous vaccinations or immunizations, including the dates of administration.

Ask the patient if he or she has recently been in a hospital or nursing home as a patient or visitor. Inquire about having invasive testing, such as a colonoscopy, or recent surgery. Ask if the patient had an indwelling urinary catheter or IV line. These invasive treatments often are the source of infections.

Determine whether the patient has been exposed to infectious agents. A history of recent exposure to someone with similar clinical symptoms or to contaminated food or water, as well as the time of exposure, assists in identifying a possible source of infection. This information helps determine the incubation period for the disease and thus provides a clue to its cause.

Contact with animals, including pets, may increase exposure to infection. Question the patient about recent animal contact at home or work or in leisure activities (e.g., hiking). Insect bites should be documented.

Obtain a travel history. Travel to areas both within and outside the patient's home country may expose a susceptible person to infectious organisms not encountered in the local community.

A thorough sexual history may reveal behavior associated with an increased risk for sexually transmitted diseases. Obtain a history of IV drug use and a transfusion history to assess the patient's risk for hepatitis B, hepatitis C, and HIV infections.

Identifying the type and location of symptoms may point to affected organ systems. The onset order of symptoms gives clues to the specific problem. Gathering a history of past infection or colonization with multidrug-resistant organisms will help determine which type of Transmission-Based Precautions is needed.

Physical Assessment/Clinical Manifestations.

Disorders caused by pathogens vary depending on the infection cause and site. Common clinical manifestations are associated with specific sites of infection. Carefully inspect the skin for symptoms of *local* infection at any site *(pain, swelling, heat, redness, pus).* Wounds can easily become infected because the integrity of the skin is broken.

Considerations for Older Adults

Patient-Centered Care QSEN

Fever (generally a temperature above 101° F [38.3° C]), chills, and malaise are primary indicators of a systemic infection. Fever may accompany other noninfectious disorders, and infection can be present without fever, especially in patients who have impaired immunity. The older adult, whose normal temperature may be 1° to 2° lower than the normal temperature in younger adults, may have a fever at 99° F (37.2° C). In most patients with an infection, fever **(hyperthermia)** is a normal immune response that can help destroy the pathogen. Assess the patient for these signs and symptoms, and carefully ask about their history and pattern.

Lymphadenopathy (enlarged lymph nodes), pharyngitis, and GI disturbance (usually diarrhea or vomiting) are often associated with infection. To detect enlargement, palpate the cervical, axillary, and other lymph nodes; examine the throat for redness. Ask about changes in stool and if the patient has had any nausea or vomiting.

Psychosocial Assessment.

The patient with an infectious disease often has psychosocial concerns. Delay in diagnosis because of the need to await clinical test results produces anxiety. Assess the patient's and family's level of understanding about various diagnostic procedures and the time required to obtain test results. Plan education on infection risk reduction at a time when they are ready to learn.

Feelings of malaise and fatigue often accompany infection. Assess the patient's current level of activity and the impact of these symptoms on family, occupational, and recreational activities.

The potential spread of infection to others is an additional stress associated with the diagnosis of infection. The patient may curtail family and social interactions for fear of spreading the illness. Determine the patient's and family's understanding of the infection, the mode of transmission, and mechanisms that may limit or prevent transmission. Special precautions, although sometimes necessary for preventing transmission of the organism, can be emotionally difficult for the patient and family.

A number of transmissible infectious diseases, especially those identified with social stigmas (e.g., IV drug abuse), are associated with labeling. The patient may feel socially isolated or have guilt related to

behavior that increased the risk for infection. Observe carefully for the patient's reaction to labels and how these feelings further affect socialization.

Laboratory Assessment.

The definitive diagnosis of an infectious disease requires identification of a microorganism in the tissues of an infected patient. Direct examination of blood, body fluids, and tissues under a microscope may not yield a definitive identification. However, laboratory assessment usually provides helpful information about organisms, such as shape, motility, and reaction to staining agents. Even when direct microscopy does not provide a conclusive specific diagnosis, often enough information is obtained for starting appropriate antimicrobial therapy.

The best procedure for identifying a microorganism is **culture,** or isolation of the pathogen by cultivation in tissue cultures or artificial media. Specimens for culture can be obtained from almost any body fluid or tissue. The health care provider usually decides when and where the specimen for culture is taken.

Proper collection and handling of specimens for culture, using Standard Precautions, are essential for obtaining accurate results. Specimens collected must be appropriate for the suspected infection. Be sure that the specimen is of adequate quantity and is freshly obtained and placed in a sterile container to preserve the specimen and microorganism. Label the specimen properly including the date and time it was collected. Follow your agency's policy if you have any questions about how to perform a culture.

After isolation of a microorganism in culture, antimicrobial **sensitivity** testing is performed to determine the effects of various drugs on that particular microorganism. An agent that is killed by acceptable levels of an antibiotic, for example, is considered sensitive to that drug. An organism that is not killed by tolerable levels of an antibiotic is considered resistant to that drug. Preliminary results are usually available in 24 to 48 hours, but the final results generally take 72 hours. *Antimicrobial therapy should not begin until after the culture specimen is obtained.*

Rapid cultures or assays are used in ambulatory care settings to provide quicker assessments of infections. The most popular is the rapid antigen detection test for group A streptococci to rule out "strep throat" in patients who present with pharyngitis (sore, inflamed throat). Other examples of newer tests are those for tuberculosis (TB) and influenza ("flu"), discussed in Chapter 31.

A *white blood cell (WBC) count with differential* is often done for the patient with a suspected infection. Five types of leukocytes (white blood cells) are measured as part of the results:

- Neutrophils
- Lymphocytes
- Monocytes
- Eosinophils
- Basophils

In most active infections, especially those caused by bacteria, the total leukocyte count is elevated. Various infections are characterized by changes in the percentages of the different types of leukocytes. The differential count usually shows an increased number of immature neutrophils, or a **shift to the left** ("left shift"). A few infectious diseases, however, such as malaria and infectious mononucleosis, are associated with neutropenia (decreased neutrophils). See Chapter 17 for further discussion.

The *erythrocyte sedimentation rate (ESR)* measures the rate at which red blood cells fall through plasma. This rate is most significantly affected by an increased number of acute-phase reactants, which occurs with inflammation. Thus an elevated ESR (>20 mm/hr) indicates inflammation or infection somewhere in the body. Chronic infection, especially osteomyelitis and chronic abscesses, is commonly associated with an elevated ESR. The ESR is chronically elevated with inflammatory arthritis and other connective tissue diseases as well (see Chapter 18). The effectiveness of therapy is often determined by a decrease in this value.

Serologic testing is performed to identify pathogens by detecting antibodies to the organism. The antibody titer tends to *increase* during the acute phase of infectious diseases such as hepatitis B. The titer *decreases* as the patient improves.

Imaging Assessment.

X-ray films may be obtained to determine activity or destruction by an infectious microorganism. Radiologic studies (e.g., chest films, sinus films, joint films, GI studies) are available for diagnosis of infection in a specific body site.

More sophisticated techniques for infection diagnosis include computed tomography (CT) scans and magnetic resonance imaging (MRI). CT and ultrasonography are helpful in assessing for abscesses. CT scans help identify suspected osteomyelitis and fluid collections that point to possible infection. MRI scans provide a cross-sectional assessment for infection.

Another diagnostic tool for the evaluation of a patient with an infectious disease is ultrasonography. This noninvasive procedure is particularly helpful in detecting infection involving the heart valves.

Scanning techniques using radioactive substances such as gallium can determine the presence of inflammation caused by infection. Inflammatory tissue is identified by its increased uptake of the injected radioactive material.

Analysis

The priority NANDA-I nursing diagnoses and collaborative problems for patients with an infection or infectious disease include:

1. Hyperthermia related to the immune response triggered by pathogenic invasion (NANDA-I)
2. Social Isolation related to being placed on Transmission-Based Precautions (NANDA-I)

Planning and Implementation

Managing Hyperthermia

Planning: Expected Outcomes.

Patients with an infection or infectious disease are expected to have a body temperature within normal limits as a result of effective interdisciplinary management.

Interventions.

The primary concern is to provide measures to eliminate the underlying cause of fever (also known as *hyperthermia*) and to destroy the causative microorganism. In collaboration with the health care team, nurses use a variety of methods to manage fever.

Drug therapy plays a major role in patient-centered collaborative care of patients with infection. Antimicrobials, also called *anti-infective agents,* are the cornerstone of drug therapy. Antipyretics are used to decrease patient discomfort and reduce fever.

Antibiotics, antiviral agents, and antifungals are common types of antimicrobial drugs that are given for infection, depending on its type. Effective antibiotics are available to treat nearly all bacterial infections, but misuse of antibiotics has contributed to the development of multidrug-resistant organisms (MDROs) discussed earlier in this chapter. A few effective antifungal agents have been developed, but these drugs

generally cause more toxicity than antibacterial agents.

Effective antimicrobial therapy requires delivery of an appropriate drug, sufficient dosage, proper administration route, and sufficient therapy duration. These four requirements ensure delivery of a concentration of drug sufficient to inhibit or kill infecting microorganisms. To ensure effectiveness of antibiotic therapy such as vancomycin, health care providers may require serum trough and peak levels be drawn. Specimens for trough levels are drawn about 30 minutes prior to the next scheduled vancomycin dose. Specimens for peak levels are drawn 30 to 60 minutes after medication administration (Rosini & Srivastava, 2013).

Health care providers collaborate on selecting drugs and dosing. Antimicrobials act on susceptible pathogens by:

- Inhibiting cell wall synthesis (e.g., penicillins and cephalosporins)
- Injuring the cytoplasmic membrane (e.g., antifungal agents)
- Inhibiting biosynthesis, or reproduction (e.g., erythromycin and gentamicin)
- Inhibiting nucleic acid synthesis (e.g., actinomycin)

Teach the drug's actions, side effects, and toxic effects to patients and their families. Observe and report side effects and adverse events. These reactions vary according to the specific classification of the drug. Most antibiotics can cause nausea, vomiting, and rashes. Stress the importance of completing the entire course of drug therapy, even if symptoms have improved or disappeared.

Nursing Safety Priority QSEN

Drug Alert

Before administering an antimicrobial agent, check to see that the patient is not allergic to it (Table 23-4). Be sure to take an accurate allergy history before drug therapy begins to prevent possible life-threatening reactions, such as anaphylaxis!

TABLE 23-4

Possible Allergic Reactions to Antibiotic Therapy

• Nausea and/or vomiting • Flushing • Wheezing • Sneezing • Pruritus • Urticaria • Rashes • Maculopapular to exfoliative dermatitis • Vascular eruptions
• Erythema multiforme (Stevens-Johnson syndrome) • Angioneurotic edema • Serum sickness (headache, fever, chills, hives, malaise, conjunctivitis) • Anaphylaxis (laryngeal edema, bronchospasm, hypotension, vascular collapse, cardiac arrest) • Death

Antipyretic drugs, such as acetaminophen (Tylenol, Ace-Tabs), are often given to reduce fever. Because these drugs mask fever, monitoring the course of the disease may be difficult. Therefore, unless the patient is very uncomfortable or if fever presents a significant risk (e.g., in the patient with heart failure, febrile seizures, or head injury), antipyretics are not always prescribed.

Teach patients that they may have waves of sweating after each dose. Sweating may be accompanied by a fall in blood pressure followed by return of fever. These unpleasant side effects of antipyretic therapy can often be alleviated by increasing fluid intake and by regular scheduling of drug administration.

Other interventions to reduce fever may include external cooling and fluid administration. Perform a thorough assessment before and after interventions are implemented.

External cooling by hypothermia blankets or ice bags or packs can be effective mechanisms for reducing a high fever. Alternative cooling methods may be used. Sponging the patient's body with tepid water or applying cool compresses to the skin and pulse points to reduce body temperature is sometimes helpful. *Teach unlicensed assistive personnel (UAP) to observe for and report shivering during any form of external cooling. Shivering may indicate that the patient is being cooled too quickly.*

The use of fans is discouraged because they can disperse airborne- or droplet-transmitted pathogens. Fans can also disturb air balance in negative pressure rooms, making them positive pressure rooms and allowing possible transmission of the agent to those outside the room.

In patients with fever, fluid volume loss is increased from rapid evaporation of body fluids and increased perspiration. As body temperature increases, fluid volume loss increases.

Nursing Safety Priority QSEN

Action Alert

If fluid volume loss increases, patients may be at risk for dehydration and require additional fluids either orally or IV. Monitor carefully for signs of dehydration, such as increased thirst, decreased skin turgor, dry mucous membranes, and acute confusion, especially in older adults. Increase oral fluid intake and provide IV fluids as prescribed. Chapter 11 discusses interventions for dehydration in detail.

Responding to Feelings of Social Isolation

Planning: Expected Outcomes.

The patient with an infection or infectious disease who is placed on Transmission-Based Precautions is expected to cope with feelings of isolation and interact with others.

Interventions.

Education is the major intervention for meeting this outcome. Teach the patient and family about the mode of transmission of infection and mechanisms that prevent spread to others. Assess coping mechanisms that the patient has used in the past. If he or she is in the hospital, collaborate with the certified hospital chaplain or social worker to help alleviate the patient's stress, anxiety, or depression.

As part of the health care team, ensure that the patient and family understand the disease process and its cause. If necessary, ensure that the patient and family can state specific ways in which precautions will be used in the home after discharge from the hospital.

Because the patient requiring precautions may feel secluded, encourage staff and family members to maintain contact with the patient. Remind them that the pathogen, not the patient, requires special precautions. Encourage family members and friends to visit and to use appropriate infection control measures. Communication by telephone or e-mail is often effective for continuing contact with loved ones. Television, Internet, and handheld mobile devices help bring the outside world into the life of the patient confined to the room.

In the long-term care setting, an outbreak of respiratory or GI infection usually requires limiting visitors, activities, and admissions to the facility. Nurses working in these settings need to be familiar with federal and state regulations regarding managing infections.

Community-Based Care

Patients with infections may be cared for in the home, hospital, nursing home, or ambulatory care setting, depending on the type and severity of the infection. Infections among older adults in nursing homes are common. Residents often have meals together in a communal dining room and participate in group activities. Confused residents may not wash their hands or may enter other resident rooms. Immunizing them against respiratory infections is highly recommended because these illnesses can cause severe complications or death in older adults.

Home Care Management.

The patient with an infectious disease such as osteomyelitis may require continued, long-term antibiotic therapy at home or in a long-term care facility. Emphasize the importance of a clean home environment, especially for the patient who continues to have compromised immunity or who is uniquely susceptible to **superinfection** (i.e., reinfection or a second infection of the same kind) to reduce the chance of infection. Drugs often need to be refrigerated. Ensure that the patient has access to proper storage facilities, and teach him or her to check for signs of improper storage, such as discoloration of the drug.

Ask about the availability of handwashing facilities in the home, and check that supplies and instructions are provided as needed. Most people do not know how to wash hands correctly. Demonstrate the procedure with the patient and family, and request a repeat demonstration.

Self-Management Education.

Explaining the disease and making certain that the patient understands what is causing the illness are the primary purposes of health teaching. Discuss whether the pathogen causing the infection can be spread to others and the modes of transmission.

If the patient has an infectious disease that is potentially transmissible, teach the patient, family, and other home caregivers about precautions. Explain whether any special household cleaning is necessary and, if so, what those special steps include. If syringes with needles are used to administer drug therapy, explain how to dispose safely and legally of needles in the community. Clothing soiled with blood or other body fluids can be washed with bleach or disinfectant (e.g., Lysol). Recommended cleaning measures should be based on actual available equipment and facilities.

For the patient who is discharged to the home setting to complete a

course of antimicrobial therapy, the importance of adherence to the planned drug regimen needs to be stressed. Explain the importance of both the timing of doses and the completion of the planned number of days of therapy. Teach the patient (and family as appropriate) how the agents need to be taken (e.g., before meals, with meals, without other agents) and the possible side effects. Side effects include those that are expected (e.g., gastric distress), as well as more severe adverse reactions (e.g., rash, fever, other systemic signs and symptoms). Teach the patient about allergic manifestations and the need to notify a health care provider if an adverse reaction occurs (see Table 23-4). Also discuss what to do if a drug dose is missed (e.g., doubling the dosage, waiting until the next dose time).

Many patients are discharged with an infusion device to continue drug therapy at home or in other inpatient facilities. The patient, family member, or home care nurse administers the drugs. Home care services are often used to teach appropriate administration of drug therapy in the patient's home. Health teaching and wound care may also be needed. These services have proved efficient, effective, psychologically supportive, and less expensive than hospitalization or skilled nursing facilities (SNFs).

The patient is often anxious and fearful that the infection will be transmitted to family members or friends. Teaching the patient and the family ways of preventing the spread of disease allays these fears. Pay careful attention to the patient's and family's concerns. Making concrete suggestions (e.g., "Your wife can wear gloves when changing your dressing") to address specific concerns may reduce these fears.

The patient with an infectious disease associated with lifestyle behaviors, such as sexual activity or IV drug abuse, may have guilt related to the disease. Encourage discussion of feelings associated with the illness, and assist in locating support systems that may help alleviate these feelings, such as clergy or other spiritual or cultural leaders.

Health Care Resources.

At times, a patient who has been hospitalized for an infectious disease may not be able to return to the home setting due to lack of caregiver support. In such cases, temporary placement in a SNF may be needed. Document care requirements, patient history of infection or colonization with multidrug-resistant organisms, medication schedules, and personal needs and preferences on transfer forms. Hand-off communication, such as the SBAR, between the two facilities is required to facilitate a smooth transition from the hospital to the intermediate care setting, according to

The Joint Commission's National Patient Safety Goals.

Evaluation: Outcomes

Evaluating the care of the patient with an infection or infectious disease on the basis of the identified priority problems is important. The expected outcomes include that the patient:

- Has body temperature and other vital signs within baseline
- Adheres to drug therapy regimen
- Copes with feelings of social isolation

Specific indicators for these outcomes are listed for each priority problem under the Planning and Implementation section (see earlier).

Clinical Judgment Challenge

Evidence-Based Practice; Quality Improvement; Informatics

QSEN

The hospital quality improvement (QI) department reports a 25% increase in CRE infections on your surgical intensive care unit during the past month. A unit-based QI team is created to identify possible causes of this increase and strategies for decreasing these infections.

1. What are some possible causes of CRE infections?
2. Using the PICOT format in Chapter 5, develop a clinical question to address the problem.
3. How will your unit QI team begin to answer the clinical question?
4. What data sources might you use?
5. What will you do with the retrieved data?
6. How will you present your findings?

Critical Issues: Emerging Infections and Global Bioterrorism

Current concerns related to infection and infection control are the risk for global bioterrorism (Table 23-5), emerging infectious diseases, and multidrug-resistant organisms (MDROs). As for any pathogen, strict infection control measures can prevent transmission of these microbes to you and your patients. Some of the most serious infections are briefly described here. Table 23-6 lists more emerging infections that may present as problems in the United States and other parts of the world.

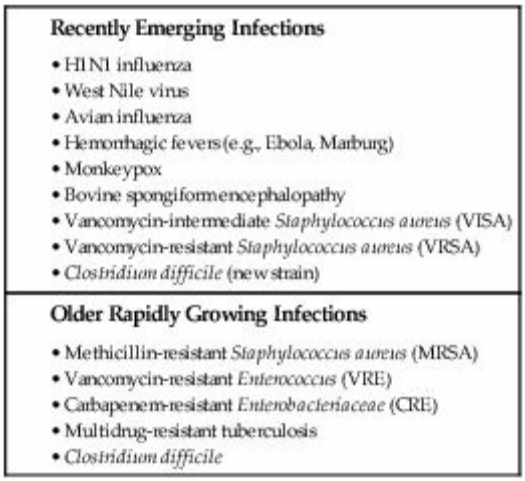
TABLE 23-5

Centers for Disease Control and Prevention* Examples of Bioterrorism Agents and General Clinical Management

PATHOGEN OR AGENT AND DISEASE INFORMATION	CLINICAL MANAGEMENT
Anthrax (*Bacillus anthracis*)	
Cutaneous: 1-7 days after contact, exposed skin itching, progressing to papular and vesicular lesions, eschar, edema, ulceration, and sloughing. If untreated, may spread to lymph nodes and bloodstream. Fatality 5%-20%. **Inhalation:** 48 hr after organism or spore inhalation, flu-like illness with possible brief improvement. 2-4 days from initial symptoms, abrupt onset of severe cardiopulmonary illness (dyspnea, tachycardia, fever, diaphoresis, thoracic edema, shock, and respiratory failure). If antibiotics delayed until onset of cardiopulmonary symptoms, mortality high. May be confused with common upper respiratory infection (URI). **Other forms:** Gastrointestinal (GI), meningeal, and sepsis.	**For cutaneous and inhaled anthrax:** No person-to-person spread. Contact Precautions are not needed unless patient presents directly from exposure. Standard Precautions for: Prescribed wound cleansing and management of lesions Ventilator support for respiratory failure Postmortem care
Botulism (*Clostridium botulinum* and Neurotoxin)	
Toxin ingestion results in dysphasia, dry mouth, drooping eyelids, and blurred or double vision. Vomiting and constipation or diarrhea may be present initially, extending to symmetric flaccid paralysis in an alert person. Acute bilateral cranial nerve impairment and descending weakness or paralysis follow. Neurologic symptoms after 12-36 hr for foodborne botulism and in 24-72 hr after aerosol exposure. Case fatality up to 10%. Recovery may take months.	Standard Precautions: decontamination of patient is not required. No person-to-person spread. Consider outbreak with suspicion of a single case. Consult with CDC and health departments. Advise careful cleanup and disposal of suspected contaminated food source *after* consultation with health department about any needed laboratory sampling. Interdisciplinary planning for nutrition and rehabilitation support during lengthy neuromuscular and respiratory recovery.
Plague (*Yersinia pestis*)	
Lymphatic infection: 2-8 days after bites from fleas of an infected rodent (rarely after infected tissue or body fluid contact), onset of fever and chills, painful lymphadenopathy (or bubo—usually inguinal, axillary, or cervical lymph nodes), headache, GI symptoms, and rapidly progressive weakness. 50%-60% fatality if untreated. **Pneumonic:** 1-3 days after aerosolized organism inhalation, fever and chills, productive cough, hemoptysis, rapidly progressive weakness, GI symptoms, and bronchopneumonia. Survival unlikely if not treated within 18 hr of symptom onset. **Other forms:** Sepsis with coagulopathy, rarely meningitis.	Droplet Precautions: required for pneumonic plague (until 72 hr of antibiotic therapy). Contact Precautions until decontamination is complete: For any suspected gross contamination. See documentation information listed under Anthrax—above. For prescribed management of bubo(s) if incised to drain. Community and other environmental modifications: Apply insecticide to infested environment and pets (to kill fleas). Reduce food and water supply for rodents. Avoid sick or dead animals.
Smallpox (Variola Virus) (Variola Major and Minor)	
10-17 days after droplet or airborne virus inhalation or contact with bleeding lesions, onset of severe myalgias, headache, and high fever. 2-3 days later, a papular rash appears on face and spreads to extremities (and palms and soles). The rash quickly (simultaneously) becomes vesicular and then painful and pustular (contrasted to varicella rash that crops and concentrates more on trunk with various stages of macules to vesicles seen at one time). Patients are infectious at onset of rash until scabs separate (3 wk). Historically, variola major kills 20%. May be confused with varicella.	Standard, Contact, and Airborne Precautions for patients with vesicular rash pending diagnosis. Same for varicella and variola. Also, avoid contact with organism while handling contaminated clothes and bedding. Wear protective attire (gloves, gown, and N95 respirator). One case is a public health emergency—highly communicable. Consult CDC and health departments at earliest suspicion. Vaccine does not give reliable lifelong immunity. Previously vaccinated persons are considered susceptible. *Following exposure:* Initiate Airborne Precautions, and observe for unprotected contacts (from days 10-17). Vaccinate within 2-3 days of exposure.
Other Key Points	
Assessment: Include account of symptoms, patient's incident (what, where, when, how, others exposed or ill, and officials aware). **Treatment:** Antibiotic-resistance possible. Vaccine and postexposure prophylaxis are subject to change. If any of the above diseases are suspected, consult infection control practitioner for coordination with community health officials and CDC about current recommendations and specimen collection. *If bioterrorism suspected,* Federal Bureau of Investigation (FBI) will coordinate evidence collection and delivery. **Multiple exposures planning:** Emergency and critical care managers must address availability and acquisition of stocks of medications, vaccines, equipment (e.g., ventilators), and communications with officials, as well as public information needs.	

TABLE 23-6

Examples of Global Emerging Infections



Recently Emerging Infections

- H1N1 influenza
- West Nile virus
- Avian influenza
- Hemorrhagic fevers (e.g., Ebola, Marburg)
- Monkeypox
- Bovine spongiform encephalopathy
- Vancomycin-intermediate *Staphylococcus aureus* (VISA)
- Vancomycin-resistant *Staphylococcus aureus* (VRSA)
- *Clostridium difficile* (new strain)

Older Rapidly Growing Infections

- Methicillin-resistant *Staphylococcus aureus* (MRSA)
- Vancomycin-resistant *Enterococcus* (VRE)
- Carbapenem-resistant *Enterobacteriaceae* (CRE)
- Multidrug-resistant tuberculosis
- *Clostridium difficile*

The 2014 Ebola epidemic was labeled as the largest in history, with many West African countries affected (CDC, 2014). An epidemic occurs when new cases of a certain disease substantially exceed expectation during a given period. The ongoing struggle with the Ebola virus outbreak in West Africa became a concern within the United States when an individual who flew back from Liberia was diagnosed, although after initial discharge, at a Dallas hospital. That individual later died. Symptoms of Ebola, which can present from 2 to 21 days after exposure (with an average of 8 to 10 days), include fever greater than 101.5° F, severe headache, muscle pain, weakness, diarrhea, vomiting, abdominal pain, and unexplained hemorrhage (bleeding or bruising) (CDC, 2014). The virus is most commonly spread through exposure to bodily fluids of the infected individual and through needle sticks in which the needle has been contaminated with the virus (CDC, 2014). Recovery from this virus is contingent on appropriate clinical care and the immune response of the patient. Patients who recover from Ebola infection develop antibodies that can last for 10 years (CDC, 2014) (Table 23-7).

TABLE 23-7

Care for Patients with Ebola Virus Disease

TRANSMISSION OF DISEASE	PREVENTION OF DISEASE	ASSESSMENT	PATIENT-CENTERED COLLABORATIVE CARE
The primary source of the Ebola virus is most likely contaminated bats or primates (apes and monkeys) in West Africa. Information that is known about transmission includes: • The Ebola virus cannot be transmitted unless a person is sick and has clinical manifestations of the disease. • The Ebola virus is not spread via air, water, or food. • Nurses can help identify people at high risk for having or transmitting the disease by taking a complete history, including asking about travel to West Africa, or exposure to family and friends who have Ebola. • The disease can be transmitted by unprotected contact with people infected with the Ebola virus or with people who have died from Ebola. • Teach patients who recover from Ebola and their partners that the virus is present in semen for up to 3 months. Using a condom may prevent transmission.	Take special training *before* caring for patients with the Ebola virus. Use these precautions: • Avoid direct contact with body fluids (blood, feces, saliva, urine, vomit, and semen). • Use Standard, Contact, and Droplet Precautions, including appropriate PPE. • Isolate patient with Ebola in a single room. • Use dedicated or disposable medical equipment and supplies. • Practice proper sterilization measures.	Clinical manifestations occur 2-21 days after exposure to the Ebola virus. Assess for: • Fever • Severe headache • Muscle pain • Weakness • Fatigue • Diarrhea • Vomiting • Abdominal pain • Unexplained hemorrhage (bleeding and bruising)	No drug therapy or vaccine is yet FDA approved for Ebola. Remember that the virus can enter the body through broken skin or unprotected mucous membranes such as the eyes, nose, and mouth. Supportive care includes: • Intravenous fluid and electrolyte replacement • Oxygen and ventilation support • Blood pressure support • Treatment of other infections • Care and comfort measures • Symptomatic care • Emotional support • Possible end-of-life care

Data from CDC. (2014). *Ebola (Ebola virus disease).* Accessed in November 2014 from www.cdc.gov/vhf/ebola/index/html.

With the Dallas Ebola incident, there was reported to be a communication concern within the electronic medical record (EMR) in which the physician was unable to view the nurse's notes and see that the nurse had recorded the patient's recent returne from West Africa. It is of vital importance that the nurse and provider of care be sure to communicate pertinent historical information both verbally and in the EMR so that appropriate interventions for both the individual and the general public can be undertaken immediately.

Pandemic infections, such as influenza, are another threat to the population. As recently as the early 1900s, the "Spanish flu" killed millions of people throughout the world. Health care workers are encouraged to have yearly influenza vaccines to prevent infection with common strains of the virus. The federal government and health care agencies around the United States include the risk for pandemic disease in their disaster planning (see Chapter 10).

Contaminated food is another source of infection. The incidence of foodborne infections has risen in the United States as contaminated fresh spinach, ground beef, and other foods were found to contain *E. coli* 0157:H7. Many illnesses and thousands of recent deaths in the United States have been caused by this infection. Safer food preparation practices and increased monitoring by federal agencies have resulted from demand for public safety.

Another pathogen, *Clostridium difficile (C. difficile),* is associated with antibiotic therapy use, especially in older adults. Associated problems have led to the development of the diagnosis of **C. difficile–associated disease (CDAD)** (Grossman & Mager, 2010). A new more virulent strain of this pathogen has developed in the past decade due to the use of

fluoroquinolone antibiotics, such as ciprofloxacin (Cipro).

C. difficile is spread by indirect contact with inanimate objects like medical equipment and commodes, and its toxins cause colon dysfunction and cell death from sepsis. CDAD is confirmed by stool culture. Patients who have three or more liquid stools per day for two or more days are suspected of having the infection. Fever and abdominal pain and cramping commonly occur with diarrheal stools. Oral metronidazole (Flagyl) and vancomycin have been the drugs of choice to treat CDAD. However, some patients experience recurrence of infection after treatment with these drugs. A new oral antibacterial drug available for specifically managing *C. difficile* is fidaxomicin (Dificid).

A new controversial treatment for CDAD is fecal bacteriotherapy to transplant stool with normal healthy flora into the infected patient. The donor stool is liquefied with saline, filtered, and administered to the patient with CDAD by nasogastric tube, fecal enema, or colonoscopy. Results of this treatment have been very positive (Meyers, 2011).

In addition to concerns about emerging infections, preparation for and education about *bioterrorism* have been major focuses of the U.S. government since September 11, 2001. In some cases, vaccines are no longer given for biologic agents like smallpox. Many people in the United States have never been vaccinated, and those who had vaccinations many years ago are not guaranteed to have lifelong immunity. Anthrax, usually seen in animals, may be spread to the skin or inhaled. These infections have a high fatality rate in humans. Plague, once seen centuries ago, is one of the biggest threats because the survival rate is low. Vaccines are being researched and stockpiled by the U.S. government for some of the common biologic agents.

Nursing Concepts and Clinical Judgment Review

What might you NOTICE if the patient has inadequate protection as a result of infection or infectious disease?

- Flushing and sweating
- Localized skin inflammation (redness, warmth, swelling, pain)
- Open wound (draining or non-draining)
- Report of diarrhea or vomiting
- Report of sore throat
- Fatigue
- Rash
- Acute confusion (in older adults)

What should you INTERPRET and how should you RESPOND to a

patient with inadequate protection as a result of infection or infectious disease?

Perform and interpret focused physical assessment findings, including:

- Vital signs
- Skin and/or wound assessment
- Lymph palpation
- Throat inspection

Respond:

- Manage fever if present.
- Take culture of drainage and send to laboratory for analysis.
- Monitor laboratory findings, including complete blood count (CBC) with white blood cell (WBC) differential.
- Place on appropriate Transmission-Based Precautions.
- Teach patients and families about Transmission-Based Precautions and hand hygiene.
- Administer antimicrobial therapy as prescribed.
- Collaborate with the facility's infection control practitioner.
- Teach patients and families about the need to adhere to the drug therapy regimen.
- Follow CDC guidelines and The Joint Commission's National Patient Safety Goals (NPSGs).

On what should you REFLECT?

- Monitor the patient's response to drug therapy.
- Monitor the patient's vital signs for return to baseline.
- Evaluate the patient's and family's knowledge of infection, Transmission-Based Precautions, and drug therapy.
- Monitor the staff's compliance with hand hygiene and personal protective equipment (PPE).
- Evaluate the patient's and family's coping ability.
- Think about what else you might do to make the patient more comfortable.
- Decide whether you need to provide alternative or additional interventions or health teaching.

Get Ready for the NCLEX® Examination!

Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Handwashing and alcohol-based hand rubs are two methods of hand hygiene (see Chart 23-3).
- The Centers for Disease Control and Prevention (CDC) recommends a ban on artificial fingernails for health care professionals when they are caring for patients at high risk for infection. **Evidence-Based Practice** QSEN
- Infections can be prevented or controlled through hand hygiene, disinfection/sterilization, personal protective equipment (PPE), patient placement, and adequate staffing; proper hand hygiene and gloves are the most important interventions because health care workers' hands are the primary way in which disease is transmitted from patient to patient. **Evidence-Based Practice** QSEN
- Standard Precautions are used with all patients in health care settings, assuming that all body excretions and secretions are potentially infectious (see Table 23-2). **Safety** QSEN
- Airborne Precautions are used for patients who have infections transmitted through the air, such as tuberculosis.
- Droplet Precautions are used for patients who have infections transmitted by droplets, such as influenza and certain types of meningitis.
- Contact Precautions are used for patients who have infections transmitted by direct contact or contact with items in the patient's environment.

Health Promotion and Maintenance

- Health teaching about clinical manifestations of infection and drug therapy is important for the patient with an infection being managed at home; some patients may need health care nursing services for IV antimicrobial therapy.
- Teach patients about antimicrobial therapy and protective measures to prevent infection transmission.
- Teach patients how to avoid community-acquired MRSA by performing frequent hand hygiene and by avoiding crowds and direct contact with others who have infections. **Safety** QSEN

Psychosocial Integrity

- Patients who have Transmission-Based Precautions may feel isolated, anxious, or depressed; they may feel neglected and dissatisfied with their care. Help patients cope with these feelings through verbalization and collaboration with the health care team. **Teamwork and Collaboration** QSEN

Physiological Integrity

- Patients at the highest risk for infection include older adults, health care professionals at risk for needle sticks, and patients who have diabetes or are immunocompromised. Patients who take long-term steroid therapy or have had invasive procedures or therapies are also at a high risk for infection.
- Multidrug-resistant organisms (MDROs) are the result of the overuse of antibiotic therapy and include methicillin-resistant *Staphylococcus aureus* (MRSA), vancomycin-resistant *Enterococcus* (VRE), and carbapenem-resistant *Enterobacteriaceae* (CRE).
- A biofilm, also called *glycocalyx,* is a complex group of microorganisms that function within a "slimy" gel coating on medical devices, such as urinary catheters, orthopedic implants, and enteral feeding tubes; on parts of the body like the teeth (plaque) and tonsils; and in chronic wounds. Biofilms are difficult to treat, and research is examining methods to manage them to better treat.
- Common clinical manifestations of infections and infectious diseases include fever and lymphadenopathy. If infections are not treated or are inadequately treated, systemic sepsis (septicemia), septic shock, and disseminated intravascular coagulation (DIC) may result.
- A culture is the most definitive way to confirm and identify microorganisms; sensitivity testing determines which antibiotics will destroy the identified microbes.
- The white blood cell differential count usually shows a shift to the left (increased number of immature neutrophils) during active infections.
- Antimicrobials and antipyretics are the most common types of drugs used when infection is accompanied by fever.
- Antipyretics are used only when the fever presents a significant risk or the patient is very uncomfortable, because antipyretics may mask the disease. **Evidence-Based Practice** QSEN
- Critical issues for the next decade include bioterrorism, emerging infectious diseases, and multidrug-resistant organisms (MDROs).

UNIT VI

Problems of Protection: Management of Patients with Problems of the Skin, Hair, and Nails

OUTLINE

CHAPTER 24

Assessment of the Skin, Hair, and Nails

Janice Cuzzell and M. Linda Workman

PRIORITY CONCEPTS

- Tissue Integrity

Learning Outcomes

Safe and Effective Care Environment

1. Protect hospitalized patients from skin injury and loss of tissue integrity.

Health Promotion and Maintenance

2. Teach all people how to protect the skin from damage and cancer development.

Psychosocial Integrity

3. Reduce the psychological impact for the patient and family regarding the assessment and testing of the integumentary system.

Physiological Integrity

4. Use knowledge of anatomy and physiology to perform a focused assessment of the skin, hair, and nails, incorporating information about genetic risk and age-related changes affecting these structures.

http://evolve.elsevier.com/Iggy/

The skin, hair, and nails are the tissues making up the integumentary system. Skin tissue integrity plays a major role in protection. Intact skin has

barrier functions, alarm functions, and even combat functions. As shown in Fig. 24-1, the skin protects the body against invasion of pathogenic organisms by providing a first line of defense (the moat), a second line of defense (the castle wall), and even a third line of defense (the knights and soldiers). The normal flora on the surfaces of skin and mucous membranes repels some of the more harmful microorganisms. Specialized cells in the skin engulf foreign substances (antigens) that invade the body when skin tissue integrity is lost and then alert the immune system to the presence of the invader. Localized tissue inflammation and swelling work to contain the invading pathogen until white blood cells can respond and remove this threat.

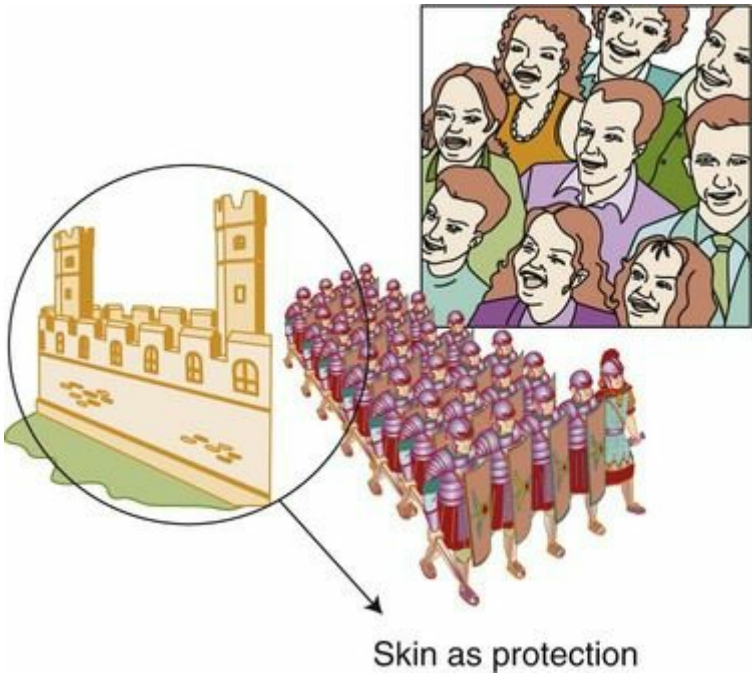


FIG. 24-1 Role of the skin in the concept of body protection.

The skin is the largest organ of the body and, when intact, helps regulate body temperature and maintains fluid and electrolyte balance. Skin changes can provide important information about a person's health and well-being. Emotional stress, systemic disease, some drugs, and skin injury or disease can alter skin function, appearance, and texture.

The skin's sensory function allows the use of touch as an intervention to provide comfort, relieve pain, and communicate caring. Because the skin has many sensory receptors, the patient can report subjective skin sensations that might indicate specific health problems.

Anatomy and Physiology Review

Structure of the Skin

The skin has three layers: subcutaneous tissue (fat), dermis, and epidermis (Fig. 24-2). Each layer has unique properties that help the skin maintain its complex functions.

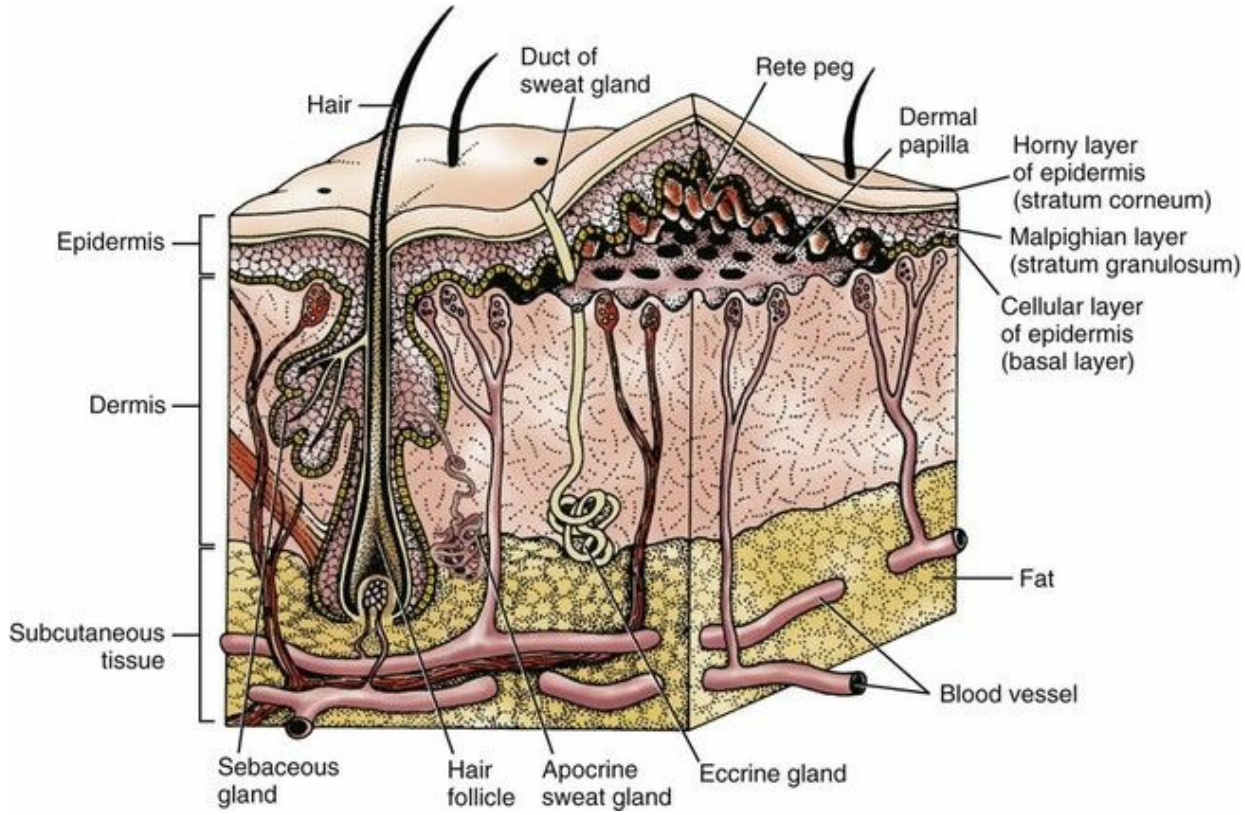

FIG. 24-2 Anatomy of the skin.

Subcutaneous fat (adipose tissue [fat]) is the innermost layer of the skin, lying over muscle and bone. Fat distribution varies with body area, age, and gender. Fat cells insulate the body and absorb shock, padding internal structures. Blood vessels go through the fatty layer and extend into the dermis, forming capillary networks that supply nutrients and remove wastes.

The dermis (corium) is the layer above the fat layer and contains no skin cells but does contain some protective mast cells and macrophages (see Chapter 17). The dermis is composed of interwoven collagen and elastic fibers that give the skin flexibility and strength.

Collagen, the main component of dermal tissue, is a protein produced by fibroblast cells. Its production increases in areas of tissue injury and helps form scar tissue. Fibroblasts also produce **ground substance,** a lubricant that contributes to skin suppleness and turgor.

Skin elasticity depends on the amount and quality of the dermal elastic fibers. The major component of the elastic fiber is elastin.

The dermis has capillaries and lymph vessels for the exchange of oxygen and heat. It is rich in sensory nerves that transmit the sensations of touch, pressure, temperature, pain, and itch.

The epidermis is the outermost skin layer. It is anchored to the dermis by fingerlike projections **(rete pegs)** that interlock with dermal structures called **dermal papillae.** Less than 1 mm thick, the epidermal layer is the first line of defense between the body and the environment.

The epidermis does not have its own blood supply. Instead it receives nutrients by diffusion from the blood vessels in the dermal layer. Attached to the basement membrane of the epidermis are the basal **keratinocytes**—skin cells that undergo cell division and differentiation to continuously renew skin tissue integrity and maintain optimal barrier function. As basal cells divide, keratinocytes are pushed upward and form the *spinous layer (stratum spinosum).* Together the basal layer and the spinous layer are referred to as the *germinative layer (stratum germinativum),* because these layers are responsible for new skin growth (McCance et al., 2014). The keratinocytes continue to enlarge and flatten as they move upward to form the outermost horny skin layer **(stratum corneum).** When these cells reach the stratum corneum (in 28 to 45 days), they are no longer living cells and are shed from the skin surface. **Keratin**, a protein produced by keratinocytes, makes the horny layer waterproof.

On the palms of the hands and soles of the feet an additional thick layer of epidermis forms known as the *stratum lucidum.* This clear layer of nonliving cells pads and protects the underlying dermal and epidermal structures in these vulnerable areas.

Vitamin D is activated in the epidermis by ultraviolet (UV) light, such as sunlight. Once activated, it is distributed by the blood to the GI tract to promote uptake of dietary calcium.

Melanocytes are pigment-producing cells found at the basement membrane. These cells give color to the skin and account for the ethnic differences in skin tone. Darker skin tones are not caused by increased numbers of melanocytes; rather, the size of the pigment granules *(melanin)* contained in each cell determines the color. Melanin protects the skin from damage by UV light, which stimulates melanin production. For this reason, people with dark skin are less likely to develop sunburn than lighter-skinned people. Freckles, birthmarks, and age spots are lesions caused by patches of increased melanin production. Melanin production also increases in areas that have endocrine changes or

inflammation.

Structure of the Skin Appendages

Hair differs in type and function in various body areas. Hair growth varies with race, gender, age, and genetic predisposition. Individual hairs can differ in both structure and rate of growth, depending on body location.

Hair follicles are located in the dermal layer of the skin but are actually extensions of the epidermal layer (see Fig. 24-2). Within each hair follicle, a round column of keratin forms the hair shaft. Hair color is genetically determined by a person's rate of melanin production.

Hair growth occurs in cycles of a growth phase followed by a resting phase. Growth is dependent on a good blood supply and adequate nutrition. Stressors can alter the growth cycle and result in temporary hair loss. Permanent baldness, such as male pattern baldness, is inherited.

Nails on fingers and toes have cosmetic value and are useful for grasping and scraping. Like hair follicles, the nails are extensions of the keratin-producing epidermal layers of the skin.

The white, crescent-shaped portion of the nail at the lower end of the nail plate is the **lunula** and is where nail keratin is formed and nail growth begins (Fig. 24-3). Nail growth is a continuous but slow process. Fingernail replacement requires 3 to 4 months. Toenail replacement may take up to 12 months.

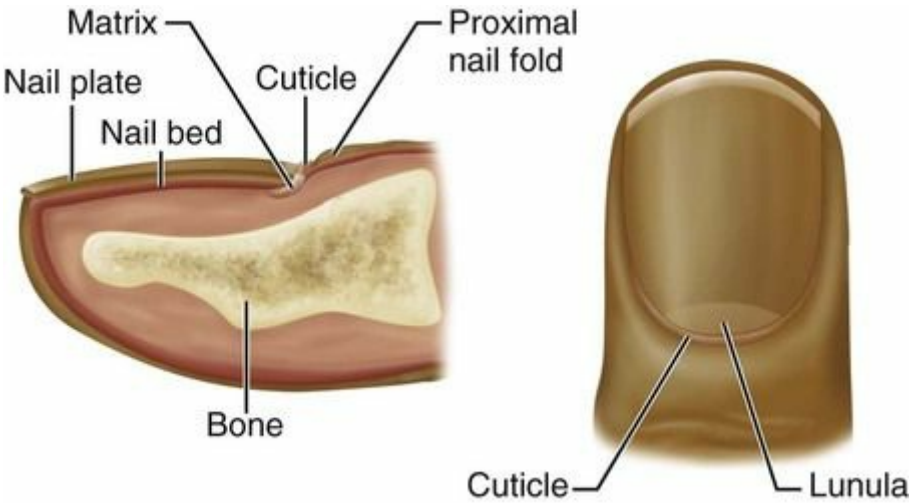

FIG. 24-3 Anatomy of the nail.

The cuticle attaches the nail plate to the soft tissue of the nail fold. The nail body is translucent, and the pinkish hue reflects a rich blood supply

beneath the nail surface. Nail growth and appearance are often altered during systemic disease or serious illness.

Sebaceous glands are distributed over the entire skin surface except for the palms of the hands and soles of the feet. Most of these glands are connected directly to the hair follicles (see Fig. 24-2).

Sebaceous glands produce **sebum,** a mildly bacteriostatic, fat-containing substance. Sebum lubricates the skin and reduces water loss from the skin surface.

Sweat glands of the skin are of two types: eccrine and apocrine. Eccrine sweat glands arise from the epithelial cells. They are found over the entire skin surface and are not associated with the hair follicle. The odorless, colorless secretions of these glands are important in body temperature regulation. This sweat and the resultant water evaporation can cause the body to lose up to 10 to 12 L of fluid in a single day.

Apocrine sweat glands are in direct contact with the hair follicle and are found mostly in the axillae, nipple, umbilical, and perineal body areas. The interaction of skin bacteria with the secretions of these glands causes body odor.

Functions of the Skin

The skin is a complex organ responsible for the regulation of many body functions throughout the life span (Table 24-1) (McCance et al., 2014). In addition to the skin's protective and regulatory functions, its location on the outside of the body makes it an important way to communicate a patient's state of health and body image.

TABLE 24-1

Functions of the Skin

EPIDERMIS	DERMIS	SUBCUTANEOUS TISSUE
Protection		
Keratin provides protection from injury by corrosive materials Inhibits proliferation of microorganisms because of dry external surface Mechanical strength through intercellular bonds	Provides cells for wound healing Provides mechanical strength: Collagen fibers Elastic fibers Ground substance Sensory nerve receptors signal skin injury and inflammation	Mechanical shock absorber Energy reserve Insulation
Homeostasis (Water Balance)		
Low permeability to water and electrolytes prevents systemic dehydration and electrolyte loss	Lymphatic and vascular tissues respond to inflammation, injury, and infection	No real function in water balance
Temperature Regulation		
Eccrine sweat glands allow dissipation of heat through evaporation of sweat secreted onto the skin surface	Cutaneous vasculature promotes or inhibits heat loss from the skin surface	Fat cells insulate and assist in retention of body heat
Sensory Organ		
Transmits a variety of sensations through the neuroreceptor system	Has many nerve receptors for relaying sensations to the brain	Contains large pressure receptors
Vitamin Synthesis		
Allows photoconversion of 7-dehydrocholesterol to active vitamin D	No function	No function
Psychosocial		
Body image alterations occur with many epidermal diseases	Body image alterations occur with many dermal diseases	Body image alterations may result from changes in body fat stores

Skin Changes Associated with Aging

The process of aging begins at birth (Touhy & Jett, 2014). As changes in physiology progress with aging, the skin also undergoes age-related changes in structure and function (Chart 24-1). Figs. 24-4 through 24-8 show age-related skin changes.

Chart 24-1 Nursing Focus on the Older Adult

Changes in the Integumentary System Related to Aging

PHYSICAL CHANGES	CLINICAL FINDINGS	NURSING ACTIONS
Epidermis		
Decreased epidermal thickness	Skin transparency and fragility	Handle patients carefully to reduce skin friction and shear. Assess for excessive dryness or moisture. Avoid taping the skin.
Decreased cell division	Delayed wound healing	Avoid skin trauma, and protect open areas.
Decreased epidermal mitotic homeostasis	Skin hyperplasia and skin cancers (especially in sun-exposed areas)	Assess non-sun-exposed areas for baseline skin features. Assess exposed skin areas for sun-induced changes.
Increased epidermal permeability	Increased risk for irritation	Teach patients how to avoid exposure to skin irritants.
Decreased immune system cells	Decreased skin inflammatory response	Do not rely on degree of redness and swelling to correlate with the severity of skin injury or localized infection.
Decreased melanocyte activity	Increased risk for sunburn	Teach patients to wear hats, sunscreen, and protective clothing. Teach patients to avoid sun exposure from 10 AM to 4 PM.
Hyperplasia of melanocyte activity (especially in sun-exposed areas)	Changes in pigmentation (e.g., liver spots, age spots)	Teach patients to keep track of pigmented lesions. Teach them what changes should be evaluated for malignancy.
Decreased vitamin D production	Increased risk for osteomalacia	Urge patients to take a multiple vitamin or a calcium supplement with vitamin D.
Flattening of the dermal-epidermal junction	Increased risk for shearing forces, resulting in blisters, purpura, skin tears, and pressure-related problems	Avoid pulling or dragging patients. Assist patients confined to bed or chairs to change positions at least every 2 hours. Avoid or use care when removing adhesive wound dressings.
	Dermis	
Decreased dermal blood flow	Increased susceptibility to dry skin	Teach patients to apply moisturizers when the skin is still moist and to avoid agents that promote skin dryness.
Decreased vasomotor responsiveness	Increased risk for heat stroke and hypothermia	Teach patients to dress for the environmental temperatures.
Decreased dermal thickness	Paper-thin, transparent skin with an increased susceptibility to trauma	Handle patients gently, and avoid the use of tape or tight dressings. Use lift sheets when positioning patients.
Degeneration of elastic fibers	Decreased tone and elasticity	Check skin turgor on the forehead or chest.
Benign proliferation of capillaries	Cherry hemangiomas	Teach patients that these are benign.
Reduced number and function of nerve endings	Reduced sensory perception	Tell patients to use bath thermometer and to lower the water heater temperature to prevent scalds.
Subcutaneous Layer		
Thinning subcutaneous layer	Increased risk for hypothermia	Teach patients to dress warmly in cold weather.
	Increased risk for pressure injury	Assist patients confined to bed or chairs to change positions at least every 2 hours.
Hair		
Decreased number of hair follicles and rate of growth	Increased hair thinning	Suggest wearing hats to prevent heat loss in cold weather and to prevent sunburn.
Decreased number of active melanocytes in follicle	Gradual loss of hair color (graying)	Inform patients that hair color loss can occur at any age.
Nails		
Decreased rate of growth	Increased risk for fungal infections	Inspect the nails of all older adults. Teach patients to keep feet clean and dry.
Decreased nail bed blood flow	Longitudinal nail ridges	Use the oral mucosa to assess for cyanosis.
Thickening of the nail	Toenails thicken and may overhang the toes	Use fingernails to assess capillary refill. Cut toenails straight across. Do not use nail appearance alone to assess for a fungal infection. Assess skin next to the nail to determine whether the thick nail is irritating it.
Glands		
Decreased sebum production	Increased size of nasal pores; large comedones	Teach patients not to squeeze the pores or comedones to prevent skin trauma.
Decreased eccrine and apocrine gland activity	Increased susceptibility to dry skin	Urge patients to use soaps with a high fat content. Teach patients to avoid frequent bathing with hot water. Teach patients to apply moisturizers after bathing while skin is moist.
	Decreased perspiration with decreased cooling effect	Do not use sweat production as an indicator of hyperthermia.

FIG. 24-4 Arcus senilis of the iris.

FIG. 24-5 Nail changes: longitudinal ridges and thickening.

FIG. 24-6 Paper-thin, transparent skin with actinic lentigo (liver spots).

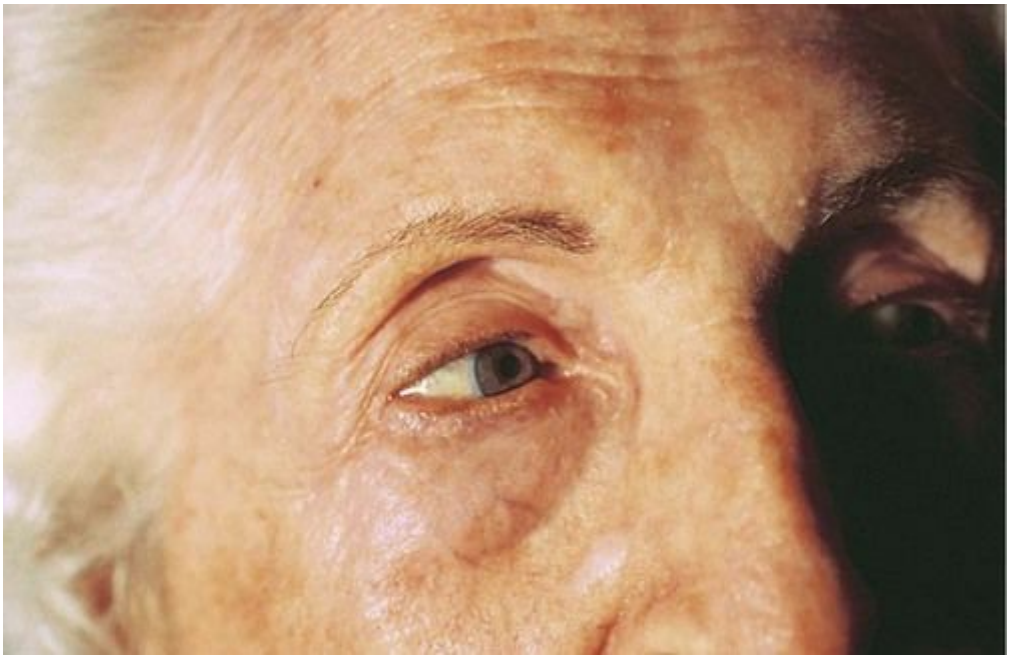

FIG. 24-7 Eyelid eversion, deepening of the eye orbit, and "bags" under the eye.

FIG. 24-8 Senile (cherry) angiomas.

Individual differences exist in how quickly and to what degree the skin ages. Although genetic factors, hormonal changes, and disease may change skin appearance over time, chronic sun exposure is the single most important factor leading to degeneration of the skin components.

Assessment Methods

Patient History

Take an accurate history from the patient so that skin problems can be readily identified. Chart 24-2 highlights specific questions to ask during a skin assessment.

Chart 24-2 Best Practice for Patient Safety & Quality Care QSEN

Questions to Obtain an Accurate Nursing History of the Patient with a Skin Problem

Medical-Surgical History

- Do you have any current or previous medical problems?
- Have you undergone any recent or previous surgical procedures?

Family History

- Is there any family tendency toward chronic skin problems?
- Do any members of your immediate family have recent skin problems?

Medication History

- Are you allergic to any drugs? If so, describe the reaction.
- What prescription drugs have you taken recently? When was the drug started? What is the dose or frequency of administration? When was the last dose taken?
- What over-the-counter drugs have you taken recently? When was the drug started? What is the dose or frequency of administration? When was the last dose taken?

Social History

- What is your occupation?
- What recreational activities do you enjoy?
- Have you traveled recently?
- What is your nutrition status?
- Do you use tobacco or recreational drugs or drink alcohol?

Current Health Problem

- When did you first notice the skin problem?
- Where on the body did the problem begin?
- Has the problem gotten better or worse?

- Has a similar skin condition ever occurred before? If so, what was the course and how was it treated?
- Is the problem associated with any itching, burning, stinging, numbness, pain, fever, nausea and vomiting, diarrhea, sore throat, cold, stiff neck, new foods, new soaps or cosmetics, new clothing or bed linens, or stressful situations?
- What seems to make the problem worse?
- What seems to make the problem better?

Demographic data include age, race, occupation, and hobbies or recreational activities. This information can help identify causative or aggravating factors for skin problems. Age is important because many changes in the skin, hair, and nails are normal for the aging process.

Ethnicity can also be important. Some variations in skin appearance are normal for patients of some ethnicities but are abnormal for those of other races or ethnicities.

Information about occupation and hobbies can provide clues to chronic skin exposure to chemicals, irritants, and other substances that can contribute to skin problems.

Socioeconomic status data can help identify environmental factors that might contribute to skin disease. Unhealthy or crowded living conditions promote the spread of contagious skin pathogens. Recent or frequent travel to tropical climates may be a source of unusual skin infections or infestations.

Regardless of skin color or ethnicity, always ask patients about the amount of time spent in the sun and tanning booths and identify skin problems related to sun overexposure. Use this time to teach the patient about the harmful aspects of sun exposure and how to reduce risk. Also determine whether he or she regularly assesses the skin for lesion development or changes.

Skin problems related to poor hygiene are common. Ask about living conditions and bathing practices. Teach people that keeping the skin and hair clean by bathing and shampooing regularly helps maintain the skin's health.

Information about drug use is important because prescribed drugs, over-the-counter (OTC) drugs, herbal preparations or remedies, and tobacco use can cause skin reactions or affect skin function. Ask about any recent use of prescription drugs, OTC drugs (e.g., laxatives, antacids, cold remedies), and herbal preparations or remedies. Determine when each drug was started, the dose and frequency of the drug, and the time the last dose was taken. Ask the patient whether skin changes began after

starting a new drug. A drug history also helps identify skin changes that result from management of other health problems, such as the changes that occur with long-term steroid or anticoagulant therapy.

Allergies to environmental substances often have skin manifestations. The allergies may be well documented or have a new onset. Ask about the use of any new personal care product (e.g., shaving products, perfumes, soap, shampoo, lotion, makeup, hair gel), laundry detergents and softeners, and home cleaning products. Ask whether the patient wears gloves to avoid direct contact with cleaning solutions. New clothing may contain chemicals that irritate the skin. Noting the body location(s) of the skin problem can help determine its cause.

Nutrition Status

Document the patient's weight, height, body build and fat distribution, and food preferences. Protein deficiencies, vitamin deficiencies, and obesity can increase the risk for skin lesions and delay wound healing. Fat-free diets and chronic alcoholism can lead to vitamin deficiencies and related skin changes. Skin problems such as chronic urticaria and acne may be worsened by certain foods or food additives.

Hydration influences overall skin health, and the skin reflects hydration status. Reduced fluid intake can lead to dry skin. Skin manifestations of severe fluid losses are seen as loose skin that tents when pinched together. Fluid overload with edema can stretch the skin, masking wrinkles and allowing the formation of skin "pits" (i.e., pitting edema) when pressure is applied to it.

Family History and Genetic Risk

Many skin problems (e.g., psoriasis, keloid formation, eczema) have a familial predisposition. Explore any family tendency of chronic skin problems. Ask about immediate family members' current health to identify a transmittable disorder (e.g., ringworm, scabies).

Current Health Problems

Begin by gathering information about skin changes and skin care practices (see Chart 24-2).

If a skin problem is identified, obtain more information about the specific problem, such as:

- When did the patient first notice the rash or skin change?
- Where on the body did the rash begin?

• Has the problem improved or become worse?

If the problem has occurred before, ask the patient to describe the course of the skin lesion and how it was treated. Try to link the problem with manifestations, such as itching, burning, numbness, pain, fever, sore throat, stiff neck, or nausea and vomiting. Ask him or her to identify anything that seems to make the problem better or worse.

Skin Assessment

Inspection

Skin changes may be related to a specific skin disease or reflect a systemic disorder. Use a thorough skin assessment to identify clues about a patient's overall state of health.

A thorough assessment of the skin is best performed with the patient undressed. (Always provide privacy to maintain the patient's dignity.) Incorporate skin examination as a routine part of daily care during the bath or when assisting with hygiene.

Inspect the patient's skin surfaces in a well-lighted room; natural or bright fluorescent lighting makes subtle skin changes more visible. Use a penlight to closely inspect lesions and to illuminate the mouth.

Assess each skin surface systematically, including the scalp, hair, nails, and mucous membranes. Give particular attention to the skinfold areas. The moist, warm environment of skinfolds can harbor organisms, such as yeast or bacteria. Observe and document these features:

• Obvious changes in color and vascularity
• Presence or absence of moisture
• Edema
• Skin lesions
• Skin integrity

Check the cleanliness of the various body areas to determine whether the patient's self-care activities need to be evaluated.

Skin color is affected by blood flow, oxygenation, body temperature, and pigmentation. The wide variation in skin tones requires different techniques for patients who have darker skin. (See the Cultural Considerations box for tips for assessing patients with darker skin.)

Describe and document changes in skin color by their appearance (Table 24-2). Include in your description whether the changes are general or confined to one body region. Color changes are more visible in the areas of least pigmentation, such as the oral mucosa, sclera, nail beds, and palms and soles. Inspect these areas to help confirm more subtle color changes of general body areas.

TABLE 24-2

Common Alterations in Skin Color

ALTERATION	UNDERLYING CAUSE	LOCATION	SIGNIFICANCE
White (pallor)	Decreased hemoglobin level	Conjunctivae	Anemia
	Decreased blood flow to the skin (vasoconstriction)	Mucous membranes Nail beds Palms and soles Lips	Shock or blood loss Chronic vascular compromise Sudden emotional upset Edema
	Genetically determined defect of the melanocyte (decreased pigmentation)	Generalized	Albinism
	Acquired patchy loss of pigmentation	Localized	Vitiligo, tinea versicolor
Yellow-orange	Increased total serum bilirubin level (jaundice)	Generalized Mucous membranes Sclera	Hemolysis of red blood cells Liver disorders
	Increased serum carotene level (carotenemia)	Perioral Palms and soles Ears and nose Absent in sclera and mucous membranes	Increased ingestion of carotene-containing foods (carrots) Pregnancy Thyroid deficiency Diabetes
	Increased urochrome level	Generalized Absent in sclera and mucous membranes	Chronic kidney disease (uremia)
Red (erythema)	Increased blood flow to the skin (vasodilation)	Generalized	Generalized inflammation (e.g., erythroderma)
		Localized (to area of involvement)	Localized inflammation (e.g., sunburn, cellulitis, trauma, rashes)
		Face, cheeks, nose, upper chest Area of exposure	Fever, increased alcohol intake Exposure to cold
Blue	Increase in deoxygenated blood (cyanosis)	Nail beds Mucous membranes Generalized	Cardiopulmonary disease Methemoglobinemia
	Bleeding from vessels into tissue:		
	Petechiae (1-3 mm)	Localized	Thrombocytopenia
	Ecchymosis (>3 mm)	Localized	Increased blood vessel fragility
Reddish blue	Increased overall amount of hemoglobin	Generalized	Polycythemia vera
	Decreased peripheral circulation	Distal extremities, nose	Inadequate tissue perfusion
Brown	Increased melanin production	Localized (to area of involvement) Pressure points, areolae, palmar creases, and genitalia	Chronic inflammation Exposure to sunlight Addison's disease
		Face, areolae, vulva, linea nigra	Pregnancy; oral contraceptives (melasma)
	Café au lait spots (tan-brown patches):		
	<6 spots	Localized	Nonpathogenic
	>6 spots	Generalized	Possible neurofibromatosis
	Melanin and hemosiderin deposits (bronze or grayish tan color)	Distal lower extremities	Chronic venous stasis
		Exposed areas or generalized	Hemochromatosis

Lesions in skin disease are clinically described in terms of primary and secondary lesions (Fig. 24-9). **Primary lesions** are an initial reaction to a problem that alters skin components. **Secondary lesions** are changes in the appearance of the primary lesion. These changes occur with progression of an underlying disease or in response to a topical or systemic therapeutic intervention. For example, acute dermatitis often occurs as primary vesicles with associated **pruritus** (itching). Secondary lesions in the form of crusts occur as the patient scratches, the vesicles are opened, and the exudate dries. With chronic dermatitis, the skin often becomes **lichenified** (thickened) because of the patient's continual

rubbing of the area to relieve itching.

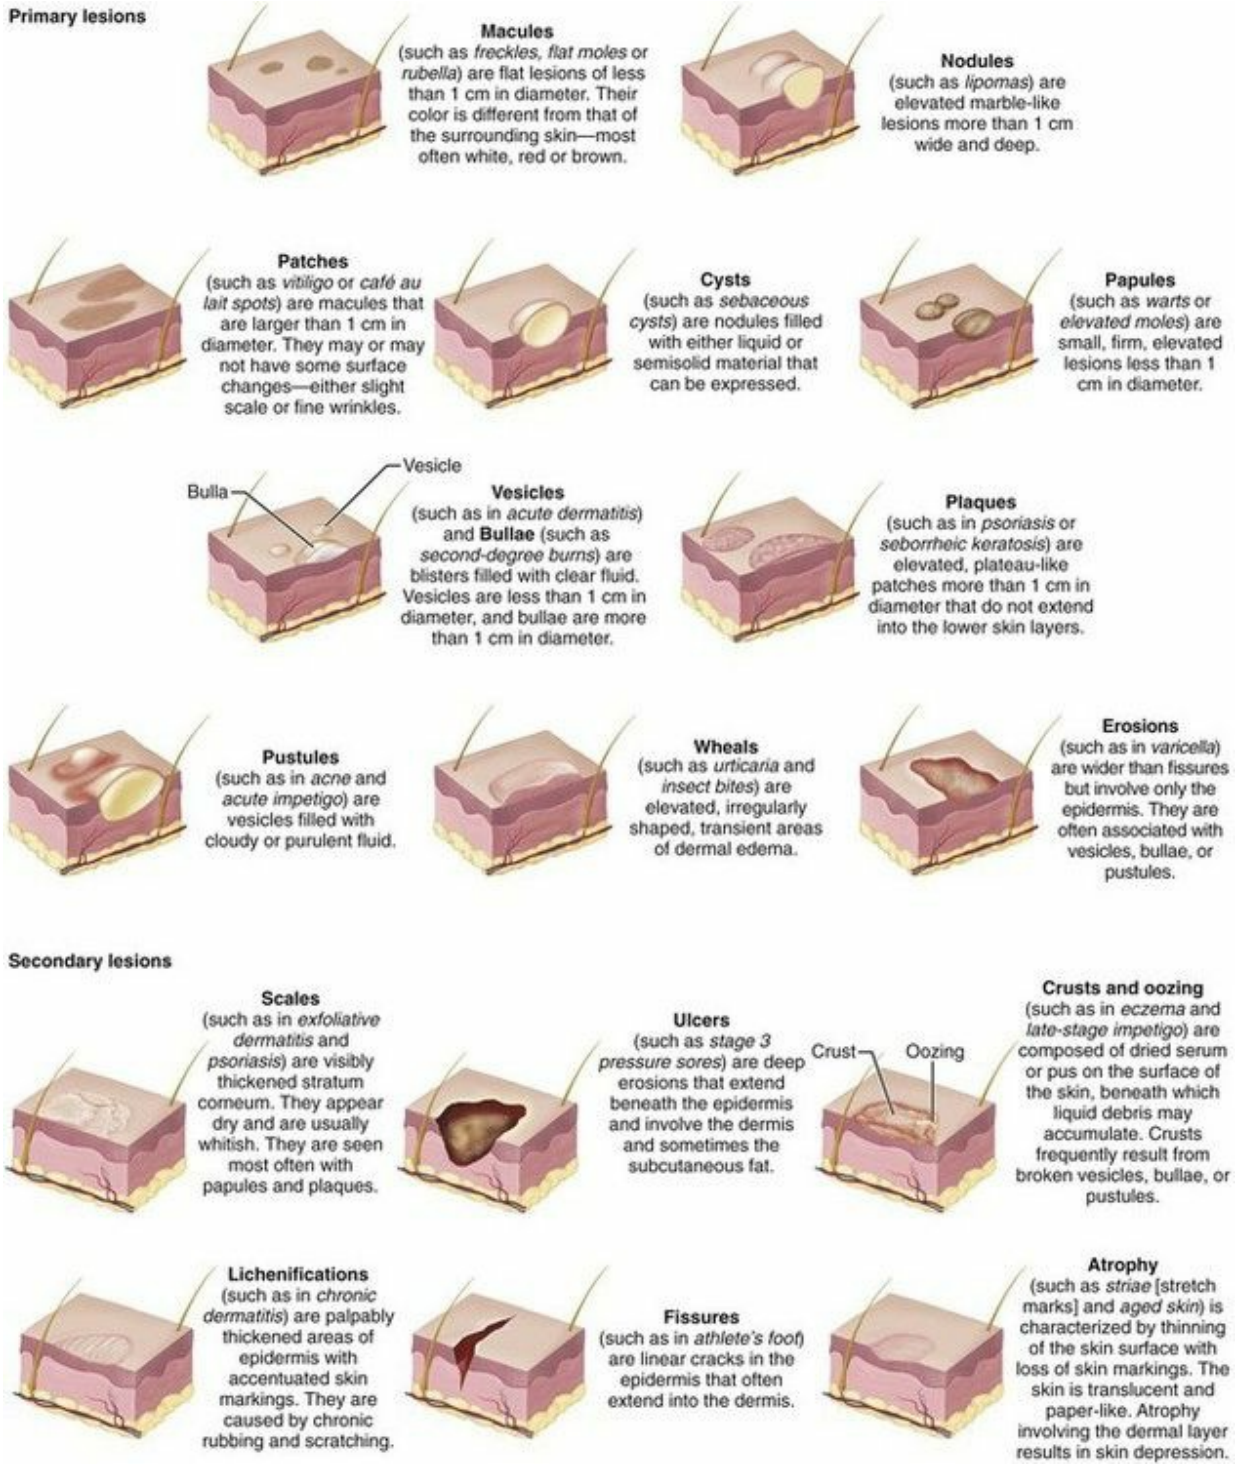

FIG. 24-9 Classification of skin lesions.

Describe lesions by color, size, location, and shape. Note whether they are isolated or are grouped and form a distinct pattern. Table 24-3 defines terms used to describe lesions.

TABLE 24-3

Terms Commonly Used to Describe Skin Lesion Configurations

annular Ringlike with raised borders around flat, clear centers of normal skin
circinate Circular
circumscribed Well-defined with sharp borders
clustered Several lesions grouped together
coalesced Lesions that merge with one another and appear confluent
diffuse Widespread, involving most of the body with intervening areas of normal skin; generalized
linear Occurring in a straight line
serpiginous With wavy borders, resembling a snake
universal All areas of the body involved, with no areas of normal-appearing skin

Assess each lesion for these ABCDE features that are associated with skin cancer (The Skin Cancer Foundation, 2014):

- **A**symmetry of shape
- **B**order irregularity
- **C**olor variation within one lesion
- **D**iameter greater than 6 mm
- **E**volving or changing in any feature (shape, size, color, elevation, itching, bleeding, or crusting)

Teach patients these signs, and encourage them to perform skin self-examination on a monthly basis (American Cancer Society, 2014). *A patient who has a lesion with one or more of the ABCDE features should be evaluated by a dermatologist or surgeon.*

In describing location, determine whether lesions are generalized or localized. If the lesions are localized, identify the specific body areas involved. This information is important because some diseases have a specific pattern of skin lesions. For example, involvement of only the sun-exposed areas of the body is important when considering possible causes. Rashes limited to the skinfold areas (e.g., on the axillae, beneath the breasts, in the groin) may reflect problems related to friction, heat, and excessive moisture.

Edema causes the skin to appear shiny, **taut** (tightly stretched), and paler than uninvolved skin. During skin inspection, document the location, distribution, and color of areas of edema.

Skin elasticity is affected by edema. Using moderate pressure, place the tip of a finger against edematous tissue to determine the degree of indentation, or pitting (see Chapter 11).

Moisture content is assessed by noting the thickness and consistency of secretions. Normally, increased moisture in the form of sweat occurs with increased activity or elevated environmental temperatures. Dampness of skinfold areas occurs with reduced air circulation where the skin surfaces

touch. Excess moisture can cause impaired tissue integrity with skin breakdown in bedridden and debilitated patients.

Overly dry skin is caused by a dry environment, poor skin lubrication, inadequate fluid intake, and the normal aging process. Dry skin usually has scaling and flaking and may be especially marked in areas of limited circulation, such as the feet and lower legs. It is a common problem during the winter months when the air contains less moisture, living in geographic areas with little humidity, and in the hospital environment where humidity is often low.

Vascular changes or markings may be normal or abnormal, depending on the cause. Normal vascular markings include birthmarks, cherry angiomas (see Fig. 24-8), spider angiomas, and venous stars. Bleeding into the skin is abnormal and results in **purpura** (bleeding under the skin that may progress from red to purple to brownish yellow), petechiae, and ecchymosis.

Petechiae are small, reddish purple lesions (<0.5 mm in diameter) that do not fade or blanch when pressure is applied (Fig. 24-10). They often indicate increased capillary fragility. Petechiae of the lower extremities often occur with stasis dermatitis, a condition usually seen with chronic venous insufficiency.

FIG. 24-10 Petechiae.

Ecchymoses (bruises) are larger areas of hemorrhage. In older adults, bruising is common after minor trauma to the skin. Certain drugs (e.g.,

aspirin, warfarin, corticosteroids) and low platelet counts lead to easy or excessive bruising. Anticoagulants and decreased numbers of platelets disrupt clotting action, resulting in ecchymosis.

Skin tissue integrity is assessed by first examining areas with actual breaks or open areas. For example, skin tears are a common finding in older people as a result of aging. The thin, fragile skin is easily damaged by friction or shearing forces, especially if bruising is already present. Look for skin tears in these areas:

- Where constricting clothing rubs against the skin
- On the upper extremities, where the skin is grasped when assisting a patient to ambulate or change position
- Where adhesive tapes or dressings have been applied and removed

Check for the presence of multiple abrasions or early pressure-related skin changes. These changes may indicate unrecognized problems in mobility or sensory perception.

Describe breaks in skin tissue integrity by their location, size, color, and distribution and by the presence of drainage or infection. The evaluation of partial-thickness and full-thickness wounds, including objective criteria that describe progress toward healing, is discussed in Chapter 25.

Cleanliness of the skin is evaluated to learn about self-care needs. Inspect the hair, nails, and skin closely for excessive soiling and offensive odor. Depending on a patient's degree of self-care deficit, hard-to-reach areas (e.g., perirectal and inguinal skinfolds, axillae, feet) may be less clean than other skin surface areas. Staining may occur during work or leisure activities.

Patients who have cognitive problems may not pay attention to hygiene measures. Assess the cognition of any patient whose hygiene of the skin, hair, or nails appears inadequate.

Tattoos and piercings can cause or mask skin problems and must be carefully examined. Bruises and rashes may be difficult to see in tattooed areas. Examine newly pierced areas for inflammation or infection. Scars may be present in old tattoos or pierced areas and should be documented. Closely examine any areas where tattoos have been removed. Skin cancer is more likely to occur in these areas.

NCLEX Examination Challenge

Physiological Integrity

During skin inspection the nurse observes two brown lesions on the older client's upper back. The lesions are large and irregular with a

consistently rough texture and a raised border. Which descriptors does the nurse use to document these observations?
A Annular, macular
B Confluent, fissured
C Circumscribed, plaquelike
D Serpiginous, pustular, linear

Palpation

Skin inspection can be misleading in areas of color changes, tattoos, and piercings. Use palpation to gather additional information about skin lesions, moisture, temperature, texture, and turgor (Table 24-4). Wash hands thoroughly before and after palpating a patient's skin. Use gloves to examine nonintact skin, and use Standard Precautions when skin areas are draining.

TABLE 24-4

Common Clinical Findings In Skin Palpation

CLINICAL FINDINGS	CAUSE	LOCATION	EXAMPLES OF PREDISPOSING CONDITIONS
Edema			
Localized	Inflammatory response	Area of involvement	Trauma
Dependent or pitting	Fluid and electrolyte imbalance Venous and cardiac insufficiency	Ambulatory: dorsum of foot and medial ankle Bedridden: buttocks, sacrum, and lower back	Congestive heart failure Kidney disease Liver cirrhosis Venous thrombosis or stasis
Nonpitting	Endocrine imbalance	Generalized, but more easily seen over the tibia	Hypothyroidism (myxedema)
Moisture			
Increased	Autonomic nervous system stimulation	Face, axillae, skinfolds, palms, and soles	Fever, anxiety, activity Hyperthyroidism
Decreased	Dehydration Endocrine imbalance	Buccal mucous membranes with progressive involvement of other skin surfaces	Fluid loss Postmenopausal status Hypothyroidism Normal aging
Temperature			
Increased	Increased blood flow to the skin	Generalized	Fever, hypermetabolic states Neurotrauma
		Localized	Inflammation
Decreased	Decreased blood flow to the skin	Generalized	Impending shock, sepsis, anxiety Hypothyroidism
		Localized	Interference with vascular flow
Turgor			
Decreased	Decreased elasticity of the dermis (tenting when pinched)	Abdomen, forehead, or radial aspect of the wrist	Severe dehydration Sudden, severe weight loss Normal aging
Texture			
Roughness or thickness	Irritation, friction	Pressure points (e.g., soles, palms, elbows) Localized areas of pruritus	Calluses Chronic eczema Atopic skin diseases
	Sun damage	Areas of sun exposure	Normal aging
	Excessive collagen production	Localized or generalized	Scleroderma Scars and keloids
Softness or smoothness	Endocrine disturbances	Generalized	Hyperthyroidism

Palpation confirms lesion size and whether they are flat or slightly raised. Consistency of larger lesions can vary from soft and pliable to firm and solid. Subtle changes, such as the difference between a fine **macular** (flat) rash and a **papular** (raised) rash, are best determined by palpating with your eyes closed. Ask the patient whether skin palpation causes pain or tenderness.

In areas of excess dryness, rub your finger against the skin surface to determine the degree of flaking or scaling. Changes in skin temperature are detected by placing the back of your hand on the skin surface. First, make certain to have warm hands. Cold hands interfere with accurate assessment and are uncomfortable for the patient.

Palpate skin surfaces to assess texture, which differs according to body area and exposure to irritants. For example, areas of long-term sun exposure have a rougher texture than protected skin surfaces. The patient

who has repeated exposure to harsh soaps or chemicals may show skin changes related to this exposure. Increased skin thickness from scarring, lichenification, or edema usually decreases elasticity.

Turgor indicates the amount of skin elasticity. Skin turgor can be altered by water content and aging. Gently pinch the patient's skin between your thumb and forefinger, and then release. If skin turgor is normal, the skin immediately returns to its original state when released. Poor skin turgor is seen as "tenting" of the skin, with a gradual return to the original state (see Chapter 11). Loss of elasticity with aging makes the assessment of skin turgor difficult in an older patient.

Nursing Safety Priority QSEN

Action Alert

To avoid mistaking dehydration for dry skin in an older adult, always assess skin turgor on the forehead or chest.

Hair Assessment

During the skin assessment, inspect and palpate the hair for general appearance, cleanliness, distribution, quantity, and quality. Hair is normally found in an even distribution over most of the body surfaces, with the hair on the scalp, in the pubic region, and in the axillary folds thicker and coarser than hair on the trunk, arms, and legs. Although color and growth patterns vary, sudden changes in hair characteristics may reflect an underlying disease. Check any abnormal findings by obtaining a detailed history of the change.

How well the hair is groomed, including the cleanliness of areas of thicker hair growth, can confirm information about a patient's social history and health care needs. If the patient has intense itching or scratches continually, examine the scalp and pubis for lice and **nits** (lice eggs). Inspect the scalp for scaling, redness, open areas, crusting, and tenderness.

Dandruff, a collection of patchy or diffuse white or gray scales on the surface of the scalp, is common. The flaking that occurs with dandruff causes many people to mistakenly think the scalp is too dry; however, it is a problem of excessive oil production. Dandruff is a cosmetic problem, but a very oily scalp can induce inflammatory changes with redness and itching. Severe inflammatory dandruff can extend to the eyebrows and the skin of the face and neck. *If severe dandruff is not treated, hair loss can occur.* Teach the patient that dandruff is not caused by dryness and should

be treated to prevent hair loss.

Although gradual hair loss occurs with aging, sudden asymmetric or patchy hair loss at any age is of concern. Assess the scalp for hair distribution and thickness, and document variations. Body hair loss, especially on the feet or lower legs, may occur with decreased blood flow to the area and also is a part of aging.

Hirsutism is excessive growth of body hair or hair growth in abnormal body areas. Increased hair growth across the face and chest in women is a sign of hirsutism. It may occur on the face of a woman as part of aging, is one manifestation of hormonal imbalance, and can also occur as a side effect of drug therapy. If hirsutism is present, look for changes in fat distribution and capillary fragility, which can occur in Cushing's disease, and for clitoral enlargement and deepening of the voice, which may indicate ovarian dysfunction.

Nail Assessment

Dystrophic (abnormal-appearing) nails may occur with a serious systemic illness or local skin disease involving the epidermal keratinocytes. Assess the fingernails and toenails for color, shape, thickness, texture, and the presence of lesions.

Many variations in color, texture, and grooming of the nails are influenced by factors unrelated to disease, such as occupation. When assessing the older adult, observe for minor variations associated with the aging process (see Fig. 24-5), such as a gradual thickening of the nail plate, the presence of longitudinal ridges, or a yellowish gray discoloration.

Color of the nail plate depends on nail thickness and transparency, amount of red blood cells, arterial blood flow, and pigment deposits (Table 24-5). Fig. 24-11 shows normal variations in nail color. Changes in color can be caused by chemical damage that occurs with some occupations and with the long-term use of nail polish. Regardless of skin color, the healthy nail blanches (lightens) with pressure.

TABLE 24-5
Common Alterations in Nail Color

ALTERATION	CLINICAL FINDINGS	SIGNIFICANCE
White	Horizontal white banding or areas of opacity	Chronic liver or kidney disease (hypoalbuminemia)
	Generalized pallor of nail beds	Shock Anemia Early arteriosclerotic changes (toenails) Myocardial infarction
Yellow-brown	Diffuse yellow to brown discoloration	Jaundice Peripheral lymphedema Bacterial or fungal infections of the nail Psoriasis Diabetes Cardiac failure Staining from tobacco, nail polish, or dyes Long-term tetracycline therapy Normal aging (yellow-gray color)
	Vertical brown banding extending from the proximal nail fold distally	Normal finding in dark-skinned patients Nevus or melanoma of nail matrix in light-skinned patients
Red	Thin, dark red vertical lines 1-3 mm long (splinter hemorrhages)	Bacterial endocarditis Trichinosis Trauma to the nail bed Normal finding in some patients
	Red discoloration of the lunula	Cardiac insufficiency
	Dark red nail beds	Polycythemia vera
Blue	Diffuse blue discoloration that blanches with pressure	Respiratory failure Methemoglobinuria Venous stasis disease (toenails)

FIG. 24-11 **A,** Diffuse nail pigmentation. **B,** Linear nail pigmentation.

During examination, the patient's fingers and toes should be free of any surface pressure that interferes with local blood flow or alters the appearance of the digits. To differentiate between color changes from the underlying blood supply and those from pigment deposits, blanch the nail bed to see whether the color changes with pressure. Gently squeeze the end of the finger or toe, exerting downward pressure on the nail bed,

and then release the pressure. Color caused by blood flow changes as pressure is applied and returns to the original state when pressure is released. Color caused by pigment deposits remains unchanged.

Nail shape changes may be related to systemic disease. For example, fingernail clubbing occurs with impaired gas exchange. (See Fig. 30-10 in Chapter 30.)

Assess nail shape by examining the curve of the nail plate and surrounding tissue from all angles. Palpate the fingertips to assess for sponginess, tenderness, or edema. Table 24-6 describes common variations in nail shape.

TABLE 24-6

Common Variations In Nail Shape

NAIL SHAPE	CLINICAL FINDINGS		SIGNIFICANCE
Normal	Angle of 160 degrees between the nail plate and the proximal nail fold Nail surface slightly convex Nail base firm when palpated		Normal finding
Clubbing:			
Early clubbing	Straightening of angle between the nail plate and the proximal nail fold to 180 degrees Nail base spongy when palpated		Hypoxia Lung cancer
Late clubbing	Angle between the nail plate and the proximal nail fold exceeds 180 degrees Nail base visibly edematous and spongy when palpated Enlargement of the soft tissue of the fingertips gives a "drumstick" appearance when viewed from above		Prolonged hypoxia Emphysema Chronic obstructive pulmonary disease Advanced lung cancer Cystic fibrosis Chronic heart disease
Spoon nails (koilonychia):			
Early koilonychias	Flattening of the nail plate with an increased smoothness of the nail surface		Iron deficiency (with or without anemia) Poorly controlled diabetes >15 yr in duration Local injury
Late koilonychias	Concave curvature of the nail plate		Psoriasis Chemical irritants Developmental abnormality
Beau's grooves	1-mm–wide horizontal depressions in the nail plates caused by growth arrest (involves all nails)		Acute, severe illness Prolonged febrile state Isolated periods of severe malnutrition
Pitting	Small, multiple pits in the nail plate May be associated with plate thickening and onycholysis Most often involves the fingernails (several or all)		Psoriasis Alopecia areata

Thickness of the nail plate varies with age, trauma, dermatologic disease, or decreased arterial blood flow. In older patients, look for a

"heaped-up" appearance of the toenails, which occurs with fungal infection *(onychomycosis).*

Consistency of the nail is described as hard, soft, or brittle. Nail plates become hard, with thickening. A warm-water soak or lubrication with petroleum jelly is required to soften the nail plates before they can be trimmed. Soft nail plates, which are thin and bend easily with pressure, are associated with malnutrition, chronic arthritis, myxedema, and peripheral neuritis.

Brittle nails can split, as with onychomycosis or advanced psoriasis involving the fingers or toes. Splitting of the nail plate is caused by repeated exposure to water and detergents, which damage the plate over time.

Lesions can occur around, on, within, or under the nail. Separation of the nail plate from the nail bed *(onycholysis)* creates an air pocket beneath the plate. The pocket first appears as a grayish white opacity. The color changes as dirt and keratin collect in the pocket, and the area begins to have a bad odor. This problem occurs with fungal infections and after trauma. Separation of the nail plate may also occur with psoriasis or with prolonged chemical contact.

Inspect the tissue folds around the nail plate for redness, heat, swelling, and tenderness. **Acute paronychia** (inflammation of the skin around the nail) often occurs with a torn cuticle or an ingrown toenail.

Chronic paronychia is common and is an inflammation that persists for months. People at risk for chronic paronychia are those with frequent exposure to water, such as homemakers, bartenders, laundry workers, and nurses.

Cultural Considerations

Patient-Centered Care QSEN

Pallor, erythema, cyanosis, and other skin color changes are less visible in patients with naturally dark skin tones. Although physiologic processes are the same for both light-skinned and dark-skinned patients, the amount of skin pigmentation alters how the skin appears in response to physiologic alterations. Different assessment skills are needed to detect the more subtle color changes. Become familiar with the normal appearance of a dark-skinned patient's mucous membranes, nail beds, and skin tone so that variations from baseline can be identified. Chart 24-3 lists assessment techniques to assess skin manifestations in people with dark skin.

Chart 24-3 Best Practice for Patient Safety & Quality Care QSEN

Assessing Changes in Dark Skin

Cyanosis

- Examine lips and tongue for gray color.
- Examine nail beds, palms, and soles for blue tinge.
- Examine conjunctiva for pallor.

Inflammation

- Compare affected area with nonaffected area for increased warmth.
- Examine the skin of the affected area to determine whether it is shiny or taut or pits with pressure.
- Compare the skin color of affected area with the same area on the opposite side of the body.
- Palpate the affected area and compare it with unaffected area to determine whether texture is different (affected area may feel hard or "woody").

Jaundice

- Check for yellow tinge to oral mucous membranes, especially the hard palate.
- Examine the sclera nearest to the iris rather than the corners of the eye.

Bleeding

- Compare the affected area with the same area on the unaffected body side for swelling or skin darkening.
- If the patient has thrombocytopenia, petechiae may be present on the oral mucosa or conjunctiva.

Skin Assessment Techniques for Patients with Darker Skin

Pallor can be detected in people with dark skin by first inspecting the mucous membranes for an ash-gray color (Jarvis, 2016). If the lips and the nail beds are not heavily pigmented, they appear paler than normal for that patient. Use good lighting to assess for the absence of the underlying red tones that normally give heavily pigmented skin a healthy glow. With decreased blood flow to the skin, brown skin appears yellow-brown and very dark brown skin is ash gray.

Cyanosis can be present when gas exchange is impaired. Examine the lips, tongue, nail beds, conjunctivae, and palms and soles for subtle color changes (Jarvis, 2016). In a patient with cyanosis, the lips and tongue are gray and the palms, soles, conjunctivae, and nail beds have a bluish tinge. To support these findings, assess for other indicators of hypoxia, including tachycardia, hypotension, changes in respiratory rate, decreased breath sounds, and changes in cognition.

Inflammation in dark-skinned patients appears as excessive warmth and changes in skin consistency or texture (Jarvis, 2016)>. Use the back of your hand to palpate areas of suspected inflammation for increased warmth. With the fingertips, palpate for hardened areas deep in the tissue, which may give the skin a "woody" feel. Inflamed skin is tender and edematous. If edema is extensive, the skin is taut and shiny.

Skin areas where inflammation has recently resolved appear *darker* than the patient's normal skin tone. This change is due to stimulation of the melanocytes during the inflammatory process and to the increased pigment production that continues after inflammation subsides. Deep skin injury with destruction of melanocytes (e.g., deep ulcer, full-thickness burn) may heal with color changes that are *lighter* than the normal skin tone. Chronic inflammatory changes are not tender. Scarred skin feels less supple, especially over the joints. If chronic inflammatory changes are suspected, ask the patient about a history of skin problems in that area.

Jaundice in a patient with dark skin is best assessed by inspecting the oral mucosa, especially the hard palate, for yellow discoloration (Jarvis, 2016). Yellowness of the conjunctivae and adjacent sclera may be misleading because normal deposits of fat produce a yellowish hue that is visible in contrast to the dark skin around the eyes. Examine the sclera closest to the cornea for a more accurate determination of jaundice. The palms and soles of dark-skinned patients may appear yellow if they are calloused even when jaundice is not present.

Skin bleeding with purpuric lesions may not be visible with deep pigmentation. Areas of ecchymoses appear darker than normal skin; they may be tender and easily palpable, depending on whether hematoma is present. Often, the patient relates a history of trauma to the area that confirms the assessment. Petechiae are rarely visible in dark skin and may be seen only in the oral mucosa and conjunctiva.

Psychosocial Assessment

Skin changes, especially of the face, hair, and hands, often affect a

person's body image. Encourage the patient to express his or her feelings about a change in appearance. Assess his or her body language for clues indicating a disturbance in self-concept. The avoidance of eye contact or the use of clothing to cover the affected areas suggests concern about appearance. Patients with chronic skin diseases often become socially isolated related to a fear of rejection by others or a belief that the skin problem is contagious.

Skin changes linked to poor hygiene are common among homeless people and among those who have reduced cognitive functioning. Assess the patient's overall appearance for excessive soiling, matted hair, body odor, or other self-care deficits. Confirm unsanitary living conditions by obtaining a social history. Patients may relate similar skin problems among family members, friends, and sexual contacts.

If skin problems related to poor hygiene are identified in older patients, also evaluate any physical limitations that might interfere with grooming. For example, visual or mobility problems can make it difficult for them to see or reach skin surfaces to clean them.

Clinical Judgment Challenge

Patient-Centered Care QSEN

A 55-year-old woman who has blonde hair, very light skin, and blue eyes is being seen because she noticed the recent development several light-brown, flat, irregularly shaped spots on her face just below and in front of her right ear. Although these spots do not extend into the surrounding skin, she is concerned about their appearance on her otherwise flawless complexion and is worried that they may be skin cancer. When asked about her sun exposure, she tells you that her only sun exposure is when she plays golf (4 times per week) and that she uses sunscreen on her arms, legs, and neck. She also says she wears a hat with a front brim while playing golf. When you ask about facial skin protection, she tells you that because she wears makeup, she does not use sunscreen on her face.

1. What other assessment data should you obtain?
2. What risk factors does this woman have for skin cancer?
3. Do the facial lesions have any concerning features? If so, which ones?
4. How should you counsel this woman?

Diagnostic Assessment

Laboratory Tests

When a fungal, bacterial, or viral infection of the skin is suspected, confirmation by microscopic examination is necessary. *Always wear gloves (use Standard Precautions) when examining skin that is not intact.*

Cultures for fungal infection are obtained by using a tongue blade and gently scraping scales from skin lesions into a clean container. Collect fingernail clippings and hair in a similar manner. Waiting for culture results can delay treatment of a superficial fungal infection. For this reason, the specimen is also treated with a potassium hydroxide (KOH) solution and examined microscopically. A positive fungal infection shows branched hyphae when viewed under a microscope after treatment with KOH and may eliminate the need for a culture.

For deeper fungal infections, a piece of tissue is obtained for culture. The physician obtains the specimen by punch biopsy (see the following Skin Biopsy section). Check with the laboratory for any specific instructions related to specimen handling.

Cultures for bacterial infection are obtained from intact primary lesions (bullae, vesicles, or pustules), if possible. Express material from the lesion, collect it with a cotton-tipped applicator, and place the material in a bacterial culture medium specified by the laboratory. For intact lesions, *unroofing* (lifting or puncturing of the outer surface) may be needed using a sterile small-gauge needle before the material can be easily expressed. If crusts are present, the nurse or other health care professional removes the crusts with normal saline and then swabs the underlying exudates to obtain a specimen for culture (Cross, 2014).

A biopsy of deep bacterial infections may be needed to obtain a specimen for culture. If bacterial cellulitis is suspected, the physician or advanced practice nurse can inject nonbacteriostatic saline deep into the tissue and then aspirate it back; the aspirant is sent for culture.

Cultures for viral infection are indicated if a herpes virus infection is suspected. A cotton-tipped applicator is used to obtain vesicle fluid from intact lesions. Viral culture specimen tubes must be placed on ice immediately after specimens are obtained and are transported to the laboratory as soon as possible.

The presence of a viral infection can be confirmed by *Tzanck smear* although the exact virus is not identified. A smear is obtained from the base of the lesion and examined under a microscope. The presence of multinucleated giant cells confirms a viral infection.

Other Diagnostic Tests

Other tests for diagnosis of skin problems include biopsy, special noninvasive examination techniques, and skin testing for allergy (discussed in Chapter 20).

Skin Biopsy.

A small piece of skin tissue may be obtained for diagnosis or to assess the effectiveness of an intervention. Check with the health care provider to determine the number, location, and type of skin biopsies to be performed. Depending on the size, depth, and location of the skin changes, the physician may perform a punch biopsy, shave biopsy, or scalpel excision (excisional biopsy).

Punch biopsy is the most common technique. A small circular cutting instrument, or "punch," ranging in diameter from 2 to 6 mm, is used. After the site is injected with a local anesthetic, a small plug of tissue is cut and removed. The site may be closed with sutures or may be allowed to heal without suturing.

Shave biopsies remove only the portion of the skin that rises above the surrounding tissue when injected with a local anesthetic. A scalpel or razor blade is moved parallel to the skin surface to remove the tissue specimen. Shave biopsies are usually indicated for superficial or raised lesions. Suturing is not needed.

Excisional biopsy is rarely used for skin problems. When needed, larger or deeper specimens are obtained by deep excision with a scalpel followed by closure with sutures. Excisional biopsies are more uncomfortable than punch or shave biopsies while healing.

Patient Preparation.

Explain to the patient what to expect and that a biopsy is a minor procedure with few complications. If a punch or shave biopsy is planned, reassure him or her that only a small amount of skin is removed and scarring is minimal. For an excisional biopsy, tell the patient that a scar similar to that of a healed surgical incision will result.

Procedure.

Establish a sterile field, and assemble all needed supplies and instruments. Local anesthesia is provided by local infiltration using a small-gauge (25-gauge) needle to reduce discomfort during injection. Preparation of the biopsy site differs by health care provider preference, but usually the skin is simply wiped with alcohol.

The injection of a local anesthetic agent, which produces a burning or stinging sensation, is uncomfortable. Reassure the patient that the

discomfort will subside as the anesthetic takes effect. Talking the patient through the procedure with a quiet voice along with a gentle touch may have a calming effect.

After removal, tissue specimens for pathologic study are placed in 10% formalin for fixation. Specimens for culture are placed in sterile saline solution. Bleeding of the site may be controlled by applying localized pressure, by applying a topical hemostatic agent, or by suturing.

Follow-up Care.

After bleeding is controlled and any sutures are placed, the site is covered with an adhesive bandage or a dry gauze dressing. Instruct the patient to keep the dressing dry and in place for at least 8 hours. Teach him or her to clean the site daily after the dressing is removed. Tap water or saline is used to remove any dried blood or crusts. An antibiotic ointment may be prescribed to reduce the risk for infection. The site may be left open or covered for cosmetic reasons or because the site is an area often soiled. Instruct the patient to report any redness or excessive drainage. Sutures are usually removed 7 to 10 days after biopsy.

Wood's Light Examination.

A handheld, long-wavelength ultraviolet (black) light or Wood's light may be used during physical examination. Exposure of some skin infections with this light produces a specific color, such as blue-green or red, that can be used to identify the infection. Hypopigmented skin is more prominent when it is viewed under black light, making evaluation of pigment changes in lighter skin easier. This examination is carried out in a darkened room and does not cause discomfort.

Diascopy.

Diascopy is a painless technique to eliminate erythema caused by increased blood flow to the skin, thereby easing the inspection of skin lesions. A glass slide or lens is pressed down over the area to be examined, blanching the skin and revealing the shape of the lesions.

NCLEX Examination Challenge

Safe and Effective Care Environment

What is the most important action the nurse needs to take when obtaining a specimen for a viral culture for a client who has a suspected viral skin infection?

A Injecting the vesicle with sterile water, aspirating the fluid, adding a preservative to the specimen, and wrapping the container to protect the specimen from light.
B Using a cotton-tipped applicator, obtain vesicle fluid from the lesion, immediately placing the specimen on ice, and transporting it to the laboratory as soon as possible.
C Cleaning the area with an antiseptic solution, removing fluid from the center of the blister with a needle, and sending it to the laboratory.
D Applying a gauze bandage to the area, removing it after one hour, and sending the entire gauze to the laboratory.

Nursing Concepts and Clinical Judgment Review

What might you NOTICE in a patient with adequate tissue integrity and body protection related to skin function?

Vital signs:

- Body temperature within normal range

Physical assessment:

- Skin intact (no rashes, abnormal lesions, open areas, or drainage)
- Skin color normal (no cyanosis, pallor, jaundice, inflammation, or areas of uneven pigmentation)
- Skin texture and elastic turgor normal (no edema, tenting, flaking, scaling, excessive oiliness, or excessive thickening)
- Oral mucous membranes moist and pink
- Nail beds pink with good capillary refill
- Fingertips and nails normal-shaped (no clubbing, nail splitting, nail separation, or increased nail thickness)
- Body hair distributed evenly over the body, no patchy areas of hair loss
- Scalp free from dandruff, no itching

Psychological assessment:

- Patient's eye contact good
- No unusual “hiding” of body areas normally visible in public
- Skin, hair, and nails clean and free of odor

Key Points

Review these Key Points for each NCLEX Examination Client Needs Category

Safe and Effective Care Environment

- Assist all patients with limited mobility to change positions at least every 2 hours. **Safety** QSEN
- Wash your hands before and after touching any areas of impaired skin tissue integrity. **Safety** QSEN
- Use Standard Precautions when providing care to a patient who has areas of impaired skin tissue integrity or skin with an abnormal appearance. **Safety** QSEN
- Use lift sheets when moving patients with fragile skin. **Safety** QSEN
- Position patients who are confined to bed in a way that promotes air circulation to skinfold areas while minimizing pressure over bony prominences.

Health Promotion and Maintenance

- Encourage all patients to reduce sun exposure and exposure to ultraviolet (UV) light. **Patient-Centered Care** QSEN
- Teach patients to examine all skin areas on a monthly basis for new lesions and changes to existing lesions using the ABCDE method of checking lesions for manifestations of melanoma. **Evidence-Based Practice** QSEN
- Encourage all patients to bathe, shampoo the hair, and keep fingernails clean and trimmed.

Psychosocial Integrity

- Use effective communication when teaching patients and family members about what to expect during tests and procedures to assess skin function and skin disease. **Patient-Centered Care** QSEN
- Explain all procedures, restrictions, drugs, and follow-up care to the patient and family. **Patient-Centered Care** QSEN
- Check the cognitive function of any patient whose hygiene of the skin, hair, and nails appears inadequate.
- Reassure patients who have skin changes that are variations of normal. **Patient-Centered Care** QSEN

Physiological Integrity

- Modify techniques to assess skin changes in patients with dark skin. **Evidence-Based Practice** QSEN
- Document any known specific allergies that have skin manifestations. **Patient-Centered Care** QSEN
- Ask any patient who has started taking a newly prescribed or over-the-counter drug whether he or she has noticed any skin changes that occurred since starting the drug. **Patient-Centered Care** QSEN
- Use proper terminology to communicate skin assessment findings.
- Distinguish between normal variations and abnormal skin manifestations with regard to skin color, texture, warmth, elastic turgor, and moisture.
- Use the ABCDE method of assessing skin lesions for cancer. **Evidence-Based Practice** QSEN

CHAPTER 25

Care of Patients with Skin Problems

Janice Cuzzell and M. Linda Workman

PRIORITY CONCEPTS

- Tissue Integrity
- Infection
- Inflammation
- Cellular Regulation

Learning Outcomes

Safe and Effective Care Environment

1. Use principles of infection control to prevent transmission when caring for a patient with a skin infection.
2. Protect hospitalized patients from skin injury, loss of tissue integrity, and infection.

Health Promotion and Maintenance

3. Teach all people how to protect the skin from damage and cancer development.

Psychosocial Integrity

4. Reduce the psychological impact for the patient and family regarding changes in the appearance or function of any part of the integumentary system.

Physiological Integrity

5. Use knowledge of anatomy and physiology to routinely perform a

complete assessment of any skin changes, lesions, and open wounds, and document findings.

6. Work with other members of the health care team to help the patient/family experiencing pressure ulcers or other skin problems achieve desired health outcomes.
7. Coordinate nursing interventions for the patient with serious skin problems in the community.

 http://evolve.elsevier.com/Iggy/

As discussed in Chapter 24, skin tissue integrity helps protect the entire body. Like the wall surrounding a castle, it provides a strong barrier, especially to invasion by harmful microorganisms.

Skin problems are common, especially among older adults. Changes in skin tissue integrity reduce protective function, and the cause of the change is often difficult to determine. In addition to its primary functions, the skin also reflects underlying medical conditions. Thus problems may truly arise in the skin, or they may be a manifestation of systemic disease or injury.

Drugs and other interventions for any health problem can trigger a skin response. Skin problems can interfere with the management of other conditions. Age-related changes and problems caused by immobility, chronic disease, debility, and reduced immune function increase the older patient's risk for skin damage and loss of tissue integrity.

Minor Skin Irritations

Pruritus

Pathophysiology

Pruritus (itching) is a distressing condition caused by stimulation of itch-specific nerve fibers. It may or may not occur with skin disease. Physical or chemical agents can directly trigger the nerve fibers or can activate chemical mediators (i.e., histamine), which then act on the itch receptors.

Itching is a subjective condition similar to pain, and severity of the sensation varies among patients. Regardless of the cause, patients often report that itching is worse at night when there are fewer distractions. Other conditions that make itching worse include skin dryness, increased temperature, perspiration, and emotional stress.

Patient-Centered Collaborative Care

The priority nursing interventions focus on increasing patient comfort and preventing skin injury with loss of tissue integrity. Patients usually try to relieve itching by scratching or rubbing the skin, a response that further stimulates the itch receptors and causes the *"itch-scratch-itch" cycle* (McCance et al., 2014). Itching with skin lesions can often be relieved by treatment of the underlying skin disorder with topical or systemic drugs. Systemic diseases, such as liver and venous disorders, can also cause itching without skin lesions. Liver disease often increases the buildup of bilirubin in the skin, which stimulates itch receptors. Pruritus can also be caused by too little or too much blood flow to an area (especially the feet and legs).

Plan care to promote comfort and prevent disruption of skin tissue integrity from vigorous scratching. Because dry skin worsens itching, emphasize interventions to prevent dry skin (Chart 25-1). Encourage patients to keep the fingernails trimmed short, with rough edges filed to reduce damage from scratching and secondary infection. Wearing mittens or splints at night can help prevent scratching during sleep. If the patient cannot perform self-care, teach the family (for home care) and unlicensed assistive personnel (UAP) to trim the patient's fingernails and apply mittens or gloves. Stress the importance of not breaking the skin or digging into nail corners when trimming the nails of patients with diabetes.

Chart 25-1 Patient and Family Education: Preparing for Self-Management

Prevention of Dry Skin

- Use a room humidifier during the winter months or whenever the furnace is in use.
- Take a complete bath or shower only every other day (wash face, axillae, perineum, and any soiled areas with soap daily).
- Use tepid water.
- Use a superfatted, nonalkaline soap instead of deodorant soap.
- Rinse the soap thoroughly from your skin.
- If you like bath oil, add the oil to the water at the end of the bath.
- Take care to avoid falls; oil makes the tub slippery.
- Pat rather than rub skin surfaces dry.
- Avoid clothing that continuously rubs the skin, such as tight belts, nylon stockings, or pantyhose.
- Maintain a daily fluid intake of 3000 mL unless contraindicated for another medical condition.
- Do not apply rubbing alcohol, astringents, or other drying agents to the skin.
- Avoid caffeine and alcohol ingestion.

A cool sleeping environment and comfort measures (e.g., cool shower, moisturizers) may help promote sleep. Using sleep-promoting herbal teas or sedating antihistamines at bedtime (when the side effect of drowsiness is welcome) may provide an uninterrupted night's sleep. Colloidal oatmeal or tar extract baths may provide temporary relief.

If antihistamines are prescribed, monitor the patient's response so that the dosage can be adjusted as needed. The effectiveness of topical steroid preparations and other topical agents is increased if the drug is applied to slightly damp skin. Using topical drugs under an occlusive dressing increases the dose being delivered. Avoid occluding treated areas unless specifically prescribed by the health care provider.

Urticaria

Urticaria (hives) is a rash of white or red edematous papules or plaques of various sizes. This problem is usually caused by exposure to allergens, which releases histamine into the skin. Blood vessel dilation and plasma protein leakage lead to formation of lesions or wheals. Some common causes of urticaria include drugs, temperature extremes, foods, infection,

diseases, cancer, and insect bites (Schaefer, 2011).

Management focuses on removal of the triggering substance and relief of manifestations. Because the skin reaction is caused by histamine release, antihistamines such as diphenhydramine (Benadryl) are helpful. Teach the patient to avoid overexertion, alcohol consumption, and warm environments, which further dilate blood vessels and make urticaria worse. Alcohol increases sedating effect of antihistamines, increasing the risk for falls.

Trauma

Pathophysiology

Skin trauma can vary from an aseptic surgical incision to a grossly infected, draining pressure ulcer with deep tissue destruction. Injury to the skin starts a series of actions to repair the skin and restore tissue integrity to this protective barrier.

Phases of Wound Healing

Wound healing occurs in three phases: inflammatory phase, proliferative phase, and maturation phase. Table 25-1 lists the key events for each stage of normal wound healing. The length of each phase depends on the type of injury and degree of loss of tissue integrity, the patient's overall health, and whether the wound is healing by first, second, or third intention (Fig. 25-1).

TABLE 25-1

Normal Wound Healing

Inflammatory Phase
• Begins at the time of injury or cell death and lasts 3 to 5 days. • Immediate responses are vasoconstriction and clot formation. • After 10 minutes, vasodilation occurs with increased capillary permeability and leakage of plasma (and plasma proteins) into the surrounding tissue. • White blood cells (especially macrophages) migrate into the wound. • Clinical manifestations of local edema, pain, erythema, and warmth are present.
Proliferative Phase
• Begins about the fourth day after injury and lasts 2 to 4 weeks. • Fibrin strands form a scaffold or framework. • Mitotic fibroblast cells migrate into the wound, attach to the framework, divide, and stimulate the secretion of collagen. • Collagen, together with ground substance, builds tough and inflexible scar tissue. • Capillaries in areas surrounding the wound form "buds" that grow into new blood vessels. • Capillary buds and collagen deposits form the "granulation" tissue in the wound, and the wound contracts. • Epithelial cells grow over the granulation tissue bed.
Maturation Phase
• Begins as early as 3 weeks after injury and may continue for a year or longer. • Collagen is reorganized to provide greater tensile strength. • Scar tissue gradually becomes thinner and paler in color. • The mature scar is firm and inelastic when palpated.

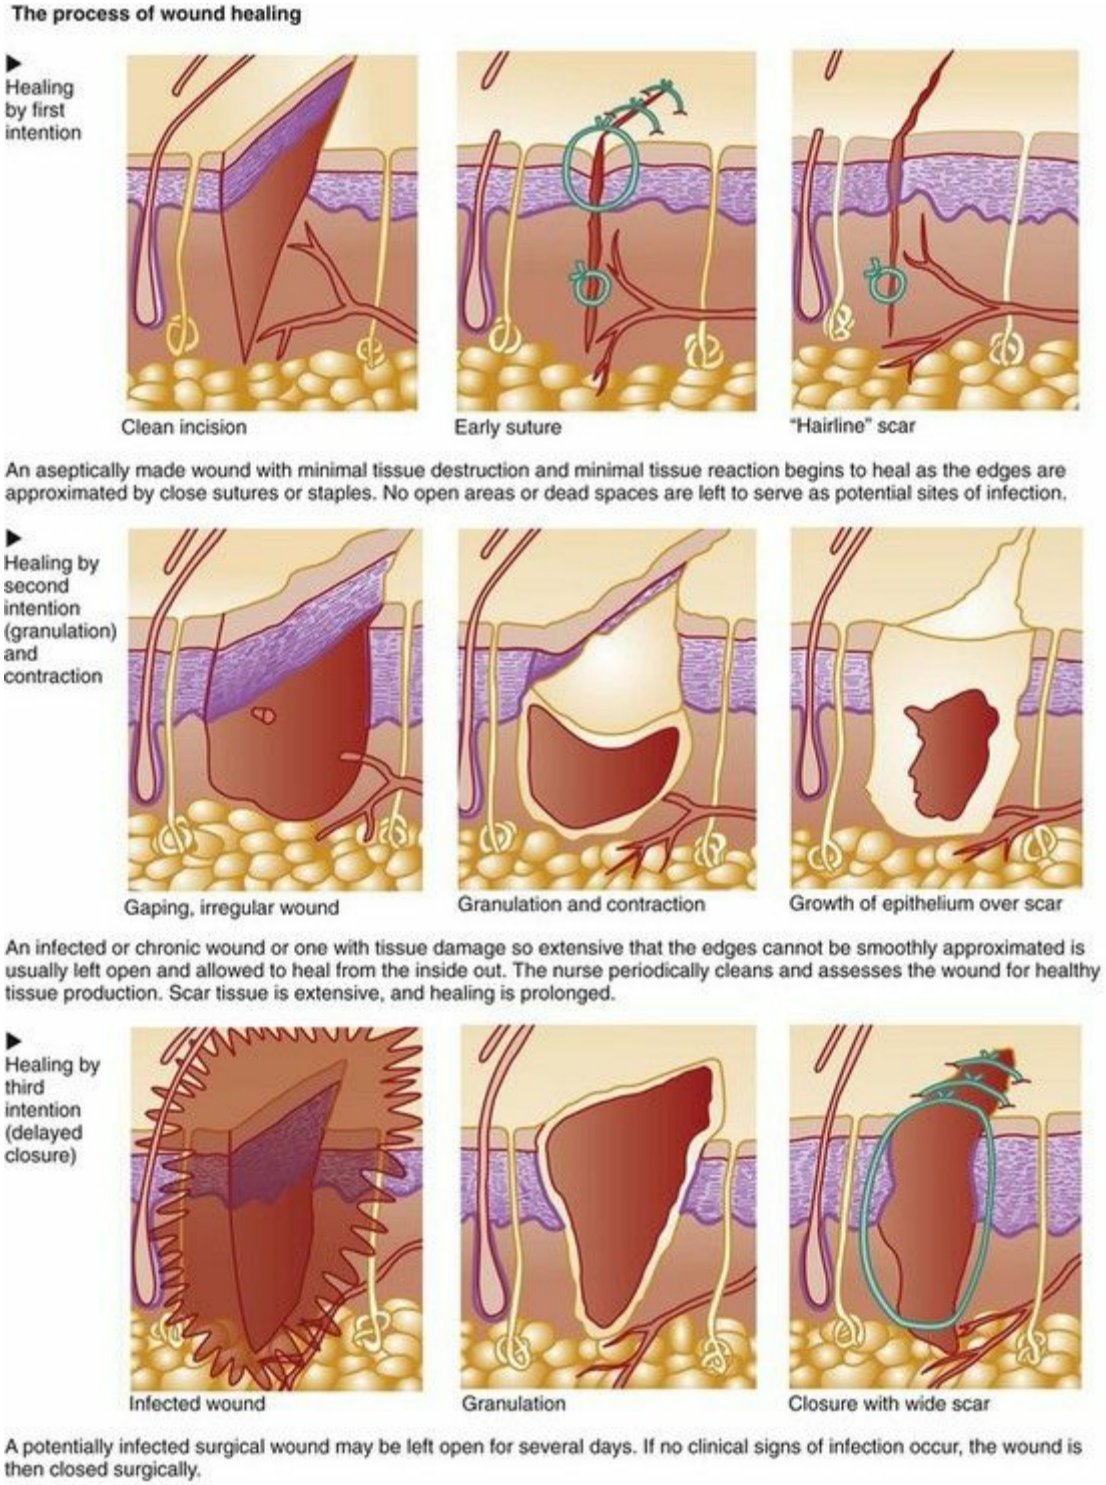

FIG. 25-1 The process of wound healing.

A wound without tissue loss, such as a clean laceration or a surgical incision, can be closed with sutures, staples, or adhesives. The wound edges are brought together with the skin layers lined up in correct anatomic position **(approximated)** and held in place until healing is complete. This type of wound represents healing by **first intention** in which the closed wound eliminates dead space and shortens the phases of tissue repair. Inflammation resolves quickly, and connective tissue repair is minimal, resulting in less remodeling and a thin scar. Fig. 25-2 shows

the healing of a surgical incision over time.

FIG. 25-2 Appearance of a normally healing surgical wound over time. **A,** Appearance at 1 day postoperative. **B,** Appearance at 1 week postoperative. **C,** Appearance at 2 weeks postoperative. **D,** Appearance at 2 months postoperative. **E,** Appearance at 6 months postoperative. **F,** Appearance at 1 year after surgery.

Deeper tissue injuries with greater loss of tissue integrity, such as a chronic pressure ulcer or venous stasis ulcer, result in a cavity that requires gradual filling in of the dead space with connective tissue. This represents healing by **second intention** and prolongs the repair process.

Wounds at high risk for infection, such as surgical incisions into a nonsterile body cavity or contaminated traumatic wounds, may be intentionally left open for several days. After **debris** (dead tissues) and exudate have been removed (débrided) and inflammation has subsided, the wound is closed by first intention. This type of healing represents delayed primary closure **(third intention)** and results in a scar similar to that found in wounds that heal by first intention. Healing can be impaired by many factors (Table 25-2).

TABLE 25-2

Causes of Impaired Wound Healing

CAUSE	MECHANISM
Altered Inflammatory Response	
Local	
Arteriosclerosis Diabetes Vasculitis Thrombosis Venous insufficiency Lymphedema Pharmacologic vasoconstriction Irradiated tissue Crush injuries Primary closure under tension	Reduced local tissue circulation, resulting in ischemia, impaired leukocytic response to wounding, and increased probability of wound infection
Systemic	
Leukemia Prolonged administration of high-dose anti-inflammatory drugs: • Corticosteroids • Aspirin	Systemic inhibition of leukocytic response, resulting in impaired host resistance to infection
Impaired Cellular Proliferation	
Local	
Wound infection Foreign body Necrotic tissue Repeated injury or irritation Movement of wound (e.g., across a joint) Wound desiccation or maceration	Prolonged inflammatory response, which can result in low tissue oxygen tension and further tissue destruction
Systemic	
Aging Chronic stress Nutritional deficiencies: • Calories • Protein • Vitamins • Minerals • Water Impaired oxygenation: • Pulmonary insufficiency • Heart failure • Hypovolemia Cirrhosis Uremia Prolonged hypothermia Coagulation disorders Cytotoxic drugs	Impaired cellular proliferation and collagen synthesis Decreased wound contraction

Mechanisms of Wound Healing

When skin injury occurs, the body restores tissue integrity through three processes: re-epithelialization, granulation, and wound contraction. The depth of injury and extent of tissue integrity loss determine to what degree each process contributes to wound healing.

Partial-Thickness Wounds.

Partial-thickness wounds are superficial with minimal loss of tissue integrity from damage to the epidermis and upper dermal layers. These wounds heal by **re-epithelialization,** the production of new skin cells by

undamaged epidermal cells in the basal layer of the dermis, which also lines the hair follicles and sweat glands (Fig. 25-3). Injury is followed immediately by local inflammation that causes the formation of a fibrin clot and releases growth factors that stimulate epidermal cell division (mitosis). New skin cells move into open spaces on the wound surface where the fibrin clot acts as a frame to guide cell movement. Regrowth across the open area **(resurfacing)** is only one cell layer thick at first. As healing continues, the cell layer thickens, stratifies (forms layers), and produces keratin to resemble normal skin.

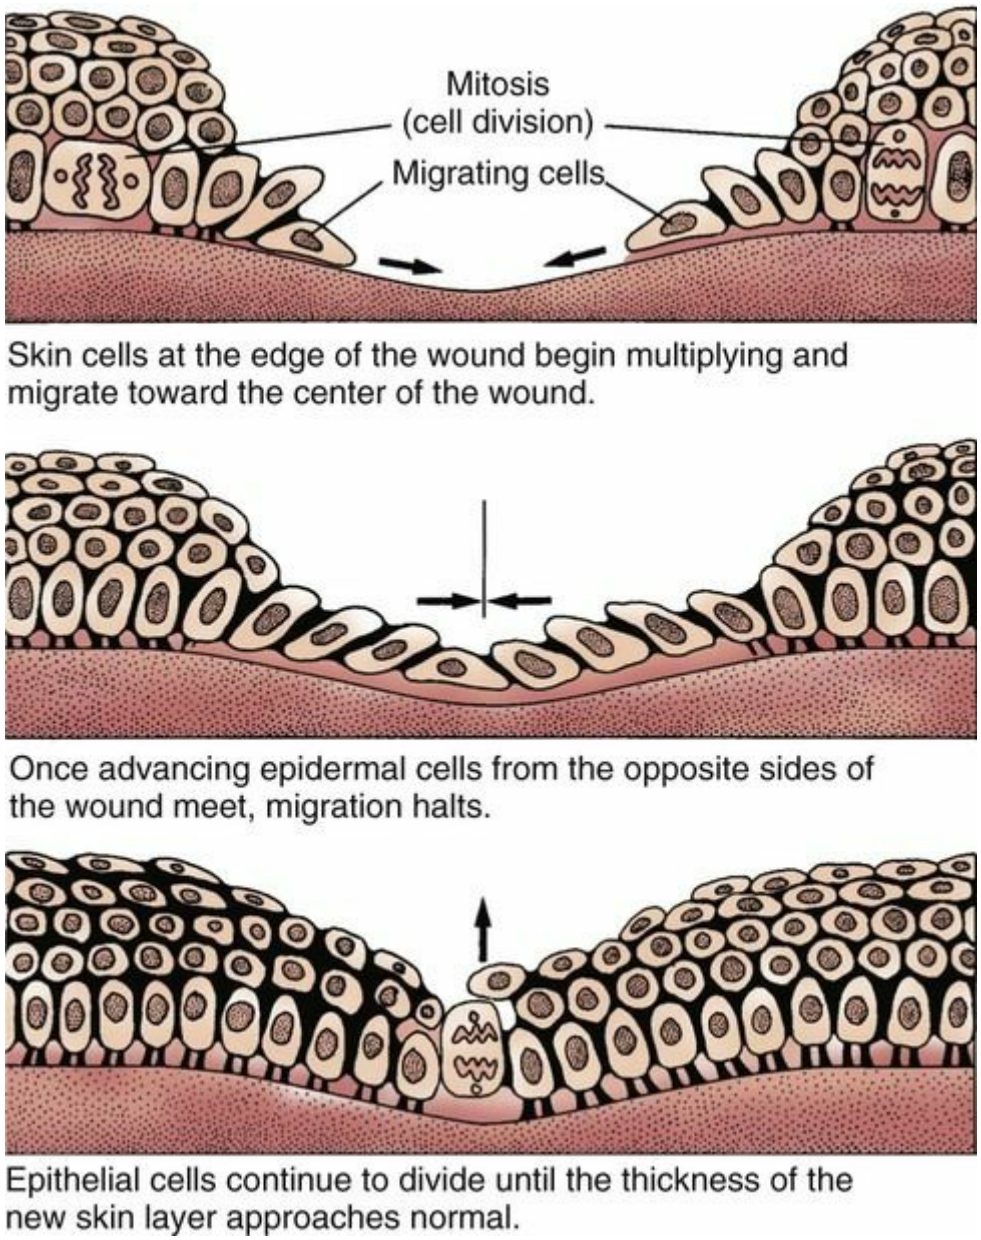

FIG. 25-3 Re-epithelialization and wound contraction.

In a healthy person, healing of a partial-thickness wound takes about 5 to 7 days. This process is more rapid in skin that is hydrated, well

oxygenated, and has few microorganisms.

Full-Thickness Wounds.

In deep partial-thickness wounds and full-thickness wounds, loss of tissue integrity and damage extend into the lower layers of the dermis and subcutaneous tissue. As a result, most of the epithelial cells at the base of the wound are destroyed and the wound cannot heal by re-epithelialization alone. Removal of the damaged tissue results in a defect that must be filled with scar tissue (**granulation)** for healing to occur. During the second phase of healing, new blood vessels form at the base of the wound and fibroblast cells begin moving into the wound space. These cells deposit new collagen to replace the lost tissue.

Fibroblasts also begin to pull the wound edges inward along the path of least resistance **(contraction)** (see Fig. 25-3). This causes the wound to decrease in size at a uniform rate of about 0.6 to 0.75 mm/day. Complete wound closure by contraction depends on the mobility of the surrounding skin as tension is applied to it. If tension in the surrounding skin exceeds the force of wound contraction, healing will be delayed until undamaged epidermal cells at the wound edges can bridge the defect. The bridging of epithelial cells across a large area of granulation tissue results in an unstable barrier rather than near-normal skin. A venous leg ulcer is one example of a skin defect that heals poorly by contraction. Re-epithelialization of these chronic wounds often results in a thin epidermal barrier that is easily re-injured.

The natural healing processes of re-epithelialization, granulation, and contraction can slow down and even stop in the presence of infection, unrelieved pressure, or mechanical obstacles. For example, dead tissue not only supports bacterial growth but also obstructs collagen deposition and wound contraction. Thus thorough wound débridement is needed for healing. In the case of chronic wounds, healing may stop spontaneously without an obvious cause. Also, infection in chronic wounds may not show the expected manifestations. Often the only manifestation is an increase in wound size or failure of the wound to decrease in size. Nonhealing chronic wounds that remain open for extended periods are of particular concern. Although rare, these wounds are at higher risk for evolving into an aggressive malignancy (Marjolin ulcer) (Yu et al., 2013).

Considerations for Older Adults

Patient-Centered Care QSEN

As skin ages, the process of wound healing is less efficient. Re-epithelialization and wound contraction slow, and replacement of connective tissue is reduced. Thus the strength of a healed wound in an older adult is reduced with poor tissue integrity and the area is at greater risk for re-injury. When inadequate nutrition, incontinence, or immobility is present, any wound in an older adult has a high risk for becoming a chronic wound. Although prevention strategies provide the best outcome, aggressive treatment of any degree of loss of skin tissue integrity, no matter how small, should be started as soon as it is discovered in an older adult (Touhy & Jett, 2014).

Patient-Centered Collaborative Care

Collaborative management of skin trauma varies with the depth and type of injury. Interventions always focus on supporting a healing environment, enhancing wound healing, preventing infection, and restoring function to the area.

Pressure Ulcers

Pathophysiology

A **pressure ulcer** (PrU) is a loss of tissue integrity caused when the skin and underlying soft tissue are compressed between a bony prominence and an external surface for an extended period. Although they commonly occur over the sacrum, hips, and ankles, *pressure ulcers can occur on any body surface.* For example, nasal cannula tubing that is too tight can cause pressure ulcers behind the ears or in the nares (Ambutas et al., 2014).

Tissue compression from pressure restricts blood flow to the skin, resulting in reduced tissue perfusion and oxygenation and, eventually, leading to cell death. Ulcers occur most often in people with limited mobility because they cannot change their position to relieve pressure. Patients who cannot feel or communicate the pain that occurs with unrelieved pressure are more likely to develop pressure ulcers. Once formed, these chronic wounds are slow to heal, resulting in increased morbidity and health care costs. Complications include sepsis, kidney failure, infectious arthritis, and osteomyelitis.

Friction and shear are mechanical forces that impair skin tissue integrity and cause skin tears, which set the stage for skin breakdown (LeBlanc & Baronoski, 2014). Excessive skin moisture, such as urinary or fecal incontinence, also increases the risk for skin damage. Nutrition status is an important concern. Protein malnutrition makes normal tissue more prone to breakdown and also delays healing (Posthauer, 2012).

Mechanical Forces

Pressure occurs as a result of gravity. Dependent tissues in contact with a fixed surface experience varying degrees of pressure. Pressure is determined by the amount and distribution of weight exerted at the point of contact and the density of the contacting surface. Excessive or prolonged pressure compresses blood vessels at the point of contact, such as over bony prominences. Pressure occurs when the patient is positioned on a hard surface that does not diffuse the weight, such as when lying on a hard floor for hours after a fall or when remaining in the same position too long. Unrelieved pressure leads to ischemia, inflammation, and tissue necrosis.

Friction occurs when surfaces rub the skin and irritate or directly pull off epithelial tissue. Such forces are generated when the patient is dragged or pulled across bed linen.

Shearing forces are generated when the skin itself is stationary and the

tissues below the skin (e.g., fat, muscle) shift or move (Fig. 25-4). The movement of the deeper tissue layers reduces the blood supply to the skin, leading to skin hypoxia, anoxia, ischemia, inflammation, and necrosis.

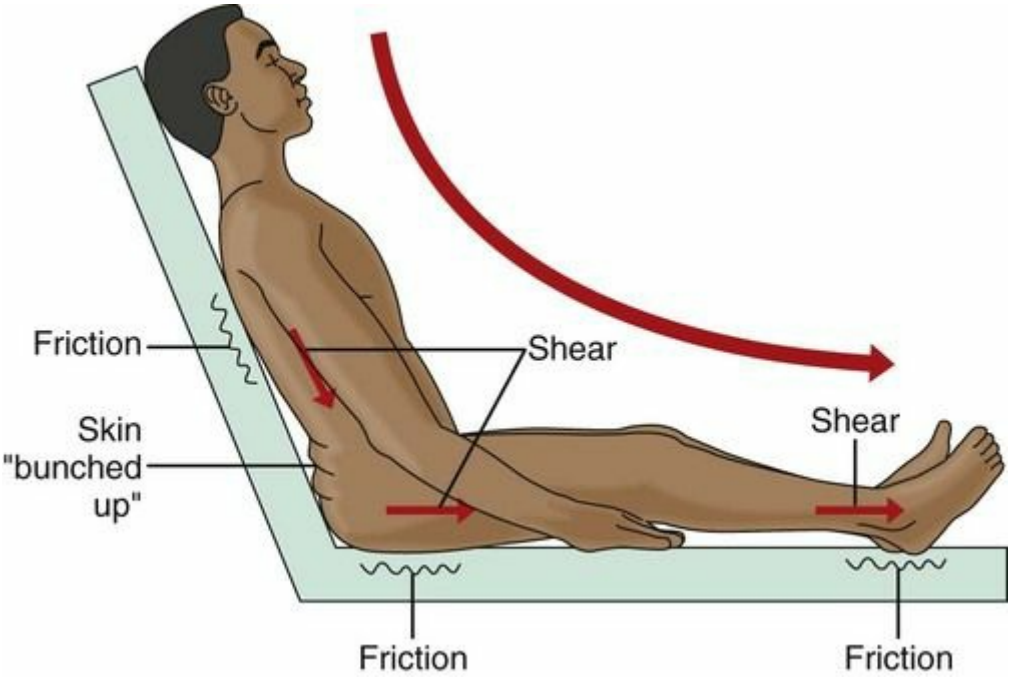

FIG. 25-4 Shearing forces pulling skin layers away from deeper tissue. The skin is "bunched up" against the back of the mattress while the rest of the bone and muscle in the area presses downward on the lower part of the mattress. Blood vessels become kinked, obstructing circulation and leading to tissue death.

A shear injury usually occurs when a patient is in a wheelchair or in bed in a semi-sitting position and gradually slides downward. The skin over the sacrum may not slide down at the same pace as the deeper tissues, mechanically "shearing" the skin, causing blood vessels to stretch and break. Shearing leads to soft-tissue ischemia and deep tissue injury, even though no external break in skin integrity is observed.

Considerations for Older Adults

Patient-Centered Care QSEN

Older adults are at higher risk for skin tears and pressure ulcers because of age-related skin changes. Flattening of cells at the dermal-epidermal junction predisposes older people to skin tears from mechanical shearing forces, such as tape removal and friction from tight restraints. Skin moisture and irritation from incontinence combined

with friction over bony prominences can lead to skin destruction with loss of tissue integrity and pressure ulcer formation. Patients with cognitive impairments may not readily report discomfort from inadequate pressure relief. **If pressure is unrelieved, tissue destruction progresses to full-thickness injury.** Assess patients with cognitive impairments more frequently for loss of skin tissue integrity.

Incidence and Prevalence

Pressure ulcer development is a problem found among patients in any care setting, including the home. Although new products are available for prevention and treatment, many hospitalized patients still experience pressure ulcer formation, which contributes significantly to morbidity and mortality in this patient population (Alderden et al., 2011; Lyder et al., 2012).

Health Promotion and Maintenance

Pressure ulcers can be prevented if the risk is recognized and intervention begins early (Chart 25-2) (Ackerman, 2011). Pressure ulcer prevention does not just happen even with conscientious nursing care. Deliberate and consistent interventions, as described in the Quality Improvement box, are needed to prevent hospital-acquired pressure ulcers. Key health care team members for pressure ulcer prevention and management are the certified wound care specialist and the dietitian. Involving unlicensed assistive personnel (UAP) in pressure ulcer prevention also enhances prevention program effectiveness.

Chart 25-2 Best Practice for Patient Safety & Quality Care QSEN

Preventing Pressure Ulcers

Positioning

- Pad contact surfaces with foam, silicon gel, air pads, or other pressure-relieving pads.
- Do not keep the head of the bed elevated above 30 degrees to prevent shearing.
- Use a lift sheet to move a patient in the bed. Avoid dragging or sliding him or her.
- When positioning a patient on his or her side, do not position directly on the trochanter.

- Re-position an immobile patient at least every 2 hours while in bed and at least every 1 hour while sitting in a chair.
- Do not place a rubber ring or donut under the patient's sacral area.
- When moving an immobile patient from a bed to another surface, use a designated slide board well lubricated with talc or use a mechanical lift.
- Place pillows or foam wedges between two bony surfaces.
- Keep the patient's skin directly off plastic surfaces.
- Keep the patient's heels off the bed surface using bed pillow under ankles.

Nutrition

- Ensure a fluid intake between 2000 and 3000 mL/day.
- Help the patient maintain an adequate intake of protein and calories.

Skin Care

- Perform a daily inspection of the patient's entire skin.
- Document and report any manifestations of skin infection.
- Use moisturizers daily on dry skin, and apply when skin is damp.
- Keep moisture from prolonged contact with skin:
  - Dry areas where two skin surfaces touch, such as the axillae and under the breasts.
  - Place absorbent pads under areas where perspiration collects.
  - Use moisture barriers on skin areas where wound drainage or incontinence occurs.
- ***Do not massage bony prominences.***
- Humidify the room.

Skin Cleaning

- Clean the skin as soon as possible after soiling occurs and at routine intervals.
- Use a mild, heavily fatted soap or gentle commercial cleanser for incontinence.
- Use tepid rather than hot water.
- In the perineal area, use a disposable cleaning cloth that contains a skin barrier agent.
- While cleaning, use the minimum scrubbing force necessary to remove soil.
- Gently pat rather than rub the skin dry.
- Do not use powders or talcs directly on the perineum.
- After cleansing, apply a commercial skin barrier to those areas in

frequent contact with urine or feces.

Quality Improvement QSEN

Use of a Team Approach to Prevent Pressure Ulcers

Armour-Burton, T., Fields, W., Outlaw, L., & Deleon, E. (2013). The healthy skin project: Changing nursing practice to prevent and treat hospital-acquired pressure ulcers. *Critical Care Nurse, 33*(3), 32-39.

The incidence of hospital-acquired pressure ulcers, defined as occurring after the first 24 hours following admission, for a 41-bed acute care unit ranged from 0% to 18.92% per quarter for 14 consecutive quarters. Although this unit had a prevention program initially in place, it relied on each patient's primary nurse for ongoing pressure ulcer risk assessment and implementation of prevention practices. This high incidence forced the staff to examine their current pressure ulcer prevention practices and design a sustainable, interdisciplinary "healthy skin project" to improve the outcomes.

Key to the "healthy skin project" was the implementation of a team approach for pressure ulcer prevention assessment and management. In addition to all nurses assigned to the unit, the team now included both a wound-liaison nurse (who has special training but was not a certified wound care nurse) and a registered dietitian. Education for all staff members was started and assessed at regular intervals. A key factor in the success of the program was the involvement of unlicensed assistive personnel (UAP) in the risk assessment and care phases of pressure ulcer prevention. Thus the responsibility of pressure ulcer prevention shifted from one person, the primary nurse, for each patient to everyone who provided care to each patient. Each patient was assessed for pressure ulcer risk every shift. Those identified at increased risk were started on evidence-based pressure-relieving and skin care algorithmic intervention. During the first 20 quarters of the project's implementation, the pressure ulcer incidence for 17 quarters was 0%. For 3 of the quarters, the incidence was 2.5%, 2.94%, and 3.33% respectively. These data suggest that consistent implementation of evidence-based strategies for pressure ulcer prevention is effective.

Commentary: Implications for Practice and Research

Although a team approach to pressure ulcer prevention is common, this project may be unique by gaining the input and participation of nonprofessional UAPs. These individuals often spend more time with patients while providing direct care, and their observations can

contribute to more accurate assessment, which is the first step in pressure ulcer prevention. Research examining the degree to which engaged UAP versus those whose observations are not considered is needed to learn what role UAP may play in the prevention of hospital-acquired pressure ulcers.

A pressure ulcer prevention program consists of two steps: (1) early identification of high-risk patients, and (2) implementation of aggressive intervention for prevention with the use of pressure-relief or pressure-reduction devices. Pressure mapping with a computerized tool that measures pressure distribution during sitting or lying can identify specific body areas at risk for breakdown and can help in planning interventions for patients who are bedridden or wheelchair bound. The map is displayed in colors on the computer screen based on temperature differences. Red indicates areas of greater heat production and increased pressure loads. Blue indicates cooler areas under lower pressure. When used in combination with risk assessment tools, pressure mapping helps identify problem areas before skin changes can be seen and allows for more targeted prevention strategies.

Effective risk identification and prevention measures include patient and caregiver education. Documentation of risk assessment, implementation of prevention measures, and education of all people involved in the care of the patient at risk for pressure ulcer formation are key to the plan's success. Continuing evaluation and risk assessment are critical, especially when the patient's condition changes.

Identification of High-Risk Patients

As suggested by The Joint Commission's National Patient Safety Goals (NPSGs), all patients admitted to a health care facility or home care agency are to be assessed for pressure ulcer risk. The use of a risk assessment tool increases the chances of identifying those patients at greater risk for skin breakdown. The Braden scale (Fig. 25-5) is a commonly used valid skin risk assessment tool. Using it helps the nurse assess and document risk categories for pressure ulcer formation (e.g., mental status, activity and mobility, nutritional status, incontinence).

Patient's name	Evaluator's name				Date of assessment		
Sensory perception Ability to respond meaningfully to pressure-related discomfort	**1. Completely limited** Unresponsive to painful stimuli (does not moan, flinch, or grasp) because of diminished level of consciousness or sedation OR limited ability to feel pain over most of body surface	**2. Very limited** Responds only to painful stimuli; cannot communicate discomfort except by moaning or restlessness OR has a sensory impairment that limits the ability to feel pain or discomfort over half of the body	**3. Slightly limited** Responds to verbal commands but cannot always communicate discomfort or need to be turned OR has some sensory impairment that limits ability to feel pain or discomfort in one or two extremities	**4. No impairment** Responds to verbal commands; has no sensory deficit that would limit ability to feel or voice pain or discomfort			
Moisture Degree to which skin is exposed to moisture	**1. Constantly moist** Skin is kept moist almost constantly by perspiration, urine; dampness is detected every time the client is moved or turned	**2. Very Moist** Skin is often but not always moist; linen must be changed at least once a shift	**3. Occasionally moist** Skin is occasionally moist, requiring an extra linen change approximately once a day	**4. Rarely moist** Skin is usually dry; linen requires changing only at routine intervals			
Activity Degree of physical activity	**1. Bedfast** Confined to bed	**2. Chairfast** Ability to walk severely limited or nonexistent; cannot bear own weight and must be assisted into chair or wheelchair	**3. Walks occasionally** Walks occasionally during the day but for very short distances, with or without assistance; spends the majority of each shift in bed or chair	**4. Walks frequently** Walks outside the room at least twice a day and inside the room at least once every 2 hours during waking hours			
Mobility Ability to change or control body position	**1. Completely immobile** Does not make even slight changes in body or extremity position without assistance	**2. Very limited** Makes occasional slight changes in body or extremity position but unable to make frequent or significant changes independently	**3. Slightly limited** Makes frequent though slight changes in body or extremity position independently	**4. No limitations** Makes major and frequent changes in position without assistance			
Nutrition Usual food intake pattern	**1. Very poor** Never eats a complete meal; rarely eats more than a third of any food offered; eats two servings or less of protein (meat or dairy products) per day; takes fluids poorly; does not take a liquid dietary supplement OR is NPO or maintained on clear liquids or IV for more than 5 days	**2. Probably inadequate** Rarely eats a complete meal and generally eats only about half of any food offered; protein intake includes only three servings of meat or dairy products per day; occasionally will take a dietary supplement OR receives less than optimal amount of liquid diet or tube feeding	**3. Adequate** Eats over half of most meals; eats a total of four servings of protein (meat, dairy products) each day; occasionally will refuse a meal, but will usually take a supplement if offered OR is receiving tube feeding or total parenteral nutrition, which probably meets most nutritional needs	**4. Excellent** Eats most of every meal; never refuses a meal; usually eats a total of four or more servings of meat and dairy products; occasionally eats between meals; does not require supplementation			
Friction and shear	**1. Problem** Requires moderate to maximum assistance in moving; complete lifting without sliding against sheets is impossible; frequently slides down in bed or chair, requiring frequent repositioning with maximum assistance; spasticity, contractures, or agitation leads to almost constant friction	**2. Potential problem** Moves feebly or requires minimum assistance during a move; skin probably slides to some extent against sheets, chair, restraints, or other devices; maintains relatively good position in chair or bed most of the time but occasionally slides down	**3. No apparent problem** Moves in bed and in chair independently and has sufficient muscle strength to lift up completely during move; maintains good position in bed or chair at all times				
Scoring system: 15-16 = mild risk, 12-14 = moderate risk, <11 = severe risk							Total score

FIG. 25-5 The Braden scale for predicting pressure ulcer risk. *IV,* Intravenous; *NPO,* nothing by mouth.

Mental status changes and decreased sensation determine whether the patient is a partner in pressure ulcer prevention. When the patient understands that turning and shifting of weight prevent tissue damage, the risk for pressure ulcers decreases. Stroke, head injury, organic brain disease, Alzheimer's disease, or other cognitive problems increase the risk for pressure ulcers.

Impaired mobility is a factor in the risk for pressure ulcer formation.

Patients who have unimpaired mobility and can respond to pain are at low risk for pressure ulcers. *Regardless of age, any patient who requires assistance with turning and positioning or who is unable to verbalize discomfort is at higher risk for pressure ulcers.* Those confined to bed or a chair also are at higher risk than a patient who requires assistance only with ambulation.

Nutrition status is a critical risk factor for pressure ulcer development and for successful healing (Posthauer, 2012). Tissue integrity and wound healing depend on a positive nitrogen balance and adequate serum protein levels. The patient in negative nitrogen balance not only heals more slowly but also is at risk for accelerated tissue destruction. Draining wounds contribute to protein loss and require aggressive intervention.

Nutrition assessment includes laboratory studies; evaluation of weight and weight change; ability of the patient to consume an adequate diet; and the need for vitamin, mineral, or protein supplementation. Serum prealbumin levels are often used to monitor nutrition status. *Nutrition is considered inadequate when the serum prealbumin level is less than 19.5 g/dL, albumin level is less than 3.5 g/dL, or the lymphocyte count is less than 1800/mm^3.* Because serum protein levels are affected by a number of other factors, laboratory values are valuable only when supported by additional assessment information. Other indicators of inadequate nutrition include poor daily intake of food and fluids with a weight loss greater than 5% change in 30 days or greater than 10% change in 180 days (Posthauer, 2012).

A positive nitrogen balance requires an intake of 30 to 35 calories per kilogram of body weight daily with a protein intake of 1.25 to 1.5 g/kg/day. Up to 2 g/kg/day of protein may be needed when nutritional deficits are severe or protein loss is ongoing. Vitamin and mineral supplementations are based on the patient's nutrition status. Collaborate with a dietitian for all patients at risk for a pressure ulcer to perform a thorough nutrition assessment and plan interventions for nutrition deficits (National Pressure Ulcer Advisory Panel, European Pressure Ulcer Advisory Panel, & Pan Pacific Pressure Injury Alliance, 2014).

Incontinence results in prolonged contact of the skin with substances that irritate the skin, destroy tissue integrity, and predispose to skin breakdown (e.g., urea, bacteria, yeast, and enzymes in urine and feces). Excessive moisture macerates skin, further increasing the risk for breakdown. Daily inspection of the skin for any areas of redness, maceration, or loss of skin tissue integrity is a major part of pressure ulcer prevention. Maintenance of clean, dry, intact skin also assists in ulcer

prevention. Wash the skin with a pH-balanced soap to maintain the normal acid level. Use creams or lotions to lubricate and moisturize the skin. Barrier ointments protect intact skin from urine and feces when incontinence is present. Change absorbent pads or garments immediately after each incontinence episode to avoid prolonged skin contact with urine or feces.

Nursing Safety Priority QSEN

Action Alert

Teach all nursing care personnel and family members not to massage reddened skin areas directly or use donut-shaped pillows for pressure relief. These actions can damage capillary beds and increase tissue necrosis.

Pressure-Relieving and Pressure-Reducing Techniques

The cornerstone in the prevention and management of pressure ulcers is maintaining adequate pressure relief so that tissue pressure remains below the **capillary closing pressure,** which is the pressure needed to occlude skin capillary blood flow in a body area. The normal capillary closing pressure ranges from 12 to 32 mm Hg. An effective pressure-relieving device keeps tissue pressure *below* the capillary closing pressure for adequate tissue perfusion and oxygenation. *Most devices have a standardized guaranteed pressure-relief reading; however, these readings do not ensure that capillary blood flow for any given patient is adequate. Observe skin color, tissue integrity, and temperature directly to determine capillary flow adequacy.*

Devices are classified according to whether they relieve pressure or only reduce pressure. They are further classified as *dynamic* or *static.* Dynamic systems alternate inflation and deflation of the device. Static devices made of gel, water, foam, or air are in a constant state of inflation that distributes the patient pressure load over a larger area and reduces the pressure experienced by any particular area.

Pressure-relief/pressure-reduction products are available as specialty beds, mattress replacements, overlays, and assistive devices. Choosing the correct product is important in the success of the prevention plan. These factors are considered in product selection: the patient's ability to move in bed, his or her comfort level, and compatibility of the product with the care setting. Re-evaluate the product in use daily for effectiveness in reducing pressure, providing comfort, and eliminating

"bottoming out." Bottoming out occurs when the product is not providing adequate pressure relief and the patient's bony prominences sink into the mattress or cushion.

Pressure-relief devices consistently reduce pressure below capillary closing pressure. These devices are recommended for patients who need:

- Prevention of skin breakdown because they cannot turn (e.g., immobility, loss of sensation)
- Prevention of extension of skin breakdown that has already occurred
- Promotion of healing for breakdown present on several turning surfaces

Pressure-reduction devices lower pressure below that of a standard hospital mattress or chair surface but do not reduce pressure consistently below the capillary closing pressure. These devices are effective for preventing pressure ulcers only when used together with a turning schedule and other skin care measures.

Frequent repositioning of bedbound patients, as described in Chart 25-2, is critical in reducing pressure over bony prominences. A good plan for positioning is the 30-degree rule. This plan ensures that the patient is positioned and propped so that whatever part of the body is elevated is tilted back to no more than a 30-degree angle to the mattress rather than resting directly on a dependent bony prominence. This rule applies to side-lying as well as head-of-bed elevation positions. The patient who requires greater head elevation because of respiratory difficulties should be tilted up above 30 degrees with pillows behind the back to keep pressure off of the sacral/coccyx area. Teach UAP the importance of proper positioning, and demonstrate how to perform it. Also teach family members to use these techniques in the home.

The patient at risk for pressure ulcers in bed is also at risk while sitting. Assess for proper chair cushioning. Collaborate with physical therapists and rehabilitation specialists for selection of these products. Periodically assist high-risk patients who are chair bound to a standing position to promote perfusion and prevent breakdown over the sacral area.

Even with an appropriate mattress or cushion, the patient needs to change or be helped to change positions periodically to prevent loss of skin tissue integrity. Many facilities require turning and positioning every 2 hours. *However, pressure can occur in less time, and the actual turning or repositioning schedule for each patient must be individualized.* When this action is delegated to UAP, teach them the importance of maintaining a repositioning schedule.

Use pillows and other positioning or padding devices to keep heels

pressure-free at all times for high-risk patients. Assess heel positioning every 4 hours to ensure that pressure is not redistributed to other high-risk areas, such as the ankles or side of the feet. Check heels even more often when devices that hide the feet (e.g., boots, heel protectors) are used, especially if the patient has a vascular problem. Also check knees and elbows regularly, especially when the patient is in a side-lying position.

Patient-Centered Collaborative Care

Assessment

History.

When a patient already has a pressure ulcer, identify the cause of skin tissue integrity loss, as well as factors that may impair healing. Ask about the circumstances of the skin loss. Patients with chronic pressure ulcers may have a history of delayed healing or recurrence of the ulcer after healing has occurred. Assess for any of these contributing factors:

- Prolonged bedrest
- Immobility
- Incontinence
- Diabetes mellitus
- Inadequate nutrition or hydration
- Decreased sensory perception or cognitive problems
- Peripheral vascular disease

Physical Assessment/Clinical Manifestations.

Inspect the entire body, including the back of the head, for areas of skin tissue integrity loss or pressure. Give special attention to bony prominences (e.g., the heels, sacrum, elbows, knees, trochanters, posterior and anterior iliac spines) and areas with excessive moisture. Make sure tubing and other medical devices are not underneath the patient and producing a pressure point. Assess the patient's general appearance for issues related to skin health, such as the proportion of weight to height. Obese patients and thin patients are at increased risk for malnutrition and pressure ulcers. Check overall cleanliness of the skin, hair, and nails. Determine whether any loss of mobility or range of joint motion has occurred. *Do not delegate this assessment to UAP.*

Wound Assessment.

The appearance of pressure ulcers changes with the depth of the injury.

Chart 25-3 lists the features of the six categories or stages of pressure ulceration, and Fig. 25-6 shows examples.

Chart 25-3

Key Features

Pressure Ulcers

Suspected Deep Tissue Injury

- The intact skin area appears purple or maroon.
- Blood-filled blisters may be present.
- Before the above-listed changes appeared, the tissue in this area may first have been painful.
- Other changes that may have preceded the discoloration include that the area may have felt more firm, boggy, mushy, warmer, or cooler than the surrounding tissue.

Stage 1

- Skin is intact.
- Area, usually over a bony prominence, is red and does not blanch with external pressure.
- For patients with darker skin that does not blanch:
  - Observable pressure-related alteration of intact skin; changes are compared with an adjacent or opposite area and include one or more of these:
    Skin color (darker or lighted than the comparison area)
    Skin temperature (warmth or coolness)
    Tissue consistency (firm or boggy)
    Sensation (pain, itching)
- The ulcer appears as a defined area of persistent redness in lightly pigmented skin, whereas in darker skin tones, the ulcer may appear with persistent red, blue, or purple hues.

Stage 2

- Skin is not intact.
- There is partial-thickness skin loss of the epidermis or dermis.
- Ulcer is superficial and may be characterized as an abrasion, a blister (open or fluid-filled), or a shallow crater.
- Bruising is *not* present.

Stage 3

- Skin loss is full thickness.
- Subcutaneous tissues may be damaged or necrotic.
- Damage extends down to but not through the underlying fascia; bone, tendon, and muscle are *not* exposed.
- The depth can vary with anatomic location; areas of thin skin (e.g., the bridge of the nose) may show only a shallow crater, whereas thicker tissue areas with larger amounts of subcutaneous fat may show a deep, crater-like appearance.
- Undermining and tunneling may or may not be present.

Stage 4

- Skin loss is full thickness with exposed or palpable muscle, tendon, or bone.
- Often includes undermining and tunneling.
- Sinus tracts may develop.
- Slough and eschar are often present on at least part of the wound.

Unstageable

- Skin loss is full thickness, and the base is completely covered with slough or eschar, obscuring the true depth of the wound.

Data from National Pressure Ulcer Advisory Panel, European Pressure Ulcer Advisory Panel, & Pan Pacific Pressure Injury Alliance. (2014). *Prevention and treatment of pressure ulcers: Quick reference guide*. Cambridge Media: Perth, Australia. Retrieved September 2014, from http://www.npuap.org/wp-content/uploads/2014/08/Quick-Reference-Guide-DIGITAL-NPUAP-EPUAP-PPPIA.pdf.

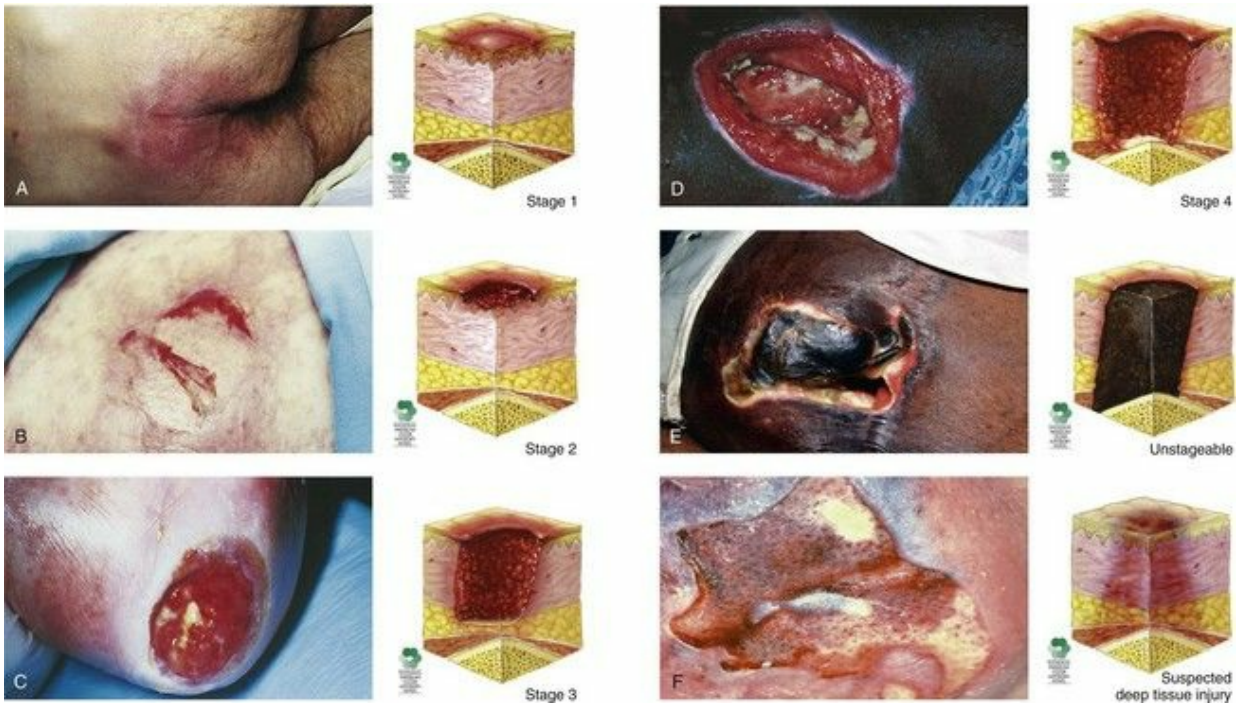

FIG. 25-6 Various stages of pressure ulcers. **A,** Stage 1 pressure ulcer. **B,** Stage 2 pressure ulcer. **C,** Stage 3 pressure ulcer. **D,** Stage 4 pressure ulcer. **E,** Unstageable ulcer. **F,** Suspected deep tissue injury.

Assess wounds for location, size, color, extent of tissue involvement, cell types in the wound base and margins, exudate, condition of surrounding tissue, and presence of foreign bodies. Document this initial assessment to serve as a starting point for determining the intervention plan and its effectiveness. How often a wound is assessed is determined by the policies and procedures at the facility or agency. Weekly documented assessment is standard in many long-term care facilities. Daily assessment is needed when the patient is in an acute care setting. *Also assess the wound at each dressing change, comparing the existing wound features with those documented previously to determine the current state of healing or deterioration.*

For intact areas that are red (in lighter-skinned patients), press firmly with fingers at the center of the area and assess whether the area **blanches** (lightens) with pressure and document the response. An area that blanches with pressure and then returns to normal when pressure is removed indicates color changes related to blood flow rather than to inflammation or tissue damage. When blanching does not occur with pressure, the redness is often from skin injury. Redness and blanching may be difficult to detect in darker-skinned patients. Look for more subtle differences in the skin color over the pressure point compared with the surrounding area. In addition, compromised skin feels warmer or cooler on palpation.

Record the location and size of the wound first. Wounds are sized by length, width, and depth using millimeters or centimeters. For standardization in documentation, assess the wound as a clock face with the 12 o'clock position in the direction of the patient's head and the 6 o'clock position in the direction of the patient's feet (van Rijswijk, 2013). Using a disposable paper tape measure, always measure the length from the 12 o'clock position to the 6 o'clock position and the width between the 9 o'clock position and the 3 o'clock position. Measure depth as the distance from the deepest portion of the wound base to the skin level. Touch the bottom of the wound with a cotton-tipped applicator or swab and mark the place on the swab that is level with the skin surface to obtain wound depth. Then measure the area of the swab between the tip and the mark. When everyone uses this format, measurement is accurate and progress can be determined.

Inspect the wound margins for **cellulitis** (inflammation of the skin and subcutaneous tissue) extending beyond the area of injury. Progressive tissue destruction, seen as an increase in the size or depth of the ulcer and increased wound drainage, may indicate an increased risk for infection if proper measures have been taken to relieve pressure.

Inspect the wound for the presence or absence of necrotic tissue. Because of the depth of tissue destruction, a full-thickness pressure ulcer is often covered by a layer of black, gray, or brown collagen called wound **eschar.**

In the early stages of wound healing, the eschar is dry, leathery, and firmly attached to the wound. As the inflammatory phase of wound healing begins and removal of wound debris progresses, the eschar starts to lift and separate from the tissue beneath. This nonliving eschar is a good breeding ground for any bacteria on the skin surface. As bacteria increase, they release enzymes that soften necrotic tissue, which becomes softer and more yellow. With bacterial colonization, wound exudate increases substantially; the color and odor of wound exudate indicate the major organism present. The features of wound exudate are listed in Table 25-3.

TABLE 25-3
Types of Wound Exudate

CHARACTERISTICS	SIGNIFICANCE
Serosanguineous Exudate	
Blood-tinged amber fluid consisting of serum and red blood cells	Normal for first 48 hr after injury Sudden increase in amount precedes wound dehiscence in wounds closed by first intention
Purulent Exudate	
Creamy yellow pus	Colonization with *Staphylococcus*
Greenish blue pus causing staining of dressings and accompanied by a "fruity" odor	Colonization with *Pseudomonas*
Beige pus with a "fishy" odor	Colonization with *Proteus*
Brownish pus with a "fecal" odor	Colonization with aerobic coliform and *Bacteroides* (usually occurs after intestinal surgery)

Beneath the dead tissue, granulation tissue appears. Early granulation is pale pink, progressing to a beefy red color as it grows and fills the wound. Palpate the wound to determine the granulation texture. Healthy granulation tissue is moist and has a slightly spongy texture. Wounds with a poor arterial blood supply or that have stopped healing appear dry with hard (fibrotic) granulation tissue on palpation. Venous obstruction causes a very moist ulcer surface with a deep reddish purple color from the deoxygenated blood beneath the ulcer surface.

Pressure ulcers may have more tissue destruction than is first seen on inspection. Deep, extensive tissue damage may be present under normal-appearing skin surrounding the wound, with separation of the skin layers from the underlying granulation tissue. This problem is known as **undermining.** Inspect undermined areas for gradual filling with healthy granulations and for wound-healing progress. Palpate the bony prominences for deep hardening of the surrounding soft tissue, which often occurs with deep tissue ischemia.

After ischemia has occurred, continued pressure over the area increases tissue destruction from the deep tissue layers toward the surface, resulting in the formation of tunnels. This "hidden" wound may have a small opening in the skin with purulent drainage. If such an opening is observed, use a cotton-tipped applicator to probe gently for a much larger tunnel or pocket of necrotic tissue beneath the opening. Additional tunnels may occur along the main wound. Check all wounds for tunneling and, if present, document the location and length of each tunnel.

Psychosocial Assessment.

The patient with pressure ulcers may have an altered body image. Many changes in lifestyle are needed for healing. Chronic ulcers are often

painful and costly to treat.

Assess the patient's and family's knowledge of the desired treatment outcomes during the healing process, as well as adherence to the prescribed treatment regimen. Also assess the patient's skills in cleaning and dressing the wound. Poor adherence to pressure ulcer care procedures may reflect an inability to cope with the pain, cost, or potential scarring associated with prolonged healing. Depending on the patient's activity level and the ulcer location, family assistance or a home care nurse may be needed to provide pressure ulcer care at home.

Teach the patient and family specific changes in ADLs to relieve pressure and promote healing. Urge increased activity whenever possible to enhance circulation to the affected tissue. Leg position changes may be needed for chronic leg ulcers, depending on whether vascular problems are present. For patients who have arterial insufficiency, keeping the legs and feet in a dependent position helps ensure adequate blood flow to the lower legs. When arterial blood flow is adequate but venous return is impaired, elevation of the legs may be needed for healing. When the patient is bedridden, frequent repositioning to relieve pressure (every 2 hours in bed, every 1 hour in a chair) can be labor intensive. In the home, repositioning, incontinence management, and dressing changes are often needed around the clock, not only increasing patient discomfort but also disrupting family routines and causing added stress.

Laboratory Assessment.

An exposed wound is always *contaminated* but is not always *infected. Contamination* is the presence of organisms without any manifestations of infection. Normal immune defenses keep the number of bacteria to a minimum and prevent infection. *Wound infection* is contamination with pathogenic organisms to the degree that organism growth and spread cannot be controlled by the body's immune defenses. Wounds that are red and indurated with moderate to heavy exudate and an odor should be cultured to identify the organism and determine antibiotic sensitivity. *The presence of purulent exudate alone does not indicate an infection because pus forms whenever necrotic tissue liquefies and separates.*

If wounds are extensive, if the patient is severely immunocompromised, or if local blood supply to the wound is impaired, bacterial growth exceeds the body's defenses against invasion into deeper tissues. The result is deep wound infection and eventually bacteremia and sepsis.

Swab cultures are helpful only in identifying the types of bacteria

present on the ulcer surface and may not identify bacteria in deeper tissues (Cross, 2014). Wound biopsies allow the numbers of bacteria to be analyzed, but these tests are time consuming, costly, and not always available. Clinical indicators of infection (cellulitis, progressive increase in ulcer size or depth, changes in the quantity and quality of exudate) and systemic signs of bacteremia (e.g., fever, elevated white blood cell [WBC] count) are used to diagnose an infection.

Other Diagnostic Assessments.

Additional laboratory studies are performed based on the suspected cause of the wound. For example, noninvasive and invasive arterial blood flow studies are indicated if arterial occlusion is suspected in delayed healing of a pressure ulcer on the heel or ankle. Blood tests to determine nutritional deficiencies (e.g., prealbumin, albumin, total protein) are helpful in managing the debilitated, malnourished patient with a pressure ulcer.

Clinical Judgment Challenge

Patient-Centered Care; Evidence-Based Practice QSEN

An 82-year-old woman, who lives alone, fell at home and lay on her right side for 10 hours on a hardwood floor before she was found. Although she broke no bones, she is very sore and does not want to move. She has an open abraded area on her right trochanter. Her other health problems include arthritis, hypertension, type 2 diabetes, osteoporosis, and gastroesophageal reflux disease.

1. Is the open area considered a pressure ulcer? Why or why not?
2. What risk factors does this patient have for pressure ulcer formation?
3. What other body areas should be inspected for possible pressure ulcer formation?
4. How will you handle her request not to move or be moved?

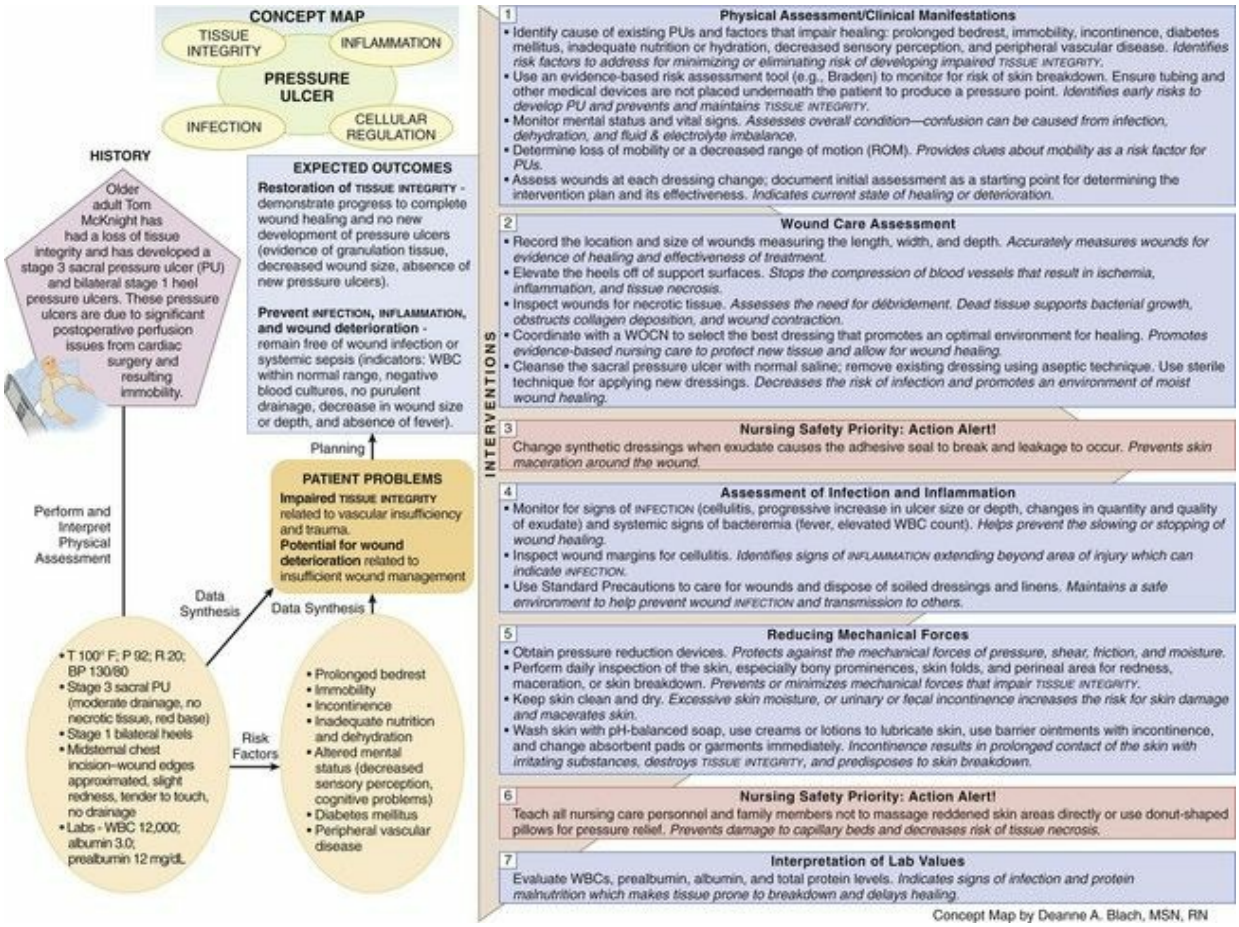
Analysis

The priority NANDA-I nursing diagnoses and collaborative problems for patients with pressure ulcers include:

1. Impaired Tissue Integrity related to vascular insufficiency and trauma (NANDA-I)
2. Potential for wound deterioration related to insufficient wound management

Planning and Implementation

The Concept Map on p. 445 addresses care issues related to patients who have or are at risk for pressure ulcers.



Managing Wounds

Planning: Expected Outcomes.

The patient with a pressure ulcer is expected to progress to complete wound healing and not develop new pressure ulcers. Indicators include:

- Presence of granulation, re-epithelialization, and scar tissue formation
- Decreased wound size
- Absence of new pressure ulcers

Interventions.

Wound care for pressure ulcers varies according to each patient's needs and the health care provider's preferences. Surgery may be indicated for some patients, whereas a nonsurgical approach to ulcer débridement is preferred for a patient who has adequate defenses but is too ill or debilitated for surgery.

Nonsurgical Management.

General interventions for pressure ulcer care are listed in Chart 25-4. Nonsurgical intervention of pressure ulcers is often left to the discretion of the nurse, who coordinates with the health care provider and certified wound care specialist (if available) to select an appropriate method of wound dressing and management. Many agencies have guidelines for wound dressings based on wound size and depth and presence of drainage.

Chart 25-4 Best Practice for Patient Safety & Quality Care QSEN

Wound Management of Pressure Ulcers

- If ulcer is covered, remove old dressings/coverings daily (unless the dressing type is to remain in place until it loosens naturally).
- Measure wound size at greatest length and width using a disposable paper tape measure or, for asymmetric ulcers, by tracing the wound onto a piece of plastic film or sheeting (plastic template) at least weekly or more often if the wound shows signs of deterioration.
- Compare all subsequent measurements against the initial measurement.
- Assess the ulcer for presence of necrotic tissue and amount of exudate.
- Assess and document the condition of the skin surrounding the pressure ulcer in terms of color, temperature, texture, moisture, and appearance.
- Remove or trim loose bits of tissue (may be done by a certified wound care specialist, physical therapist, advanced practice nurse, or other as specified by the agency and the state's nurse practice act).
- Cleanse the ulcer with saline or a prescribed solution (after diluting it as per manufacturer's directions or prescriber's instructions).
- Rinse and dry the ulcer surface.
- In collaboration with the certified wound care specialist, select and apply the dressing materials most appropriate for the volume of wound drainage.
- If possible, avoid positioning the patient on the pressure ulcer.
- Re-position at least every 1 to 2 hours to prevent ulcer extension or generation of additional pressure ulcers.
- Use prescribed pressure-relieving and pressure-reducing devices and techniques as described in Chart 27-2.

Dressings.

A well-designed dressing helps healing by removing surface debris, protecting exposed healthy tissues, and creating a barrier until the ulcer is closed. *For a draining, necrotic ulcer, the dressing must also remove excessive exudate and loose debris without damaging healthy epithelial cells or new granulation tissue. Extensive necrosis and thick eschar require surgical or chemical removal before débridement with dressings can be effective.* Different dressing materials help remove debris by **mechanical débridement** (mechanical entrapment and detachment of dead tissue), by **topical chemical débridement** (topical enzyme preparations to loosen necrotic tissue), or by **natural chemical débridement** (promoting self-digestion of dead tissues by naturally occurring bacterial enzymes *[autolysis]*) (Table 25-4).

TABLE 25-4

Common Dressing Techniques for Wound Débridement

TECHNIQUE	MECHANISM OF ACTION
Wet-to-damp saline-moistened gauze	As with the wet-to-dry technique, necrotic debris is mechanically removed but with less trauma to healing tissue.
Continuous wet gauze	The wound surface is continually bathed with a wetting agent of choice, promoting dilution of viscous exudate and softening of dry eschar.
Topical enzyme preparations	Proteolytic action on thick, adherent eschar causes breakdown of denatured protein and more rapid separation of necrotic tissue.
Moisture-retentive dressing	Spontaneous separation of necrotic tissue is promoted by autolysis.

After all the dead tissue has been removed, protection of exposed healthy tissues is critical to pressure ulcer care. The ideal healing environment is a clean, *slightly* moist ulcer surface with minimal bacterial colonization. Heavy moisture from an excessively draining ulcer or a dressing that is too wet promotes the growth of organisms and causes maceration (mushiness) of healthy tissue. Likewise, if a clean ulcer surface is exposed to air or if highly absorbent dressing materials are used for prolonged periods, overdrying can dehydrate surface cells, form scabs, and convert the wound to a deeper injury. The right balance of moisture is the key to maintaining a healing environment. The type of dressing should change as wound features change with healing (Baranoski & Ayello, 2012).

Assess the ulcer for necrotic tissue and amount of exudate. Coordinate with a wound care specialist to select a dressing material that promotes an optimal environment for healing. For example, a material that does

not stick to the wound surface and does not remove new epithelial cells when it is changed is used for protecting new tissue. Depending on the amount of drainage, select either a hydrophobic or a hydrophilic material:

- A **hydrophobic** (nonabsorbent, waterproof) material is useful when the wound has little drainage and needs to be protected from external contamination.
- A **hydrophilic** (absorbent) material draws excessive drainage away from the ulcer surface, preventing maceration.

A variety of synthetic materials with different absorbent properties are available. Unlike cotton gauze dressings, these may be left intact for extended periods. Biologic and synthetic skin substitutes are the newest materials being researched. Although useful, these "smart" dressings may be cost-prohibitive for many patients.

The frequency of dressing changes depends on the amount of necrotic material or exudate. Dry gauze dressings are changed when "strike through" occurs—when the outer layer of the dressing first becomes saturated with exudate. Gauze dressings used for débridement of a wet wound (allowed to become damp and then removed) are changed often enough to take off any loose debris or exudate, usually every 4 to 6 hours.

Nursing Safety Priority QSEN

Action Alert

Change synthetic dressings when exudate causes the adhesive seal to break and leakage to occur.

Before reapplying any dressing, gently clean the ulcer surface with saline or another wound cleanser as prescribed. If an antibacterial cleanser is prescribed, dilute the agent to reduce tissue toxicity and then rinse with tap water and dry the surface before applying the dressing.

Physical Therapy.

Daily whirlpool treatments along with dressing changes for débridement can help remove dead tissue. The ulcerated area is immersed in or saturated with warm tap water that contains a cleansing agent. Continuous agitation of the water loosens the debris and washes away exudate and debris. During treatment, the ulcer surface is cleansed with a gauze pad. After treatment, the therapist or wound specialist often uses instruments to trim away any obvious bits of dead tissue that are

still loosely attached to the ulcer surface.

Drug Therapy.

Clean, healthy granulation tissue has a blood supply and is capable of providing white blood cells and antibodies to the ulcer to combat infection. If extensive necrosis is present or if local tissue defenses are impaired, topical antibacterial agents are often needed to control bacterial growth (see Chart 26-5 in Chapter 26 for a list of topical antibacterial agents). Antibiotic use is avoided in the absence of infection to reduce the development of resistant bacterial strains.

Nutrition Therapy.

Successful healing of pressure ulcers depends on adequate intake of calories, protein, vitamins, minerals, and water. Nutrition deficiencies are common among chronically ill patients and increase the risk for skin breakdown and delayed wound healing. Severe protein deficiency inhibits healing and impairs host infection defenses.

Coordinate with the dietitian to help the patient eat a well-balanced diet, emphasizing protein, vegetables, fruits, whole grains, and vitamins. Fats also are needed to ensure formation of cell membranes. (See Chapter 60 for interventions to ensure adequate nutrition.) If the patient cannot eat sufficient amounts of food, other types of feedings may be needed to increase protein and caloric intake (see Chapter 60). Vitamin and mineral supplements are also indicated.

New Technologies.

For chronic ulcers that remain open for months, new technologies have had some success. These include electrical stimulation, negative pressure wound therapy, hyperbaric oxygen therapy, topical growth factors, and skin substitutes.

Electrical stimulation is the application of a low-voltage current to a wound area to increase blood vessel growth and promote granulation. This treatment is usually performed by a certified wound care specialist. The voltage is delivered in "pulses" that may cause a "tingling" sensation. Usually this technique is performed for 1 hour a day, 5 to 7 days a week. It is not used with patients who have a pacemaker or a wound over the heart.

Negative pressure wound therapy (NPWT) can reduce or even close chronic ulcers by removing fluids or infectious materials from the wound and enhancing granulation. This technique requires that a suction tube be covered by a special sponge and sealed in place. Per manufacturer's

instructions, the foam dressing is changed every 48 to 72 hours (or at least 3 times weekly). Continuous low-level negative pressure is applied through the suction tube. Duration of the treatment is determined by the wound's response. It should not be used in areas of skin cancer. Failure of NPWT is often due to the inability to maintain an adequate dressing seal (Rock, 2011).

Current evidence does not support greater effectiveness of NPWT in closing chronic wounds than more traditional methods. Serious bleeding and even deaths have occurred with NPWT, and these devices have received a warning from the Food and Drug Administration (FDA) to exclude high-risk patients from its use. Any patient who is receiving this therapy must be monitored at least every 2 hours for bleeding at or near the wound site.

Nursing Safety Priority QSEN

Critical Rescue

Do not use a continuous negative pressure wound therapy device with any patient who is on anticoagulant therapy; has reduced tissue health near the wound (e.g., with radiation therapy or poor nutrition); or has any exposed blood vessels, nerves, or organs in the wound area.

Hyperbaric oxygen therapy (HBOT) is the administration of oxygen under high pressure, raising the tissue oxygen concentration. This type of therapy is usually reserved for life- or limb-threatening wounds such as burns, necrotizing infections, brown recluse spider bites, osteomyelitis, and diabetic ulcers. The patient is enclosed in a large chamber and exposed to 100% oxygen at pressures greater than normal atmospheric pressure. Systemic oxygen enhances the ability of white blood cells to kill bacteria and reduce swelling. Treatment usually lasts from 60 to 90 minutes. Smaller topical oxygen delivery devices are also available. These devices are applied directly over an open wound to promote local tissue oxygenation; however, their effectiveness in promoting wound healing requires further study (Woo et al., 2012).

Topical growth factors are normal body substances that stimulate cell movement and growth. These factors are deficient in chronic wounds, and topical application is used to stimulate wound healing. For example, platelet-derived growth factor (PDGF) stimulates the movement of fibroblasts into the wound space. Use of this and other growth factors has been effective for healing of some chronic wounds, but further study

is needed (Demidova-Rice et al., 2012b).

Skin substitutes are engineered products that aid in the closure of different types of wounds. These products vary widely in design and application and are used mainly for surgically débrided wounds before reconstruction with grafts or muscle flaps.

Surgical Management.

Surgical management of a pressure ulcer includes removal of necrotic tissue and skin grafting or use of muscle flaps to close wounds that do not heal by re-epithelialization and contraction. Not all wounds are candidates for grafting. Those with poor blood flow are unlikely to have successful graft take and heal. The procedures are very similar to the surgical management of burn wounds. See the Surgical Management section of Managing Wound Care on pp. 483–485 of Chapter 26.

Preventing Infection and Wound Deterioration

Planning: Expected Outcomes.

The patient with a pressure ulcer is expected to remain free of wound infection or sepsis. Indicators include that the patient will have mild or no:

- White blood cell elevation
- Positive blood culture
- Purulent or malodorous drainage
- Increase in wound size or depth
- Fever

Interventions.

Priority nursing interventions focus on preventing wound infection and identifying wound infection early to prevent complications.

Monitoring the ulcer's appearance using objective criteria allows evaluation of the response to treatment and early recognition of infection. If an ulcer shows no progress toward healing within 7 to 10 days or worsens, the treatment plan is re-evaluated. Chart 25-5 outlines objectives of monitoring wounds with and without tissue loss. Patients who are at highest risk for infection are those who are older, have white blood cell (WBC) disorders, are receiving steroid therapy, or have wounds with a compromised blood supply.

Chart 25-5 Best Practice for Patient Safety & Quality Care QSEN

Monitoring the Wound

VARIABLE	FREQUENCY OF ASSESSMENT	RATIONALE
Wounds Without Tissue Loss		
Examples		
Surgical incisions and clean lacerations closed primarily by sutures or staples		
Observations (using first postoperative dressing change as baseline)		
Check for the presence or absence of increased: • Localized tenderness • Swelling of the incision line • Erythema of the incision line >1 cm on each side of wound • Localized heat	At least every 24 hr until sutures or staples are removed	To detect cellulitis (bacterial infections)*
Check for the presence or absence of: • Purulent drainage from any portion of the incision site • Localized fluctuance (from fluid accumulation) and tenderness beneath a *portion* of the wound when palpated	At least every 24 hr until sutures or staples are removed	To detect abscess formation related to presence of foreign body (suture material) or deeper wound infection*
Check for the presence or absence of: • Approximation (sealing) of wound edges with or without serosanguineous drainage • Necrosis of skin edges	At least every 24 hr until sutures or staples are removed	To detect potential for wound dehiscence
Wounds with Tissue Loss		
Examples		
Partial- or full-thickness skin loss caused by pressure necrosis, vascular disease, trauma, etc., and allowed to heal by secondary intention		
Observations		
Wound Size		
Measure wound size at greatest length and width using a disposable paper tape measure or, for asymmetric ulcers, by tracing the wound onto a piece of plastic film or sheeting (plastic template) Measure depth of full-thickness wounds using cotton-tipped applicator Compare all subsequent measurements against the initial measurement	Once per week	To detect increase in wound size and depth secondary to infectious process
Ulcer Base		
Check for the presence or absence of: • Necrotic tissue (loose or adherent) • Foul odor from wound when dressing is changed Note the frequency of dressing changes or dressing reinforcements owing to drainage	At least every 24 hr	To detect the need for débridement or the response to treatment (necrotic tissue) and to detect local wound infection (frequent dressing changes and foul odor)
Wound Margins		
Check for the presence or absence of: • Erythema and swelling extending outward >1 cm from wound margins • Increased tenderness at wound margins	At least every 24 hr or at each dressing change	To detect wound infection*
Systemic Response		
Check for the presence or absence of elevated body temperature or WBCs or positive blood culture	Check temperature daily; if elevated, check WBCs and blood culture	To detect bacteremia

WBCs, White blood cells.

*The wounds of patients who are severely immunosuppressed or those wounds with compromised blood supply may not exhibit a typical inflammatory response to local wound infection.

Preventing infection and its complications starts with monitoring the ulcer's progress. Routinely check for manifestations of wound infection: increased pain, tenderness, and redness at the wound margins, edema, and purulent and malodorous drainage. Report these changes to the health care provider:

- Sudden deterioration of the ulcer, seen as an increase in the size or depth of the lesion
- Changes in the color or texture of the granulation tissue
- Changes in the quantity, color, or odor of exudate

These changes may occur with or without manifestations of

bacteremia, such as fever, an elevated WBC, and positive blood cultures. Use the previously described interventions to prevent the formation of new pressure ulcers and to prevent early-stage ulcers from progressing to deeper wounds (see Chart 25-2).

Maintaining a safe environment can help prevent wound infection. Because of the variety of organisms in the hospital environment, keeping an ulcer totally free of bacteria is impossible. Optimal ulcer management is based on maintaining acceptably low levels of organisms through meticulous wound care and reducing contamination with pathogenic organisms that could lead to sepsis and death. *Teach all personnel to use Standard Precautions and to properly dispose of soiled dressings and linens.*

Community-Based Care

Patients with pressure ulcers may be in acute care, subacute care, long-term care, or home care settings. If pressure ulcer therapy requires hospitalization, most patients are discharged before complete wound closure is achieved. Discharge may be to the home setting or to a long-term care facility, depending on the degree of debilitation and other patient factors.

Home Care Management.

Ulcer care in the patient's home is similar to care in the hospital. Most dressing supplies and pressure-relief devices can be obtained at a pharmacy or medical supply store. If ulcer débridement is needed, a handheld shower device or forceful irrigation of the wound with a 35-mL syringe and 19-gauge angiocatheter can be substituted for whirlpool therapy.

Many patients cannot change their own dressings because of wound location, distress over an altered body image, or the pain of dressing removal. Others depend on family members or support personnel because of limited physical mobility.

For some patients, drastic changes in daily activities are needed to promote healing. Patients with leg ulcers may need frequent rest periods with leg elevation to avoid or reduce edema. Immobile patients with pressure ulcers require around-the-clock repositioning as often as every 1 to 2 hours to prevent further breakdown, which takes its toll on caregivers. Explain the rationale for activity changes to the patient and family, and explore ways of coping with these changes.

Some patients may need to continue the use of special beds or mattress overlays at home. Although these items can be expensive, home use can keep the patient out of more-costly health care settings. Consider

both the space and power supply when choosing a pressure-relief device for home use. Coordinate with the case manager to work with the insurance company in providing these important aids for quality patient care.

Self-Management Education.

Before the patient is discharged, have the patient or caregiver demonstrate competence in removing the dressing, cleaning the wound, and applying the dressing. When choosing a dressing to be used at home, consider the patient's or caregiver's ability to apply the dressing properly. If the patient's finances are limited, address the cost of the dressing material. At times, the more expensive dressing materials that require less frequent changing may be preferred. Explain the manifestations of wound infection, and remind the patient and family to report their presence to the health care provider or wound care clinic.

Encourage the patient to eat a balanced diet, including high-protein snacks. Discuss diet preferences with the patient and consult a dietitian as needed to design a food plan to promote wound healing. Vitamin and mineral supplements may be needed to prevent or treat deficiencies. If the patient is incontinent, emphasize the need to keep the skin clean and dry. If bowel and bladder training are not possible, discuss the use of absorbent underpads, briefs, and topical moisture barrier creams and ointments as methods to reduce skin exposure to urine and feces.

Health Care Resources.

A home care nurse may be needed to follow wound progress after discharge. As indicated by The Joint Commission's NPSGs, the hospital nurse provides details of ulcer size and appearance and any special wound care needs in a hand-off report to the home care nurse, who can then accurately judge changes in ulcer appearance. Chart 25-6 is a guideline for a focused assessment of the patient with pressure ulcers.

Chart 25-6 Home Care Assessment

The Patient at Risk for Pressure Ulcers

Assess cardiovascular status:

- Presence or absence of peripheral edema
- Hand-vein filling in the dependent position
- Neck-vein filling in the recumbent and sitting positions
- Weight gain or loss

Assess cognition and mental status:
- Level of consciousness
- Orientation to time, place, and person
- Can the patient accurately read a seven-word sentence containing words of three syllables or fewer?

Assess condition of skin:
- Assess general skin cleanliness
- Observe all skin areas, paying particular attention to bony prominences and those areas in greatest contact with the bed and other firm surfaces
- Measure and record any areas of redness or loss of integrity
- If possible, photograph areas of concern
- Note the presence or absence of skin tenting over the sternum or the forehead
- Note the moistness of skin and mucous membranes
- If wounds are present, remove dressings (noting condition of dressings), cleanse the wound, and compare with previous notations of wound condition:
  Presence, amount, and nature of exudate
  Use a disposable paper tape measure to measure wound diameter and depth
  Amount (%) and type of necrotic tissue
  Presence of granulation/epithelium
  Presence or absence of cellulitis
  Presence or absence of odor

Take the patient's temperature.

Assess the patient's understanding of illness and compliance with treatment:
- Manifestations to report to health care provider
- Drug therapy plan (correct timing and dose)
- Ambulation or positioning schedule
- Dressing changes/skin care
- Nutrition modifications (24-hour diet recall)

Assess the patient's nutritional status:
- Change in muscle mass
- Lackluster nails, sparse hair
- Recent weight loss of more than 5% of usual weight
- Impaired oral intake
- Difficulty swallowing
- Generalized edema

To help decrease the cost of treatment, emphasize proper use of dressing materials. Clean tap water and nonsterile supplies are used for home management of chronic wounds and are less costly than sterile products. Stress the importance of properly cleaning reused items and of handwashing before touching any supplies.

The patient with activity restrictions may need daily assistance from a home care aide. Collaborate with a physical therapist or occupational therapist to help the patient and family continue rehabilitation efforts in the home.

Evaluation: Outcomes

Evaluate the care of the patient with a pressure ulcer on the basis of the identified priority patient problems. The expected outcomes include that the patient will:

- Experience progress toward wound healing by second intention as evidenced by granulation, epithelialization, and reduction or resolution of wound size
- Re-establish skin tissue integrity and restore skin barrier function
- Remain infection free

Specific indicators for these outcomes are listed for each priority patient problem under the Planning and Implementation section (see earlier).

Common Infections

Pathophysiology

Skin infection can be bacterial, viral, or fungal. Chart 25-7 lists key features and common locations of each type.

Chart 25-7 Key Features

Common Skin Infections

CLINICAL MANIFESTATIONS	DISTRIBUTION
Bacterial Infections	
Folliculitis	
Isolated erythematous pustules occur singly or in groups; hairs grow from centers of many of the lesions. Occasional papules are present. There is little or no associated discomfort. There is no residual scarring.	Areas of hair-bearing skin, especially buttocks, thighs, beard area, and scalp
Furuncle	
Small, tender, erythematous nodules become pus filled and more tender over time. Lesions may be single or multiple and also recurrent. Regional lymphadenopathy is sometimes present; fever is rare. Occasional scarring results.	Areas of hair-bearing skin, especially buttocks, thighs, abdomen, posterior neck regions, and axillae
Cellulitis	
Localized area of inflammation may enlarge rapidly if not treated. Redness, warmth, edema, tenderness, and pain are present. On rare occasions, blisters are present. Cellulitis is often accompanied by lymphadenopathy and fever.	Lower legs, areas of persistent lymphedema, and areas of skin trauma (e.g., leg ulcer, puncture wound)
Viral Infections	
Herpes Simplex	
Grouped vesicles are present on an erythematous base. Vesicles evolve to pustules, which rupture, weep, and crust. Older lesions may appear as punched-out, shallow erosions with well-defined borders. Lesions are associated with itching, stinging, or pain. Secondary bacterial infection with necrosis is possible in immunocompromised patients.	Type 1 classically on the face and type 2 on the genitalia, but either may develop in any area where inoculation has occurred; recurrent infections occur repeatedly in the same skin area
Herpes Zoster (Varicella Zoster)	
Lesions are similar in appearance to herpes simplex and also progress with weeping and crusting. Grouped lesions present unilaterally along a segment of skin following the pathway of a spinal or cranial nerve (dermatomal distribution). Eruption is preceded by deep pain and itching. Postherpetic neuralgia is common in older adults. Secondary infection with necrosis is possible in immunocompromised patients.	Anterior or posterior trunk following involved dermatome; face, sometimes involving trigeminal nerve and eye
Fungal Infections	
Dermatophytosis	
Annular or serpiginous patches are present with elevated borders, scaling, and central clearing. Itching is common. Lesions may be single or multiple.	Anywhere on the body
Candidiasis	
Erythematous macular eruption occurs with isolated pustules or papules at the border (satellite lesions). Candidiasis is associated with burning and itching. Oral lesions (thrush) appear as creamy white plaques on an inflamed mucous membrane. Cracks or fissures at the corners of the mouth may be present.	Skinfold areas: perineal and perianal region, axillae, beneath breasts, and between the fingers; under wet or occlusive dressings Lesions possibly present on the oral or vaginal mucous membranes

Bacterial Infections

Bacterial skin lesions usually start at the hair follicle, where bacteria

easily collect and grow in the warm, moist environment. **Folliculitis** is a superficial infection involving only the upper portion of the follicle and is often caused by *Staphylococcus.* The rash is raised and red and usually shows small pustules. **Furuncles** (boils) are also caused by *Staphylococcus,* but the infection is much deeper in the follicle (Fig. 25-7). This larger, sore-looking, raised bump may or may not have a pustular "head" at its point. Cellulitis often occurs as a generalized infection with either *Staphylococcus* or *Streptococcus* and involves the deeper connective tissue.

FIG. 25-7 A furuncle.

Minor skin trauma usually occurs before the appearance of folliculitis and furuncles and may contribute to the development of cellulitis. Patients may spread the infection to other parts of their bodies by scratching or rubbing the skin with fingernails. Furuncles most often occur in areas of heat and moisture, such as in the hair-bearing skinfold areas. Cellulitis can occur as a result of secondary bacterial infection of an open wound, or it may be unrelated to skin trauma.

A common skin problem is infection with methicillin-resistant *Staphylococcus aureus* (MRSA). This infection can range from mild folliculitis to extensive furuncles. It is easily spread to other body areas and to other people by direct contact with infected skin and by contact with clothing, linens, athletic equipment, and other objects used by a person with MRSA. The infection does not respond to cleansing with antibacterial soaps or most types of topical and many oral antibiotic therapies. If MRSA infects a wound or enters the bloodstream, deep

wound infection, sepsis, organ damage, and death can occur. The incidence is highest among adults living in communal environments, such as dormitories or prisons, and among patients in hospitals or other health care settings. (See Chapter 23 for a more detailed MRSA discussion.)

Viral Infections

Herpes simplex virus (HSV) infection is the most common viral infection of adult skin and has two types. Type 1 (HSV-1) infections cause the classic recurring cold sore. The severity of the disease increases with age and is worse when the patient is immunosuppressed. Genital herpes, caused by type 2 infection (HSV-2), is also recurrent (see Chapter 74).

After the first infection, the virus remains in a dormant state in the nerve ganglia and the patient has no manifestations. Reactivation stimulates the virus to travel down sensory nerves to the skin, where lesions reappear. Recurrence of HSV infection in healthy people is triggered by stressors, such as dry lips, sunburn, trauma, fever, menses, and fatigue. The virus can also be spread by contact between an actively infected person and a susceptible host. *Autoinoculation,* or transfer of either viral type from one part of the body to another, is also possible.

The time span between episodes and the severity of each attack vary. Outbreaks of oral herpes simplex usually last 3 to 10 days. The patient may have tingling or burning of the lip before any lesion is evident. The patient sheds virus and is contagious for the first 3 to 5 days.

The clinical picture of HSV-1 infection is isolated or grouped painful vesicles on a red base. The infection can occur anywhere on the skin and may be spread by respiratory droplets or by direct contact with an active lesion or virus-containing fluid (e.g., saliva).

Herpetic whitlow is a form of herpes simplex that occurs on the fingertips of health care personnel who come into contact with viral secretions. It can be spread easily to patients and can become severe in immunosuppressed patients.

Herpes zoster (shingles) is infection caused by reactivation of the varicella-zoster virus (VZV) in patients who have previously had chickenpox. The dormant virus resides in the dorsal root ganglia of sensory nerves. Multiple lesions occur in a segmental distribution on the skin area innervated by the infected nerve (Fig. 25-8). Herpes zoster eruptions usually occur after several days of discomfort, which may vary from minor irritation and itching to severe, deep pain. The eruption usually lasts several weeks. **Postherpetic neuralgia** (severe pain persisting after the lesions have resolved) is common in older patients. Early diagnosis of

shingles and prompt treatment with antiviral drugs help decrease the duration and severity of postherpetic neuralgia.

FIG. 25-8 Herpes zoster (shingles).

Herpes zoster occurs most often in older people or in anyone who is immunosuppressed for any reason. The disorder can be accompanied by fever and malaise. *It is contagious to people who have not previously had chickenpox and have not been vaccinated against the disease.* Keeping patients with fluid-filled blisters separated from other patients until the lesions have crusted reduces the risk for transmitting the virus to others. Complications include full-thickness skin necrosis, Bell's palsy, or eye infection, and scarring if the virus is introduced into the eye.

Fungal Infections

Dermatophyte infections, especially superficial infections, differ in lesion appearance, body location, and species of the organism. The term *tinea* is used to describe dermatophytoses; this term is then followed by the location description. For example *tinea pedis* involves the foot (athlete's foot), *tinea manus* involves the hands, *tinea cruris* involves the groin (jock itch), *tinea capitis* involves the head, and *tinea corporis* involves the rest of the body (ringworm).

Depending on the species, dermatophytes live mainly in the soil, on animals, and on humans. Superficial infection can start only when the infecting organism comes in contact with impaired skin in a susceptible host. Infections are spread by direct contact with infected humans or

animals. Some infections, such as tinea capitis and tinea corporis, can be transmitted by inanimate objects. For example, tinea capitis can be spread by sharing contaminated combs, hats, pillowcases, and other objects with people who have poor personal hygiene.

Candida albicans, also known as *yeast infection,* is a common fungal infection of skin and mucous membranes. The organism is present almost everywhere and easily grows in a warm, moist environment. Risk factors for this infection include immunosuppression, long-term antibiotic therapy, diabetes mellitus, and obesity.

Infected skin has a moist, red, irritated appearance with itching and burning. Common areas for infection are the perineum, vagina, axillae, under the breasts, and in the mouth (where it is known as *thrush* or *oral candidiasis*).

Prevention is aimed at keeping skinfold areas clean and dry. Turning patients and positioning to enhance airflow also aid in prevention. When the infection is present, meticulous cleanliness and the use of topical antifungal agents are needed.

Health Promotion and Maintenance

Preventing skin infection, especially bacterial and fungal infections, involves avoiding the offending organism and practicing good hygiene to remove the organism before infection can occur. *Handwashing and not sharing personal items with others are the best ways to avoid contact with these organisms, including MRSA.* Chart 25-8 lists strategies to teach patients and family members to prevent infection spread to other body areas and to other people.

Chart 25-8 Patient and Family Education: Preparing for Self-Management

Preventing the Spread of MRSA

- Avoid close contact with others, including participation in contact sports, until the infection has cleared.
- Take all prescribed antibiotics exactly as prescribed for the entire time prescribed.
- Keep the infected skin area covered with clean, dry bandages.
- Change the bandage whenever drainage seeps through it.
- Place soiled bandages in a plastic bag, and seal it closed before placing it in the regular trash.
- Wash your hands with soap and warm water before and after touching

the infected area or handling the bandages.
- Shower (rather than bathe) daily, using an antibacterial soap.
- Wash all uninfected skin areas before washing the infected area, or use a fresh washcloth to wash the uninfected areas.
- Use each washcloth only once before laundering, and avoid using bath sponges or puffs.
- Sleep in a separate bed from others until the infection is cleared.
- Avoid sitting on or using upholstered furniture.
- Do not share clothing, washcloths, towels, athletic equipment, shavers or razors, or any other personal items.
- Clean surfaces that may have come into contact with your infected skin, drainage, or used bandages (e.g., bathroom counters, shower/bath stalls, toilet seats) with household disinfectant or bleach water mixed daily (1 tablespoon of liquid bleach to 1 quart of water).
- Wash all soiled clothing and linens with hot water and laundry detergent. Dry clothing either in a hot dryer or outside on a clothesline in the sun.
- Urge family members and close friends to shower daily with an antibacterial soap.
- If another person assists you in changing the bandages, make certain he or she uses disposable gloves, pulls them off inside out when finished, places them with the soiled bandages in a sealed bag, and washes his or her hands thoroughly.

MRSA, Methicillin-resistant *Staphylococcus aureus.*

For older adults who have had chickenpox and are, therefore, at risk for shingles (herpes zoster), the vaccine *Zostavax* is available to prevent VZV reactivation and shingles. The Centers for Disease Control and Prevention (CDC) recommends the vaccine for anyone older than 50 years who has a healthy immune system. This one-time subcutaneous injection significantly reduces the incidence of shingles. Cost remains a factor in vaccination, and few insurance carriers currently include this coverage.

Nursing Safety Priority QSEN

Drug Alert

Zostavax is a live viral vaccine and should not be used in patients with severe immunosuppression because of the risk for viral dissemination. Always check with the prescriber before giving any live vaccines to

severely immune compromised patients or those receiving biologic agents for autoimmune disease.

Patient-Centered Collaborative Care

Assessment

History.

Concentrate on risk factors for each type of infection. If the location and appearance of lesions suggest a bacterial infection, ask about a recent history of skin trauma or recent staphylococcal or streptococcal infections. Assess living conditions, home sanitation, personal hygiene habits, and leisure or sport activities. Ask whether fever and malaise are also present.

Lesions appearing on the lips, in the mouth, or in the genital region are more likely to be a possible viral infection. Ask about:

- A history of similar lesions in the same location
- Presence of burning, tingling, or pain
- Recent stress factors that preceded the outbreak
- Recent contact with an infected person

Information that the same type of lesions has occurred before is important in helping differentiate viral from bacterial lesions. Ask whether the patient has had chickenpox in the past and about a history of shingles. Also ask whether he or she has received the shingles vaccination *Zostavax*.

Obtain information about a probable dermatophyte infection based on lesion location. If tinea corporis or tinea capitis is present, assess the social and home factors that may contribute to infection, such as direct contact with an infected person, poor personal hygiene, or frequent contact with animals. If tinea cruris and tinea pedis are suspected, ask about the type and frequency of athletic activities.

Physical Assessment/Clinical Manifestations.

Because most skin infections are contagious, take precautions to prevent the spread of infection when performing a physical assessment. See Chart 25-7 for a listing of the manifestations of common skin infections.

Laboratory Assessment.

When pustules are present in bacterial infections, the infecting organism is confirmed by swab culture of the purulent material. Blood cultures may be helpful if fever and malaise are present. Various cultures and other

techniques are used to identify viral and fungal infections (see Chapter 24).

Interventions

Most skin infections heal well with nonsurgical management. Surgery may be required when an infectious agent is present in deep tissue layers. *Priority nursing interventions focus on patient and family education to prevent infection spread to other body areas or to other people* (see Chart 25-8). Meticulous skin care is needed for prevention of infection spread. In some instances, drug therapy is needed.

Skin care with proper cleansing is the most effective intervention to prevent infection spread. Teach patients with bacterial infections to bathe daily with an antibacterial soap and to not squeeze any pustules or crusts. Teach them to gently remove crusts before applying topical drugs so that the drugs can be more easily absorbed. Teach the patient to apply warm compresses to furuncles or areas of cellulitis to increase comfort. Most superficial skin infections resolve more quickly if the involved skin dries between treatments. Excessive moisture, especially if occluded by dressings, clothing, or bedding, promotes organism growth. Position bedridden patients for optimal air circulation to the area, and avoid occlusive dressings or garments.

Transmission-Based Precautions may be needed to reduce the infection spread to other people. For most superficial bacterial infections, proper handwashing prevents cross-contamination. However, when hospitalized patients are colonized with antibiotic-resistant *Staphylococcus,* strict adherence to isolation procedures is necessary.

Of the dermatophyte infections, tinea capitis, tinea corporis, and tinea pedis are most easily transmitted to others. Teach patients to avoid sharing personal items, such as hairbrushes, articles of clothing, or footwear. Repeated infections transmitted by dogs or cats indicate that the pet also needs to be treated.

Drug therapy for superficial infection involves topical agents. Mild bacterial infections of the skin usually resolve with topical antibacterial treatment. Patients with extensive infections, especially if fever or lymphadenopathy is present, require systemic antibiotic therapy. The most common systemic drugs used for bacterial skin infections are the penicillins and cephalosporins. For those who are allergic to drugs from these classes, tetracyclines, macrolides, or aminoglycoside antibiotics may be used. For patients infected with MRSA or other drug-resistant organisms, drug therapy may involve IV vancomycin or oral linezolid or clindamycin.

Acyclovir (Zovirax), valacyclovir (Valtrex), or famciclovir (Famvir) is used for the treatment of viral infections. Topical treatment decreases the numbers of active viruses on the skin surface and reduces pain in herpetic infections and localized lesions in immunocompromised patients during an initial outbreak. Topical treatment is of little benefit in recurrent infection. IV administration is limited to severe primary infections, immunosuppressed patients with manifestations of systemic infection, and recurrent outbreaks.

Topical antifungal agents are used for patients with dermatophyte or yeast infections at least twice a day until the lesions have cleared. To prevent recurrence, therapy is usually continued for 1 to 2 weeks after clearing. In some instances, antifungal powders may also help suppress fungal growth. For widespread or resistant fungal infections, systemic antifungal agents, such as ketoconazole (Nizoral), are given.

NCLEX Examination Challenge

Health Promotion and Maintenance

Which statement made by a client with a furuncle in the groin indicates to the nurse that teaching about the care needed for this problem has been effective?

A "I will wear tight jeans to keep the infection from spreading to other areas."

B "I will shower with an antibacterial soap before applying the topical ointment."

C "I will squeeze the lesion until it opens so I can remove all the pus and other material."

D "I will shave the area around the lesion and apply cortisone cream to reduce the inflammation."

Cutaneous Anthrax

Cutaneous anthrax is an infection caused by the spores of the bacterium *Bacillus anthracis*. In the United States, the most common risk factor is contact with an infected animal. Those most at risk for cutaneous anthrax include farm workers, veterinarians, and tannery and wool workers. This organism has now become a tool for terrorism.

Nursing Safety Priority QSEN

Action Alert

Consider the possibility of bioterrorism whenever lesions consistent with cutaneous anthrax appear in patients who do not have a history of exposure to infected animals.

The infection can be confined to the skin, or it may be systemic. At first a raised vesicle appears on an exposed body area such as the head or arms (Fig. 25-9). The lesion may itch and often resembles an insect bite. Within a few days, the center of the vesicle becomes hemorrhagic and sinks inward, starting an area of necrosis and ulceration. The tissue around the wound swells and can become very edematous. With necrosis, an eschar forms (see Fig. 25-9). The two features that distinguish anthrax lesions from insect bites or other skin lesions are that it is painless and that eschar forms regardless of treatment. Patients may have only one lesion, or there may be multiple lesions, usually in the same body area.

FIG. 25-9 Cutaneous anthrax. Note ulcer with vesicular ring, induration, and erythema (**A**). As eschar forms, induration lessens, surrounding desquamation occurs, but erythema persists (**B**).

Some patients develop systemic manifestations with cutaneous anthrax. The area becomes edematous and tender. Fever, chills, and enlarged lymph nodes may be present.

Diagnosis is made based on lesion features, a positive culture, or the presence of anthrax antibodies in the patient's blood. Cultures are obtained from patients who have a fever.

Oral antibiotics for 60 days are indicated for patients who have no edema or systemic manifestations and whose lesions are not located on the head or neck. The antibiotics of choice are ciprofloxacin (Cipro) or doxycycline (Doryx, Vibramycin). For patients who have a fever, have lesions on the head or neck, are pregnant, or have extensive edema, antibiotics are given IV and then followed by an oral course of 60 days.

Parasitic Disorders

Parasitic skin disorders occur most often in patients with poor hygiene and in those who are homeless. Examine any patient who shows obvious signs of a self-care deficit for contagious parasitic infections.

Pediculosis

Pediculosis is a lice infestation: *pediculosis capitis* (head lice), *pediculosis corporis* (body lice), and *pediculosis pubis* (pubic, or crab, lice). Human lice are oval and 2 to 4 mm long. The female louse lays many eggs *(nits)* at the hair shaft base in hair-bearing areas.

The most common manifestation of pediculosis is itching (pruritus). Excoriation from scratching also may be present. Some parasites may carry disease (e.g., typhus).

Pediculosis capitis occurs more often in people with longer hair. Scalp itching from parasite bites is intense. A secondary infection may also be present from scratching.

Because the louse is difficult to see, examine the scalp for visible white flecks of the nits attached to the hair shaft near the scalp. Matting and crusting of the scalp and a foul odor indicate a probable secondary infection.

Pediculosis corporis is caused by lice that live and lay eggs in the seams of clothing. The parasites also cause itching. The only visible sign of infestation may be excoriations on the trunk, abdomen, or extremities.

Pediculosis pubis causes intense itching of the vulvar or perirectal region. Pubic lice are more compact and crablike in appearance than body lice and can be contracted from infested bed linens or during sexual intercourse with an infected person. Although these lice are usually found in the genital region, they can also infest the axillae, the eyelashes, and the chest.

The treatment of pediculosis is chemical killing of the parasites with topical sprays, creams, and shampoos. Agents used include permethrin (Elimite), lindane (Bio-Well, Kwell, Kwellada), or topical malathion (Ovide, Prioderm). Oral agents may also be used, such as ivermectin (Stromectol). In the case of pediculosis capitis, areas where the patient's head has rested (e.g., on pillows or chair backs) are also treated. Clothing and bed linens should be washed in hot water with detergent or dry-cleaned. The use of a fine-tooth comb helps remove nits but does not cure the infection. For any louse infestation, social contacts are treated when possible.

Scabies

Scabies is a contagious skin infection caused by mite infestations. It is transmitted by close contact with an infested person or infested bedding. Infestation is common among patients with poor hygiene or crowded living conditions. The scabies mite is carried by pets and is found among homeless people and institutionalized older patients. Health care personnel are at risk for contracting scabies from contact with an infected patient or his or her bed linen.

Scabies is manifested by curved or linear ridges in the skin (Fig. 25-10). The itching is very intense, and patients often report that the itching becomes unbearable at night.

FIG. 25-10 Scabies. Note the horizontal lines indicating burrowing of the organism under the skin.

The visible horizontal white skin ridges are formed by burrowing of the mite into the outer skin layers. Examine the skin between the fingers and on the palms and inner aspects of the wrists, where these ridges are most common. A hypersensitivity reaction to the mite results in excoriated erythematous papules, pustules, and crusted lesions on the

elbows, nipples, lower abdomen, buttocks, and thighs and in the axillary folds. Males can have lesions on the penis.

Infestation is confirmed by taking a scraping of a lesion and examining it under the microscope for mites and eggs. Close contacts also should be examined for possible infestation.

Treatment involves the use of scabicides, such as permethrin (Acticin), lindane (Kwell, Kildane, Scabene, Thionex), malathion (Ovide), or benzyl benzoate (Ascabiol). Laundering clothes and personal items with hot water and detergent is sufficient to eliminate the mites.

Bedbugs

A common parasite is the bedbug, *Cimex lectularius*. Infestations are increasingly common as a result of travel and resistance to pesticides. This pest does not live on humans; however, it feeds on human blood. The bite causes an itchy discomfort. The most common mode of infestation is carrying the "hitch-hiking" bug home from an infested environment such as a hotel room. This problem is not related to socioeconomic level or to a lack of cleanliness.

The adult bedbug is about the size, shape, and color of an apple seed. After feeding, it may double in size and have a red or black color. The insect bites a human host at night and sucks blood for 3 to 10 minutes. The bite area resembles a mosquito or flea bite with a raised bite mark surrounded by a wheal. The degree of itching and redness is related to how allergic the person is to the insect's saliva. All body areas are susceptible, and one insect can bite multiple times, resulting in clusters of bite marks.

Management of the patient with bedbug bites is symptomatic for discomfort from itching, usually with topical antihistamines. When the discomfort is more widespread or the allergic reaction is severe, systemic antihistamines or corticosteroids may be used. Because humans do not harbor the insect, the usual topical insecticides are not needed.

Bedbugs can live anywhere, hiding in cracks and crevices. They can live and lay their eggs in soft upholstery or in wooden crevices. Eradicating the infestation and preventing re-infestations require considerable effort and can be frustrating. Often the home environment needs the extensive eradication efforts of a licensed professional pest control company with experience in the management of bedbugs (Barnes & Murray, 2013).

Common Inflammations

Pathophysiology

Skin inflammation can have many nonspecific manifestations, including severe itching, lesions with indistinct borders, and different distribution patterns. The cause may not be identified. Rashes from inflammation can evolve from acute to chronic conditions.

Most skin inflammations are related to allergic immune responses. The responses may be triggered by external skin exposure to allergens or by internal exposure to allergens and irritants. The result is tissue destruction or skin changes induced by the immune system. (A more detailed description of these immune mechanisms is presented in Chapter 17.)

The specific cause of skin inflammation is not always known. When this is the case, the catch-all diagnosis of *nonspecific eczematous dermatitis,* or *eczema*, is often used.

Contact dermatitis is an acute or chronic rash caused by direct contact with either an irritant or an allergen. Irritants cause a toxic injury to the skin. Allergens result in a cell-mediated immune reaction in the skin.

Atopic dermatitis is a chronic rash that occurs with allergies and atopic skin disease. It is made worse by dry or irritated skin, food allergies, chemicals, or stress. (Atopic reactions are described in Chapter 20.)

Patient-Centered Collaborative Care

Because all skin eruptions from inflammation appear similar, personal data are needed to identify the cause. Inflammatory skin problems differ from eczematous dermatitis in chronicity, lesion distribution, and associated manifestations. Chart 25-9 lists the manifestations of many types of inflammatory skin conditions.

Chart 25-9 Key Features

Common Inflammatory Skin Conditions

CLINICAL MANIFESTATIONS	DISTRIBUTION
Nonspecific Eczematous Dermatitis	
Evolution of lesions from vesicles to weeping papules and plaques. Lichenification occurs in chronic disease. Oozing, crusting, fissuring, excoriation, or scaling may be present. Itching is common.	Anywhere on the body; localized eczema commonly involves the hands or feet.
Contact Dermatitis	
Localized eczematous eruption with well-defined, geometric margins that are consistent with contact by an irritant or allergen. Usually seen in the acute form, but may become chronic if exposure is repeated. Allergy to plants (e.g., poison ivy or oak) classically occurs as linear streaks of vesicles or papules.	Cosmetic/perfume allergy: head and neck. Hair product allergy: scalp. Shoe/rubber allergy: dorsum of feet. Nickel allergy: earlobes. Mouthwash/toothpaste allergy: perioral region. Airborne contact allergy (e.g., paint, ragweed): generalized.
Atopic Dermatitis	
Hallmark in adults is lichenification with scaling and excoriation. Extremely itchy. Face involvement is seen as dry skin with mild to moderate erythema, perioral pallor, and skinfolds beneath the eyes (Dennie-Morgan lines). Associated with linear markings on the palms.	Face, neck, upper chest, and antecubital and popliteal fossae.
Drug Eruption	
Bright red erythematous macules and papules are found. Skin blisters in extreme cases. Lesions tend to be confluent in large areas. Moderately itchy. Fever is rare. Dehydration and hypothermia can occur with extensive involvement. Condition clears only after offending drug has been discontinued.	Generalized. Involvement begins on trunk, proceeds distally (legs are the last to be involved).

If the cause of the rash is identified, avoidance therapy is used to reverse the reaction and clear the rash. For example, if a new soap for handwashing causes contact dermatitis of the hands, teach the patient to avoid that substance. Even when the cause is unclear, certain irritants may worsen the rash and increase discomfort. Additional interventions promote comfort through suppression of inflammation.

Steroid therapy with topical, intralesional, or systemic steroids is prescribed to suppress inflammation. Because a side effect of oral corticosteroids (e.g., prednisone) is adrenal suppression, patients receiving long-term systemic therapy must taper their drug dosages rather than stop them abruptly.

Remember that corticosteroids never cure the inflammation. During active disease, these drugs reduce manifestations and relieve discomfort. Moisten dressings with warm tap water and place them over topical steroids for short periods to increase absorption. Avoid applying topical steroids under occlusive dressings unless prescribed by the health care provider.

Nursing Safety Priority QSEN

Drug Alert

Caution patients not to apply topical corticosteroids to potentially infected skin lesions anywhere on the body, but especially on the face. These agents suppress the local immune response and can worsen the infection.

Avoid applying oil-based ointments and pastes to the sweaty skinfold areas to prevent blocking of pores and folliculitis. Water-soluble creams are better for these areas. Lotions and gels prevent matting of the hair and are more appropriate for the scalp and other hairy areas. Thick, stiff ointments or pastes (e.g. zinc oxide pastes) are applied to localized areas because they cling to the skin where applied and resist spreading to uninvolved skin.

Antihistamines provide some relief of itching but may not keep the patient totally comfortable. The sedative effects of these drugs may be better tolerated if most of the daily dose is taken near bedtime. Teach patients to avoid driving or operating heavy machinery if these drugs are taken during the day.

Comfort measures such as cool, moist compresses and lukewarm baths with bath additives have a soothing effect, decrease inflammation, and help débride crusts and scales. Colloidal oatmeal, tar extracts, cornstarch, or oils added to baths may relieve itching.

Psoriasis

Pathophysiology

Psoriasis is a chronic, autoimmune disorder affecting the skin with exacerbations and remissions. It results from overstimulation of the immune system (Langerhans' cells) in the skin that activates T-lymphocytes. These cells then target the keratinocytes, causing increased cell division (because some degree of cellular regulation is lost) and plaque formation. Even though psoriasis cannot be cured, patients can often achieve control of manifestations with proper management.

Psoriasis lesions are scaled with underlying dermal inflammation from an abnormality in the growth of epidermal cells. Normally, basal cells take about 28 days to reach the outermost layer where they are shed. In a person with psoriasis, the rate of cell division is speeded up so that cells are shed every 4 to 5 days.

Genetic/Genomic Considerations

Patient-Centered Care QSEN

A genetic predisposition is associated with psoriasis as indicated by the fact that when one identical (monozygotic) twin develops the disease, the second twin also develops the disease about 70% of the time. Variations in many gene sequences, labeled *PSORS1* through *PSORS13,* influence the development of this autoimmune disorder. It is likely that different variations of these gene loci also influence individual patient responses to therapy. Always ask about a family history of the disorder when assessing the patient with psoriasis (Online Mendelian Inheritance in Man [OMIM], 2014b).

Many environmental factors lead to outbreaks and influence the severity of manifestations, but these vary from person to person. Triggering factors may be local or systemic. A psoriatic lesion may appear after skin trauma (Koebner's phenomenon, in which a previously injured area is more susceptible to development of cancer or chronic skin problems) such as surgery, sunburn, or excoriation.

Patients with psoriasis often improve with more exposure to sunlight. Systemic factors that can aggravate the disease include infection (severe streptococcal throat infection, *Candida* infection, upper respiratory infections), hormonal changes (e.g., puberty, menopause), stress, drugs (lithium, beta-blocking agents, indomethacin), obesity, and the presence

of other diseases.

Some patients with psoriasis also develop debilitating *psoriatic arthritis*. This arthritis may lead to severe joint changes similar to those seen in rheumatoid arthritis and indicates that psoriasis is a systemic disorder (McCance et al., 2014). See Chapter 18 for more discussion of arthritis.

Patient-Centered Collaborative Care

Assessment

History.

Ask the patient about any family history of psoriasis, including the age at onset, a description of the disease progression, and the pattern of recurrences. Have the patient describe the current flare-up of psoriasis, including whether the onset was gradual or sudden, where the lesions first appeared, whether there have been any changes in severity over time, and whether fever and itching are present. Explore possible precipitating factors, and ask about the effectiveness of any previous interventions.

Physical Assessment/Clinical Manifestations.

The appearance of psoriasis and its course vary among patients. Typically during flare-ups of the disease, lesions thicken and extend into new body areas. As psoriasis responds to treatment, lesions become thinner with less scaling.

Psoriasis vulgaris is the most common type of psoriasis, with thick, reddened papules or plaques covered by silvery white scales (Fig. 25-11). Borders between the lesions and normal skin are sharply defined. Patches are less red and moister in skinfold areas. Lesions are usually present in the same areas on both sides of the body (bilateral distribution). Common sites include the scalp, elbows, trunk, knees, sacrum, and outside surfaces of the limbs. Facial skin is rarely affected. The patient may have only a few lesions, or the entire skin surface may be affected.

FIG. 25-11 **A,** Psoriasis vulgaris in a white patient. **B,** Psoriasis vulgaris in a patient with dark skin.

Exfoliative psoriasis (erythrodermic psoriasis) is an explosively eruptive and inflammatory form with generalized erythema and scaling but no obvious lesions. Fluid loss with this severe inflammatory reaction can lead to dehydration and hypothermia or hyperthermia.

Palmoplantar pustulosis (PPP) is a type of psoriasis that forms pustules on the palms of the hands and soles of the feet along with reddened hyperkeratotic plaques. The course of the disease is cyclic, with new outbreaks of pustules occurring after older lesions have resolved. PPP is difficult to treat, and patients often have social and physical problems.

Interventions

The three different approaches to therapy are based on the extent of disease, the patient's distress, and the response of the psoriasis to treatment. Patients must understand that no cure for psoriasis exists yet. Therapy is aimed at reducing cell proliferation and inflammation. *Priority nursing strategies include teaching the patient about the disease and its treatment and providing emotional support for the changes in body image often experienced with psoriasis.*

Topical Therapy.

The topical agents used to treat psoriasis are topical steroids, topical tar and anthralin preparations, and ultraviolet (UV) light.

Corticosteroids have anti-inflammatory actions. When applied to psoriatic lesions, corticosteroids suppress cell division. The effectiveness of a topical steroid depends on its potency and ability to be absorbed into the skin. The more potent agents are used as therapy for patients with psoriasis.

Teach patients to enhance the skin penetration of these drugs by

applying the steroid directly to the skin. When prescribed, using warm, moist dressings and an occlusive outer wrap of plastic (film, gloves, booties, or similar garments) may enhance absorption.

Tar preparations applied to the skin suppress cell division from impaired cellular regulation and reduce inflammation. These drugs are available as solutions, ointments, lotions, gels, and shampoos. The ointments are messy, cause staining, and have an unpleasant odor.

Topical therapy with anthralin (Anthraforte, Drithocreme, Lasan), a hydrocarbon similar in action to tar, also relieves chronic psoriasis. These drugs can be used alone or in combination with coal tar baths and UV light.

Teach the patient to apply the high-potency anthralin, suspended in a stiff paste, to each lesion for short periods (not exceeding 2 hours). The drug is a strong irritant and can cause chemical burns. Remind the patient to check for local tissue reaction and to take care to prevent this drug from coming into contact with uninvolved skin.

Other topical therapies can be effective for many patients with mild to moderate psoriasis. These drugs include calcipotriene (Dovonex), a synthetic form of vitamin D that regulates skin cell division, and tazarotene (Avage, Tazorac), a derivative of vitamin A that slows cell division and reduces inflammatory responses. In some cases, calcitriol (Vectical ointment) has been helpful but is quite expensive.

Nursing Safety Priority QSEN

Drug Alert

Tazorac is **teratogenic** (can cause birth defects) even when used topically. Teach sexually active women of childbearing age using this drug to adhere to strict contraceptive measures.

Light Therapy.

Ultraviolet (UV) radiation is a physical agent commonly used as a topical therapy in many skin conditions, including psoriasis. Ultraviolet B (UVB) light, which produces more energy, is responsible for the obvious biologic effects of the sun, such as burning. Although the sun is an inexpensive source of UV radiation, better availability and intensity control occur with the use of artificial light sources. These sources include lamps or cabinets containing UV tubes. *The use of commercial tanning beds is not recommended for the patient with psoriasis.*

Ultraviolet therapy is limited by exposure time and effects on the

surrounding normal skin. The time of exposure is gradually increased to achieve a mild suntan effect without burning or tenderness. The patient's skin pigmentation determines the exposure times. Because of the extremely high intensity of most artificial UVB light sources, therapy is measured in seconds of exposure and patients must wear eye protection during treatment. Narrow band UVB light therapy, although intense, can shorten the time to effectiveness and reduce the number of exposures needed to maintain the response.

Light therapy with lasers can be effective in controlling mild to moderate psoriasis. Laser sources, whether administered in a continuous or pulsed exposure, allow for better focus on the lesions and reduce exposure to the surrounding normal skin.

Teach patients to inspect the skin carefully each day for signs of overexposure. If tenderness on palpation occurs and severe erythema or blister formation develops, notify the health care provider before therapy is resumed.

Psoralen and ultraviolet A (UVA) (PUVA) therapy involves the ingestion of a photosensitizing agent (psoralen) 2 hours before exposure to UVA light. Therapy sessions are limited to 2 or 3 times a week and are not given on consecutive days. Exposure is gradually increased until tanning occurs. Dosages are adjusted according to the erythema reaction of normal skin as well as the response of psoriatic lesions.

Teach the patient to check for redness with edema and tenderness. If these are present, treatment must be interrupted until they subside. Because psoralen is a strong photosensitizer, patients must wear dark glasses during treatment and for the rest of the day.

Systemic Therapy.

Systemic agents are used when psoriasis does not respond to topical therapies. The most commonly used drugs are oral vitamin A derivatives —retinoids. These drugs include acitretin (Soriatane) and bexarotene (Targretin).

Nursing Safety Priority QSEN

Drug Alert

Both acitretin and bexarotene are teratogenic. Teach sexually active women of childbearing age using this drug to adhere to strict contraceptive measures.

A variety of biologic (immunomodulating) agents that alter the immune response and prevent overstimulation of keratinocytes from impaired cellular regulation are now being used to manage moderate to severe plaque psoriasis. These agents may be prescribed when other drugs are not effective and when psoriatic arthritis is also present. Most of these drugs are given by intravenous infusion, intramuscular injection, or subcutaneous injection. All of these agents induce some degree of immunosuppression, and patients are at an increased risk for serious infection.

Nursing Safety Priority QSEN

Drug Alert

Instruct patients to discontinue the biologic agent and notify the health care provider immediately if manifestations of infection occur.

Biologics currently approved for the treatment of psoriasis are listed in Chart 25-10. These drugs should NOT be used by patients who are pregnant or breast-feeding.

Chart 25-10 Common Examples of Drug Therapy

Plaque Psoriasis

AGENT	ROUTE	DOSE	FREQUENCY
adalimumab (Humira)	Subcutaneous	Loading dose: 80 mg Maintenance dose: 40 mg	Loading dose followed by maintenance dose every other week starting 1 week after the loading dose.
alefacept (Amevive)	Intramuscular	15 mg	Once a week for 12 weeks followed by a 12-week drug-free interval. Cycle may be repeated based on response.
etanercept (Enbrel)	Subcutaneous	50 mg	Twice weekly for 3 months followed by once-a-week injections.
infliximab (Remicade)	Intravenous	5 mg/kg	Infusions at 0, 2, and 6 weeks, then every 8 weeks.
ustekinumab (Stelara)	Subcutaneous	90 mg	Initial dose 90 mg; second dose 4 weeks later
			Maintenance injections of 90 mg subcutaneously every 12 weeks starting at week 16 after initial dose.

Other less commonly used systemic drugs for the patient whose disease is resistant to topical therapy include methotrexate (Folex, Mexate), cyclosporine (Sandimmune), and azathioprine (Imuran). The many health risks associated with these therapies must be considered along with the potential benefits, especially in older adults (Wong & Woo, 2012).

Emotional Support.

Often patients' self-esteem suffers because of the presence of skin lesions. Encourage the patient and family members to express their feelings about having an incurable skin problem that can alter appearance. Support groups for people with psoriasis are available in many communities. Urge patients and families to consider participating in these groups.

The use of touch takes on an added significance for patients with psoriasis. For example, shake the patient's hand during an introduction or place a hand on the patient's shoulder when explaining a procedure. *Do not wear gloves during these social interactions. Touch, more than any other gesture, communicates acceptance of the person and the skin problem.*

NCLEX Examination Challenge

Health Promotion and Maintenance

Which precaution is most important for the nurse to teach the 32-year-old female client prescribed topical tazarotene (Tazorac) cream for psoriasis?

A Apply a dressing over the site with each application.
B Stop the drug use when psoriasis manifestations decrease.
C Report symptoms of infection to the prescriber immediately.
D Adhere to strict contraceptive measures while using the drug.

Skin Cancer

Pathophysiology

Any skin cancer occurs as a result of failure of cellular regulation over cell division. (See Chapter 21 for a discussion of the general mechanisms leading to changes in cellular regulation and cancer development.) *Overexposure to sunlight is the major cause of skin cancer, although other factors also are associated.* Because sun damage is an age-related skin finding, screening for suspicious lesions is an important part of physical assessment of the older adult. The most common skin cancers are actinic or solar keratosis, squamous cell carcinoma, basal cell carcinoma, and melanoma. Table 25-5 describes common skin cancers. A biopsy of suspicious lesions is necessary to determine whether a skin lesion is malignant.

TABLE 25-5

Common Skin Cancers

CLINICAL MANIFESTATIONS	DISTRIBUTION	COURSE
Actinic Keratosis (Premalignant)		
Small (1-10 mm) macule or papule with dry, rough, adherent yellow or brown scale Base may be erythematous Associated with yellow, wrinkled, weather-beaten skin Thick, indurated keratoses more likely to be malignant	Cheeks, temples, forehead, ears, neck, backs of hands, and forearms	May disappear spontaneously or reappear after treatment. Slow progression to squamous cell carcinoma is possible.
Squamous Cell Carcinoma		
Firm, nodular lesion topped with a crust or with a central area of ulceration Indurated margins Fixation to underlying tissue with deep invasion	Sun-exposed areas, especially head, neck, and lower lip Sites of chronic irritation or injury (e.g., scars, irradiated skin, burns, leg ulcers)	Rapid invasion with metastasis via the lymphatics occurs in 10% of cases. Larger tumors are more prone to metastasis.
Basal Cell Carcinoma		
Pearly papule with a central crater and rolled, waxy borders Telangiectasias and pigment flecks visible on close inspection	Sun-exposed areas, especially head, neck, and central portion of face	Metastasis is rare. May cause local tissue destruction. 50% recurrence rate related to inadequate treatment.
Melanoma		
Irregularly shaped, pigmented papule or plaque Variegated colors, with red, white, and blue tones	Can occur anywhere on the body, especially where nevi (moles) or birthmarks are evident Commonly found on upper back and lower legs Soles of feet and palms in dark-skinned people	Horizontal growth phase followed by vertical growth phase. Rapid invasion and metastasis with high morbidity and mortality.

Etiology and Genetic Risk

Actinic keratoses are premalignant lesions of the cells of the epidermis. These lesions are common in people with chronically sun-damaged skin. Progression to squamous cell carcinoma may occur if lesions are untreated.

Squamous cell carcinomas are cancers of the epidermis. They can invade

locally and are potentially metastatic (Fig. 25-12). Chronic skin damage from repeated injury or irritation also predisposes to this malignancy. Chronic wounds that remain open for long periods are also at increased risk for malignant transformation to cancer.

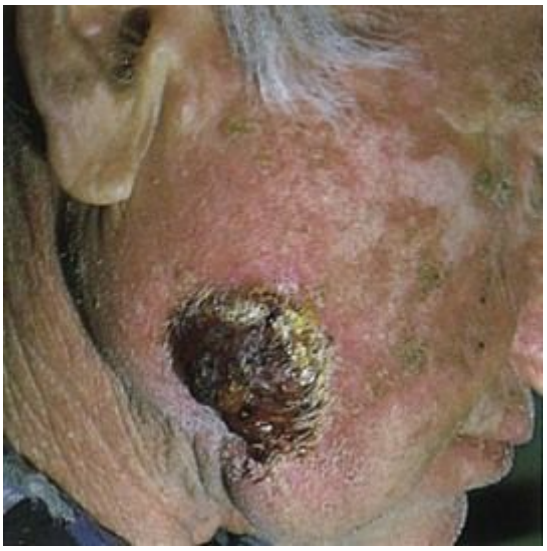


FIG. 25-12 Squamous cell carcinoma.

Basal cell carcinomas arise from the basal cell layer of the epidermis (Fig. 25-13). Early lesions often go unnoticed, and although metastasis is rare, underlying tissue destruction can occur. Genetic predisposition and chronic irritation are risk factors; however, UV exposure is the most common cause.

FIG. 25-13 Basal cell carcinoma.

Melanomas are pigmented cancers arising in the melanin-producing

epidermal cells (Fig. 25-14). Most often they start as the benign growth of a **nevus** (mole) (Skin Cancer Foundation, 2014). Normal nevi have regular, well-defined borders and are uniform in color, ranging from light colors to dark brown. The lesion's surface may be rough or smooth. Nevi with irregular or spreading borders and those with multiple colors are abnormal. Other suspicious features include sudden changes in lesion size and reports of itching or bleeding.

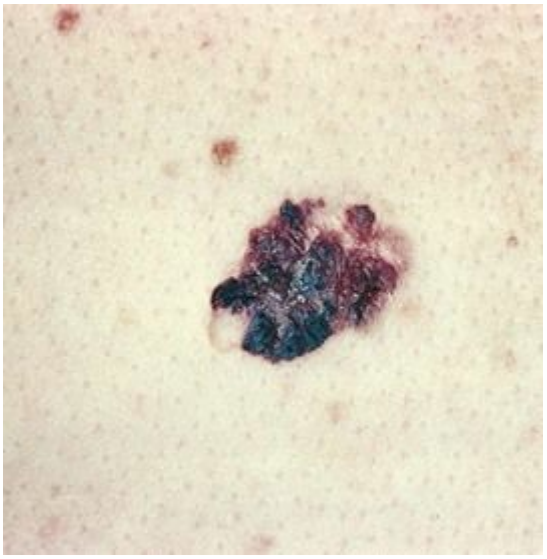

FIG. 25-14 Melanoma.

Risk factors include genetic predisposition, excessive exposure to UV light, and the presence of one or more precursor lesions that resemble unusual moles. *This skin cancer is highly metastatic, and a person's survival depends on early diagnosis and treatment.*

Genetic/Genomic Considerations

Patient-Centered Care QSEN

Genetic mutations in the *CDKN2A* and *CDK4* have been identified for some cases of familial melanoma. These mutations in a suppressor gene result in loss of cellular regulation for cell growth. Other genetic considerations for melanoma are that some specific mutations in the genes of the actual tumor cells increase the response of these cells to targeted therapy. All melanomas should be tested for mutations of the *BRAF* and *KIT* genes (OMIM, 2014a). Always ask patients who have a diagnosed melanoma whether any other family members have ever had this disease.

Incidence and Prevalence

The incidence of skin cancer is highest among light-skinned races and people older than 60 years (American Cancer Society [ACS], 2014). Skin cancer occurs more often among those who work outdoors, live at higher altitudes or lower latitudes, or spend much time sunbathing. Occupational exposure to arsenic or other chemical carcinogens also increases risk. The incidence of melanoma has increased during the past 30 years, accounting for 4% to 5% of all cancers, although the death rate from melanoma is decreasing (ACS, 2014).

Health Promotion and Maintenance

The most effective prevention strategy for skin cancer is avoiding or reducing skin exposure to sunlight. However, even when people understand the cause of skin cancer and the seriousness of the disease, preventive behaviors are not always practiced. Common prevention practices are listed in Chart 25-11. *Teach all people to avoid tanning beds and salons.*

Chart 25-11 Patient and Family Education: Preparing for Self-Management

Prevention of Skin Cancer

- Avoid sun exposure between 11 am and 3 pm.
- Use sunscreens with the appropriate skin protection factor for your skin type.
- Wear a hat, opaque clothing, and sunglasses when you are out in the sun.
- Keep a "body map" of your skin spots, scars, and lesions to detect when changes have occurred.
- Examine your body monthly for possibly cancerous or precancerous lesions.
- Seek medical advice if you note any of these:
  - A change in the color of a lesion, especially if it darkens or shows evidence of spreading
  - A change in the size of a lesion, especially rapid growth
  - A change in the shape of a lesion, such as a sharp border becoming irregular or a flat lesion becoming raised
  - Redness or swelling of the skin around a lesion
  - A change in sensation, especially itching or increased tenderness of a lesion

- A change in the character of a lesion, such as oozing, crusting, bleeding, or scaling

Secondary prevention (early detection) is critical to survival with melanoma. Teach all people to be aware of their skin markings. Keeping a total body spot and lesion map can provide baseline information about suspicious new lesions and help identify changes in existing lesions. Once a map is made, the person should systematically inspect his or her body monthly for new lesions and for changes in any existing lesions by performing thorough *skin self-examination (SSE)*. Some people find taking pictures of their skin on a regular basis makes identifying changes easier. Teach everyone to evaluate all skin lesions using the ABCDE guide for melanoma (see Chapter 24) and to consult his or her health care provider to examine any lesion having unusual features. When lesions, such as moles, are present, they should be monitored yearly by a dermatologist or other health care professional.

Patient-Centered Collaborative Care

Assessment

In addition to age and race, ask the patient about any family history of skin cancer and any past surgery for removal of skin growths. Recent changes in the size, color, or sensation of any mole, birthmark, wart, or scar are also significant. Ask about which geographic regions the patient has lived in and where he or she currently resides. Obtain information about occupational and recreational activities in relation to sun exposure, as well as any occupational history of exposure to chemical carcinogens (e.g., arsenic, coal tar, pitch, radioactive waste, radium). Ask whether any skin lesions are repeatedly irritated by the rubbing of clothing.

Skin that has been injured previously is at greater risk for cancer development, an effect known as *Koebner's phenomenon.* Ask the patient if he or she has ever experienced a severe skin injury that resulted in a scar. Examine all scarred skin areas for the presence of potentially cancerous lesions. A biopsy may be required to rule out cancer in a chronic open wound that fails to close with proper treatment.

Skin cancers vary in their appearance and distribution. Although most skin cancers appear in sun-exposed areas of the body, inspect the entire skin surface and any unusual lesions, particularly moles, warts, birthmarks, and scars. Also examine hair-bearing areas of the body, such as the scalp and genitalia. Palpate lesions to determine surface texture. Document the location, size, color, and features of all lesions and any

reports of tenderness or itching. Use the ABCDE method of evaluating all lesions for possible melanoma (see Chapter 24).

Interventions

Surgical and nonsurgical interventions are combined for the effective management of skin cancer. Treatment is determined by the size and severity of the malignancy, the location of the lesion, and the age and general health of the patient.

Surgical Management.

Surgical intervention is needed to manage any type of skin cancer. It can range from local removal of small lesions to massive excision of large areas of the skin and underlying tissue for treatment of melanoma. Surgical types for skin cancer include:

- Cryosurgery—cell destruction by the local application of liquid nitrogen (−200° C) to isolated lesions, causing cell death and tissue destruction.
- Curettage and electrodesiccation—removal of cancerous cells with the use of a dermal curette to scrape away cancerous tissue, followed by the application of an electric probe to destroy remaining tumor tissue.
- Excisional biopsy—total surgical removal of small lesions for pathologic examination.
- Mohs' surgery—a specialized form of excision usually for basal and squamous cell carcinomas. Tissue is sectioned horizontally in layers, and each layer is examined histologically to determine the presence of residual tumor cells.
- Wide excision—deep skin resection often involving removal of full-thickness skin in the area of the lesion. Depending on tumor depth, subcutaneous tissues and lymph nodes may also be removed.

Nonsurgical Management.

Drug therapy may involve topical or systemic chemotherapy, biotherapy, or targeted therapy. Topical chemotherapy with 5-fluorouracil cream is used for treatment of multiple actinic keratoses or for widespread superficial basal cell carcinoma that would require several surgical procedures to eradicate. Therapy is continued for several weeks, and the treated areas become increasingly tender and inflamed as the lesions crust, ooze, and erode. Prepare the patient for an unsightly appearance during therapy, and reassure him or her that the cosmetic result will be positive.

Systemic chemotherapeutic agents are used in the treatment of locally

advanced or metastatic squamous cell skin cancer. These include a platinum based-agent (Cisplatin or Carboplatin), 5-fluorouracil, and cetuximab (Erbitux). A new drug approved for locally advanced or metastatic basal cell skin cancer is vismodegib (Erivedge).

Biotherapy with interferon, monoclonal antibodies, and targeted therapy are now accepted treatment for melanoma after surgical removal. Interferon is used for melanomas that are at stage III or higher. The patient is first started on high-dose IV interferon infusions daily for 5 days per week for 4 weeks. Maintenance doses, given subcutaneously, are then continued 3 times per week for 1 year. The patient must learn to self-inject the drug.

Monoclonal antibody therapy with ipilimumab (Yervoy), a drug that targets the *CTLA4* (cytotoxic T-lymphocyte associated antigen 4) receptor and blocks it, leads to greater T-cell lymphocyte activity. (T-cells are a type of lymphocyte that can stimulate antitumor immune responses.) The side effects of this drug include significant inflammation in many tissues, including the pituitary gland, liver, skin, GI tract, and nervous system. Some of the side effects can be life threatening (Rubin, 2012).

Targeted therapy is available for melanomas with specific mutations in the *BRAF* gene. Normally, the *BRAF* gene is involved in cellular regulation of growth. Mutations in this gene allow melanoma to grow and metastasize. When melanoma cells are positive for a specific *BRAF* mutation *(V600E)*, the cells respond to the drug *vemurafenib* (Zelboraf). The drug inhibits an enzyme important in signaling cell division and prevents melanoma cell division. This oral drug interacts with a variety of other drugs, and allergic reactions are common.

Radiation therapy for skin cancer is limited to older patients with large, deeply invasive basal cell tumors and to those who are poor risks for surgery. Melanoma is relatively resistant to radiation therapy.

NCLEX Examination Challenge

Psychosocial Integrity

The client who has stage III metastatic melanoma and whose tumor is negative for a *BRAF* mutation asks why the treatment plan does not include the new drug *Zelboraf* (vemurafenib) that she has read about. What is the nurse's best response?

A "Your immune system is too weak to tolerate Zelboraf."

B "This drug is experimental and too dangerous for you to take before trying other therapies."

C “Your melanoma does not have the gene mutation that responds to this drug, so you would not benefit from this therapy.”
D “You are young and can better tolerate the standard therapies for melanoma that have been proven effective but have strong side effects.”

Other Skin Disorders

Toxic Epidermal Necrolysis

Toxic epidermal necrolysis (TEN) is a rare acute drug reaction of the skin resulting in diffuse erythema and large blister formation. Mucous membranes are often involved, and systemic toxicity is evident. The most common causative drugs are chemotherapy agents, sulfonamides, pyrazolones, barbiturates, and antibiotics. Removal of the drug is usually followed by gradual healing in 2 to 3 weeks, with widespread peeling of the epidermis.

This problem can occur at any age and as a result of almost any drug therapy. However, older patients with cancer who are receiving chemotherapy, some targeted therapies, and immunotherapy are at greatest risk. Other precipitating factors include stem cell transplantation and neutropenia-induced infections.

The drug thought to be causing a toxic reaction is discontinued, and management focuses on systemic support and prevention of secondary infection. Patients are often admitted to burn units, where fluid and electrolyte balance, caloric intake, and hypothermia can be closely monitored. Topical antibacterial drugs are used to suppress bacterial growth until healing occurs.

Stevens-Johnson Syndrome

Stevens-Johnson syndrome is often a drug-induced skin reaction caused by an immunologic mechanism, similar to toxic epidermal necrolysis. The disorder may be mild with only skin involvement, or it may be severe and systemic. The skin lesions are widely distributed, including mucous membranes, and varied in appearance (Fig. 25-15). The patient has a mix of vesicles, erosions, and crusts. With severe involvement, the patient may have respiratory problems, excessive fluid loss, kidney failure, and blindness (Cooper, 2012).

FIG. 25-15 Stevens-Johnson syndrome.

Removal of the offending drug is critical. Mild forms of the disorder are usually self-limiting in 10 to 14 days unless the episode was triggered by a bacterial infection. Then, antibiotics are needed. Severe problems require high doses of steroids to suppress the inflammation. Supportive care may include fluid replacement, mechanical ventilation, and even renal replacement therapy.

Plastic Surgery

Assessment

The two main types of plastic surgery are aesthetic and reconstructive. **Aesthetic plastic surgery** is cosmetic, with the aim of altering a person's physical appearance. This intervention is sought by those who are unsatisfied with their body image. These procedures are considered elective surgery and are not covered by insurance. **Reconstructive plastic surgery** is the correction or improvement of functional defects that have occurred as a result of congenital problems or trauma and scarring (e.g., skin and joint contractures from burn wounds) or from other types of therapy (e.g., mastectomy for breast cancer therapy). These interventions are sought by patients who cannot perform ADLs as a result of an anatomic problem; the cost is often covered by insurance.

Regardless of whether a person is having reconstructive surgery or cosmetic surgery, body image and sense of self are always involved. These feelings may evoke emotional responses in the person, including shame, anger, resentment, and desperation. Use a sensitive, nonjudgmental approach when interacting with the person having or considering plastic surgery. It is important to avoid being directive or expressing your own opinions. Often a patient who asks the nurse "Do you think I need this surgery?" is not comfortable with his or her decision.

Address the patient's expectations of plastic surgery. Often people who seek plastic surgery have unrealistic expectations. The patient with minor deformities who is seeking perfection is sure to be disappointed. The patient who wants a procedure mainly to please a partner is also a poor candidate.

Interventions

Many techniques to improve skin and general appearance without surgery are available. Superficial techniques for skin enhancement include chemical peels, laser resurfacing, and dermabrasion to remove or reduce small scars, fine lines, and other irregular skin surfaces. Dermal filling involves injecting substances to change the contour of a feature or an area. Generally, these fillers replace the collagen lost from the skin through aging. Injection with nerve paralyzing agents (e.g., Botulinum Toxin Type A) can improve appearance temporarily by relaxing muscles beneath the skin surface, which smoothes out some wrinkles and grooves.

Depending on the planned intervention, surgery is performed either in

the ambulatory care setting with the patient under local anesthesia or in the hospital. The types and complications of common cosmetic procedures are listed in Table 25-6.

TABLE 25-6
Common Plastic Surgery Procedures

DESCRIPTION	INDICATIONS	COMPLICATIONS
Blepharoplasty		
Excision of bulging fat and redundant skin of the periorbital area with primary closure	Bags under the eyes	Hematoma Ectropion Corneal injury Visual loss (rare) Wound infection (rare)
Breast Augmentation (Augmentation Mammoplasty)		
Insertion of synthetic breast-shaped implants through a skin incision	Inadequate breast volume or contour	Hematoma or hemorrhage Wound infection (with gram-positive organisms) Phlebitis
Breast Reduction (Reduction Mammoplasty)		
Excision of excessive breast tissue and skin with primary closure	Hypertrophy of breast tissue caused by elevated hormone levels, endocrine abnormalities, or obesity Weight of large breasts can contribute to back pain	Hematoma or hemorrhage Nipple, areola, and skin flap necrosis Wound infection Fat necrosis Wound dehiscence
Dermabrasion		
Abrasive removal of the facial epidermis and portion of the dermis followed by healing by second intention	Moderate to severe acne scar Deep wrinkling Multiple actinic keratoses Hyperpigmentation (postinflammatory or after the use of estrogens)	Hypertrophic scarring Altered skin pigmentation Acne flare Wound infection (rare)
Rhinoplasty		
Removal of excessive cartilage and tissue from the nose with correction of septal defects if indicated	Disproportionate anatomy Post-traumatic nasal deformity Difficulty breathing through the nose	Hematoma or hemorrhage Ecchymosis and edema (temporary) Wound infection (with gram-positive organisms) Septal perforation Minor skin irritation
Rhytidectomy (Facelift)		
Removal of excess skin and tissue from the face at the level of the hairline followed by primary closure	Excessive wrinkling or sagging of facial skin	Hematoma or hemorrhage Facial nerve damage (temporary or permanent) Wound infection Ecchymosis and edema (temporary) Skin necrosis Hair loss
Liposuction (Suction Lipectomy)		
Removal of subcutaneous fat from localized areas of accumulation such as the hips, abdomen, neck, and arms	Disproportionate distribution of adipose tissue	Hematoma Severe pain Infection Emboli Sagging of skin (if skin is not elastic enough to contract after fat removal)

All plastic and reconstructive surgeries have a risk for complications and failure, especially bleeding, infection, and skin reattachment problems. Procedures vary depending on the location, purpose, and extent of reconstruction.

General care after surgery focuses on monitoring for typical postoperative complications (see Chapter 16). Pressure dressings may be

applied at the time of surgery and left in place for several days to control hemorrhage and edema formation. Monitor dressings for bright red bleeding, and monitor changes in vital signs and level of consciousness. Positioning varies with the specific procedure performed and the surgeon's preference.

Monitor for wound infection and progress toward healing. Of particular concern are any areas of skin necrosis or eschar formation near the operative site—a complication from excessive tension on the suture line as a result of edema and blood vessel obstruction. See Chart 25-5 for a listing of wound monitoring criteria. Regardless of the planned procedure, inform the patient to expect edema and discoloration of the operative site. Swelling and bruising alter the facial features and may not resolve for several weeks after surgery. The final results of surgery will not be visible until healing is complete—usually 6 months to a year or longer after surgery.

Nursing Concepts and Clinical Judgment Review

What might you NOTICE if the patient is experiencing inadequate protection as a result of loss of skin tissue integrity?

- Open skin areas
- Possible presence of drainage
- Sensation changes in or around the area (patient reports pain, itching, or tightness)

What should you INTERPRET and how should you RESPOND to a patient experiencing inadequate protection as a result of loss of skin tissue integrity?

Perform and interpret physical assessment, including:

- Assessing the wound for pain, size, depth, drainage, and presence of infection
- Assessing the skin immediately surrounding the wound for redness and swelling
- Monitoring oxygen saturation by pulse oximetry in the affected extremity (if the open area is on an extremity)
- Assessing the patient for risk factors for wound development (pressure, shear, immobility, reduced cognition, poor nutrition, advanced age, incontinence)
- Assessing the rest of the patient's skin (especially over bony prominences, between skinfolds, in the perineal area)

Respond by:

- Documenting wound features
- Cleansing the wound (obtaining cultures, if within agency policy)
- Dressing the wound if drainage is present
- Planning a turning or repositioning schedule
- Teaching UAP or family how to relieve/reduce pressure
- Collaborating with the certified wound care specialist and dietitian

On what should you REFLECT?

- Observe the patient for evidence of restored skin integrity (see Chapter 24).
- Think about what may have precipitated this loss of skin tissue integrity and what steps could be taken to either prevent a similar problem or identify it earlier.
- Think about what additional resources could improve the nursing response to this situation.

Get Ready for the NCLEX® Examination!

Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Wash your hands before and after touching any skin lesions. **Safety** QSEN
- Use Standard Precautions when providing care to a patient who has any areas of nonintact skin. **Safety** QSEN
- Ensure that the skin of incontinent patients is kept clean and dry. **Evidence-Based Practice** QSEN
- Assist all patients with limited mobility to change positions at least every 2 hours while awake. **Evidence-Based Practice** QSEN
- Use a structured approach (e.g., Braden scale or other validated tool) to evaluate the pressure ulcer risk for all patients on admission and regularly thereafter. **Evidence-Based Practice** QSEN
- Be proactive in the use of pressure-relieving devices for any patient who is identified to be at risk for pressure ulcer formation (i.e., requires prolonged bedrest, is an older adult, has some degree of immobility, is incontinent, has some degree of malnutrition, is dehydrated, has decreased sensory perception, or has an altered mental state).
- Use a lift sheet or mechanical lift to move immobilized older patients rather than pulling or dragging them across bed linens. **Safety** QSEN

Health Promotion and Maintenance

- Teach the patient with mobility problems and his or her caregivers how to reduce and relieve skin pressure in the home environment. **Patient-Centered Care** QSEN
- Encourage all patients to reduce sun exposure and exposure to ultraviolet (UV) light. **Patient-Centered Care** QSEN
- Teach patients how to examine all skin areas on a monthly basis for new lesions and changes to existing lesions. They should keep a record or "body map" of skin lesions. **Patient-Centered Care** QSEN
- Teach patients who have skin scarring from a previous skin injury to examine this area at least monthly for changes related to cancer development or chronic skin conditions. **Patient-Centered Care** QSEN
- Urge all patients to bathe, shampoo the hair, and keep fingernails clean and trimmed on a regular basis.

- Teach patients with infected skin lesions or infestations how to limit transmission to others in the home or community.
- Teach all patients the ABCDE method of evaluating a lesion for melanoma. **Patient-Centered Care** QSEN
- Assess the ability of the patient with a skin problem to see and reach the affected area and care for the problem. **Patient-Centered Care** QSEN

Psychosocial Integrity

- Assess the patient's and family's feelings about a chronic skin condition or visible scar. **Patient-Centered Care** QSEN
- Support the patient and family in coping with changes in skin integrity and in body image. **Patient-Centered Care** QSEN
- Encourage the patient with a visible wound or other skin problem to participate in the care of the wound.
- Assess and manage the patient's pain. **Patient-Centered Care** QSEN
- Allow the patient the opportunity to express feelings about a change in body image as a result of changes in the skin, hair, or nails. **Patient-Centered Care** QSEN
- Explain all procedures, restrictions, drugs, and follow-up care to the patient and family.
- Touch the patient who has skin problems to show acceptance. **Patient-Centered Care** QSEN

Physiological Integrity

- Keep skin well hydrated to promote tissue integrity. **Evidence-Based Practice** QSEN
- Use appropriate risk assessment tools to perform a focused skin assessment and re-assessment to determine risk for pressure ulcer development and adequacy of the skin's protective functions. **Safety** QSEN
- Keep skinfold areas clean and dry. **Evidence-Based Practice** QSEN
- Ask any patient who has started taking a newly prescribed drug if he or she has noticed whether any skin changes have occurred since starting the drug. **Patient-Centered Care** QSEN
- Avoid massaging or vigorously rubbing any area of the skin that is reddened or has been subjected to pressure. **Evidence-Based Practice** QSEN
- Encourage patients with itching to avoid scratching the skin.
- Teach patients to avoid using over-the-counter cortisone preparations

on skin lesions until the cause has been identified. **Patient-Centered Care** QSEN

- Teach patients who have a skin infection how to avoid spreading the infection to other parts of their own bodies and to other people. **Safety** QSEN
- Evaluate any open skin area on a patient daily for size, depth, exudate, presence of infection, and indicators of healing. **Patient-Centered Care** QSEN
- Differentiate the manifestations for these pressure ulcer categories: stage I through stage IV, unstageable ulcers, and suspected deep tissue injury. **Evidence-Based Practice** QSEN
- Evaluate wounds for size, depth, presence of infection, and indications of healing. **Patient-Centered Care** QSEN
- Supervise skin care delegated to licensed practical nurses/licensed vocational nurses (LPNs/LVNs) or unlicensed assistive personnel (UAP). **Safety** QSEN
- Urge patients with chronic skin problems, especially those that alter appearance, to become involved in a community support group.

CHAPTER 26

Care of Patients with Burns

Tammy Coffee

PRIORITY CONCEPTS

- Tissue Integrity
- Infection
- Pain
- Fluid and Electrolyte Balance
- Perfusion
- Nutrition
- Mobility

Learning Outcomes

Safe and Effective Care Environment

1. Apply the principles of infection prevention to protect burn patients with open wounds.

Health Promotion and Maintenance

2. Teach everyone fire prevention strategies.

Psychosocial Integrity

3. Reduce the psychosocial impact of burn injury for the patient and family.

Physiological Integrity

4. Ensure optimal pain control for the patient with a burn injury.
5. Work with all members of the health care team to help the patient and family experiencing a burn injury achieve desired health outcomes.

6. Prioritize nursing care for the patient during the resuscitation phase of burn injury.
7. Prioritize nursing care for the patient during the acute phase of burn injury.
8. Coordinate care for the patient during the rehabilitation phase of burn injury.

 http://evolve.elsevier.com/Iggy/

Burns are complex injuries with loss of tissue integrity that cause patients to develop many physiologic, metabolic, and psychological changes. These injuries can range from a "sunburn" to major injuries involving all layers of the skin. When the skin is injured, the function of many body systems is changed. The burn patient needs comprehensive care for weeks to months to survive the injury, reduce complications, and return to his or her best functional status. For best care and patient outcomes, nurses coordinate the activities of an interdisciplinary team of health care providers.

Pathophysiology of Burn Injury

The tissue destruction caused by a burn injury leads to local and systemic problems that affect fluid and electrolyte balance and lead to protein losses, sepsis, and changes in metabolic, endocrine, respiratory, cardiac, hematologic, and immune functioning. The extent of problems is related to age, general health, extent of injury, depth of injury, and the specific body area injured. Even after healing, the burn injury may cause late complications such as contracture formation and scarring. Thus care priorities are the prevention of infection and closure of the burn wound. A lack of or delay in wound healing is a key factor for all systemic problems and a major cause of disability and death among patients who are burned.

Skin Changes Resulting from Burn Injury

Anatomic Changes

The skin is the largest organ of the body (see Chapter 24). Each of its two major layers, the epidermis and the dermis, has several sublayers. The epidermis is the outer layer of skin. It can grow back after a burn injury because the epidermal cells surrounding sweat and oil glands and hair follicles extend into dermal tissue and regrow to heal partial-thickness wounds. Together, the sweat and oil glands and the hair follicles are the *dermal appendages,* which vary in depth in different body areas. The sweat and oil glands in the palm of the hand and the sole of the foot, for example, extend deep into the dermis. This allows for healing of deep burns in these areas. The epidermis has no blood vessels, and nutrients must diffuse from the second layer of skin, the dermis.

The dermis is thicker than the epidermis and is made up of collagen, fibrous connective tissue, and elastic fibers. Within the dermis are the blood vessels, sensory nerves, hair follicles, lymph vessels, sebaceous glands, and sweat glands.

When burn injury occurs, skin can regrow as long as parts of the dermis are present. When the entire dermal layer is burned, all cells and dermal appendages are destroyed and the skin can no longer restore itself. The subcutaneous tissue lies below the dermis and is separated from the dermis by the basement membrane, a thin, noncellular protein surface. With deep burns, the subcutaneous tissues may be damaged, leaving bones, tendons, and muscles exposed.

Functional Changes

The skin has many functions when tissue integrity is intact (see Table 24-1 in Chapter 24). It is a protective barrier against injury and microbial invasion. Burns break this barrier, greatly increasing the risk for infection.

The skin helps maintain the delicate fluid and electrolyte balance essential for life. After a burn injury, massive fluid loss occurs through excessive evaporation. The rate of evaporation is in proportion to the total body surface area (TBSA) burned and the depth of injury.

The skin is an excretory organ through sweating. Full-thickness burns destroy the sweat glands, reducing excretory ability.

The sensations of pain, pressure, temperature, and touch are triggered on the skin in normal daily activities, which allows a person to react to changes in the environment. *All burn injuries are painful*. With partial-thickness burns, nerve endings are exposed, increasing sensitivity and pain. With full-thickness burns, nerve endings are completely destroyed. At first, these wounds may not transmit sensation except at wound edges. Despite this destruction, patients often have dull or pressure-type of pain in these areas.

Skin exposed to sunlight activates vitamin D. Partial-thickness burns reduce the activation of vitamin D, and this function is lost completely in areas of full-thickness burns.

The internal body temperature remains within a narrow range (about 84.2° to 109.4° F [29° to 43° C]) compared with the temperatures of the external environment. Skin tissue integrity is important in maintaining normal body temperature. Circulating blood in the skin both provides and dissipates heat efficiently. When heat is applied to the skin, the temperature under the dermis rises rapidly. As soon as the heat source is removed, compensatory processes quickly return the area to a normal temperature. If the heat source is not removed or if it is applied at a rate that exceeds the skin's capacity to dissipate it, cells are destroyed.

Physical identity is partly determined by the skin's cosmetic quality, which contributes to each person's unique appearance. A patient who sustains a major burn often develops reduced self-image and other psychosocial problems as a result of a change in appearance.

Depth of Burn Injury

The severity of a burn is determined by how much of the body surface area is involved and the depth of the burn. The degree of tissue integrity loss is related to the agent causing the burn and to the temperature of the heat source, as well as to how long the skin is exposed to it.

Differences in skin thickness in various parts of the body also affect

burn depth. In areas where the skin is thin (e.g., eyelids, ears, nose, genitalia, tops of the hands and feet, fingers, and toes), a short exposure to high temperatures causes a deep burn injury. The skin is thinner in older adults (Touhy & Jett, 2014), which increases their risk for greater burn severity, even at lower temperatures of shorter duration.

Burn wounds are classified as superficial-thickness wounds, partial-thickness wounds, full-thickness wounds, and deep full-thickness wounds. The partial-thickness wounds are further divided into superficial and deep subgroups. Table 26-1 lists the differences of these burns.

TABLE 26-1

Classification of Burn Depth

CHARACTERISTIC	SUPERFICIAL	SUPERFICIAL PARTIAL-THICKNESS	DEEP PARTIAL-THICKNESS	FULL-THICKNESS	DEEP FULL-THICKNESS
Color	Pink to red	Pink to red	Red to white	Black, brown, yellow, white, red	Black
Edema	Mild	Mild to moderate	Moderate	Severe	Absent
Pain	Yes	Yes	Yes	Yes and no	Absent
Blisters	No	Yes	Rare	No	No
Eschar	No	No	Yes, soft and dry	Yes, hard and inelastic	Yes, hard and inelastic
Healing time	3-6 days	About 2 wk	2-6 wk	Weeks to months	Weeks to months
Grafts required	No	No	Can be used if healing is prolonged	Yes	Yes
Example	Sunburn, flash burns	Scalds, flames, brief contact with hot objects	Scalds; flames; prolonged contact with hot objects, tar, grease, chemicals	Scalds; flames; prolonged contact with hot objects, tar, grease, chemicals, electricity	Flames, electricity, grease, tar, chemicals

Burns also are described as minor, moderate, or major depending on the depth, extent, and location of injury (Table 26-2). Fig. 26-1 shows the tissue layers involved with different depths of injury.

TABLE 26-2

Classification of Burn Injury and Burn Center Referral Criteria

CHARACTERISTICS	COMMENTS
Minor Burns	
Partial-thickness burns less than 10% TBSA Full-thickness burns less than 2% TBSA No burns of eyes, ears, face, hands, feet, or perineum No electrical burns No inhalation injury No complicated additional injury Patient is younger than 60 years and has no chronic cardiac, pulmonary, or endocrine disorder	Patients in this category should receive emergency care at the scene and be taken to a hospital emergency department. A special expertise hospital or designated burn center is usually not necessary.
Moderate Burns	
Partial-thickness burns 15%-25% TBSA Full-thickness burns 2%-10% TBSA No burns of eyes, ears, face, hands, feet, or perineum No electrical burns No inhalation injury No complicated additional injury Patient is younger than 60 years and has no chronic cardiac, pulmonary, or endocrine disorder	Patients in this category should receive emergency care at the scene and be transferred either to a special expertise hospital or to a designated burn center.
Major Burns	
Partial-thickness burns greater than 25% TBSA Full-thickness burns greater than 10% TBSA Any burn involving the eyes, ears, face, hands, feet, perineum Electrical injury Inhalation injury Patient is older than 60 years Burn complicated with other injuries (e.g., fractures) Patient has cardiac, pulmonary, or other chronic metabolic disorders	Patients who meet *any one* of the criteria for a major burn should receive emergency care at the nearest emergency department and then be transferred to a designated burn center as soon as possible.

TBSA, Total body surface area.

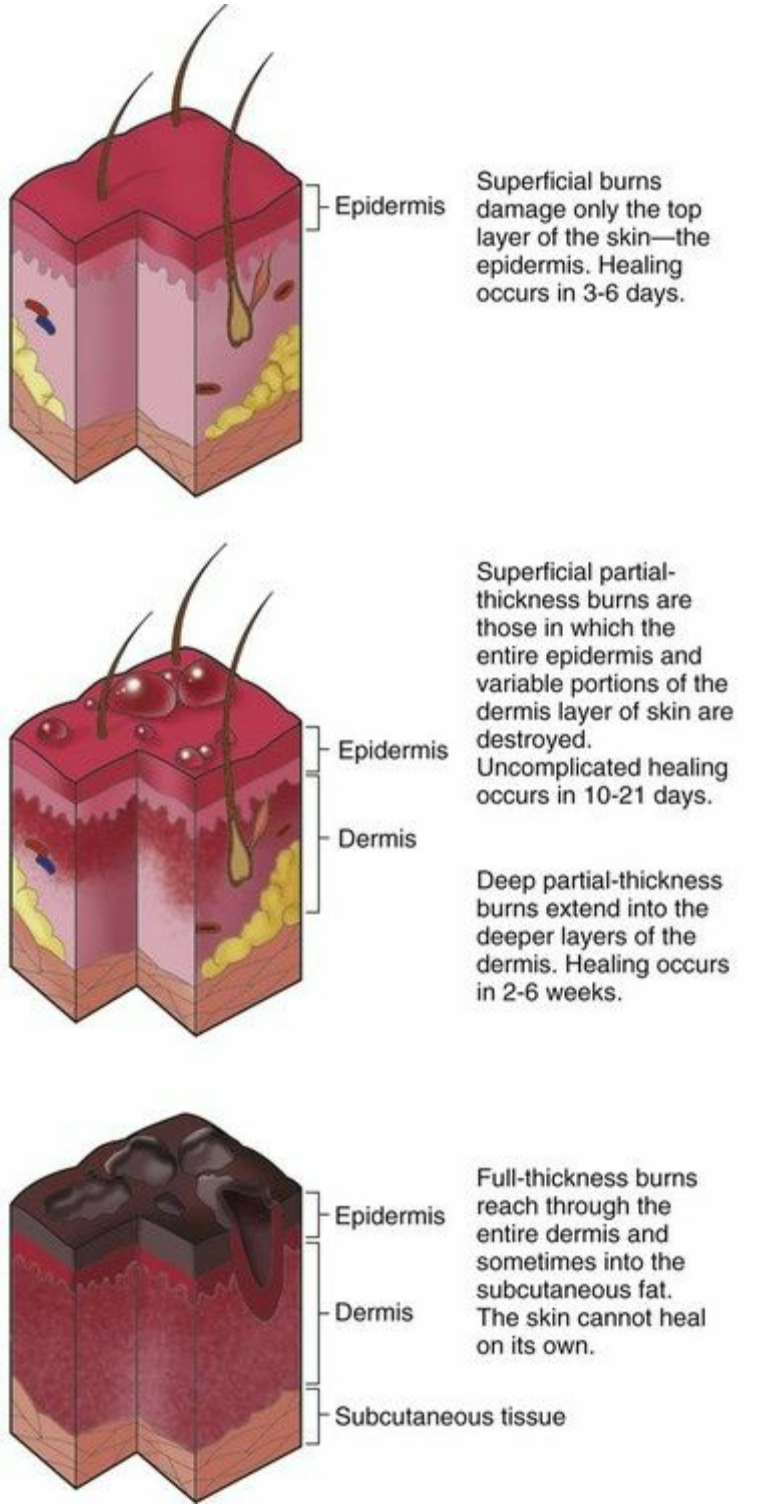

FIG. 26-1 The tissues involved in burns of various depths.

Superficial-Thickness Wounds.

Superficial-thickness wounds have the least damage because the epidermis is the only part of the skin that is injured. The epithelial cells and basement membrane, needed for total regrowth, remain present.

These wounds are caused by prolonged exposure to low-intensity heat (e.g., sunburn) or short (flash) exposure to high-intensity heat. Redness

with mild edema, pain, and increased sensitivity to heat occurs as a result. **Desquamation** (peeling of dead skin) occurs 2 to 3 days after the burn. The area heals rapidly in 3 to 6 days without a scar or other complication.

Partial-Thickness Wounds.

A partial-thickness wound involves tissue integrity loss of the entire epidermis and varying depths of the dermis. Depending on the amount of dermal tissue damaged, partial-thickness wounds are further subdivided into superficial partial-thickness and deep partial-thickness injuries.

Superficial partial-thickness wounds are caused by injury to the upper third of the dermis, leaving a good blood supply. These wounds are pink and moist and **blanch** (lighten) when pressure is applied (Fig. 26-2). The small vessels bringing blood to this area are injured, resulting in the leakage of large amounts of plasma, which in turn lifts the heat-destroyed epidermis, causing blister formation. The blisters continue to increase in size after the burn as cell and protein breakdown occur. Small blisters are often left intact if they are not located over a joint. Large blisters usually are opened and débrided to promote healing.

FIG. 26-2 The typical appearance of a superficial partial-thickness burn injury.

Superficial partial-thickness wounds increase pain sensation. Nerve endings are exposed, and any stimulation (touch or temperature change) causes intense pain. With standard care, these burns heal in 10 to 21 days with no scar, but some minor pigment changes may occur.

Deep partial-thickness wounds extend deeper into the skin dermis, and fewer healthy cells remain. Blisters usually do not form because the dead tissue layer is thick, sticks to the underlying dermis, and does not readily lift off the surface. The wound surface is red and dry with white areas in deeper parts (dry because fewer blood vessels are patent). When

pressure is applied to the burn, it blanches slowly or not at all (Fig. 26-3). Edema is moderate, and pain is less than with superficial burns because more of the nerve endings have been destroyed.

FIG. 26-3 The typical appearance of a deep partial-thickness burn injury.

Blood flow to these areas is reduced, and progression to deeper injury can occur from hypoxia and ischemia. Adequate hydration, nutrients, and oxygen are needed for regrowth of skin cells and prevention of conversion to deeper burns. These wounds can convert to full-thickness wounds when tissue damage increases with infection, hypoxia, or ischemia. Deep partial-thickness wounds generally heal in 2 to 6 weeks, but scar formation results. Surgical intervention with skin grafting can reduce healing time.

Full-Thickness Wounds.

A full-thickness wound occurs with destruction of the entire epidermis and dermis, leaving no skin cells to repopulate (Fig. 26-4). This wound does not regrow, and areas not closed by wound contraction (see Chapter 25) require grafting.

FIG. 26-4 The typical appearance of a full-thickness burn injury.

The full-thickness burn has a hard, dry, leathery *eschar* that forms from coagulated particles of destroyed skin. *The eschar is dead tissue; it must slough off or be removed from the wound before healing can occur.* These thick particles often stick to the lower tissue layers, making eschar removal difficult. Edema is severe under the eschar in a full-thickness wound. When the injury is **circumferential** (completely surrounds an extremity or the chest), blood flow and chest movement for breathing may be reduced by tight eschar. **Escharotomies** (incisions through the eschar) or **fasciotomies** (incisions through eschar and fascia) may be needed to relieve pressure and allow normal blood flow and breathing. (See p. 478 of the Surgical Management discussion in the Preventing Hypovolemic Shock and Inadequate Oxygenation section.)

A full-thickness burn may be waxy white, deep red, yellow, brown, or black. Thrombosed and heat-coagulated blood vessels may be seen beneath the surface of the burn and leave the burned tissue without a blood supply. Sensation is reduced or absent because of nerve ending destruction. Healing time depends on establishing a good blood supply in the injured areas. This process can range from weeks to months.

Deep Full-Thickness Wounds.

Deep full-thickness wounds extend beyond the skin and damage muscle, bone, and tendons. These burns occur with flame, electrical, or chemical injuries. The wound is blackened and depressed, and sensation is completely absent (Fig. 26-5). All full-thickness burns need early excision and grafting. Grafting decreases pain and length of stay and hastens recovery. Amputation may be needed when an extremity is involved.

FIG. 26-5 The typical appearance of a deep full-thickness burn injury.

Vascular Changes Resulting from Burn Injuries

Circulation to the burned skin is disrupted immediately after injury by blood vessel occlusion. Macrophages in damaged tissues release chemicals that at first cause blood vessel constriction. Blood vessel thrombosis may occur, causing necrosis, which can lead to deeper injuries in these areas.

Fluid shift occurs after initial vasoconstriction as a result of blood vessels near the burn dilating and leaking fluids into the interstitial space (Fig. 26-6). This fluid shift, also known as *third spacing* or *capillary leak syndrome,* is a continuous leak of plasma from the vascular space into the interstitial space. The impaired fluid and electrolyte balance leads to loss of plasma fluids and proteins, which decreases blood volume and blood pressure (McCance et al., 2014). Leakage of fluid and electrolytes from the vascular space continues, causing extensive edema, even in areas that were not burned. Fluid shift, with excessive weight gain, occurs in the first 12 hours after the burn and can continue for 24 to 36 hours.

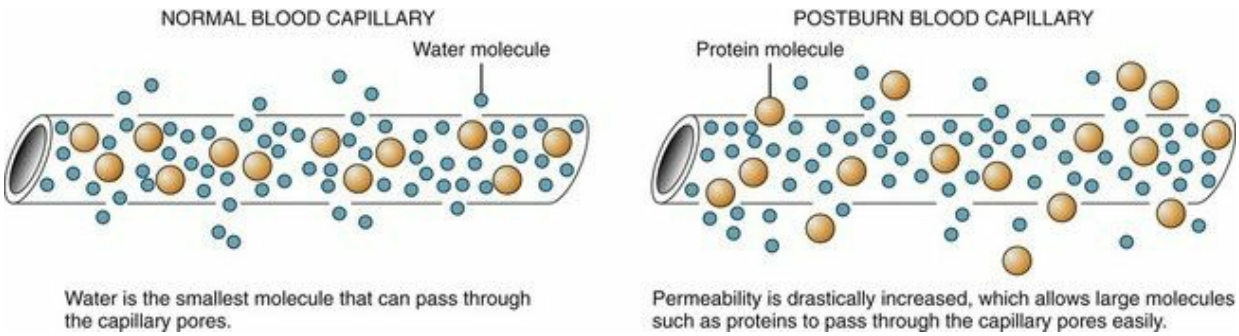

FIG. 26-6 The capillary response to burn injury (early phase). This response is also known as *capillary leak syndrome.*

The amount of fluid shifted depends on the extent and severity of injury. Capillary leak occurs in both burned and unburned areas when tissue damage is extensive (i.e., more than 25% total body surface area [TBSA]). Edema develops as plasma and electrolytes escape into the interstitial space. The proteins now in the interstitial space increase the movement of *fluids* out from the vascular space.

Profound disruptions of fluid and electrolyte balance and acid-base balance occur as a result of the fluid shift and cell damage. These imbalances often include hypovolemia, metabolic acidosis, **hyperkalemia** (high blood potassium level), and **hyponatremia** (low blood sodium level). Hyperkalemia occurs as a result of direct cell injury that releases large amounts of cellular potassium. Sodium is retained by the body as a result of the endocrine response to stress. Aldosterone secretion increases, leading to increased sodium reabsorption by the kidney. This sodium, however, quickly passes into the interstitial spaces of the burned area with the fluid shift. Thus, despite the increased amount of sodium in the body, most of the sodium is trapped in the interstitial space and a sodium deficit occurs in the blood. **Hemoconcentration** (elevated blood osmolarity, hematocrit, and hemoglobin) develops from vascular dehydration. This problem increases blood viscosity, reducing blood flow and increasing tissue hypoxia.

Fluid remobilization starts at about 24 hours after injury, when the capillary leak stops. The diuretic stage begins at about 48 to 72 hours after the burn injury as capillary membrane integrity returns and edema fluid shifts from the interstitial spaces into the intravascular space. Blood volume increases, leading to increased kidney blood flow and diuresis unless kidney damage has occurred. Body weight returns to normal over the next few days as edema subsides.

During this phase, hyponatremia develops because of increased kidney sodium excretion and the loss of sodium from wounds. **Hypokalemia** (low blood potassium level) results from potassium moving back into the

cells and also being excreted in urine. Anemia often develops as a result of hemodilution, but it is generally not severe enough to require blood transfusions. Transfusions are needed only if the patient's hematocrit is less than 20% to 25% and the patient has manifestations of hypoxia. Protein continues to be lost from the wounds. Metabolic acidosis is possible because of the loss of bicarbonate in the urine and the increased rate of metabolism.

Cardiac Changes Resulting from Burn Injury

Heart rate increases and cardiac output decreases because of the initial fluid shifts and hypovolemia that occur after a burn injury. Cardiac output may remain low until 18 to 36 hours after the burn injury. Cardiac output improves with fluid resuscitation and reaches normal levels before plasma volume is restored completely. Proper fluid resuscitation and support with oxygen prevent further complications.

Pulmonary Changes Resulting from Burn Injury

Direct injury to the lung from contact with flames rarely occurs. Rather, respiratory problems are caused by superheated air, steam, toxic fumes, or smoke. *Such problems are a major cause of death in patients with burns and are most likely to occur when the burn takes place indoors.* Respiratory failure with burn injuries can result from airway edema during fluid resuscitation, pulmonary capillary leak, chest burns that restrict chest movement, and carbon monoxide poisoning.

Respiratory damage from an inhalation injury can occur in the upper and major airways and the lung tissue. The upper airway is affected when inhaled smoke or irritants cause edema and obstruct the trachea. Heat can reach the upper airway, causing an inflammatory response that leads to edema of the mouth and throat with the potential of airway obstruction.

Chemicals and toxic gases produced during combustion can cause airway injury. The ciliated membranes lining the trachea normally trap foreign materials. Smoke and gases slow this activity, allowing particles to enter the bronchi. The lining of the trachea and bronchi may slough 48 to 72 hours after injury and obstruct the lower airways.

Lung tissue injuries result from toxic irritant damage to the alveoli and capillaries. Leaking capillaries cause alveolar edema, which can occur immediately or up to a week after the injury. The *fluid* that diffuses into the lung tissue spaces contains proteins that form fibrinous membranes and lead to respiratory distress. Progressive pulmonary failure develops,

leading to acute pulmonary insufficiency and infection.

Gastrointestinal Changes Resulting from Burn Injury

The fluid shifts and decreased cardiac output that occur after injury decrease blood flow to the GI tract. Gastric mucosal tissue integrity and motility are impaired. The sympathetic nervous system stress response increases secretion of epinephrine and norepinephrine, which inhibit GI motility and further reduce blood flow to the area. Peristalsis decreases, and a paralytic ileus may develop. Secretions and gases collect in the GI tract, causing abdominal distention.

Curling's ulcer (acute gastroduodenal ulcer that occurs with the stress of severe injury) may develop within 24 hours after a severe burn injury because of reduced GI blood flow and mucosal damage (McCance et al., 2014). The mucus lining the stomach normally protects the tissue from the hydrogen ions secreted into the stomach. With decreased gastric mucus production and increased hydrogen ion production, ulcers may develop. This complication is now less common because of the use of H_2 histamine blockers, proton pump inhibitors, drugs that protect GI tissues, and early enteral feeding.

Metabolic Changes Resulting from Burn Injury

A serious burn injury greatly increases metabolism by increasing secretion of catecholamines, antidiuretic hormone, aldosterone, and cortisol. With this hypermetabolism, the patient's oxygen use and calorie needs are high.

The catecholamines activate the stress response. The increased production (and loss) of heat breaks down protein and fat *(catabolism)*, rapidly uses glucose and calories, and increases urine nitrogen loss. The heat and water lost from the burn also increase metabolic rate and calorie needs. Depending on the extent of injury, the patient's calorie needs double or triple normal energy needs. These increased rates peak 4 to 12 days after the burn and can remain elevated for months until all wounds are closed.

The hypermetabolic condition also increases core body temperature. The patient loses heat through the burned areas. Core body temperature increases as a response to the adjustment in temperature regulation by the hypothalamus, resulting in a low-grade fever.

Immunologic Changes Resulting from Burn Injury

Burn injury disrupts or destroys the protective skin tissue integrity, increasing the risk for infection. The injury activates the inflammatory response and often suppresses all types of immune functions. Antibiotic therapy and other interventions for burns further reduce immune function.

Compensatory Responses to Burn Injury

Any injury is a stressor and can disrupt homeostasis. Two compensatory (adaptive) responses have immediate benefit: the inflammatory response and the sympathetic nervous system stress response. Together these responses cause changes that result in many of the manifestations seen in the first 2 to 3 days after a burn injury.

Inflammatory compensation is helpful by triggering healing in the injured tissues and also is responsible for the serious problems that occur with the fluid shift. This compensation causes blood vessels to leak fluid into the interstitial space and white blood cells to release chemicals that trigger local tissue reactions. These responses cause the massive fluid shift, edema, and hypovolemia that are seen in the **resuscitation phase** (first 24 to 48 hours) after a burn injury. The extent of the inflammatory response depends on the burn severity. Chapter 17 explains inflammation and the inflammatory responses in detail.

Sympathetic nervous system compensation is the stress response that occurs when any physical stressors are present. Changes caused by sympathetic compensation are most evident in the cardiovascular, respiratory, and GI systems. Fig. 26-7 shows the results of sympathetic nervous system stimulation.

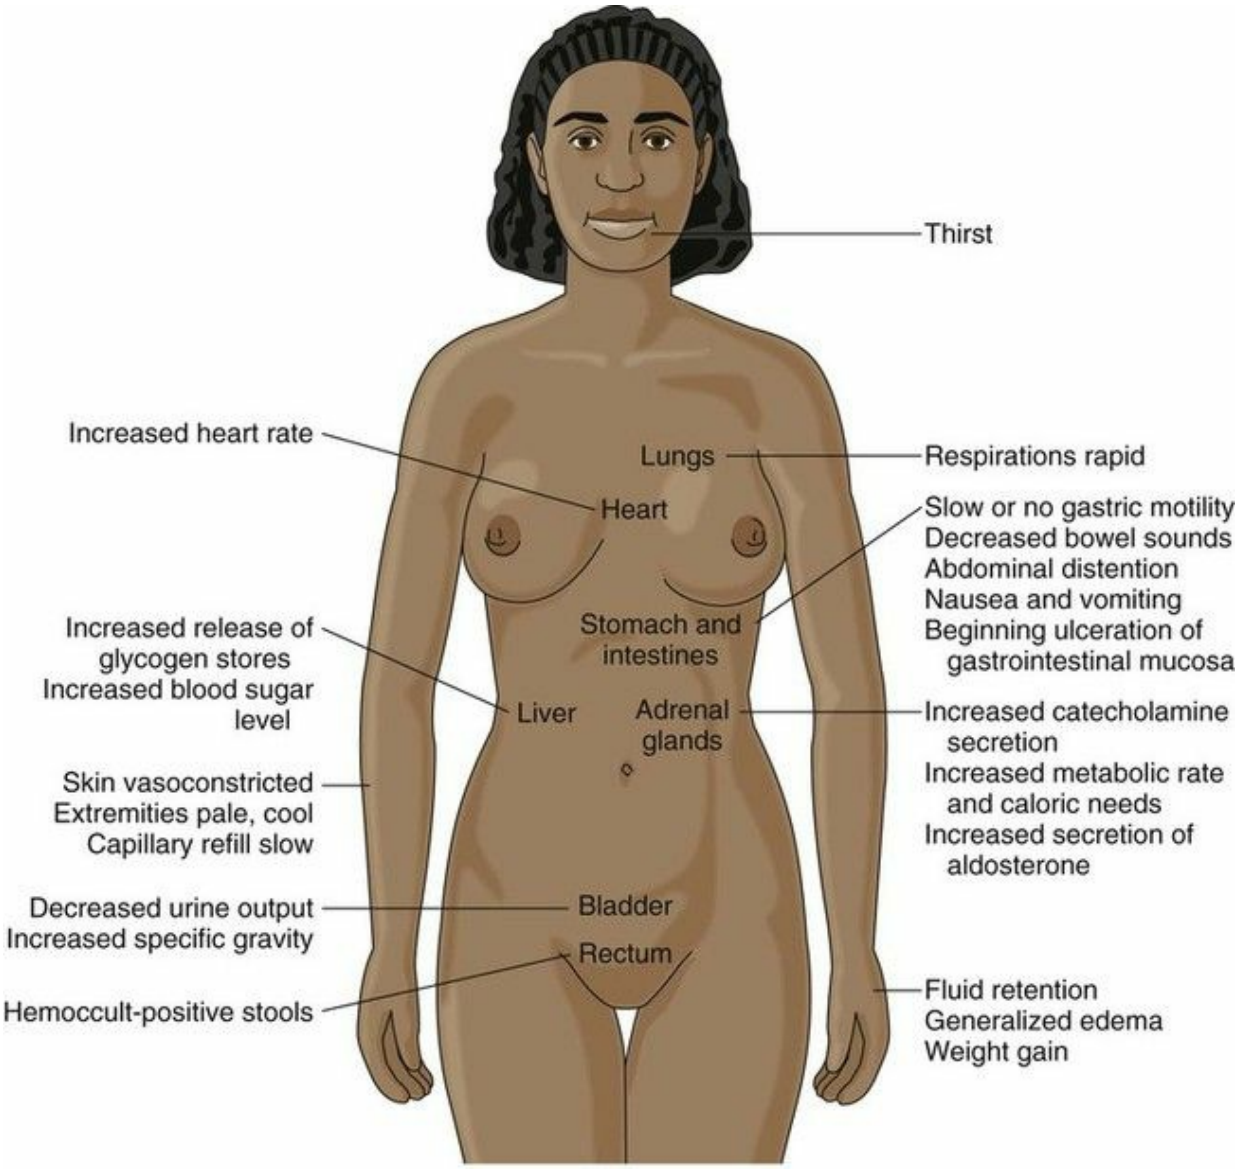

FIG. 26-7 The physiologic actions of the sympathetic nervous system compensatory responses to burn injury (early phase).

Etiology of Burn Injury

Burn injuries are caused by dry heat (flame), moist heat (scald), contact with hot or rough surfaces, chemicals, electricity, and ionizing radiation. The cause of the injury affects both the prognosis and the treatment.

Dry heat injuries are caused by open flame in house fires and explosions. Explosions usually result in flash burns because they produce a brief exposure to very high temperatures.

Moist heat (scald) injuries are caused by contact with hot liquids or steam. Scald injuries are more common among older adults than younger adults. Hot liquid spills usually burn the upper, front areas of the body. Immersion scald injuries usually involve the lower body.

Contact burns occur when hot metal, tar, or grease contacts the skin,

often leading to a full-thickness injury. Hot metal injuries occur when a body part contacts a hot surface, such as a space heater or iron. They also can occur in industrial settings from molten metals. Tar and asphalt temperatures usually are greater than 400° F, and deep injuries occur within seconds when the skin is immersed in or splashed with them. Hot grease injuries from cooking are usually deep because of the high temperature of the grease.

Chemical burns occur in home or industrial accidents or as the result of assault. Injury occurs when chemicals directly contact the skin and epithelial tissues or are ingested. The severity of the injury depends on the duration of contact, the concentration of the chemical, the amount of tissue exposed, and the action of the chemical.

Alkalis found in oven cleaners, fertilizers, drain cleaners, and heavy industrial cleaners damage the tissues by causing the skin and its proteins to liquefy. This allows for deeper spread of the chemical and more severe burns. Acids found in bathroom cleaners, rust removers, pool chemicals, and industrial drain cleaners damage tissue integrity by coagulating cells and skin proteins, which can limit the depth of tissue damage. Chemical disinfectants and gasoline are easily absorbed through the skin and have toxic effects on the kidneys and liver.

Electrical injuries are burns occurring when an electrical current enters the body (Fig. 26-8). These injuries have been called the "grand masquerader" of burns because the surface injuries may look small but the associated internal injuries can be huge. Tissue injury from electrical trauma results from electrical energy being converted to heat energy. The extent of injury depends on the type of current, the pathway of flow, the local tissue resistance, and the duration of contact. Once the current penetrates the skin, it flows throughout the involved body part generating heat and damaging tissues. Deep muscle injury may be present even when superficial muscles appear normal or uninjured.

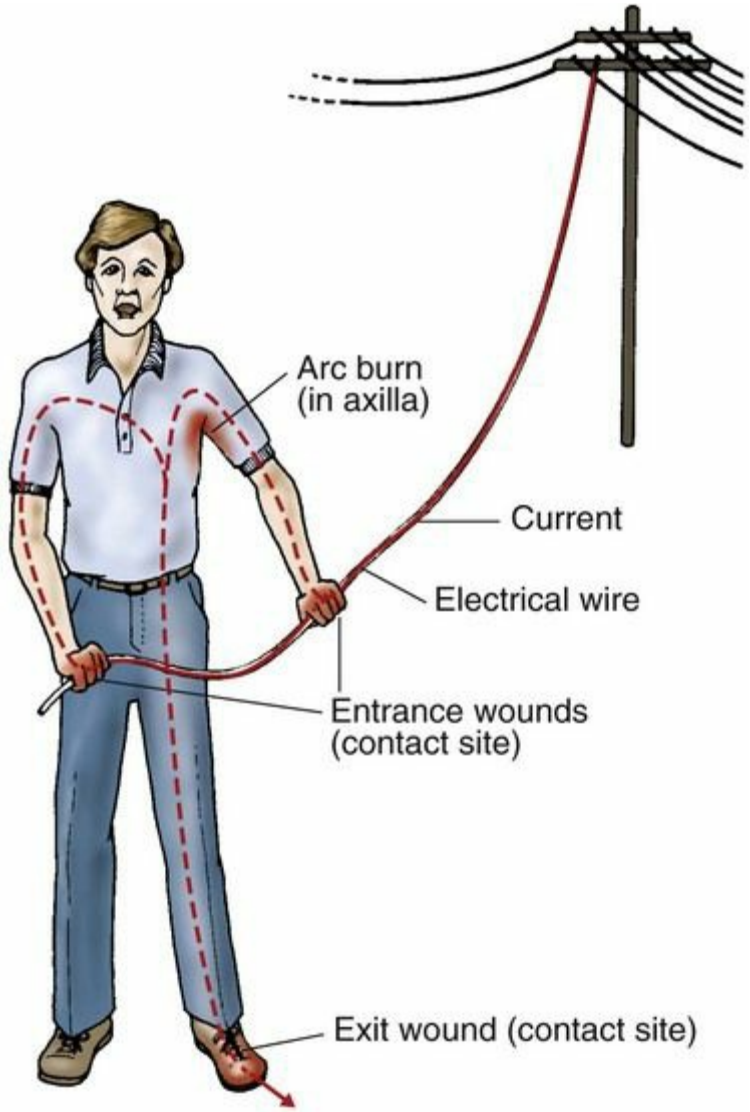

FIG. 26-8 The mechanism of electrical injury: currents passing through the body follow the path of least resistance to the ground.

The longer the electricity is in contact with the body, the greater the damage. The duration of contact is increased by tetanic contractions of the strong flexor muscles in the forearm, which can prevent the person from releasing the electrical source.

It is difficult to know the exact path a current takes in the body. The course of flow is defined by the locations of the "contact sites," which are the entrance and exit wounds (Fig. 26-9). At first, the wounds may not be obvious. The path of the injury may involve many internal organs between the two contact sites.

FIG. 26-9 Electrical contact sites. **A,** Possible entrance site. **B,** Possible exit site.

Burn injuries from electricity can occur as *thermal burns, flash burns,* or *true electrical injury.* Thermal burns occur when clothes ignite from heat or flames produced by electrical sparks. External burn injuries can occur when the electrical current jumps, or "arcs," between two body surfaces. These injuries usually are severe and deep. True electrical injury occurs when direct contact is made with an electrical source. Internal damage results and can be devastating. Damage starts on the inside and goes out; deep-tissue destruction may not be apparent immediately after injury. Organs in the path of the current may become ischemic and necrotic.

Radiation injuries occur when people are exposed to large doses of radioactive material. The most common type of tissue injury from radiation exposure occurs with therapeutic radiation. This injury is usually minor and rarely causes extensive skin damage.

Radiation exposure is more serious in industrial settings where radioactive energy is produced or used. Injury severity depends on the type of radiation, distance from the source, duration of exposure, absorbed dose, and depth of penetration into the body. Chapter 22 discusses potential tissue damage from alpha, beta, and gamma radiation.

Incidence and Prevalence of Burn Injury

Fires and burns are the fifth most common cause of unintentional injury deaths in the United States and the third leading cause of fatal home injuries (American Burn Association [ABA], 2012). Although the number of fatalities and injuries caused by residential fires has declined gradually over the past several decades, many residential fire-related deaths remain preventable and continue to pose a significant public health problem.

An estimated 3400 fire and burn deaths occur each year from all sources of burn injury (ABA, 2012). Most deaths occur at the scene of the

incident or during transport.

The number of deaths from burn injuries decreases with appropriate intervention. Factors that increase the risk for death include age older than 60 years, a burn greater than 40% TBSA, and the presence of an inhalation injury. When a patient has all three of these factors, the risk for death is very high. Better outcomes from burn injuries occur because of vigorous fluid resuscitation, early burn wound excision, improved critical care monitoring, early enteral nutrition, antibiotics, and the use of specialized burn centers.

Health Promotion and Maintenance

Minor burns are common, and prevention involves planning and awareness. Teach all people to assess how hot the water is before bathing, showering, or immersing a body part in it. Hot water tanks should be set below 140° F (60° C). Reinforce the use of potholders when taking food from ovens. Stress the importance of never adding a flammable substance (e.g., gasoline, kerosene, alcohol, lighter fluid, charcoal starter) to an open flame. Suggest the use of sunscreen agents and protective clothing to avoid sunburn.

Teach people to reduce the risk for house fires by never smoking in bed, avoiding smoking when drinking alcohol or taking drugs that induce sleep, and keeping matches and lighters out of the reach of children or people who are cognitively impaired. When space heaters are used, stress the importance of keeping clothing, bedding, and other flammable objects away from them. Remind people to keep the screens and doors closed on the fronts of fireplaces and to have chimneys swept each year. Also remind patients using home oxygen not to smoke or have open flames in a room where oxygen is in use (Murabit & Tredget, 2012).

Leaving a burning building is critical to prevent injury or death. Teach all people to use home smoke detectors and carbon monoxide detectors and to ensure these are in good working order. The number of detectors needed depends on the size of the home. Recommendations are that each bedroom has a separate smoke detector, there should be at least one detector in the hallway of each story, and at least one detector is needed for the kitchen, each stairwell, and each home entrance. Teach everyone to develop a planned escape route with alternatives for when a main route is blocked by fire. Reinforce that no one should ever re-enter a burning building to retrieve belongings.

Resuscitation Phase of Burn Injury

Events within the first hour after injury can make the difference between life and death for the patient with a burn injury. Immediate care focuses on maintaining an open airway, ensuring adequate breathing and circulation, limiting the extent of injury, and maintaining the function of vital organs. Chart 26-1 outlines the emergency management of a burn injury.

Chart 26-1 Best Practice for Patient Safety & Quality Care QSEN

Emergency Management of Burns

General Management for All Types of Burns

- Assess for airway patency.
- Administer oxygen as needed.
- Cover the patient with a blanket.
- Keep the patient on NPO status.
- Elevate the extremities if no fractures are obvious.
- Obtain vital signs.
- Initiate an IV line, and begin fluid replacement.
- Administer tetanus toxoid for prophylaxis.
- Perform a head-to-toe assessment.

Specific Management

Flame Burns

- Smother the flames.
- Remove smoldering clothing and all metal objects.

Chemical Burns

- If dry chemicals are present on skin or clothing, DO NOT WET THEM.
- Brush off any dry chemicals present on the skin or clothing.
- Remove the patient's clothing.
- Ascertain the type of chemical causing the burn.
- Do not attempt to neutralize the chemical unless it has been positively identified and the appropriate neutralizing agent is available.

Electrical Burns

- At the scene, separate the patient from the electrical current.
- Smother any flames that are present.
- Initiate cardiopulmonary resuscitation.

• Obtain an electrocardiogram (ECG).

Radiation Burns

• Remove the patient from the radiation source.
• If the patient has been exposed to radiation from an unsealed source, remove his or her clothing (using tongs or lead protective gloves).
• If the patient has radioactive particles on the skin, send him or her to the nearest designated radiation decontamination center.
• Help the patient bathe or shower.

The **resuscitation phase** is the first phase of a burn injury. It begins at the onset of injury and continues for about 24 to 48 hours. During this phase, the injury is evaluated and the immediate problems of fluid imbalance (loss), edema, and reduced blood flow are assessed. The priorities for management during this period are to (1) secure the airway, (2) support circulation and organ perfusion by fluid replacement, (3) keep the patient comfortable with analgesics, (4) prevent infection through careful wound care, (5) maintain body temperature, and (6) provide emotional support.

❖ Patient-Centered Collaborative Care

◆ Assessment

History.

Knowledge of circumstances surrounding the burn injury is valuable in planning the management of a burn patient. If possible, obtain information directly from the patient. If this is not possible, ask family members or witnesses to the event. Ask about the circumstances of the injury, the time and place of injury, and the source and cause of injury. Asked detailed questions about how the burn occurred and the events occurring from the time of injury until help arrived. Also obtain demographic data, health history (including pre-existing illness), drug use, any additional injuries, and pain information.

Demographic data include age, weight, and height. The rate of serious complications and death from burn injuries is increased among adults older than 50 years. Chart 26-2 lists the age-related differences in older adults' responses to a burn injury. The patient's preburn weight is used to calculate fluid rates, energy requirements, and drug doses. This weight is the *dry weight*, because it is the patient's weight before edema forms. Calculations based on a weight obtained after fluid replacement is

started are not accurate. Height is important in determining total body surface area (TBSA), which is used to calculate nutrition needs.

Chart 26-2 Nursing Focus on the Older Adult

Age-Related Changes Increasing Complications from Burn Injury

AGE-RELATED CHANGES	COMPLICATIONS AND NURSING CONSIDERATIONS
Thinner skin, sensory impairment, decreased mobility	Sensory impairment and decreased mobility increase the risk for burn injury. Thinner skin increases the depth of injury even when the exposure to the cause of injury is of shorter duration.
Slower healing time	Longer time with open areas results in a greater risk for infection, metabolic derangements, and loss of function from contracture formation and scar tissue.
More likely to have cardiac impairments	Limits the aggressiveness of fluid resuscitation. Increases the risk for shock and acute kidney injury (AKI).
Reduced inflammatory and immune responses	Increases the risk for infection and sepsis. Patient may not have a fever when infection is present.
Reduced thoracic and pulmonary compliance	Increased risk for atelectasis, hypoxia, and other pulmonary complications.
More likely to have pre-existing medical conditions such as diabetes mellitus, kidney impairment, or pulmonary impairment	Any of these disorders compromise vital organ function and can interfere with fluid resuscitation efforts or other treatments.

A health history, including any pre-existing illnesses, must be known for appropriate management. Obtain specific information about the patient's history of cardiac or kidney problems, chronic alcoholism, substance abuse, and diabetes mellitus; any of these problems influence fluid resuscitation. The stress of a burn can make a mild disease process worsen. Obtain a drug history that includes allergies, current drugs, and immunization status from the patient or family. Determine the dose and time the last drug was taken. Ask whether the patient smokes or drinks alcohol daily; these factors influence treatment plans and responses.

Other injuries may occur at the time of the burn. Such injuries increase the risk for complications or death. Determine whether additional injuries such as fractures, chest injuries, and abdominal trauma are causing pain or discomfort.

Physical Assessment/Clinical Manifestations.

Physical assessment findings in the resuscitation phase differ greatly from findings later in the course of the injury. Use a systematic approach to ensure that no problem is missed. Assessment of the respiratory system is most critical to prevent life-threatening complications.

Respiratory Assessment.

Patients with major burn injuries and those with inhalation injury are at risk for respiratory problems. Respiratory manifestations common with a burn injury are listed in Table 26-3. *Thus continuous airway assessment is a nursing priority.*

TABLE 26-3

Factors Determining Inhalation Injury or Airway Obstruction

- Patients who were injured in a closed space
- Patients with extensive burns or with burns of the face
- Intra-oral charcoal, especially on teeth and gums
- Patients who were unconscious at the time of injury
- Patients with singed scalp hair, nasal hairs, eyelids, or eyelashes
- Patients who are coughing up carbonaceous sputum
- Changes in voice such as hoarseness or brassy cough
- Use of accessory muscles or stridor
- Poor oxygenation or ventilation
- Edema, erythema, and ulceration of airway mucosa
- Wheezing, bronchospasm

Direct Airway Injury.

The degree of inhalation damage depends on the fire source, temperature, environment, and types of toxic gases generated. Ask about the source of the fire, duration of exposure, and whether the fire was in an enclosed space. Inspect the mouth, nose, and pharynx. Burns of the lips, face, ears, neck, eyelids, eyebrows, and eyelashes are strong indicators that an inhalation injury may be present. Burns inside the

mouth and singed nasal hairs also indicate possible inhalation injury. Black particles of carbon in the nose, mouth, and sputum; edema of the nasal septum; and a "smoky" smell to the patient's breath indicate smoke inhalation.

A change in respiratory pattern may indicate a pulmonary injury. The patient may:

- Become progressively hoarse
- Develop a brassy cough
- Drool or have difficulty swallowing
- Produce sounds on exhalation that include audible wheezes, crowing, and stridor

Any of these changes may mean the patient is about to lose his or her airway.

Nursing Safety Priority QSEN

Critical Rescue

For a burn patient in the resuscitation phase who is hoarse, has a brassy cough, drools or has difficulty swallowing, or produces an audible breath sound on exhalation, immediately apply oxygen and notify the Rapid Response Team.

Upper airway edema and inhalation injury are most common in the trachea and mainstem bronchi. Auscultation of these areas may reveal wheezes, which indicate partial obstruction. *Patients with severe inhalation injuries may have such rapid obstruction that, within a short time, they cannot force air through the narrowed airways. As a result, the wheezing sounds disappear. This finding indicates impending airway obstruction and demands immediate intubation.* Many patients are intubated when an inhalation injury is first suspected rather than waiting until obstruction makes intubation difficult or impossible.

Carbon Monoxide Poisoning.

Carbon monoxide (CO) is one of the leading causes of death from a fire. It is a colorless, odorless, tasteless gas released in the process of combustion. Inhalation injury is a risk for carbon monoxide poisoning (Alharbi et al., 2012).

CO is rapidly transported across the lung membrane and binds tightly to hemoglobin in place of oxygen to form carboxyhemoglobin (COHb), which impairs oxygen unloading at the tissue level. Even though the

oxygen-carrying capacity of the hemoglobin is reduced, the blood gas value of partial pressure of arterial oxygen (Pa_{O_2}) is normal (Laing, 2013). The vasodilating action of carbon monoxide causes the "cherry red" color (or at least the absence of cyanosis) in these patients. Manifestations vary with the concentration of COHb (Table 26-4).

TABLE 26-4

Physiologic Effects of Carbon Monoxide Poisoning

CARBON MONOXIDE LEVEL	PHYSIOLOGIC EFFECTS
1%-10% (normal)	Increased threshold to visual stimuli Increased blood flow to vital organs
11%-20% (mild poisoning)	Headache Decreased cerebral function Decreased visual acuity Slight breathlessness
21%-40% (moderate poisoning)	Headache Tinnitus Nausea Drowsiness Vertigo Altered mental state Confusion Stupor Irritability Decreased blood pressure, increased and irregular heart rate Depressed ST segment on ECG and dysrhythmias Pale to reddish purple skin
41%-60% (severe poisoning)	Coma Convulsions Cardiopulmonary instability
61%-80% (fatal poisoning)	Death

ECG, Electrocardiogram.

Thermal (Heat) Injury.

Except for steam inhalation, aspiration of scalding liquid, or explosion of flammable gases under pressure, thermal burns to the respiratory tract are usually limited to the upper airway above the glottis (nasopharynx, oropharynx, and larynx). *Heat damage of the pharynx is often severe enough to produce edema and upper airway obstruction, especially epiglottitis. The problem can occur any time during resuscitation. In the unresuscitated patient, supraglottic edema may be delayed because of the dehydration that occurs with hypovolemia. During fluid resuscitation, however, the tissues rehydrate and then swell. When it is known that the upper airways were exposed to heat, intubation may be performed as an early intervention before obstruction occurs.*

Nursing Safety Priority QSEN

Action Alert

When intubation has not been performed in a patient whose upper airways were exposed to heat or toxic gases, continually assess the upper airway for recognition of edema and obstruction.

Inhaled steam can injure the lower respiratory tract down to the major bronchioles. Ulcerations, redness, and edema of the mouth and epiglottis occur first, with rapid swelling leading to upper airway obstruction. Stridor, hoarseness, and shortness of breath result.

Smoke Poisoning.

Smoke poisoning, or chemical injury from the inhalation of combustion by-products, is a common type of inhalation injury. Toxic by-products are produced when plastics or home furnishings are burned. The products impair respiratory cell function.

Pulmonary Fluid Overload.

Pulmonary edema can occur even when the lung tissues have not been damaged directly. Other damaged tissues release such large amounts of inflammatory mediators causing capillary leak that even lung capillaries leak fluid into the pulmonary tissue spaces.

Circulatory overload from fluid resuscitation may cause congestive heart failure. This problem creates high pressure within pulmonary blood vessels that pushes fluid into the lung tissue spaces. Excess lung tissue fluid makes gas exchange difficult. *The patient is short of breath and has dyspnea in the supine position. Crackles are heard on auscultation.*

Nursing Safety Priority QSEN

Critical Rescue

When manifestations of pulmonary edema are present, elevate the head of the bed to at least 45 degrees, apply oxygen, and notify the burn team or the Rapid Response Team.

External Factors.

Patients with burn injuries also may have breathing problems from external factors, such as tight eschar from deep circumferential chest

burns. The eschar either restricts chest movement or compresses structures in the neck and throat so that airflow is impaired. Inspect the patient's chest hourly for ease of respiration, amount of chest movement, rate of breathing, and effort. If the patient is being mechanically ventilated, increased airway pressures may indicate the need for an escharotomy. Use continuous pulse oximetry to assess breathing effectiveness in maintaining blood oxygen levels.

NCLEX Examination Challenge

Physiological Integrity

For which type of burn injury is it most important for the nurse to assess the client for a respiratory injury?
A Hot liquid scald burn
B Liquid chemical burn
C Electrical burn
D Dry heat burn

Cardiovascular Assessment.

Changes in the cardiovascular system begin immediately after the burn injury and include shock as a result of disrupted fluid and electrolyte balance. *Hypovolemia shock is a common cause of death in the resuscitation phase in patients with serious injuries*. See Chapter 37 for discussion of shock.

At first, cardiac manifestations are from hypovolemia and decreased cardiac output. Monitor the degree of edema, and assess cardiac status by measuring central and peripheral pulses, blood pressure, capillary refill, and pulse oximetry. Noninvasive blood pressure readings are inaccurate in patients with large burns of the upper extremities, and invasive blood pressure monitoring may be needed. At first, the patient has tachycardia, decreased blood pressure, and decreased peripheral pulses. Peripheral capillary refill is slow or absent as blood flow decreases. With fluid resuscitation, peripheral edema increases, as does the patient's weight.

Electrocardiographic (ECG) changes can indicate damage to the heart as a result of electrical burn injuries or stress that induces a myocardial infarction. Obtain baseline ECG tracings at the time of admission, and continue the ECG monitoring throughout the resuscitation phase. Compare current ECG tracings with the initial tracings to assess whether the patient is experiencing new-onset conduction abnormalities from the burn injury or the fluid resuscitation.

Kidney/Urinary Assessment.

Changes in kidney function with burn injury are related to decreased blood flow and to cellular debris. During the fluid shift, blood flow to the kidney may not be adequate for filtration. As a result, urine output is greatly decreased compared with IV fluid intake. The urine is very concentrated and has a high specific gravity.

Other substances may be present in the blood that flows through the kidney. Destroyed red blood cells release hemoglobin and potassium. When muscle damage occurs from a major burn or electrical injury, *myoglobin* is released from damaged muscle and circulates to the kidney. Most damaged cells release proteins that form uric acid. All of these large molecules in the blood may precipitate in the kidney tubular system. A "sludge" then forms that blocks kidney blood and urine flow and may cause kidney failure.

Assess kidney function by accurately measuring urine output hourly and comparing this value with fluid intake. Urine output is decreased during the first 24 hours of the resuscitation phase. Fluid resuscitation is provided at the rate needed to maintain urine output at 30 to 50 mL per hour or 0.5 mL/kg/hr. Assess response to fluid resuscitation by measuring urine specific gravity, blood urea nitrogen (BUN), serum creatinine, and serum sodium levels in addition to hourly urine output. Examine the urine for color, odor, and the presence of particles or foam.

Skin Assessment.

Assess the skin to determine the size and depth of burn injury. The size of the injury is first estimated in comparison with the *total body surface area (TBSA).* For example, a burn that involves 40% of the TBSA is a 40% burn. The size of the injury is important not only for diagnosis and prognosis but also for calculating drug doses, fluid replacement volumes, and caloric needs.

Inspect the skin tissue integrity to identify injured areas and changes in color and appearance. Except with electrical burns, this initial size assessment usually can be made accurately with specific assessment tools and charts.

The most rapid method for calculating the size of a burn injury in adult patients whose weights are in normal proportion to their heights is the *rule of nines* (Fig. 26-10). With this method, the body is divided into areas that are multiples of 9%. It is useful at the site of injury, but more accurate evaluations using other methods are made in the burn unit.

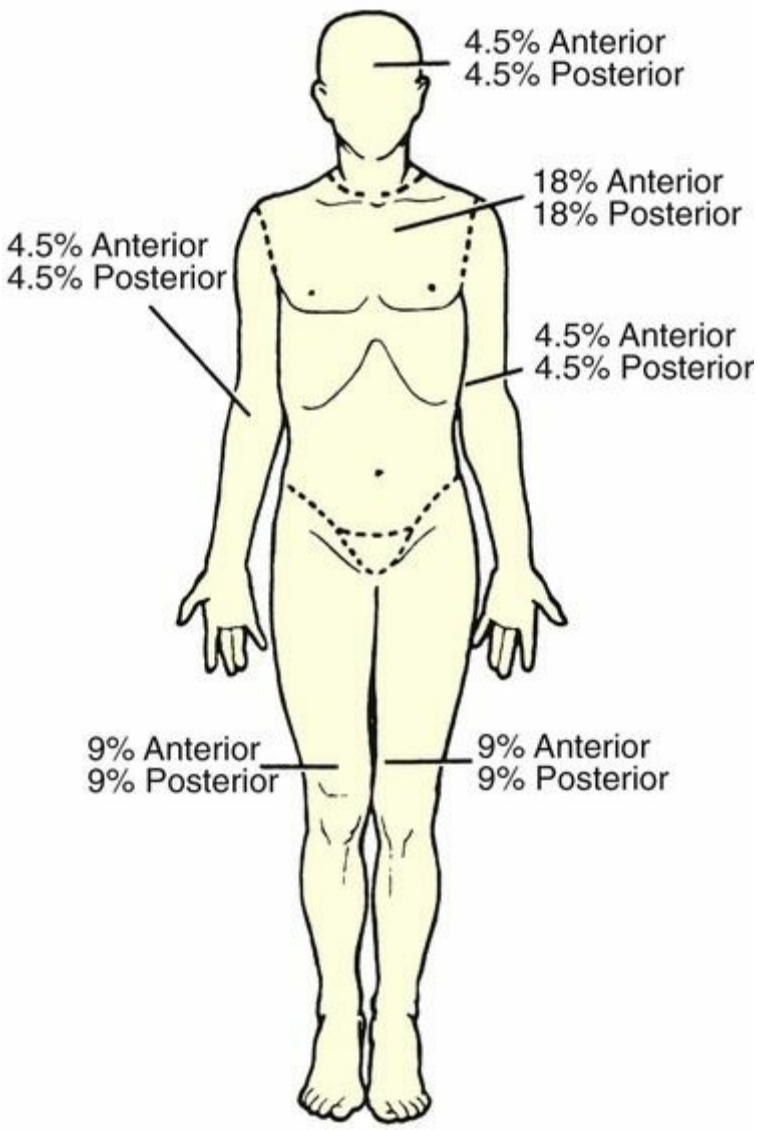

FIG. 26-10 The rule of nines for estimating burn percentage.

Because specific treatments are related to the depth of the burn injury, initial assessment of the skin includes estimations of burn depth. Criteria for depth of injury are based on appearance and associated characteristics (see Depth of Burn Injury section, p. 466).

Accurate evaluation of burn depth is performed using thermography, vital dyes, indocyanine green (ICG) video angiography, and laser Doppler imaging (LDI) that provide precise measurement of the amount of perfusion of the injured tissue. ICG and LDI are the most accurate of the three methods. LDI is used more frequently because it is relatively accurate, less invasive, and faster than the other methods (Park et al., 2013).

Gastrointestinal Assessment.

Although the GI tract usually is not directly injured, changes in function occur in all burn patients. The decreased blood flow and sympathetic

stimulation reduce GI motility and promote development of a paralytic ileus. Bowel sounds are usually reduced or absent in a patient with severe burns. Other indications of a paralytic ileus include nausea, vomiting, and abdominal distention. Patients with burns of 25% TBSA or who are intubated generally require a nasogastric (NG) tube inserted to prevent aspiration and remove gastric secretions. Assess the tube for placement and patency after insertion. Examine each stool and vomitus for gross blood or other material that indicates partially digested blood ("coffee ground"–appearing crumbs). Test for the presence of occult blood on any vomit or stool.

Laboratory Assessment.

Certain changes in laboratory test values are found in different phases of postburn recovery and reflect tissue damage or compensatory responses. However, other changes in specific laboratory findings may suggest complications.

During the resuscitation phase and before the start of fluid resuscitation, blood analysis reflects the fluid shift and direct tissue damage. Baseline laboratory test values and early postburn expected changes are listed in Chart 26-3.

Chart 26-3

Laboratory Profile

Burn Assessment During the Resuscitation Phase

TEST	NORMAL RANGE FOR ADULTS	SIGNIFICANCE OF ABNORMAL FINDINGS
Serum Studies		
Hemoglobin	12-16 g/dL (women) 14-18 g/dL (men)	Elevated as a result of fluid volume loss
Hematocrit	37%-47% (women) 42%-52% (men)	Elevated as a result of fluid volume loss
Urea nitrogen	10-20 mg/dL	Elevated as a result of fluid volume loss
Glucose	70-110 mg/dL	Elevated as a result of the stress response and altered uptake across injured tissues
Electrolytes		
Sodium	136-145 mEq/L (mmol/L)	Decreased; sodium is trapped in edema fluid and lost through plasma leakage
Potassium	3.5-5.0 mEq/L (mmol/L)	Elevated as a result of disruption of the sodium-potassium pump, tissue destruction, and red blood cell hemolysis
Chloride	98-106 mEq/L (mmol/L)	Elevated as a result of fluid volume loss and reabsorption of chloride in urine
Arterial Blood Gas Studies		
Pa_{O_2}	80-100 mm Hg	Slightly decreased
Pa_{CO_2}	35-45 mm Hg	Slightly increased from respiratory injury
pH	7.35-7.45	Low as a result of metabolic acidosis
Carboxyhemoglobin	0%-10%	Elevated as a result of inhalation of smoke and carbon monoxide
Other		
Total protein	6.4-8.3 g/dL	Low; protein exudate is lost through the wound
Albumin	3.5-5.0 g/dL	Low; protein is lost through the wound and through vascular membranes because of increased permeability

Data from Pagana, K., & Pagana, T. (2014). *Mosby's manual of diagnostic and laboratory tests* (5th ed). St. Louis: Mosby.

Changes in the total white blood cell (WBC) count and differential reflect immune function and inflammatory responses to the burn injury. The burn patient's total WBC count, especially the neutrophil percentage, first rises and then drops rapidly, with a "left shift" (see Chapter 17) as the immune system becomes unable to sustain its defenses. If sepsis occurs, the total WBC count may be as low as 2000 cells/mm^3.

Other laboratory tests that provide useful information about the burn patient's status include urine electrolyte assays, urine cultures, liver enzyme studies, and clotting studies. Drug and alcohol screens are obtained if drug or alcohol intoxication is suspected.

Cultural Considerations

Patient-Centered Care QSEN

For African-American patients, a sickle cell preparation is performed if sickle status is unknown. The trauma of a burn injury can trigger a sickle cell crisis in patients who have the disease and in those who carry the trait.

Imaging Assessment.

Standard x-rays and scans do not provide direct assessment data about the burn wound. These assessments are not performed unless other trauma is suspected.

Other Diagnostic Assessment.

Specific diagnostic studies are performed when deep organ trauma is suspected. Such studies include renal scans, computed tomography (CT), ultrasonography, bronchoscopy, and magnetic resonance imaging (MRI). When burn injuries involve the eye, an ophthalmic evaluation is performed to detect corneal damage (see Chapters 46 and 47 for specific eye and vision evaluation procedures).

Analysis

The priority NANDA-I nursing diagnoses and collaborative problems for patients with burn injuries in the resuscitation phase who have sustained a burn injury greater than 25% of the TBSA include:

1. Potential for inadequate oxygenation related to upper airway edema,

pulmonary edema, airway obstruction, or pneumonia
2. Risk for Shock related to increase in capillary permeability, active fluid volume loss, electrolyte imbalance, and inadequate fluid resuscitation (NANDA-I)
3. Potential for organ ischemia (brain, heart, kidney, gastrointestinal) related to hypovolemia and hypotension
4. Pain (Acute and Chronic) related to tissue injury, damaged or exposed nerve endings, débridement, dressing changes, invasive procedures, and donor sites (NANDA-I)
5. Potential for acute respiratory distress syndrome (ARDS) related to inhalation injury

Planning and Implementation

Supporting Oxygenation

Planning: Expected Outcomes.

With proper intervention, the patient is expected to maintain a patent airway and have adequate oxygenation. Indicators include that the patient should have either normal or nearly normal oxygen saturation, Pa_{O_2}, Pa_{CO_2}, and arterial pH.

Interventions.

Nursing and medical interventions are used to support normal pulmonary function and prevent the pulmonary problems that can result from lung injury or from fluid overload and heart failure. (Even young, healthy people can develop fluid overload and heart failure.) Specific management plans depend on the cause of the problem and the status of the respiratory tract. *Thus a priority nursing intervention is monitoring the patient's respiratory status.*

Nonsurgical Management.

Interventions include airway maintenance, promotion of ventilation, monitoring gas exchange, oxygen therapy, drug therapy, positioning, and deep breathing.

Airway maintenance begins at the burn scene in an unconscious patient and may involve only a chin-lift or a head-tilt maneuver. *Remember that upper airway edema becomes pronounced 8 to 12 hours after the beginning of fluid resuscitation. Then patients often require nasal or oral intubation if crowing, stridor, or dyspnea is present.*

A bronchoscopy is performed to examine the vocal cords and airways

of patients at risk for obstruction. Patients with severe smoke inhalation or poisoning may require a bronchoscopy on admission and routinely thereafter for examination of the respiratory tract, deep suctioning of the lungs, and removal of sloughing necrotic tissue. Assess the endotracheal tube hourly to ensure patency and location in intubated patients.

Other causes of airway obstruction are excessive secretions and sloughed tissue from damaged lungs. Suction as indicated based on clinical assessment. Vigorous endotracheal or nasotracheal tube suctioning is performed after chest physiotherapy and aerosol treatments. Patients report that deep endotracheal suctioning is extremely painful. Therefore suctioning the endotracheal tube often requires increased analgesia or sedation.

Promoting ventilation includes ensuring that skeletal muscle movement of the chest is adequate for ventilation. Chest movement can be restricted by eschar and by tight dressings that cover the neck, chest, and abdomen. Observe the patient for ease of respiratory movements, and loosen tight dressings as needed to assist with ventilation.

Monitor for gas exchange by using laboratory tests (e.g., arterial blood gas, carboxyhemoglobin levels) and by assessing for cyanosis, disorientation, and increased pulse rate. Additional monitoring may include chest x-ray findings, pulmonary artery catheter pressures, and central venous pressure measurement.

Cyanide poisoning may occur in patients burned in house fires. An elevated plasma lactate level is one indicator of cyanide toxicity even in patients who do not have severe burns.

Oxygen therapy with humidified oxygen by facemask, cannula, or hood is used to manage any breathing impairment in the burn patient. Arterial oxygenation less than 60 mm Hg is an indication for intubation and mechanical ventilation. Keep emergency airway equipment near the bedside. This equipment includes oxygen, masks, cannulas, manual resuscitation bags, laryngoscope, endotracheal tubes, and equipment for tracheostomy. Chapter 32 addresses specific nursing actions for patients during mechanical ventilation.

Drug therapy with antibiotics is used when pneumonia or other pulmonary infections impair breathing. Drug selection is based on known culture and sensitivity reports or on the specific organisms common to that burn unit.

Patients with pulmonary edema and any degree of heart failure may receive beta blockers to improve left ventricular function and prevent or treat pulmonary edema. Diuretics, a mainstay of therapy for pulmonary edema from other causes, may or may not be used in the resuscitation

phase, depending on the patient's blood volume and kidney function.

When a patient's activity during mechanical ventilation severely compromises respiratory mechanics, it may be necessary to use a paralytic drug, such as atracurium (Tracrium) or vecuronium (Norcuron). Paralytic drugs remove all breathing control from the patient, making mechanical ventilation easier. *These drugs do not prevent the patient from seeing and hearing or from experiencing fear, pain, and loss of control. Any patient receiving neuromuscular blockade drugs must also receive drugs for sedation, analgesia, and antianxiety unless clinically contraindicated.*

Nursing Safety Priority QSEN

Critical Rescue

As required by The Joint Commission's National Patient Safety Goals, ensure that all alarms are operative on ventilators. Check patients who are receiving neuromuscular blockage frequently, because they cannot call for help if they become extubated accidentally.

Positioning and deep breathing can improve breathing and oxygenation. Turn the patient frequently, and assist him or her out of bed to a chair as much as possible. Teach the patient to use coughing and deep-breathing exercises. Urge him or her to use incentive spirometry hourly while awake. Chest physiotherapy may be helpful to mobilize lung secretions.

Surgical Management.

A tracheotomy may be needed when long-term intubation is expected. This procedure increases the risk for infection in burn patients even more than in nonburned patients. Emergency tracheotomies are performed when an airway becomes occluded and oral or nasal intubation cannot be achieved.

Other surgical procedures for improving the burn patient's oxygenation include inserting chest tubes and performing an escharotomy. Chest tubes are used to re-expand the lung when a pneumothorax or hemothorax has occurred (see Chapter 32). Tight eschar on the neck, chest, or abdomen can restrict respiratory movement. Escharotomies (described on p. 479) can relieve this restriction and permit greater respiratory movement.

Preventing Hypovolemic Shock and Inadequate Oxygenation

Planning: Expected Outcomes.

With appropriate intervention, the patient is expected to have blood pressure and tissue oxygenation restored to normal. Indicators include these vital signs and assessment parameters:

- Blood pressure at or near the patient's normal range
- Palpable peripheral pulses (or heard with Doppler) in all extremities
- Oxygen saturation, partial pressure of arterial oxygen (Pa_{O_2}), partial pressure of arterial carbon dioxide (Pa_{CO_2}), and arterial pH at or near the normal ranges

Interventions.

Interventions focus on increasing blood fluid volume, supporting compensation, and preventing complications. Nonsurgical management is often sufficient for achieving these aims. Surgical management may be needed for full-thickness burns.

Nonsurgical Management.

Fluid volume and tissue blood flow (perfusion) are restored through IV fluid therapy and drug therapy. Priority nursing interventions are carrying out fluid resuscitation and monitoring for indications of effectiveness or complications.

Rapid infusion of IV fluids, known as *fluid resuscitation,* is needed to maintain sufficient blood volume for normal cardiac output, mean arterial pressure, and tissue oxygenation. Chart 26-4 lists best practices for fluid resuscitation. There are many formulas for calculating IV fluid needs, but the most commonly used one for adult patients is the Parkland Formula (4 mL/kg/%TBSA burn of crystalloid solution). Although the types and amounts of electrolytes, crystalloids, and colloids vary, the purpose of any formula is to prevent shock by maintaining blood fluid volume.

Chart 26-4 Best Practice for Patient Safety & Quality Care QSEN

Fluid Resuscitation of the Burn Patient

- Initiate and maintain at least one large-bore IV in an area of intact skin (if possible).
- Coordinate with physicians to determine the appropriate fluid type and total volume to be infused during the first 24 hours postburn.
- Administer one half of the total 24-hour prescribed volume within the first 8 hours postburn and the remaining volume over the next 16

hours.
- Assess IV access site, infusion rate, and infused volume at least hourly.
- Monitor these vital signs at least hourly:
  - Blood pressure
  - Pulse rate
  - Respiratory rate
  - Breath sounds
  - Voice quality (if not intubated)
  - Oxygen saturation
  - End-tidal carbon dioxide levels
- Assess urine output at least hourly:
  - Volume
  - Color
  - Specific gravity
  - Character
  - Presence of protein
- Assess for fluid overload:
  - Formation of dependent edema
  - Engorged neck veins
  - Rapid, thready pulse
  - Presence of lung crackles or wheezes on auscultation
- Measure additional body fluid output hourly.

Resuscitation for a severe burn requires large fluid loads in a short time to maintain blood flow to vital organs. All common formulas recommend that half of the calculated fluid volume for 24 hours be given in the first 8 hours after injury. The other half is given over the next 16 hours for a total of 24 hours (Culleiton & Simko, 2013b). Fluid boluses are avoided because they increase capillary pressure and worsen edema. In the second 24-hour period after a burn injury, the volume and content of the IV fluids are based on the patient's specific fluid and electrolyte balance needs and his or her response to treatment. This resuscitation involves hourly infusion volumes that are greatly in excess of the 125 mL to 150 mL per hour common infusion rates.

Fluid replacement formulas are calculated from the time of injury and not from the time of arrival at the hospital. For example, if a burn injury occurred at 8 am but the patient was not admitted to the hospital until 10 am, the first 8-hour period would be completed at 4 pm (8 hours after the injury). Thus if resuscitation was delayed by 2 hours until admission to the hospital, calculated fluids would need to be given over the next 6-hour period rather than an 8-hour period. Burn resuscitation formulas are guides. The patient's response to

therapy determines exact fluid requirements.

The management of extensive burns requires a large-bore central venous catheter so that massive fluid loads can be given. Peripheral lines are less useful.

Monitoring patient responses is critical to determine the adequacy of resuscitation for hydration and blood perfusion of the brain, heart, and kidneys. Urine output is the most common and most sensitive noninvasive assessment parameter for cardiac output and tissue perfusion. *Regardless of the total amount of fluid calculated as needed for the patient, the amount of fluid given depends on how much IV fluid per hour is needed to maintain the hourly urine output at 0.5 mL/kg (about 30 mL/hr).* Adjustment of the IV fluid rate on the basis of urine output plus serum electrolyte values is known as the *titration* of fluid. In burns larger than 35% TBSA, the use of invasive cardiac and pulmonary function monitoring may be needed in addition to urine output and vital signs to guide resuscitation.

Burn patients can develop severe hypovolemic shock and need invasive cardiac monitoring. Vital parameters such as central venous pressure, pulmonary artery pressures, and cardiac output are obtained on an hourly to continuous basis.

Monitor the ECG activity of patients who have sustained large burns. Compare current ECG findings with those obtained on admission.

NCLEX Examination Challenge

Safe and Effective Care Environment

Which client response does the nurse interpret as an indication of fluid resuscitation adequacy?
A Decreasing pulse pressure
B Decreasing urine specific gravity
C Decreasing core body temperature
D Increasing respiratory rate and depth

Drug therapy for shock prevention in burn patients is different from that for the heart failure patient. A common mistake in management is giving diuretics to increase urine output rather than changing the amount and rate of fluid infused. *Diuretics do not increase cardiac output; they actually decrease circulating volume and cardiac output by pulling fluid from the circulating blood volume to enhance diuresis.* This effect reduces blood flow to other vital organs (especially the heart, lungs, and brain)

and greatly increases the risk for severe hypovolemic shock. Therefore diuretics are not generally used to improve urine output for burn patients. An exception is the patient with an electrical burn injury. In electrical burns, muscle and deep-tissue damage release the large protein *myoglobin,* which precipitates in and obstructs the renal tubules. Although the diuretic *mannitol* (Osmitrol) is often used in this situation, it should always be given after adequate urine output has been established.

Considerations for Older Adults

Patient-Centered Care QSEN

In older patients, especially those with cardiac disease, a complicating factor in fluid resuscitation may be heart failure or myocardial infarction. Drugs that increase cardiac output (e.g., dopamine [Intropin]) or that strengthen the force of myocardial contraction may be used along with fluid therapy. Assess the cardiac status of older adults at least every hour during fluid resuscitation.

Surgical Management.

The surgical procedure for the treatment of inadequate tissue perfusion is *escharotomy.* An incision through the burn eschar relieves pressure caused by the constricting force of fluid buildup under circumferential burns on the extremity or chest and improves circulation. If the pressure is not relieved, arterial compression can occur with a loss of blood flow to the extremity, leading to ischemia and possible necrosis. Incisions are made along the length of the extremity and extend into the subcutaneous tissue, relieving the tourniquet effect of the eschar (Figs. 26-5 and 26-11). If tissue pressure remains elevated after escharotomy, a *fasciotomy* (a deeper incision extending through the fascia) may be needed.

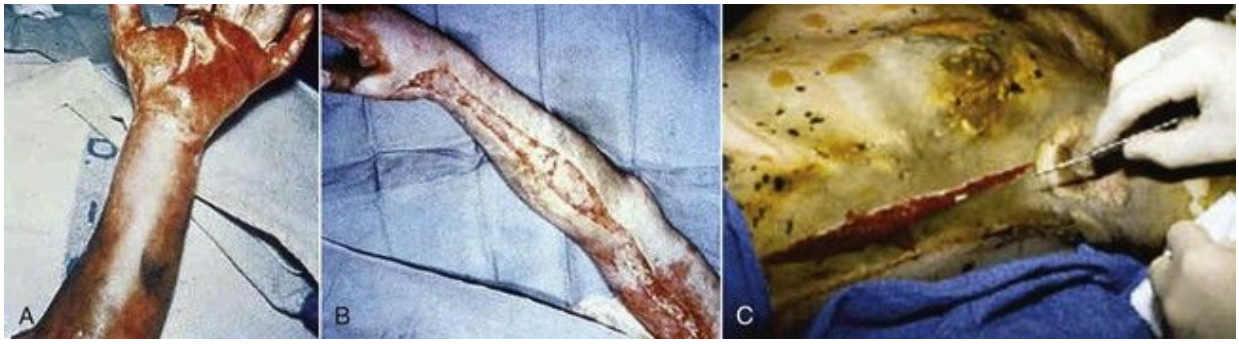

FIG. 26-11 Escharotomy to release circumferential burn eschar and improve circulation to a distal extremity. **A,** Tight circumferential eschar restricting swelling as edema forms in the tissue beneath the eschar. Edema compresses blood vessels, which inhibits blood flow to the distal extremity. **B,** An escharotomy incision allows outward swelling of edematous tissues. The restricted blood flow to the distal extremity is relieved. **C,** An anterior axillary incision is made bilaterally to relieve respiratory distress.

Managing Pain.

The pain with burn injuries is both chronic and acute. Many factors contribute to burn pain and may be altered to reduce pain perception. Accurate assessment of the patient's pain before and during procedures is an essential part of pain management.

Planning: Expected Outcomes.

The patient's pain level is expected to be alleviated or reduced. Indicators include that the patient should rarely demonstrate these behaviors:

- Reporting pain
- Moaning and crying
- Making facial expressions of pain
- Losing his or her appetite

Interventions.

Pain management is tailored to the patient's tolerance for pain, coping mechanisms, and physical status. *The priority nursing actions include continually assessing the patient's pain level, using appropriate pain-reducing strategies, and preventing complications.*

Nonsurgical Management.

Interventions for the patient having pain include drug therapy, complementary therapy measures, and environmental manipulation.

Drug therapy for pain usually requires opioid analgesics (e.g., morphine

sulfate, hydromorphone [Dilaudid], fentanyl) and non-opioid analgesics. Although these drugs may provide adequate pain relief when no procedures are being performed, they rarely offer more than moderate relief during painful procedures. They may depress respiratory function and reduce intestinal motility. Thus nonpharmacologic interventions also are needed for the burn patient.

During the resuscitation phase, the IV route is used for giving opioid drugs because of problems with absorption from the muscle and stomach (Culleiton & Simko, 2013c). When given IM or subcutaneously, these drugs remain in the tissue spaces and do not relieve pain. In addition, when edema is present, all the doses are rapidly absorbed at once when the fluid shift is resolving. This delayed but rapid absorption can result in lethal blood levels of opioids.

Nursing Safety Priority QSEN

Drug Alert

Give opioid drugs for pain only by the intravenous route during the resuscitation phase to prevent delayed rapid absorption leading to lethal blood levels.

Anesthetic agents, such as ketamine (Ketalar) and nitrous oxide, also reduce pain. Use strict protocols when giving these agents to prevent serious complications.

Complementary and alternative therapy measures for pain reduction include relaxation techniques, meditative breathing, guided imagery, music therapy, massage, and healing or therapeutic touch. Hypnosis and autohypnosis can be used by lucid, cooperative patients under the direction of trained therapists. Therapeutic touch, acupuncture, and acupressure are used to a limited extent for burn patients; the results are variable. Active music interventions for distraction have been useful in reducing patients' perceptions of pain and anxiety.

Environmental changes, such as providing a quiet environment, using nonpainful tactile stimulation, and increasing the patient's control, can increase comfort. Sleep deprivation increases patients' discomfort. Increasing sleep or rest time in a quiet environment helps reduce the adverse effects of sleep deprivation, replenishes hormone stores, helps prevent critical care unit psychosis, and restores the diurnal effects of endorphins. Coordinate with the health care team to ensure that procedures are performed during the patient's waking hours.

Tactile stimulation can reduce pain. Help the patient change positions every 2 hours to reduce pressure on any specific area, improve circulation to painful areas, and ease pain. Massage nonburn areas to reduce pain transmission and stimulate endorphin release. Apply heat and maintain warm room temperatures to prevent shivering.

To reduce anxiety and increase feelings of confidence and independence, encourage the patient to participate in pain control measures. For example, make a contract with him or her that specifies how long a painful procedure will last. This helps patients deal with the pain for that particular period. Patient-controlled analgesia (PCA) also reduces pain. Important issues and techniques for the best use of PCA include giving an initial bolus of 5 to 10 mg of morphine (or equivalent drug), increasing the PCA dose as needed to achieve pain relief, and planning for a change in dosing regimens at night (e.g., giving a bolus dose at bedtime). See Chapter 3 for a detailed discussion of combination drug therapy for pain management.

Surgical Management.

Early surgical excision of the burn wound is used in many burn centers (see the Surgical Excision section on p. 484). Early excision under anesthesia reduces the pain from daily débridement at the bedside or during hydrotherapy.

Clinical Judgment Challenge

Patient-Centered Care; Safety; Evidence-Based Practice QSEN

A 50-year-old tree trimmer has been brought to hospital after coming in contact with an 8000-volt power line while trimming trees with a pole trimmer. The emergency medical technicians (EMTs) report that they recovered this man from an insulated bucket in which he was working. According to bystanders, the metal pole-saw made contact with the power line. The patient was rendered unconscious only momentarily. The EMTs report that he had pain in both arms when they transported him to the hospital. He now has pain in the neck. The patient is agitated and restless and continues to report increasing pain in both arms and hands and in the neck even though there is no area of burn on the neck. The exit wound is the right hand, including the fingers and thumb. The right arm is cyanotic and tense, and the wrist is acutely flexed and rigid in that position. There is an arc burn in the right axilla. The left arm is tense and cyanotic, and the wrist, hand, and fingers are charred.

1. What initial consideration must be given in moving the patient from the stretcher to the bed?
2. Is the patient at risk for compartment syndrome? Provide a rationale for your response. If yes, what would you expect to find on assessment that would indicate compartment syndrome?
3. A Foley catheter has been placed in this patient, and it is documented that the urine is wine pigmented. What is the etiology and potential complication if this symptom persists?
4. What interventions would you expect to be ordered to resolve myoglobinuria?

Preventing Acute Respiratory Distress Syndrome

Planning: Expected Outcome.

The patient with a burn injury is expected to:
- Not experience acute respiratory distress
- Have arterial blood gases (ABGs) within normal limits
- Maintain normal lung compliance

Interventions.

Patients who develop acute respiratory distress syndrome (ARDS) from burn injuries require thorough assessments and interventions. Interventions focus on increasing lung compliance and improving partial pressure of arterial oxygen (Pa_{O_2}) levels. The priority nursing care actions are coordinating respiratory therapy strategies and monitoring the patient's response to these interventions.

In collaboration with the physician and respiratory therapist, give positive end-expiratory pressure (PEEP) to provide a continuous positive pressure in the airways and alveoli. This procedure enhances the diffusion of oxygen across the alveolar-capillary membrane. PEEP can be combined with intermittent mandatory volume (IMV) to enhance its effectiveness.

Assess and document the patient's response so that needed ventilator changes can be made. Monitor pulse oximetry and ABG levels to assess changes in respiratory status.

Nursing Safety Priority QSEN

Critical Rescue

Document and immediately report any signs of respiratory distress or

change in respiratory patterns to the burn team and the respiratory therapist.

Neuromuscular blocking drugs (atracurium) can be used in patients receiving mechanical ventilation to reduce oxygen consumption (see the discussion of specific nursing care in the Supporting Oxygenation section, pp. 477-478).

Clinical Judgment Challenge

Patient-Centered Care; Teamwork and Collaboration; Evidence-Based Practice QSEN

The patient who sustained an electrical injury described on the left has adequate IV access and is undergoing fluid resuscitation. While obtaining history from this patient, you find that he has not had a tetanus shot is the past 10 years. He continues to have pain in both arms and hands. On examination you note the burns are tan and dry and there are no blisters or capillary refill. The radial pulses are no longer palpable.

1. Based on the information provided about the injury and the data gathered by examination, what degree of burn injury has this patient suffered? Provide a rationale for your choice.
2. What is the preferred route for analgesic administration? Provide a rationale for your choice.
3. What additional medications do you expect to be ordered for this patient given his history?
4. The patient requires escharotomies to both his upper extremities. What steps would you take to prepare the patient for this procedure? What postprocedure care would you perform?

Acute Phase of Burn Injury

The acute phase of burn injury begins about 36 to 48 hours after injury, when the fluid shift resolves, and lasts until wound closure is complete. During this phase, the nurse coordinates interdisciplinary care that is directed toward continued assessment and maintenance of the cardiovascular and respiratory systems, as well as toward GI and nutrition status, burn wound care, pain control, and psychosocial interventions.

Patient-Centered Collaborative Care

Assessment

Physical Assessment/Clinical Manifestations

Cardiopulmonary Assessment.

In the acute phase of burn injury, the priority nursing interventions are to assess the cardiovascular and respiratory systems to maintain these systems and to identify or prevent complications. At this time, the patient may develop pneumonia that can result in respiratory failure requiring mechanical ventilation. Although cardiovascular problems related to the fluid shift should be resolved, the patient is at risk for infection and sepsis, which affect cardiovascular function.

Neuroendocrine Assessment.

The increased metabolic demands placed on the body after a severe burn injury can severely deplete nutrition stores. Weigh the patient daily without dressings or splints, and compare it with his or her preburn weight. A 2% loss of body weight indicates a mild deficit. A 10% or more weight loss requires the evaluation and modification of calorie intake. For very accurate calorie requirements, indirect calorimetry may be used. This method assesses energy expenditure by measuring oxygen consumption and carbon dioxide production. Measurements are taken while the patient is at rest—usually at least 30 minutes after the most recent dressing changes or other stressful procedures. Indirect calorimetry may be performed on admission to a burn center and then weekly until the wounds are closed.

Immune Assessment.

The patient with a burn injury is at risk for infection because of open wounds and reduced immune function. *Burn wound sepsis is a serious*

complication of burn injury, and infection is the leading cause of death during the acute phase of recovery. Continually assess the patient for manifestations of local and systemic infections (Table 26-5), including changes in wound appearance, changes in neurologic and GI function, and subtle changes in vital signs. Monitor for manifestations of gram-positive, gram-negative, and fungal infections (Table 26-6). Enforce meticulous handwashing by all care personnel.

TABLE 26-5

Local and Systemic Indicators of Infection

Local Indicators	Systemic Indicators
• Conversion of a partial-thickness injury to a full-thickness injury • Ulceration of healthy skin at the burn site • Erythematous, nodular lesions in uninvolved skin and vesicular lesions in healed skin • Edema of healthy skin surrounding the burn wound • Excessive burn wound drainage • Pale, boggy, dry, or crusted granulation tissue • Sloughing of grafts • Wound breakdown after closure • Odor	• Altered level of consciousness • Changes in vital signs (tachycardia, tachypnea, temperature instability, hypotension) • Increased fluid requirements for maintenance of a normal urine output • Hemodynamic instability • Oliguria • GI dysfunction (diarrhea, vomiting, abdominal distention, paralytic ileus) • Hyperglycemia • Thrombocytopenia • Change in total white blood cell count (above normal or below normal) • Metabolic acidosis • Hypoxemia

TABLE 26-6

Indications of Sepsis Caused by Different Organisms

MANIFESTATIONS	GRAM-POSITIVE	GRAM-NEGATIVE	FUNGAL
Onset	Insidious, 2-6 days	Rapid, 12-36 hr	Delayed
Cognition	Severe disorientation and lethargy	Mild disorientation	Mild disorientation
Ileus	Severe	Severe	Mild
Diarrhea	Rare	Severe	Occasional
Temperature	Fever	Hypothermia	Fever
Hypotension	Late	Early	Late
White blood cell count	Neutrophilia	Neutropenia	Neutrophilia
Platelets	Normal	Low	Low

Nursing Safety Priority QSEN

Action Alert

Use aseptic technique in caring for wounds and during invasive monitoring to prevent infection.

Musculoskeletal Assessment.

Patients with a burn injury are at risk for musculoskeletal and mobility problems as a result of other injuries, immobility, healing processes, and treatment. The musculoskeletal status is evaluated on admission and throughout the postburn period. Assess active and passive range of motion for all joints, including the neck. Give special attention to joints in the burn area. Ranges and limitations are documented for future reference.

Analysis

During the acute phase of the burn injury, the patient may have initial problems that extend into the acute phase and may develop new problems.

The priority NANDA-I nursing diagnoses and collaborative problems for patients with burn injuries greater than 25% TBSA in the acute phase of recovery include:

1. Wound care management related to burn injury, skin grafting procedures, and immobilization
2. Risk for Infection related to open burn wounds, the presence of multiple invasive catheters, reduced immune function, and poor nutrition (NANDA-I)
3. Excessive weight loss related to increased metabolic rate, reduced calorie intake, and increased urinary nitrogen losses
4. Impaired Mobility: Physical related to open burn wounds, pain, and scars and contractures (NANDA-I)
5. Reduced self-image related to trauma, changes in physical appearance and lifestyle, and alterations in sensory and motor function

Planning and Implementation

Managing Wound Care

Planning: Expected Outcomes.

With appropriate intervention, the burn patient is expected to have no wound extension and have wounds healed. Indicators include that the patient:

- Has presence of granulation, re-epithelialization, and scar tissue formation
- Has decreased wound size
- Has no new wounds

Interventions.

Interventions focus on preserving skin tissue integrity, enhancing burn wound healing, and preventing complications.

Nonsurgical Management.

Nonsurgical burn wound management involves removing exudates and necrotic tissue, cleaning the area, stimulating granulation and revascularization, and applying dressings. Restoring skin tissue integrity, whether by natural healing or grafting, starts with the removal of eschar and other cellular debris from the burn wound. This removal is called **débridement,** and can be performed nonsurgically through mechanical or enzymatic actions that separate eschar over time. The purpose is to prepare the wound for grafting and wound closure by a natural process. *Priority nursing interventions include assessing the wound, providing wound care, and preventing infection and other complications.*

Mechanical Débridement.

Burn wounds are débrided and cleaned 1 or 2 times each day during **hydrotherapy** (the application of water for treatment). Nurses, unlicensed assistive personnel (UAP), and physical therapists perform hydrotherapy daily to débride and examine the wounds. Hydrotherapy is performed by showering the patient on a special shower table or washing only small areas of the wound at the bedside. Showering enhances wound inspection and allows water temperature to be kept constant. Immersion of the patient in a tub or whirlpool is no longer performed because it increases the risk for infection.

Nurses and skilled technicians use forceps and scissors to remove loose, dead tissue during hydrotherapy. At most burn units, small blisters are left intact because they are a protective barrier that promotes wound healing. Larger blisters are opened. Washcloths or gauze sponges are used to débride soft, "cheesy" eschar. Wash burn areas thoroughly and gently with mild soap or detergent and water. Then rinse these areas with room-temperature water.

Enzymatic Débridement.

Enzymatic débridement can occur naturally by autolysis or artificially by the application of exogenous agents. **Autolysis** is the disintegration of tissue by the action of the patient's own cellular enzymes. This process is seldom used alone in North America for larger burns because it is slow and prolongs the hospital stay, increasing the risk for infection.

Topical enzyme agents, such as collagenase (Santyl), are used for rapid wound débridement. When these agents are applied to the burn wound

in a once-a-day dressing change, the enzymes digest collagen in necrotic tissues.

Dressing the Burn Wound.

After burn wounds are cleaned and débrided, topical antibiotics are reapplied to prevent infection. Some type of dressing is then applied to the burn wound. Burn dressings include standard wound dressings, biologic dressings, synthetic dressings, and artificial skin.

Standard Wound Dressings.

Standard dressings are multiple layers of gauze applied over the topical agents on the wound. The number of gauze layers depends on:

- Depth of the injury
- Amount of drainage expected
- Area injured
- Patient's mobility
- Frequency of dressing changes

The gauze layers are held in place with roller-type gauze bandages applied in a distal to proximal direction or with circular net fabrics. Cover gauze dressings on the patient's extremities with elastic wraps, especially if the patient is ambulatory. Dressings are generally changed and are reapplied every 12 to 24 hours after thoroughly cleaning the areas.

Biologic Dressings.

Biologic dressings are often used for temporary wound coverage and closure. These dressings are skin or membranes obtained from human tissue donors (homograft or allograft) or animals (heterograft or xenograft). When applied over open wounds, a biologic dressing adheres and promotes healing or prepares the wound for permanent skin graft coverage.

Various biologic materials are used in healing partial-thickness and granulating full-thickness wounds that are clean and free of eschar. The type of biologic dressing selected depends on the type of wound to be covered and the availability of the material.

Homografts, also called *allografts*, are human skin obtained from a cadaver and provided through a skin bank. Disadvantages to the use of homografts are the high costs and the risk for transmitting a bloodborne infection.

Heterografts, also called *xenografts*, are skin obtained from another species. Pigskin (porcine) is the most common heterograft and is compatible with human skin. Pigskin is assessed daily for adherence and

need for replacement. Fig. 26-12 shows a small burn covered with a porcine dressing.

FIG. 26-12 Burn wound covered with a porcine dressing.

Cultured skin can be grown from a small specimen of epidermal cells from an unburned area of the patient's body. The cells are grown in a laboratory to produce cell sheets that can be grafted on the patient to generate a permanent skin surface. The length of time for culturing and growing the skin is long, and the cell sheets are fragile. This process is very costly.

Artificial skin is a substance with two layers—a Silastic epidermis and a porous dermis made from beef collagen and shark cartilage. After the artificial skin is applied to a clean, excised wound surface, fibroblasts move into the collagen portion and create a structure similar to normal dermis. The artificial dermis slowly dissolves and is replaced with blood vessels and connective tissue *(neodermis)*. The neodermis supports a standard autograft placed over it when the Silastic layer is removed.

Biosynthetic Wound Dressings.

Biosynthetic wound dressings are a combination of biosynthetic and synthetic materials. Biobrane is commonly used and effective in the treatment of clean superficial partial-thickness burns such as scalds, as a covering for meshed autografts, and as a donor site dressing. It is made up of a nylon fabric that is partially embedded into a silicone film. Collagen is incorporated into both the silicone and the nylon

components. The nylon fabric comes into contact with the wound surface and adheres to it until epithelialization has occurred. The porous silicone film allows exudates to pass through.

Synthetic Dressings.

Synthetic dressings are made of solid silicone and plastic membranes. They are applied directly to the surface of a prepared wound and remain in place until they fall off or are removed. Many of these dressings are transparent or translucent, and the wound can be inspected without removing the dressing. Pain is reduced at the site because these agents also prevent contact of the wound's nerve endings with air. These dressings also are used to cover donor sites where skin was obtained for autografting.

Transparent film is the dressing commonly used for the care of donor site wounds (Fig. 26-13). This dressing type promotes faster healing with low infection rates, minimal pain, and reduced cost.

FIG. 26-13 Donor sites covered with dressings. **A,** Transparent dressing. **B,** Xeroform dressing.

Surgical Management.

Grafting is used for wound closure when full-thickness injuries cannot close and when natural healing would result in loss of joint function, an unacceptable cosmetic appearance, or a high potential for wound recurrence. Successful skin grafting requires a clean and granulating or freshly excised wound bed. Partial-thickness (split-thickness) or full-thickness strips of skin are removed from the donor area, transferred to the ulcer, and sutured or stapled in place. Full-thickness free grafts and myocutaneous flaps are used to cover deep, massive ulcers or ulcers in which vital structures, such as bone or tendon, are exposed.

Surgical management of burn wounds involves excision and wound covering. Surgical excision is performed early in the postburn period. Autografting by taking an area of the patient's healthy skin with intact tissue integrity and transplanting it to an excised burn wound may be performed throughout the acute phase when wounds are ready and donor sites are available. Early grafting reduces the time patients are at risk for infection and sepsis.

Surgical Excision.

Surgical excision is a common treatment for full-thickness and deep partial-thickness wounds. The patient is taken to the operating room within the first 5 days after injury and again as needed until all wounds are closed permanently.

The surgeon excises the burn wound usually by removing very thin layers of the necrotic burn surface until bleeding tissue is encountered. (Bleeding indicates that a bed of healthy dermis or subcutaneous fat has been reached.) For very deep burns, the surgeon cuts away the wound to the level of superficial fascia. Blood loss is minimal, and grafting is usually successful.

Wound Covering.

Permanent skin coverage for large full-thickness injuries occurs by applying an autograft. Skin for an autograft is taken from the patient's body. The surgeon removes a piece of skin from a remote unburned area of the body and transplants it to cover the burn wound. Skin grafts are generally of split thickness, and a partial-thickness injury is formed at the site of surgical removal (the *donor site*). Grafts are placed either on a clean granulated bed or over an area from which dead tissue has just been removed.

Patients with larger burns may have only 5% to 20% of the skin surface available to use for covering the 80% to 95% burned area. Coverage for these wounds may require either repeated skin removal from the same donor site (with time allowed between harvests for healing) or meshing of the split-thickness skin grafts (Fig. 26-14). This technique allows a small graft to be stretched to cover a larger area. Healing time is slower for a meshed graft because the skin must fill in open meshed areas (interstices), as well as attach to the granulation bed.

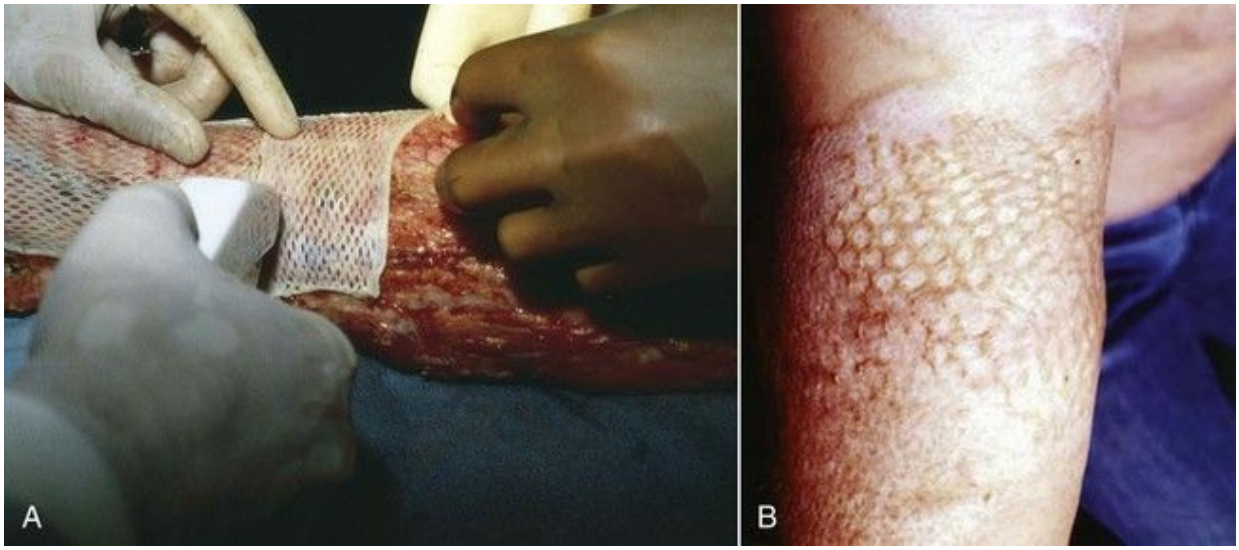

FIG. 26-14 The typical appearance of meshed autografts. **A,** Appearance of meshed autograft at application. **B,** Appearance of meshed autograft after healing.

After surgery, graft sites are immobilized with bulky cotton pressure dressings for 3 to 5 days to allow vascularization, or "take," of the newly grafted skin. Do not disturb the dressing, and encourage elevation and complete rest of the grafted area to allow blood vessels to connect the graft with the wound bed. Any activity that might cause movement of the dressing against the body and separation of the graft from the wound is prohibited.

After dressings are removed, monitor the graft for indications of failure to vascularize, nonadherence to the wound, or graft necrosis. A dusky color or sharp line of color change suggests inadequate venous or lymphatic drainage. Other techniques to monitor trends of blood flow in the graft, depending on the graft's location, include pulse oximetry, laser Doppler imaging, ultrasonography, and transcutaneous oxygen determination.

Grafts and donor sites on posterior body surfaces present special problems. For the graft to become fully vascularized or for the donor sites to dry, the patient must be immobilized in a side-lying or prone position for 7 to 10 days.

An alternative to this positioning is the use of special low-pressure or air-fluidized beds, such as the Clinitron bed or KinAir bed, which not only reduce ischemia of the graft while the patient is supine but also help prevent breakdown of intact skin.

Minimizing Infection.

Burn wound infection occurs through **auto-contamination,** in which the patient's own normal flora overgrows and invades other body areas; and

cross-contamination, in which organisms from other people or environments are transferred to the patient.

Planning: Expected Outcomes.

The patient is expected to remain free from infection and not develop sepsis. Indicators are that the patient has only mild or none of these manifestations:

- Foul-smelling discharge
- Fever
- Blood culture colonization
- Wound site colonization
- White blood cell count elevation

Interventions.

Interventions focus on preventing infection and removing infected tissue.

Nonsurgical Management.

Priority nursing interventions include using principles of infection control to prevent transmission, providing a safe environment, and monitoring for early detection of infection. Drug therapy, isolation therapy, and environmental management are strategies for preventing and managing infection.

Drug Therapy for Infection Prevention.

Burn wound conditions promote the growth of *Clostridium tetani,* and all burn patients are at risk for this deadly infection. Tetanus toxoid, 0.5 mL given IM, enhances immunity to *C. tetani* and is routinely given on admission. Administration of tetanus immune globulin (human) (HyperTet) is recommended when the patient's tetanus immunization status is not known.

Topical antimicrobial drugs are used for infection prevention in burn wounds. Chart 26-5 lists commonly used agents. The expected outcome of this therapy is to reduce bacterial growth in the wound and prevent sepsis. A variety of agents can be used. Some topicals come in a form of ointments and creams (e.g., silver sulfadiazine, Sulfamylon, bacitracin) and need to be applied once or twice daily (Silverstein et al., 2011). Other products such as Acticoat, Mepilex Ag, and Aquacel Ag contain antimicrobials, which release over a period of several days and can be left on the wound for up to 7 days, thus eliminating the need for daily dressing changes.

Chart 26-5 Common Examples of Drug Therapy

Burn Wounds

TOPICAL DRUG	ACTION	INTERVENTIONS
Silver sulfadiazine (Silvadene, Thermazene)	Adheres to bacterial cell membranes inhibiting DNA synthesis and bacterial replication	Watch for allergic reaction causing a drop in white blood cell count. Do not use if reaction to sulfonamide has occurred. Use on deep partial-thickness or full-thickness wounds. Monitor wounds for infection.
Collagenase (Santyl) with polysporin powder	Digests collagen in necrotic tissue	Apply once a day. Use on partial-thickness wounds with eschar. Monitor wounds for infection. May be used with barrier dressing such as Xeroform.
Mafenide acetate (Sulfamylon)	Bacteriostatic action against many gram-positive and gram-negative organisms	Premedicate for pain before application. Monitor blood gas and serum electrolyte levels. Monitor wounds for infection.
Nitrofurazone (Furacin)	Wide-spectrum antibacterial agent	Observe closely for signs of allergic reaction and evidence of superinfection.
Gentamicin sulfate (Garamycin, Gentamar)	Aminoglycoside antibacterial that inhibits bacterial protein synthesis and results in bactericidal responses	Nephrotoxic; monitor kidney function closely, especially changes in serum creatinine and blood urea nitrogen. Ototoxic; monitor hearing weekly.
Polymyxin B-bacitracin (Poly-Bac, Polysporin)	Inhibits bacterial cell wall synthesis and destroys bacterial membranes, leading to bacterial killing effects	Apply every 2-8 hours to keep area moist.
Acticoat	Releases antimicrobial silver ions when moistened with sterile water	Do not use with oil-based products or other antimicrobials. Do not use for any patient with a known sensitivity to any of the components of this drug. May dry out and adhere to wound surface; soak off to remove.
PolyMem	Dressing material containing silver granules that suppress bacterial growth	Normally leave in place for 7 days. Remove earlier if exudate is visible through outer membrane. Use on partial-thickness wounds and on donor sites. Cover with a secondary dressing.

		Monitor wounds for infection.
Aquacel Ag	Dressing material that releases ionic silver in a controlled manner as exudate is absorbed into dressing to support wound healing	Use on partial-thickness wounds and on donor-sites. Cover with a secondary dressing. Do not use for patients who have allergic reactions to the dressing or any of its components. Moisten with sterile water or normal saline to ease removal. Do not use with oil-based products.
Mepilex Ag	Dressing material containing silver ions that begin to inactivate wound pathogens within 30 minutes of application	Do not use along with oxidizing agents such as hydrogen peroxide. Cover with secondary dressing. May be used with partial-thickness burns, full-thickness burns, skin grafts, and donor-sites.

Drug Therapy for Treatment of Infection.

Systemic antibiotics are used when burn patients have symptoms of an actual infection, including septicemia. Broad-spectrum antibiotics are given until the results of blood cultures and sensitivity status are available. At that time, antibiotics that are effective against the specific organism(s) causing the infection are used. Often burn patients require a higher dose of these drugs to maintain effective blood levels. Peak and trough blood levels may be used to determine treatment effectiveness and risk for toxicity.

Providing a Safe Environment.

Providing a safe environment can include isolation therapy, which is used in some burn centers in the belief that it reduces cross-contamination. More often, it involves coordinating all members of the health care team in the use of asepsis and monitoring for early recognition of actual infection. Proper and consistent handwashing is the most effective technique for preventing infection transmission.

Use of asepsis requires all health care personnel to wear gloves during all contact with open wounds. The use of sterile versus clean gloves for routine wound care varies by agency and is a matter of debate. Regardless of sterility, change gloves when handling wounds on different areas of the body and between handling old and new dressings.

The equipment on burn units is not shared among patients. Disposable items (e.g., pillows, dishes) are used as much as possible. Assign any equipment used in daily routine care (e.g., blood pressure

cuffs, stethoscopes) to each patient for the duration of his or her stay. Daily cleaning of the equipment and general housekeeping are essential for infection control. All other equipment must be cleaned after use on one patient and before use on another. Because *Pseudomonas* has been found in plants, the presence of plants and flowers is prohibited. Some burn units do not permit patients to eat raw foods (e.g., salads, fruit, pepper) to reduce exposure to organisms. Rugs and upholstered articles harbor organisms, and their use is restricted.

Visitors are restricted when the patient is immunosuppressed. Ill people, small children, and other patients should not come into direct contact with the burn patient. Some burn units recommend that all visitors wear protective clothing (gowns, gloves, masks, and shoe and hair covers) in the burn patient's room, but no data support the effectiveness of this approach.

Early detection involves careful monitoring of the burn wounds at each dressing change. Examine all wounds for these manifestations of infection:

- Pervasive odor
- Color changes—focal, dark red, brown discoloration in the eschar
- Change in texture
- Purulent drainage
- Exudate
- Sloughing grafts
- Redness of wound edges extending to nonburned skin

Laboratory cultures and biopsies are recommended. Quantitative biopsies of the eschar and granulation tissue are performed routinely to monitor the growth of organisms.

Surgical Management.

Infected burn wounds with colony counts at or near 10^5 colonies per gram of tissue may be life threatening, even with antibiotic therapy. Surgical excision of the wound may be needed to control these infections.

NCLEX Examination Challenge

Safe and Effective Care Environment

Which action by the nurse changing the dressings on the client who has burns on the right arm, the left arm, and the upper chest is most effective at preventing auto-contamination?

A Changing gloves after cleaning and dressing one wound area before cleaning and dressing the next wound area.

B Using sterile gloves to remove the old dressings and changing to fresh sterile gloves before applying the new dressings.
C Ensuring that the blood pressure cuff used on another client is thoroughly cleaned before using it on this client.
D Warning the client's family not to bring fresh fruits and vegetables or house plants into the client's environment.

Minimizing Weight Loss

Planning: Expected Outcomes.

The patient is expected to maintain adequate nutrient intake for meeting the body's calorie needs. Indicators include that the patient should have mild or no deviations from the normal ranges for:

- Weight/height ratio
- Food intake
- Hematocrit and hemoglobin
- Serum albumin and prealbumin
- Blood glucose

Interventions.

Interventions include calculating the patient's calorie needs and providing an adequate daily source of calories and nutrients that the patient can ingest. Coordinate with a registered dietitian to meet the expected outcomes regarding the patient's nutrition status. Therapy begins with calculating the patient's current daily calorie needs. Several formulas and charts are used for this calculation. Nutrition requirements for a patient with a large burn area can exceed 5000 kcal/day. Not meeting this need leads to very rapid weight loss (Williams et al., 2011). In addition to a high-calorie intake, a diet high in protein is needed for wound healing. Work with the dietitian and the patient to plan additions to standard nutrition patterns.

Oral diet therapy may be delayed for several days after the injury until the GI tract is motile. Nasoduodenal tube feedings are often started soon after admission. Beginning enteral feedings early helps decrease weight loss, gut atrophy, bacterial translocation, and sepsis. This type of supplement prevents nutrition deficits in severely burned patients.

Encourage patients who can eat solid foods to ingest as many calories as possible. Consider the patient's preferences with diet planning and food selection. Encourage patients to request food whenever they feel they can eat, not just according to the hospital's standard meal schedule. Offer frequent high-calorie, high-protein supplemental feedings. Keep an

accurate calorie count for foods and beverages that are actually ingested by the patient.

Patients who cannot swallow but who have adequate gastric motility may meet calorie and nutrition needs through enteral tube feedings (see Chapter 60). Parenteral nutrition may be used when the GI tract is not functional or when the patient's nutrition needs cannot be met by oral and enteral feeding. This method is used as a last resort because it is invasive and can lead to infectious and metabolic complications.

Maintaining Mobility

Planning: Expected Outcomes.

The patient with a burn injury is expected to maintain or regain an optimal mobility. Indicators include that the patient has minimal limitations in these actions:

- Muscle movement
- Joint mobility
- Walking
- Self-positioning

Interventions.

Interventions focus on maintaining or achieving the patient's preburn range of joint motion and mobility and preventing contracture formation.

Nonsurgical Management.

Nonsurgical management includes the nursing interventions of positioning, range-of-motion exercises, ambulation, and pressure dressings.

Positioning is critical for patients with burn injuries because the position of comfort for the patient is often one of joint flexion, which leads to contracture development. Maintain the patient in a neutral body position with minimal flexion. Best practices for preventing contractures are listed in Chart 26-6. Splints and other devices may be used to maintain good positioning of the hands, elbows, knees, neck, and axillae.

Chart 26-6 Best Practice for Patient Safety & Quality Care QSEN

Positioning to Prevent Contractures

AFFECTED BODY PART	POSITION OF FUNCTION	INTERVENTION
Head and neck	Hyperextension	No pillow. Place a towel roll under the patient's neck or shoulder. Neck splint.
Posterior neck	Flexion	Have patient turn the head from side to side.
Upper chest and chest	Shoulder retraction	Place patient in supine position. Place a folded towel under the spine, between the scapulae.
Lateral trunk	Flexion to uninvolved side	Place patient supine with arm on the affected side up over the head.
Anterior shoulder	Abduction and external rotation	Maintain the upper arm at 90 degrees of abduction from the lateral aspect of the trunk.
Posterior shoulder	Slight flexion and interior rotation	Keep the arm slightly behind the midline.
Axilla	Abduction with 10- to 15-degree forward flexion and external rotation	Support the abducted arm with suspension from IV pole or bedside table. Axilla splint.
Elbow	Extension and supination	Keep the joint in the extended position.
Wrist	30 to 45 degrees of extension	Use a splint.
Fingers		
MP joints	70 to 90 degrees of flexion	Use a splint.
PIP and DIP joints	Extension	Use a splint.
Ankle	90 degrees of dorsiflexion	Use a padded footboard or splint with heels free of pressure.
Legs	15 to 20 degrees of abduction	Place small pillow between legs.
Hip	Extension and neutral rotation	Place patient supine with lower extremity extended. Use trochanter roll. Use foam wedge along lateral aspect of thigh.

DIP, Distal interphalangeal; *MP*, metatarsophalangeal; *PIP*, proximal interphalangeal.

Range-of-motion exercises to maintain mobility are performed actively at least 3 times a day. If the patient cannot move a joint actively, perform passive range-of-motion exercises. Give burned hands special attention. Urge the patient to perform active range-of-motion exercises for the hand, thumb, and fingers every hour while he or she is awake.

Ambulation is started as soon as possible after the fluid shifts have resolved because it maintains mobility, inhibits bone density loss, strengthens muscles, stimulates immune function, promotes ventilation, and prevents many complications. Patients with attached equipment (IV catheters, nasogastric tubes, ECG leads, extensive dressings) can ambulate with preparation and assistance. This activity is performed 2 or 3 times a day and progresses in length each time.

Compression dressings are applied after grafts heal to help prevent contractures and tight hypertrophic scars, which can inhibit mobility. They also inhibit venous stasis and edema in areas with decreased lymph flow. Compression dressings may be elastic wraps or specially designed, custom-fitted, elasticized clothing that provides continuous pressure. Fig. 26-15 shows such a garment. For best effectiveness, pressure garments must be worn at least 23 hours a day, every day, until the scar tissue is mature (12 to 24 months). They can be uncomfortable with itchiness and increased warmth. Reinforce to the patient and family that wearing pressure garments is beneficial in saving mobility and reducing scarring.

FIG. 26-15 A patient wearing full-body compression garments.

Surgical Management.

Surgical management restores mobility rather than prevents immobility. Surgical release of contractures is commonly performed in the neck, axilla, elbow flexion areas, and hand. Specific surgical procedures vary for each patient.

Nursing responsibilities include interventions to prevent contractures from re-forming, as well as the care of new grafts and suture lines. Constantly reinforce the need for the patient to adhere to exercise and splinting regimens to prevent the recurrence of joint immobility.

Supporting Positive Self-Image

Planning: Expected Outcomes.

After intervention, the patient with a burn injury is expected to have a positive perception of his or her own appearance, body functions, and self-worth. Indicators include that the patient should consistently demonstrate these behaviors:

- Willingness to touch the affected body part

- Adjustment to changes in body function
- Willingness to use strategies to enhance appearance and function
- Successful progression through the grieving process
- Use of support systems

Interventions.

Nonsurgical and surgical interventions can assist patients who have self-image problems as a result of burn injury.

Nonsurgical Management.

Understanding the stages of grief is helpful in managing care for the patient with burns. Assess which stage of grief the patient is currently experiencing, and help interpret his or her behaviors. The patient often is unaware of or is confused by his or her feelings. Reassure the patient that feelings of grief, loss, anxiety, anger, fear, and guilt are normal. The patient may be grieving the loss of body parts, appearance, role identity, social identity, and family members. Coordinate with other health care team members (e.g., psychologist/psychiatrist, social worker, clergy or religious leader) to address these issues.

Accept the physical and psychological features of the patient. Present patients and families with realistic expected outcomes for the patient's functional capacity and physical appearance. Provide information sessions and counseling for the family to identify patterns of support. Facilitate the patient's use of these systems and the development of new support systems. Make referrals to support groups. Evaluate the effectiveness and use of support resources throughout the course of recovery.

Engaging in decision making and independent activities fosters feelings of self-worth. Plan and encourage the patient's active participation in care activities. Assist family members to understand that it is more beneficial for the patient to perform these activities than to have them performed by someone else. Urge families to include the patient in family decision making to the same degree that he or she participated in this process before the injury.

Surgical Management.

Reconstructive and cosmetic surgery can be performed many years after the burn injury. Restoring function and improving appearance through surgical techniques often promote the patient's positive self-image and self-worth. Many patients have unrealistic expectations of reconstructive surgery and envision an appearance identical or equal in quality to the

preburn state. Teach the patient and family about expected cosmetic outcomes.

Rehabilitative Phase of Burn Injury

Although rehabilitation efforts are started at the time of admission, the technical rehabilitative phase begins with wound closure and ends when the patient achieves his or her highest level of functioning. The emphasis is on the psychosocial adjustment of the patient, the prevention of scars and contractures, and the resumption of preburn activity, including resuming work, family, and social roles. This phase may take years or even last a lifetime as patients adjust to permanent limitations (Dahl et al., 2012).

Patient-Centered Collaborative Care

Although attention is placed first on the physical interventions for the burn injury, psychological care is equally important. Continue to provide psychosocial support to the patient and family throughout hospitalization and in the rehabilitative phase.

Obtaining information from the patient and family aids in the assessment and diagnosis of psychological problems and directs management. Explore the patient's feelings about the burn injury. It is extremely difficult for patients to concentrate on the many tasks before them when obstacles such as guilt and grief are in the forefront.

Ask whether there is a history of psychological problems. To assist with a future plan of care, assess and document the type of coping mechanisms the patient has used successfully during times of stress. Also assess the patient's family unit and the history of interaction. Consider cultural and ethnic factors when planning psychosocial interventions.

Throughout the hospitalization, the patient progresses through a variety of stages and exhibits many feelings, including denial, regression, and anger. Assess the patient's feelings at each stage so appropriate plans of care can be implemented.

Community-Based Care

Discharge planning for the patient with a burn injury begins at admission to the hospital or burn center. The interdisciplinary team meets regularly to evaluate the progress of each discipline and help the patient reach mutually established discharge outcomes. Table 26-7 lists common discharge needs of the patient with burns.

TABLE 26-7

Needs to Address Before Discharge of the Patient with Burns

- Early patient assessment
- Financial assessment
- Evaluation of family resources
- Weekly discharge planning meeting
- Psychological referral
- Patient and family teaching (home care)
- Designation of principal learners (specific family members or significant others who will help with care)
- Development of teaching plan
- Training for wound care
- Rehabilitation referral
- Home assessment (on-site visit)
- Medical equipment
- Public health nursing referral
- Evaluation of community resources
- Visit to referral agency
- Re-entry programs for school or work environment
- Long-term care placement
- Environmental interventions
- Auditory testing
- Speech therapy
- Prosthetic rehabilitation

Psychosocial Preparation.

During the recovery period and for some time after discharge, patients with severe burn injuries often have psychological problems that require intervention. Such problems include post-traumatic stress disorder, sexual dysfunction, and severe depression. Assistance is coordinated with the patient, family, and health care team. Psychosocial assistance is best provided by a professional counselor with experience in helping burn patients.

One specific area to address with the patient is the reaction of others to the sight of healing wounds and disfiguring scars. Patients with facial burns are especially subjected to stares and other negative reactions from the public. Visits from friends and short public appearances before discharge may help the patient begin adjusting to this problem. Community reintegration programs can assist the psychosocial and physical recovery of the patient with serious burns.

Home Care Management.

The patient with severe burns is discharged from the acute care setting when serious complications are resolved and minimal wound areas remain open. During the first weeks at home, the patient usually needs at least daily wound care, physical therapy, nutrition support, symptom management, and drug therapy.

Although the patient usually views going home positively, the problems of physical care and the psychological stresses from changes in

appearance, role, function, and lifestyle may overwhelm the patient and family. Successful discharge depends on extensive planning and preparation of the patient, family, and home environment through education and the involvement of appropriate support agencies and services.

Preparation for discharge includes assessment of the family and home care situation from physical and social perspectives. Consider the needs of the patient when evaluating the home for cleanliness; access to bathing facilities, electricity, and running water; stairways; number of occupants; temperature control; and safety. If the burn injuries occurred in a house fire, a new residence may need to be established.

Self-Management Education.

Education about burn care and living with the consequences of burn injuries begins when the patient is admitted to the hospital or burn center. A weekly plan for patient education is outlined; a positive outcome is progression toward independence for the patient and family. Critical for this outcome is teaching patients and family members to perform such care tasks as dressing changes. Allow patients and family members to first observe dressing changes, then to assist in performing the changes, and then to change the dressings independently under your supervision.

Before discharge, all people who will be involved in the patient's home care participate in discharge planning and teaching sessions. In addition to details about dressing changes, explain:

- Indications of infection
- Drug regimens
- Proper use of prosthetic and positioning devices
- Correct application and care of pressure garments
- Comfort measures to reduce pruritus
- Dates for follow-up appointments

Health Care Resources.

The health care team evaluates the family's capacity and willingness to assist in caring for the patient after discharge. A visiting nurse or case manager with extensive experience in providing burn care can assist the family with care problems arising at home. This nurse can help the family determine what special equipment, supplies, or services will be needed. The frequency of home visits depends on the patient's condition and the ability of family members to function as care providers. The home care nurse may need a brief visit to the patient while in the

hospital and may need to observe burn wound care.

The home care of a patient after a serious burn often involves daily physical therapy and rehabilitation sessions at special centers. Address and resolve transportation problems before the patient is discharged.

When rehabilitation is prolonged, the patient may be discharged to a rehabilitation facility. Consult with the rehabilitation team, and provide copies of the care and teaching plans used with the patient.

Evaluation: Outcomes

Evaluate the care of the patient with a burn injury on the basis of the identified priority patient problems. The expected outcomes include that the patient should:

- Maintain adequate oxygenation and circulation to all vital organs
- Maintain a patent airway
- Have cardiac output restored to normal
- Have pain alleviated or reduced
- Experience no further loss of skin tissue integrity
- Have wounds healed without complications
- Remain free from infection
- Not experience sepsis
- Maintain an adequate nutrition for meeting the body's calorie needs
- Regain and maintain an optimal ability to move purposefully
- Have a positive perception of his or her own appearance and body functions

Specific indicators for these outcomes are listed for each priority patient problem in the Planning and Implementation section (see earlier).

Nursing Concepts and Clinical Judgment Review

What might you NOTICE if the patient is experiencing infection as a result of a problem of protection from a burn injury?

- Change in burn wound, including:
  - Pervasive odor
  - Color changes—focal, dark red, brown discoloration in the eschar
  - Change in texture
  - Purulent drainage
  - Exudate
  - Sloughing grafts
  - Redness of wound edges extending to nonburned skin

• Elevated temperature
• Change in sensation in burn wound
• Change in cognition or level of consciousness

What should you INTERPRET and how should you RESPOND to a patient experiencing infection as a result of a problem of protection from a burn injury?

Perform and interpret physical assessment, including:

• Taking vital signs, especially temperature
• Checking for change in cognitive status or level of consciousness
• Assessing burn wound for changes in appearance or amount/type of exudate

Interpret laboratory values:

• Elevated white blood cell count
• Positive burn wound cultures
• Positive blood cultures

Respond by:

• Documenting indicators of infection
• Notifying health care professional
• Implementing appropriate infection protocols
• Assisting the patient and family to understand the rationale for infection protocols

On what should you REFLECT?

• Observe patient for evidence of response to antimicrobial therapy and infection protocols.
• Determine whether the infection occurred by auto-contamination or cross-contamination.
• Think about what staff and patient teaching focus could help reduce the occurrence of a wound infection in the future.

Get Ready for the NCLEX® Examination!

Key Points

Review these Key Points for each NCLEX Client Needs Category.

Safe and Effective Care Environment

- Use strict aseptic technique when caring for patients who have open burn wounds to prevent infection. **Safety** QSEN
- Monitor the patient's vital signs at least every 8 hours for indications of wound infection or sepsis. (For patients with greater than 25% TBSA burn, monitor vital signs more frequently.) **Safety** QSEN
- Assess burn wounds at least daily for indicators of infection. **Safety** QSEN
- Give prescribed opioid analgesics by the IV route during the resuscitation phase of burn recovery. **Safety** QSEN

Health Promotion and Maintenance

- Encourage all people to have and maintain home smoke and carbon monoxide detectors.
- Warn patients who smoke about not smoking in bed or in rooms where home oxygen is in use and not smoking when taking any substance that induces sedation (drugs or alcohol). **Safety** QSEN
- Instruct patients who have reduced sensation in hands or feet to use a bath thermometer to check water temperature before bathing. **Safety** QSEN
- Teach patients to avoid exposing burned skin to the sun or to temperature extremes. **Patient-Centered Care** QSEN
- Instruct everyone to set hot water tank temperatures to the manufacturer's recommendations. **Safety** QSEN

Psychosocial Integrity

- Allow patients time to grieve over a change in body image. **Patient-Centered Care** QSEN
- Reassure patients that pain will be managed effectively. **Patient-Centered Care** QSEN
- Explain all procedures to the patient and family.
- Assess the patient's and family's use of coping strategies related to burn injury, treatment, possible role changes, and possible outcomes. **Patient-Centered Care** QSEN
- Support the patient and family in coping with permanent changes in

appearance and function. **Patient-Centered Care** QSEN

- Encourage the burn patient with wounds and scars to participate in self-care. **Patient-Centered Care** QSEN
- Allow patients who have lost family members, homes, or jobs time to grieve for these losses.

Physiological Integrity

- Assess the burn patient's airway and adequacy of breathing before assessing any other body system. **Safety** QSEN
- Keep an endotracheal kit or tracheostomy kit at the bedside of any patient with facial burns, burns inside the mouth, singed nasal hairs, or a "smoky" smell to the breath. **Safety** QSEN
- Notify the Rapid Response Team immediately if the patient with an inhalation injury becomes more breathless or audible wheezes disappear. **Safety** QSEN
- Give analgesics, sedatives, and antianxiety drugs to patients receiving paralytic drugs during mechanical ventilation. **Patient-Centered Care** QSEN
- Give half of the fluid volume calculated for the first 24 hours after burn injury in the first 8 hours postburn. **Evidence-Based Practice** QSEN
- Use laboratory data and clinical manifestations to determine the effectiveness of fluid resuscitation during the resuscitation phase of burn injury. **Evidence-Based Practice** QSEN
- Encourage the patient to actively participate in pain control measures. **Patient-Centered Care** QSEN
- Position patients to prevent contractures and promote joint function. **Evidence-Based Practice** QSEN
- Assist patients to ambulate several times each day as soon as the fluid shifts have resolved.
- Coordinate with the registered dietitian to meet the nutrition needs for the patient during the acute phase of burn injury. **Teamwork and Collaboration** QSEN
- Evaluate the patient's wound healing during the acute phase of burn injury. **Patient-Centered Care** QSEN
- Use appropriate positioning and range-of-motion interventions for prevention of mobility problems in the patient with burns. **Patient-Centered Care** QSEN

UNIT VII

Problems of Oxygenation: Management of Patients with Problems of the Respiratory Tract

OUTLINE

Concept Overview: Oxygenation

Meeting the body's need for oxygenation is dependent on the concepts of gas exchange and perfusion (Giddens, 2013). All cells and tissues need oxygen to live and function. Some cells, such as brain cells and heart muscle cells, are very dependent on oxygen. Without oxygen, brain cells stop functioning and die in about 5 to 10 minutes. Other cells, such as skin cells, can live and function for many hours with low oxygen levels or even without oxygen. Skeletal muscle cells can survive for hours with low levels of oxygen but cannot function for very long without it.

The source of the oxygen for all body cells is the air we breathe into our lungs. The process of gas exchange first occurs in the alveoli of lungs. The carbon dioxide generated in body cells as a result of metabolism diffuses from the blood into the alveoli where it is exhaled down its concentration gradient into atmospheric air. At the same time, atmospheric oxygen is inhaled into the alveoli where it then moves down its concentration gradient into capillary blood. These steps compose alveolar or pulmonary gas exchange even though the exchange is not equal (not a one-for-one exchange between oxygen molecules and carbon dioxide molecules). Delivery of oxygen to the cells and tissues, perfusion, requires the pumping mechanism of the heart and the oxygen-carrying mechanism of the hemoglobin in red blood cells. Once perfusion delivers oxygen to the tissues, a second gas exchange takes place with oxygen moving from capillary blood into cells at the same time that carbon dioxide leaves the

cells and enters capillary blood.

In health, the need of body tissues for oxygen is balanced by the body's gas exchange and perfusion systems (Fig. 1). When oxygen needs increase, such as during mild to moderate exercise, oxygen intake through the respiratory system and pulmonary gas exchange increase to compensate (or adjust) and keep tissue oxygen perfusion in balance with cellular oxygen need (Fig. 2).

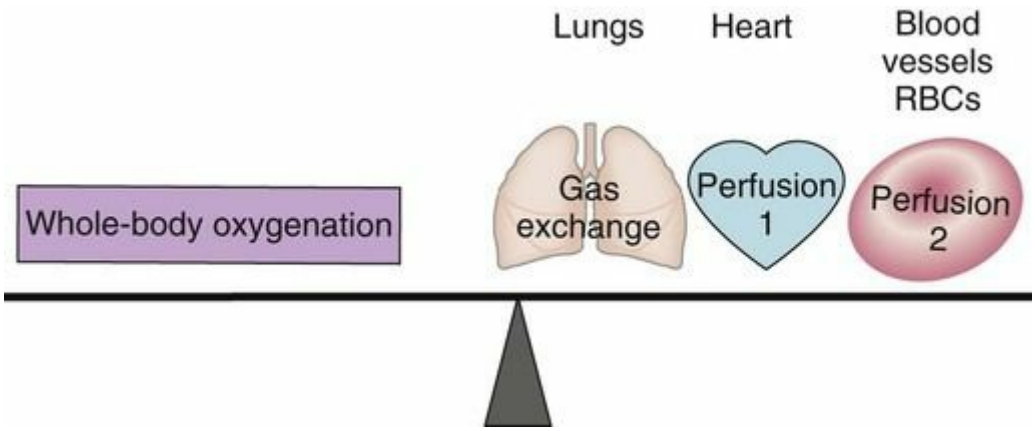

FIG. 1

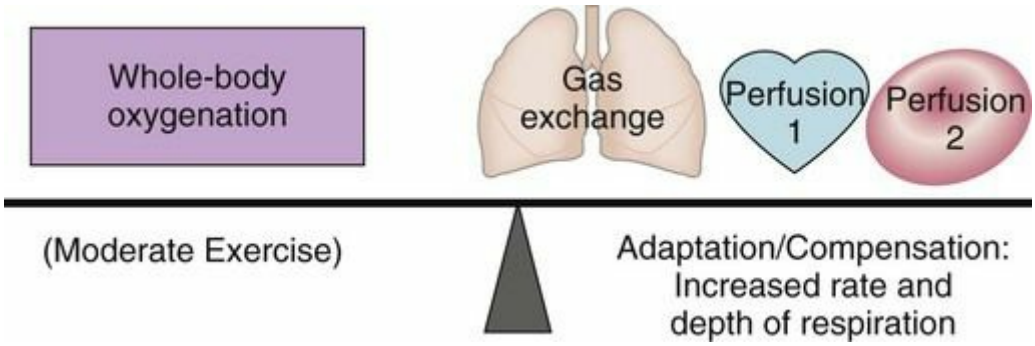

FIG. 2

When oxygen need increases as a result of heavy exercise or an illness in which metabolism is increased (and the person has a fever), all gas exchange and perfusion systems must adjust by increasing their activity to match the increased oxygen need. When this compensation is perfect, the increased rate and depth of respiration, along with the increased heart rate and blood pressure, keep oxygenation in balance with oxygen need (Fig. 3).

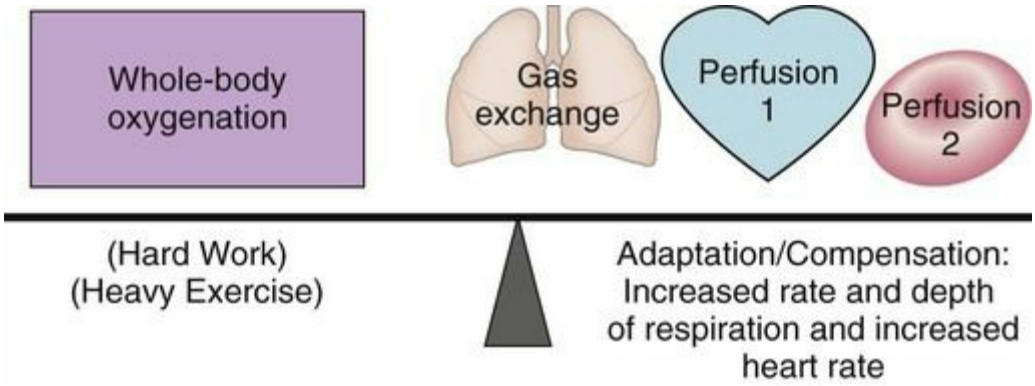

FIG. 3

Some health problems reduce the body's ability to compensate when oxygen need is greater than basic (basal) levels. For example, in a person who has asthma, the lungs may be able to take in enough oxygen to meet basic oxygen needs but cannot adjust or compensate when a greater oxygen intake is needed, such as during mild to moderate exercise (Fig. 4). In this situation, the heart and blood need to compensate *more* to increase delivery of the set amount of oxygen taken in (Fig. 5).

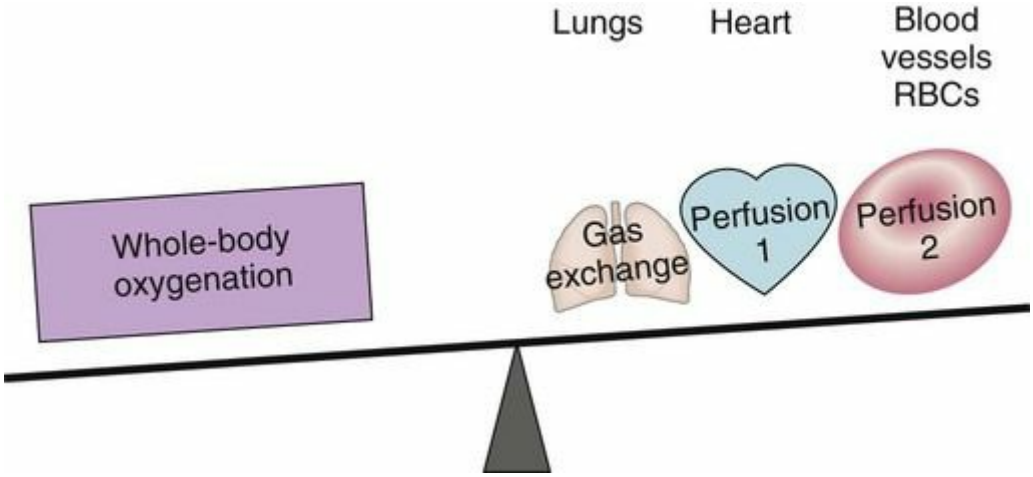

FIG. 4

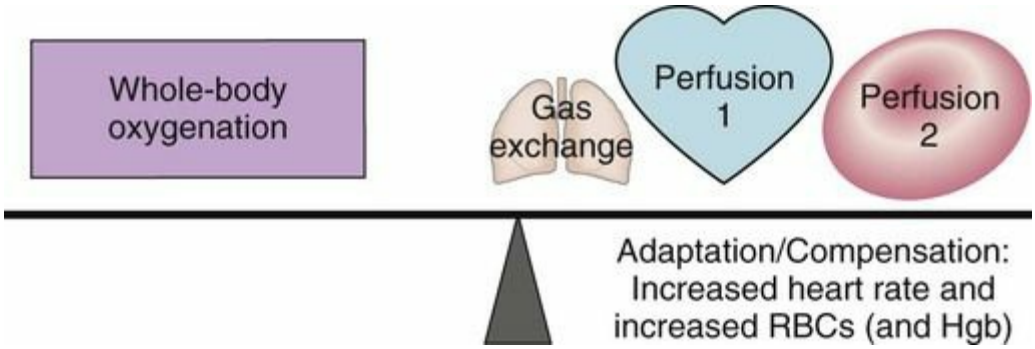

FIG. 5

In another situation, when the person has a cardiac problem and the heart rate alone cannot increase oxygen delivery during mild to moderate exercise (Fig. 6), his or her respiratory rate would have to increase more than usual to keep oxygen delivery in balance with oxygen need.

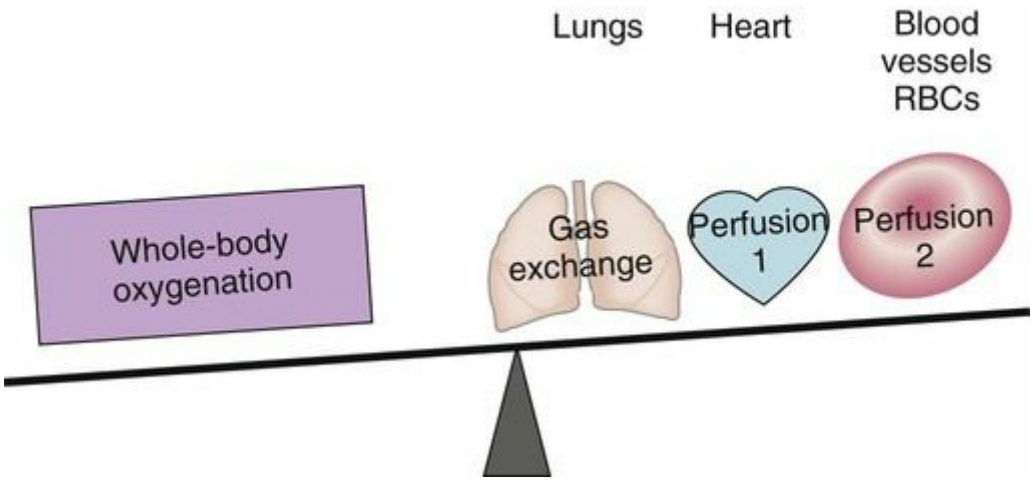

FIG. 6

What happens when any part of the oxygen intake (gas exchange) or delivery systems (perfusion) has a problem that interferes with ensuring that the cells have enough oxygen? Consider a person with pneumonia who has great difficulty with pulmonary gas exchange to the point that the body's basic oxygen need is not met. Even though the oxygen need is at a basic level, the need is unbalanced compared with pulmonary gas exchange and oxygen perfusion. The person's compensation mechanisms are working (respiratory rate is increased, heart rate is increased) but are not completely effective. How could balance be restored? Interventions are needed to support the body's compensation efforts to restore balance.

The best way is to eliminate the pneumonia, which could take days even with proper drug therapy. Other ways involve (1) reducing oxygen need to the lowest possible level by having the patient rest and (2) improving pulmonary gas exchange by increasing the percentage of oxygen

in the air that he or she breathes (oxygen therapy) (Fig. 7).

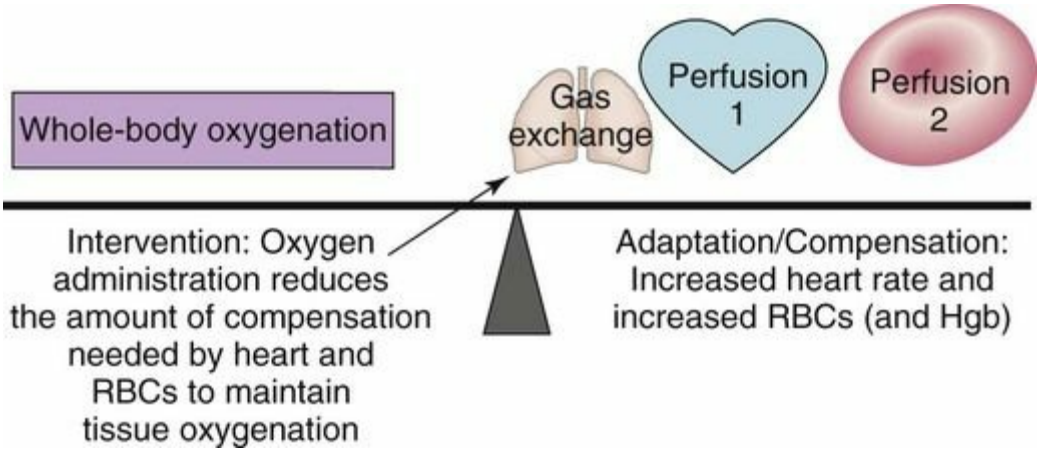

FIG. 7

CHAPTER 27

Assessment of the Respiratory System

Harry Rees

PRIORITY CONCEPTS

- Gas Exchange
- Perfusion

Learning Outcomes

Health Promotion and Maintenance

1. Teach all people measures to take to protect the respiratory system, including the avoidance of tobacco use.

Psychosocial Integrity

2. Reduce the psychological impact for the patient and family regarding the assessment and testing of the respiratory system with regard to gas exchange and perfusion.

Physiological Integrity

3. Perform a focused assessment of respiratory function, incorporating information about genetic risk and age-related changes affecting respiratory function.
4. Coordinate appropriate care for patients after invasive and noninvasive testing of respiratory function.

http://evolve.elsevier.com/Iggy/

Oxygen (O_2) is an essential nutrient for all cells to live and perform their specific jobs. Oxygen intake with gas exchange and perfusion depends on

the respiratory system because the source of the oxygen for all body cells is the air we breathe (Fig. 27-1). This system includes the upper airways, lungs, lower airways, and alveolar air sacs. Air with oxygen enters the nose and mouth and moves through the airways or respiratory tubes (trachea, bronchi, bronchioles) and into the air sacs (alveoli) of the lungs. Once in the air sacs, the oxygen from the air moves into the blood so that it can be carried to all tissues and organs. Carbon dioxide (CO_2), the waste gas created in the tissues, moves from the blood into the lungs so it can be exhaled. All systems depend on adequate oxygen intake with gas exchange for tissue perfusion. Any respiratory problem affects total body health and well-being.

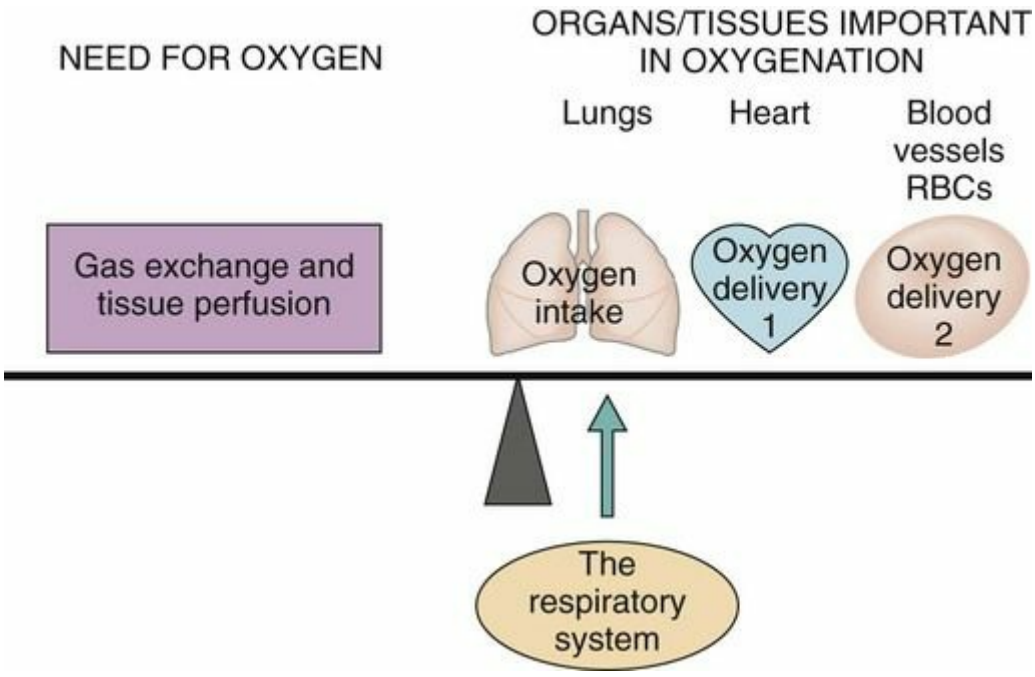

FIG. 27-1 Role of the respiratory system in the concepts of gas exchange and tissue perfusion. *RBCs*, Red blood cells.

Health Promotion and Maintenance

Lung and breathing problems are common causes of death in North America (McCance et al., 2014). Some respiratory problems are chronic, and the patient has physical and lifestyle limitations. Many acute health problems, medical therapies, and surgeries adversely affect respiratory function temporarily or permanently. Exposure to inhalation irritants, especially to tobacco smoke, is the most common cause of chronic respiratory problems and physical limitations. In addition, cigarette smoking is a modifiable factor that greatly increases the risk for cardiovascular disease, stroke, and many types of cancer. Three compounds in cigarette smoke that have been implicated in the development of these serious diseases are tar, nicotine, and carbon monoxide. In the years after a patient has stopped smoking, his or her risk for respiratory-related disorders decreases significantly. Therefore assessing smoking habits, actively promoting smoking cessation, determining exposure to other inhalation irritants, and teaching people to protect the respiratory system are important nursing functions.

Assessing smoking habits begins by determining whether the patient is a current smoker or has ever smoked. The smoking history includes the number of cigarettes smoked daily, the duration of the smoking habit, and the age of the patient when smoking started even for patients who are not current smokers. Record the smoking history in **pack-years,** which is the number of packs per day multiplied by the number of years the patient has smoked.

Be sure to ask those who do not currently smoke whether and to what extent they are exposed to the smoke of others. This passive smoking has two origins: direct exposure to smoke by being in the same environment with a person(s) who is actively smoking *(secondhand smoke [SHS]);* and indirect exposure from smoke that clings to hair and clothing *(thirdhand smoke)*. Both types of passive smoking contribute to health problems, especially when exposure occurs in small, confined spaces and is chronic.

Another category of cigarette smoking, particularly among younger adults, is *social smoking.* This term is used to describe people who claim to smoke cigarettes only in the presence of others, borrow rather than purchase cigarettes, prefer the company of nonsmokers, and do not smoke for stress relief (Butler et al., 2012). Often the social smoker does not consider himself or herself to be a smoker and must be asked specifically, "Do you ever smoke in social situations?" Although this type of smoking is intermittent, it can still have an adverse effect on respiratory and cardiovascular health and may lead to nicotine addiction.

Hookah or water pipe smoking is becoming more popular in North America. The highest incidence is among young people. Studies have determined that the exposure to inhaled toxins is as great or greater than with cigarette smoking. Although many cities have instituted smoking bans, water pipe smoking may be exempt, raising concerns for secondhand smoke exposure (Fiala et al., 2012).

E-cigarettes have emerged as an alternative to traditional cigarettes and are used as a method of quitting smoking. The cartridges within an e-cigarette, as well as the vapors produced, may contain nicotine or other toxins. Thus the safety for the user or the bystander has not been established. E-cigarettes are not currently an approved method of smoking cessation (Riker et al., 2012).

Gender Health Considerations

Patient-Centered Care QSEN

Gay men, lesbian women, and bisexual men and women report higher rates of smoking cigarettes, cigars, and cigarillos when compared with their heterosexual counterparts (King et al., 2012). The rate of smoking may be 2.0 to 2.5 times more likely among gay, bisexual, and transgender men than heterosexual men. Lesbian, bisexual, and transgender women may be 1.5 to 3.5 times more likely to smoke than heterosexual women, and lesbian, gay, bisexual, and transgender (LGBT) youth may pose the highest risk (American Lung Association, 2012). Concern exists that the LGBT community may not focus enough attention on prevention and smoking-cessation programs. Thus many LGBT people who smoke are highly susceptible to smoking-related health problems, such as chronic lung disease and throat and lung cancers. Therefore screening for smoking and tobacco-related health conditions is especially important when working with LGBT patients.

Promoting smoking cessation is a sensitive and sometimes uncomfortable issue for nurses and other health care professionals to approach with patients who smoke. However, this opportunity for a "teachable moment" may be the beginning support a patient needs to be successful in this healthful pursuit. Many acute care settings now have automatic smoking-cessation protocols that attach to the patient's electronic medical record as soon as an active smoking history is recorded. The Centers for Medicare and Medicaid Services (CMS) no longer requires smoking cessation as part of their Core Measures. However, The Joint Commission requires documentation of screening for

tobacco use and that a tobacco treatment program was offered or provided, as part of their quality measures.

Ask about the patient's desire to quit, past attempts to quit, and the methods used. Determine nicotine dependence by asking questions such as:

- How soon after you wake up in the morning do you smoke?
- Do you wake up in the middle of your sleep time to smoke?
- Do you find it difficult not to smoke in places where smoking is prohibited?
- Do you smoke when you are ill?

A variety of drug therapies are available over the counter and by prescription to help those addicted to nicotine to modify their behavior and stop smoking. Over-the-counter nicotine replacement therapies (NRTs) include nicotine-releasing transdermal patches, gums, and lozenges. Prescribed NRT products include nasal sprays and inhalers. NRT products have a success rate of smoking cessation between 50% and 70% (Grief, 2011). They have been shown to have the highest success rates when used in association with a smoking-cessation program. Chart 27-1 lists suggestions for you to use in providing support to the person interested in stopping cigarette smoking.

Chart 27-1 Patient and Family Education: Preparing for Self-Management

Smoking Cessation

- Make a list of the reasons you want to stop smoking (e.g., your health and the health of those around you, saving money, social reasons).
- Set a date to stop smoking, and keep it. Decide whether you are going to begin to cut down on the amount you smoke or are going to stop "cold turkey." Whatever way you decide to do it, keep this important date!
- Ask for help from those around you. Find someone who wants to quit smoking and "buddy up" for support. Look for assistance in your community, such as formal smoking-cessation programs, counselors, and certified acupuncture specialists or hypnotists.
- Consult your health care provider about nicotine replacement therapy (e.g., patch, gum) or other pharmacologic therapy to assist in smoking cessation.
- Remove ashtrays and lighters from your view.
- Talk to yourself! Remind yourself of all the reasons you want to quit.

- Think of a way to reward yourself with the money you save from not smoking for a year.
- Avoid places that might tempt you to smoke. If you are used to having a cigarette after meals, get up from the table as soon as you are finished eating. Think of new things to do at times when you used to smoke (e.g., taking a walk, exercising, calling a friend).
- Find activities that keep your hands busy: needlework, painting, gardening, even holding a pencil.
- Take five deep breaths of clean, fresh air through your nose and out your mouth if you feel the urge to smoke.
- Keep plenty of healthy, low-calorie snacks, such as fruits and vegetables, on hand to nibble on. Try sugarless gum or mints as a substitute for tobacco.
- Drink at least eight glasses of water each day.
- Begin an exercise program with the approval of your health care provider. Be aware of the positive, healthy changes in your body since you stopped smoking.
- List the many reasons why you are glad that you quit. Keep the list handy as a reminder of the positive things you are doing for yourself.
- If you have a cigarette, think about what the conditions were that caused you to light it. Try and think of a strategy to avoid that (or those) conditions.
- Don't beat yourself up for backsliding; just face the next day as a new day.
- Think of each day without tobacco as a major accomplishment. It is!!

Nursing Safety Priority QSEN

Drug Alert

Teach people using drugs for nicotine replacement therapy that smoking while taking these drugs greatly increases circulating nicotine levels and the risk for stroke or heart attack.

Additional drug therapy for smoking cessation includes the oral drugs *bupropion* (Zyban) and *varenicline* (Chantix). Bupropion encourages smoking cessation by decreasing cravings and withdrawal manifestations as well as reducing the depression associated with nicotine withdrawal symptoms. Varenicline interferes with the nicotine receptors. This promotes smoking cessation by reducing the pleasure derived from nicotine and by reducing the manifestations of nicotine withdrawal.

Nursing Safety Priority QSEN

Drug Alert

Both bupropion and varenicline carry a black box warning that use of these drugs can cause manic behavior and hallucinations. These drugs also may unmask serious mental health issues. Teach the patient prescribed either of these drugs and their families to report any change in behavior or thought processes to the prescriber immediately.

Cultural Considerations

Patient-Centered Care QSEN

The prevalence of smoking remains higher among African Americans, blue-collar workers, and less-educated people than in the overall population of the United States. Smoking prevalence is highest among Northern Plains American Indians and Alaskan Natives. Development of culturally appropriate smoking-cessation programs as well as research examining barriers to cessation in these populations may help reduce this disparity.

Assessing exposure to inhalation irritants should be part of any health assessment. Usually this information is obtained as part of the demographic history, which includes the patient's current and past geographic living area, occupation, home conditions, and hobbies. Geographic areas with high levels of air pollution contribute to respiratory problems. Exposures to dust, particles, chemicals, gases, or toxic fumes can occur in the workplace, making work history information important. Ask about the exact dates of employment and a brief job description. Exposure to industrial dusts of any type or to the chemicals found in smoke and fumes may cause breathing disorders. Bakers, coalminers, stone masons, cotton handlers, woodworkers, welders, potters, plastic and rubber manufacturers, printers, asbestos workers, farm workers, and steel foundry workers are at risk for breathing problems.

Ask about home conditions, such as the type of heat used (e.g., gas heater, wood-burning stove, fireplace, kerosene heater). Determine exposure to irritants (e.g., fumes, chemicals, animals, birds, air pollutants). Ask about hobbies such as painting, ceramics, model airplanes, refinishing furniture, or woodworking, which may expose the patient to harmful chemicals.

Protecting the respiratory system starts with making people aware of the sources of inhalation irritants. Teach people who live in areas with high levels of air pollution to remain indoors with windows closed on days when air quality is poor and not to engage in heavy physical activity. Teach people who have workplace or home exposure to inhalation irritants to wear masks during these exposures and to ensure the area is well ventilated.

Anatomy and Physiology Review

The purpose of breathing is to ensure gas exchange. This process has two parts: (1) oxygenation for tissue perfusion so that cells have enough oxygen to metabolize and generate energy; and (2) removal of carbon dioxide, the waste product of metabolism. The respiratory system also influences acid-base balance, speech, sense of smell, fluid balance, and temperature control. The lungs are also an excretory organ because they can also break down some toxins and eliminate them from the body during exhalation.

Upper Respiratory Tract

The upper airways include the nose, the sinuses, the pharynx, and the larynx (Fig. 27-2).

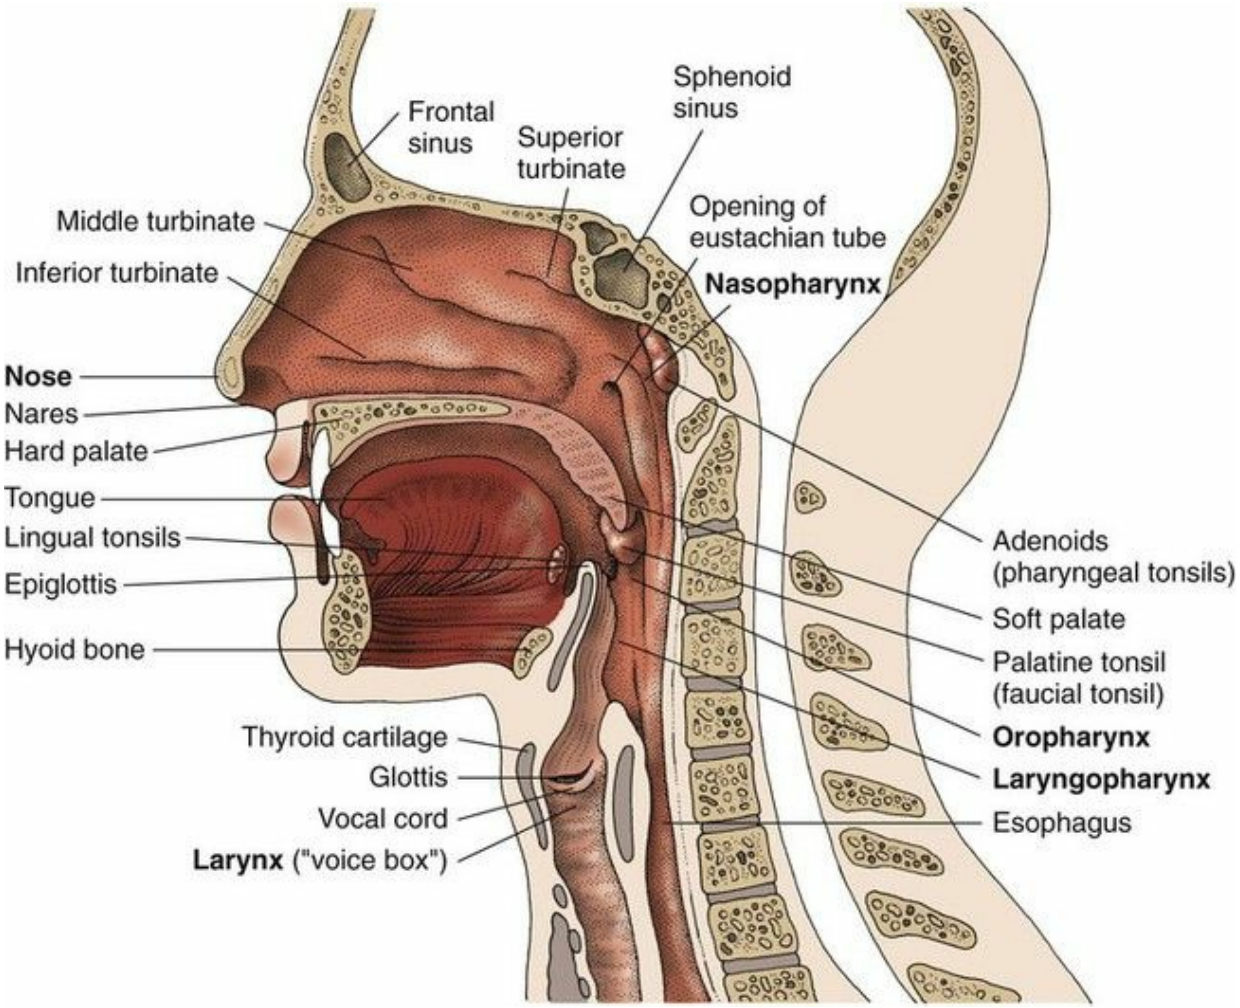

FIG. 27-2 Structures of the upper respiratory tract.

Nose and Sinuses

The nose is the organ of smell, with receptors from cranial nerve I *(olfactory)* located in the upper areas. The nose is rigid with a bony upper portion and a cartilaginous lower portion that can move to some extent. The septum divides the nose into two cavities that are lined with mucous membranes that have a rich blood supply. The **anterior nares** are the external openings into the nasal cavities. The posterior nares are openings from the nasal cavity into the throat.

The **turbinates** are three bones that protrude into the nasal cavities from the internal portion of the nose (see Fig. 27-2). Turbinates increase the total surface area for filtering, heating, and humidifying inspired air before it passes into the nasopharynx. Inspired air is humidified by the mucous membrane and is warmed by heat from the vascular network.

The **paranasal sinuses** are air-filled cavities within the bones that surround the nasal passages (Fig. 27-3). Lined with ciliated membrane, the sinuses provide resonance during speech, decrease the weight of the skull, and act as shock absorbers in the event of facial trauma.

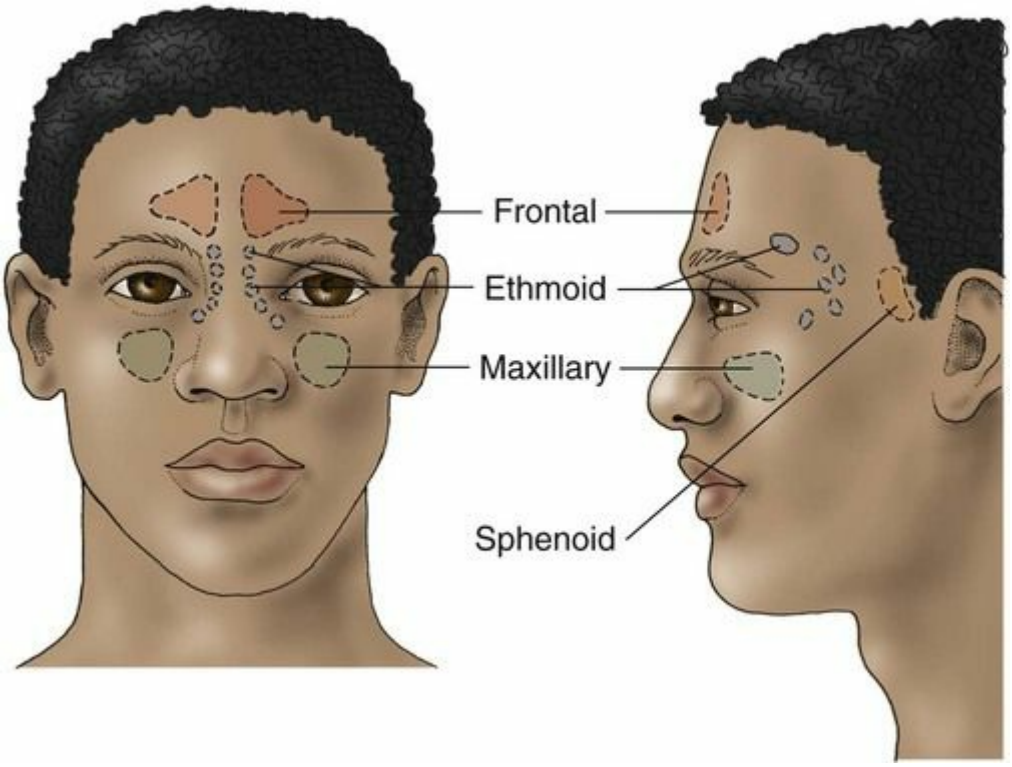

FIG. 27-3 The paranasal sinuses.

Pharynx

The pharynx, or throat, is a passageway for both the respiratory and digestive tracts. It is located behind the oral and nasal cavities. The throat is divided into the nasopharynx, the oropharynx, and the

laryngopharynx (see Fig. 27-2).

The nasopharynx is located behind the nose, above the soft palate. It contains the adenoids and the opening of the eustachian tube. The adenoids trap organisms that enter the nose or mouth. The **eustachian tubes** connect the nasopharynx with the middle ears and open during swallowing to equalize pressure within the middle ear.

The oropharynx is located behind the mouth, below the nasopharynx. It extends from the soft palate to the base of the tongue and is used for breathing and swallowing. The *palatine tonsils,* which are part of the immune system, are located on the sides of the oropharynx and protect against invading organisms.

The **laryngopharynx** is the area located behind the larynx from the base of the tongue to the esophagus. It is the dividing point between the larynx and the esophagus.

Larynx

The **larynx** is the "voice box" and is located above the trachea, just below the throat at the base of the tongue. It is composed of several cartilages (Fig. 27-4). The *thyroid cartilage* is the largest and is commonly called the "Adam's apple." The *cricoid cartilage,* which contains the vocal cords, lies below the thyroid cartilage. The *cricothyroid membrane* is located below the level of the vocal cords and joins the thyroid and cricoid cartilages. This site is used in an emergency for access to the lower airways. In this procedure, called a *cricothyroidotomy,* an opening is made between the thyroid and cricoid cartilage and results in a tracheostomy. The two *arytenoid* cartilages work with the thyroid cartilage in vocal cord movement.

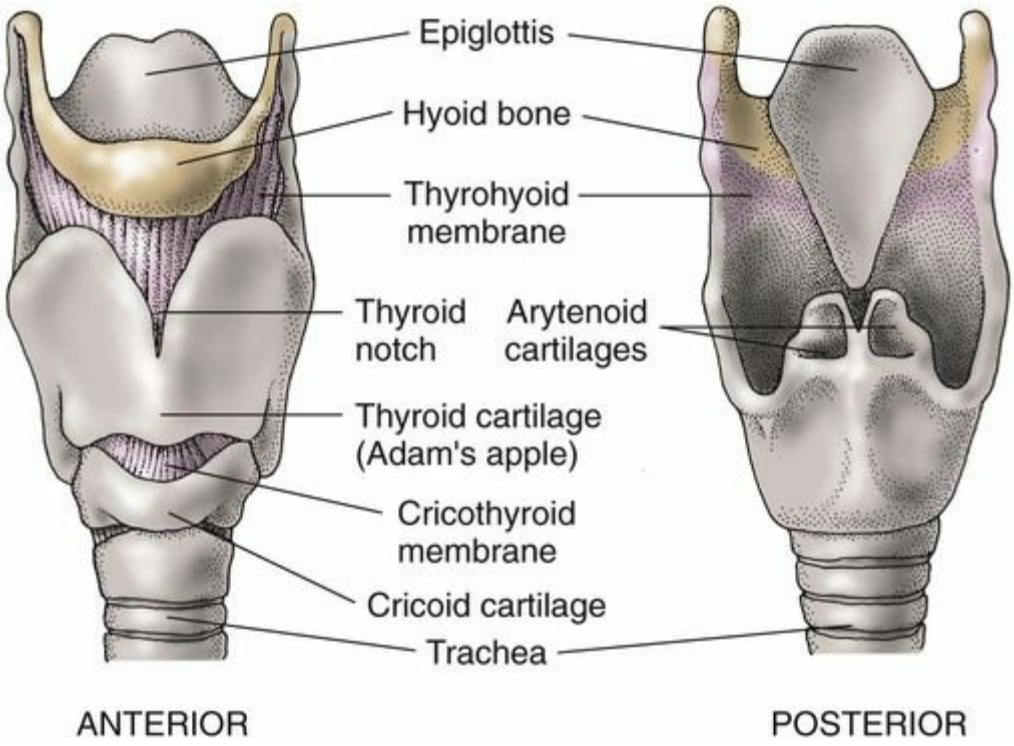

FIG. 27-4 Structures of the larynx.

Inside the larynx are two pairs of vocal cords: the false vocal cords and the true vocal cords. The **glottis** is the opening between the true vocal cords (Fig. 27-5). The **epiglottis** is a small, elastic structure attached along one edge to the top of the larynx. It prevents food from entering the trachea (aspiration) by closing over the glottis during swallowing. The epiglottis opens during breathing and coughing.

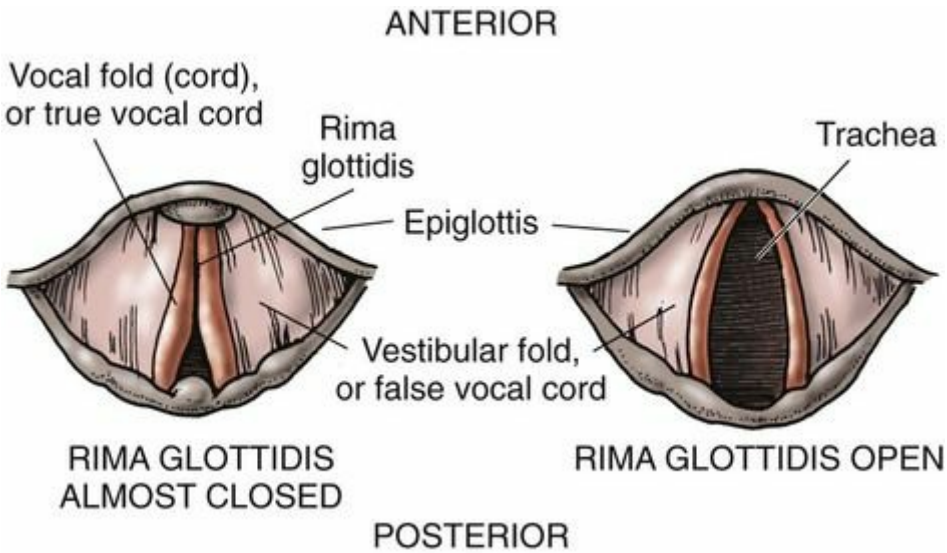

FIG. 27-5 Detail of the glottis (two vocal folds and the intervening space, the rima glottidis).

Lower Respiratory Tract

Airways

The lower airways are the trachea; two mainstem bronchi; lobar, segmental, and subsegmental bronchi; bronchioles; alveolar ducts; and alveoli (Fig. 27-6). The lower respiratory tract *(tracheobronchial tree)* consists of muscle, cartilage, and elastic tissues forming branching tubes. These tubes decrease in size from the trachea to the respiratory bronchioles and allow gases to move to and from the lungs. Gas exchange takes place in the lung tissue between the alveoli and the lung capillaries, not in the airways.

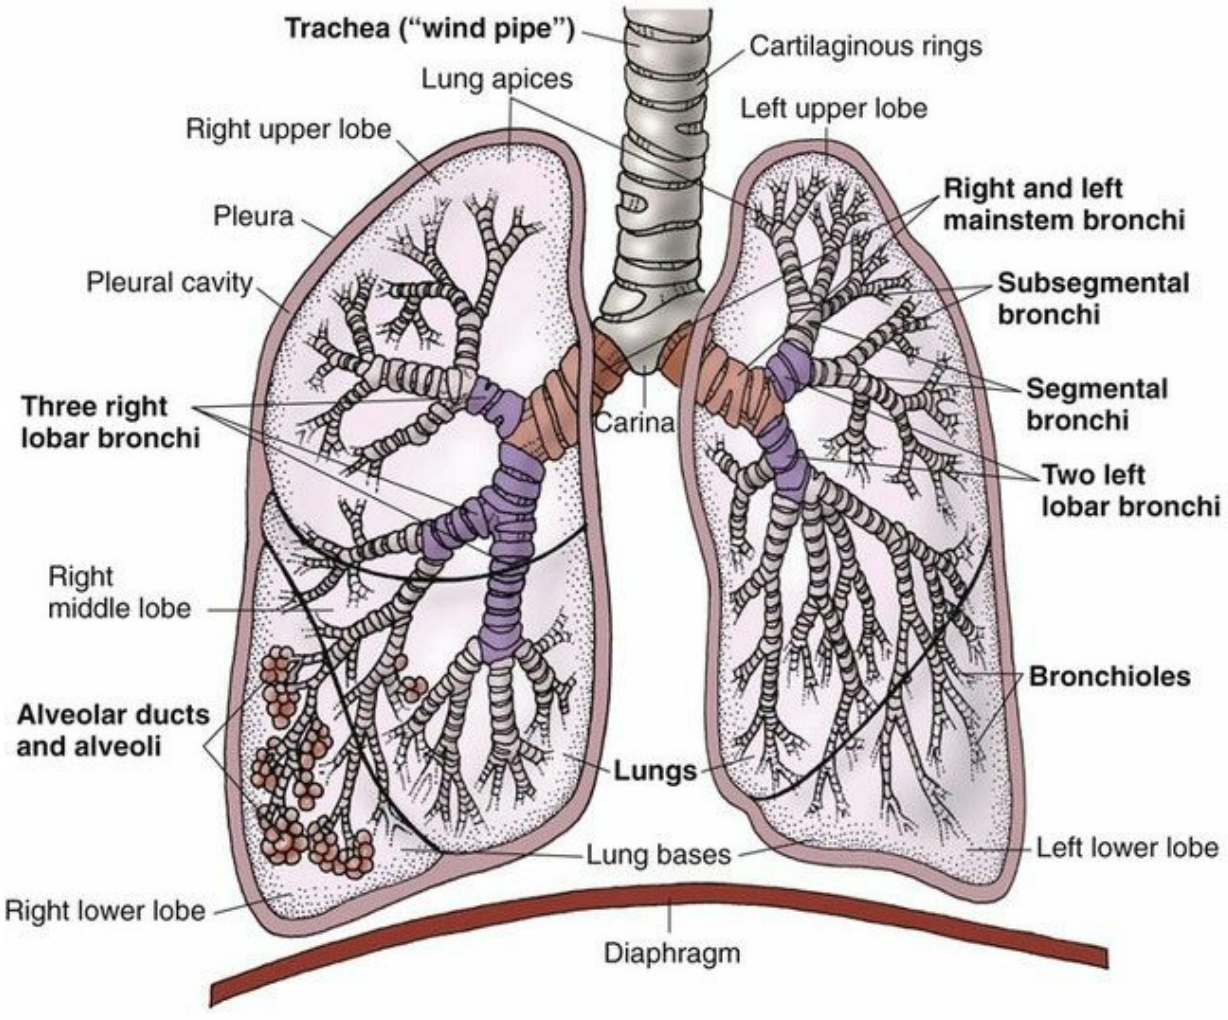

FIG. 27-6 Structures of the lower respiratory tract.

The trachea is in front of the esophagus. It branches into the right and left mainstem bronchi at the *carina* junction. The trachea contains 6 to 10 C-shaped rings of cartilage. The open portion of the C is the back portion of the trachea and shares a wall with the esophagus.

The mainstem bronchi, or primary bronchi, begin at the carina and contain the same tissues as the trachea. The right bronchus is slightly wider, shorter, and more vertical than the left bronchus and can more easily be accidentally intubated when an endotracheal tube is passed. Also, when a foreign object is aspirated from the throat, it usually enters the right bronchus.

The mainstem bronchi branch into the secondary (lobar) bronchi that enter each of the five lobes of the two lungs. Each lobar bronchus branches into progressively smaller divisions. The cartilage rings of these lobar bronchi are complete and resist collapse. The bronchi are lined with a ciliated, mucus-secreting membrane that moves particles away from the lower airways.

The bronchioles branch from the secondary bronchi and divide into smaller and smaller tubes, which are the terminal and respiratory bronchioles (Fig. 27-7). These tubes have a small diameter, have no cartilage, and depend entirely on the elastic recoil of the lung to remain open.

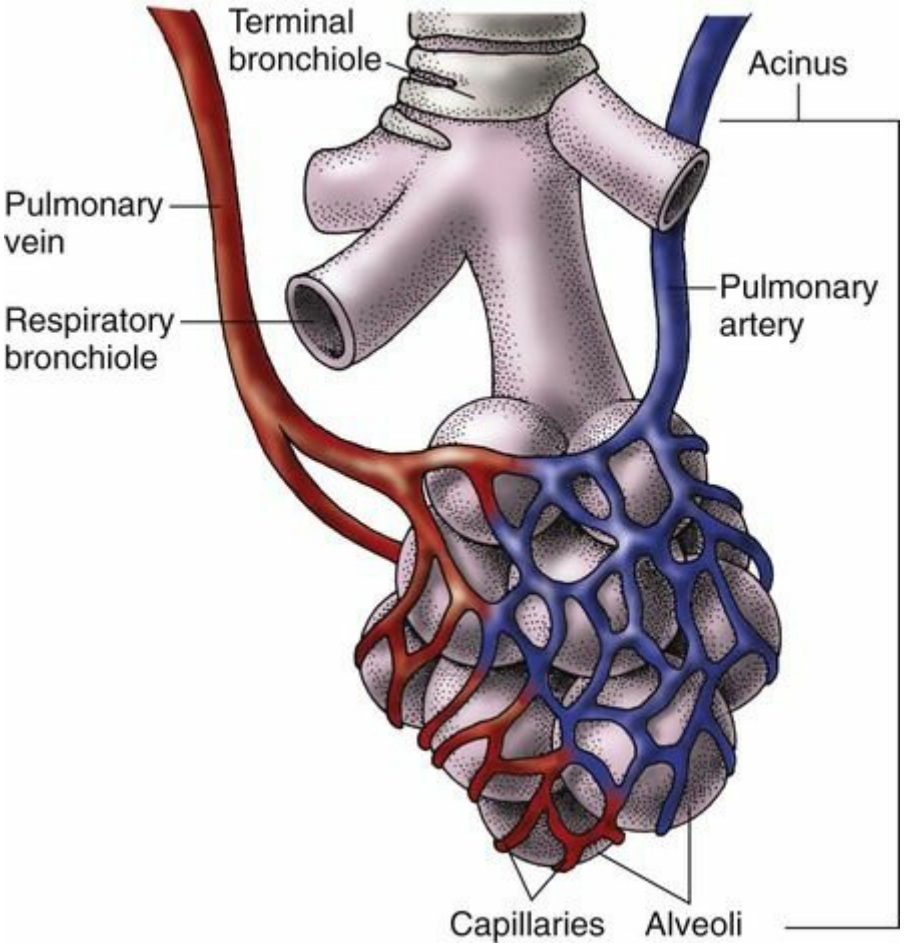

FIG. 27-7 The terminal bronchioles and the acinus.

Alveolar ducts branch from the respiratory bronchioles and resemble a bunch of grapes. Alveolar sacs arise from these ducts and contain groups of alveoli, which are the basic units of gas exchange (see Fig. 27-7). A pair of healthy adult lungs has about 290 million alveoli, which are surrounded by lung capillaries. These numerous small alveoli normally make a large surface area for gas exchange (about the size of a tennis court). **Acinus** is a term for the structural unit consisting of a respiratory bronchiole, an alveolar duct, and an alveolar sac.

The alveolar walls have cells called *type II pneumocytes* that secrete **surfactant,** a fatty protein that reduces surface tension in the alveoli. Without surfactant, **atelectasis** (alveolar collapse) occurs, reducing gas exchange because the alveolar surface area is reduced.

Lungs

The lungs are elastic, cone-shaped organs located in the pleural cavity in the chest. The apex (top) of each lung extends above the clavicle; the base (bottom) of each lung lies just above the diaphragm. The lungs are composed of millions of alveoli and their related ducts, bronchioles, and bronchi. The right lung, which is larger and wider than the left, is divided into three lobes: upper, middle, and lower. The left lung is divided into only two lobes. About 60% to 65% of lung function occurs in the right lung. Any problem with the right lung interferes with gas exchange and perfusion to a greater degree than a problem in the left lung.

The **pleura** is a continuous smooth membrane with two surfaces that totally enclose the lungs. The parietal pleura lines the inside of the chest cavity and the upper surface of the diaphragm. The visceral pleura covers the lung surfaces. These surfaces are lubricated by a thin fluid that allows the surfaces to glide across each other smoothly during breathing.

Blood flow in the lungs occurs through two separate systems: bronchial and pulmonary. The bronchial system carries the blood needed to oxygenate lung tissues. These arteries are part of systemic circulation and do not participate in gas exchange.

The pulmonary circulation is a highly vascular capillary network. Oxygen-poor blood travels from the right ventricle of the heart into the pulmonary artery. This artery eventually branches into arterioles to form capillary networks that are meshed around and through the alveoli—the site of gas exchange (see Fig. 27-7). Freshly oxygenated blood travels from the capillaries to the pulmonary veins and then to the left atrium. From the left atrium, oxygenated blood flows into the left ventricle, where it is pumped throughout the systemic circulation.

Accessory Muscles of Respiration

Breathing occurs through changes in the size of and pressure within the chest cavity. Contraction and relaxation of chest muscles (and the diaphragm) cause changes in the size and pressure of the chest cavity. At times, back and abdominal muscles are used in addition to chest muscles when the work of breathing is increased.

Oxygen Delivery and the Oxygen-Hemoglobin Dissociation Curve

Oxygen delivery to the tissues requires the binding of oxygen to hemoglobin in red blood cells. Each molecule of hemoglobin can bind four oxygen molecules, which fills *(saturates)* all of its binding sites. Each red blood cell normally has hundreds of thousands of hemoglobin molecules. When blood passes through the lung alveoli, where oxygen concentration is the greatest, oxygen diffuses from the alveoli into red blood cells and binds to all those hemoglobin molecules. This oxygen-rich blood then goes to the left side of the heart and is pumped out into systemic circulation. In tissues away from the source of oxygen, hemoglobin unloads **(dissociates)** the oxygen molecules and delivers them to the tissues. Fig. 27-8 shows the oxygen-hemoglobin dissociation curve.

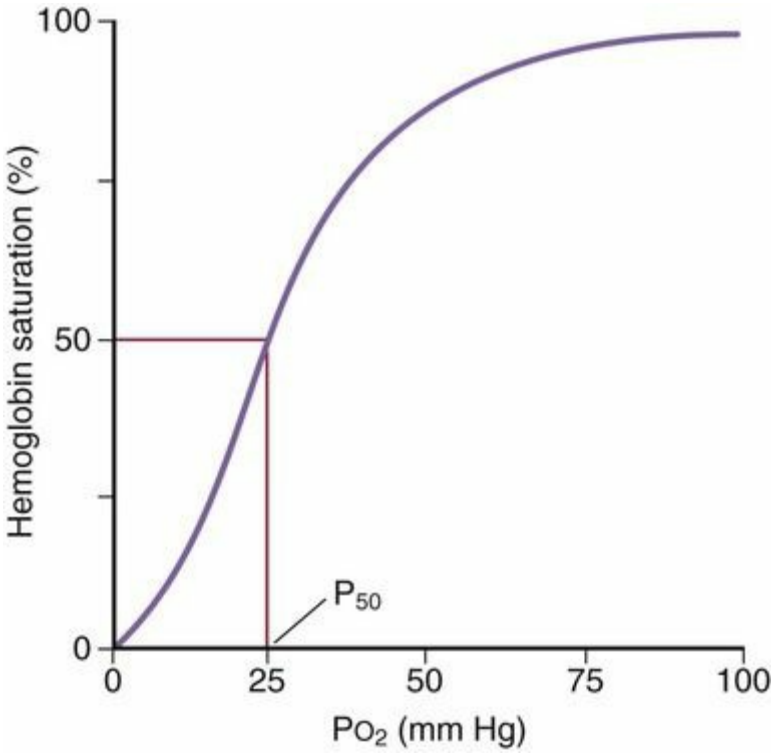

FIG. 27-8 The oxygen-hemoglobin dissociation curve. P_{50}, The partial pressure of O_2 at which hemoglobin is 50% saturated; P_{O_2}, oxygen partial pressure.

Tissue oxygen delivery through dissociation or unloading from hemoglobin is based on tissues' need for oxygen. The curve in Fig. 27-8 shows that the rate of this unloading changes depending on how much oxygen is already in the tissues. When blood perfuses tissues in which the oxygen levels are high, as indicated in the upper right-hand corner of the figure, hemoglobin binds oxygen very tightly and little oxygen is unloaded or dissociated from the hemoglobin into the tissues. This prevents oxygen delivery from being wasted by unloading it where it is not needed. When blood perfuses tissues in which oxygen levels are very low, as indicated in the lower left-hand corner of Fig. 27-8, hemoglobin binds oxygen less tightly and will rapidly and easily unload its remaining oxygen to provide these tissues with needed oxygen. So, how rapidly and easily hemoglobin dissociates oxygen to the tissues changes depending on oxygen need. The S-shaped curve indicates that it is harder for oxygen to dissociate from hemoglobin in tissues that are well-oxygenated and much easier in tissues that are "starving" for oxygen.

The curve in Fig. 27-8 indicates that, on average, 50% of hemoglobin molecules have completely dissociated their oxygen molecules when blood perfuses tissues that have an oxygen tension (concentration) of 26 mm Hg. This is considered a "normal" point at which 50% of hemoglobin molecules are no longer saturated with oxygen.

When the need for oxygen is greater in tissues, this curve shifts to the *right,* which means the hemoglobin will dissociate oxygen faster even when the tissue oxygen tension levels are greater than 26 mm Hg. Conditions that shift the curve to the right include increased tissue temperature, increased tissue carbon dioxide concentration, and decreased tissue pH (acidosis). This means that it is easier for hemoglobin to unload oxygen to these tissues because they need it to support the higher metabolism and is a tissue protection that increases oxygen delivery to the tissues that need it the most.

When tissues have less need of oxygen because they are metabolizing more slowly than usual, the oxygen-hemoglobin dissociation curve shifts to the *left,* which means that the tissue oxygen tension level has to be even *lower* for hemoglobin to unload oxygen. Tissue conditions that cause a shift to the left include decreased tissue temperature, decreased carbon dioxide levels, decreased glucose breakdown products, and a higher tissue pH (alkalosis). This action prevents wasting oxygen delivery to tissues that are not using the oxygen they already have.

A clinical example of how these actions are helpful is one in which a person is having a myocardial infarction (heart attack). Blood flow to the area is reduced and the heart muscle is metabolizing under hypoxic conditions, which creates more carbon dioxide in the tissue and acidosis. As a result, the hemoglobin that reaches this hypoxic tissue unloads more oxygen at a faster rate to prevent ischemia and cardiac muscle cell death. What if this person believes he or she is having indigestion, which can have similar manifestations, and tries to correct the problem by taking in large amounts of bicarbonate-based antacids? The antacids increase the pH in the blood and all tissues, shifting the oxygen-hemoglobin dissociation curve to the left. As a result, the hypoxic cardiac muscle cells receive even less oxygen and more of them die.

Respiratory Changes Associated with Aging

The respiratory changes that occur with aging are described in Chart 27-2. Many additional respiratory changes in older patients result from heredity and a lifetime of exposure to environmental pollutants (e.g., cigarette smoke, bacteria, industrial fumes and irritants).

Chart 27-2 Nursing Focus on the Older Adult

Changes in the Respiratory System Related to Aging

PHYSIOLOGIC CHANGE	NURSING INTERVENTIONS	RATIONALES
Alveoli		
Alveolar surface area decreases. Diffusion capacity decreases. Elastic recoil decreases. Bronchioles and alveolar ducts dilate. Ability to cough decreases. Airways close early.	Encourage vigorous pulmonary hygiene (i.e., encourage patient to turn, cough, and deep breathe) and to use incentive spirometry, especially if he or she is confined to bed or has had surgery.	Potential for mechanical or infectious respiratory complications is increased in these situations.
	Encourage upright position.	The upright position minimizes ventilation-perfusion mismatching.
Lungs		
Residual volume increases. Vital capacity decreases. Efficiency of oxygen and carbon dioxide exchange decreases. Elasticity decreases.	Include inspection, palpation, percussion, and auscultation in lung assessments.	Inspection, palpation, percussion, and auscultation are needed to detect normal age-related changes.
	Help patient actively maintain health and fitness.	Health and fitness help keep losses in respiratory functioning to a minimum.
	Assess patient's respirations for abnormal breathing patterns.	Periodic breathing patterns (e.g., Cheyne-Stokes) can occur.
	Encourage frequent oral hygiene.	Oral hygiene aids in the removal of secretions.
Pharynx and Larynx		
Muscles atrophy. Vocal cords become slack. Laryngeal muscles lose elasticity, and airways lose cartilage.	Have face-to-face conversations with patient when possible.	Patient's voice may be soft and difficult to understand.
Pulmonary Vasculature		
Vascular resistance to blood flow through pulmonary vascular system increases. Pulmonary capillary blood volume decreases. Risk for hypoxia increases.	Assess patient's level of consciousness and cognition.	Patient can become confused during acute respiratory conditions.
Exercise Tolerance		
Body's response to hypoxia and hypercarbia decreases.	Assess for subtle manifestations of hypoxia.	Early assessment helps prevent complications.
Muscle Strength		
Respiratory muscle strength, especially the diaphragm and the intercostals, decreases.	Encourage pulmonary hygiene, and help patient actively maintain health and fitness.	Regular pulmonary hygiene and overall fitness help maintain maximal functioning of the respiratory system and prevent illness.
Susceptibility to Infection		
Effectiveness of the cilia decreases. Immunoglobulin A decreases. Alveolar macrophages are altered.	Encourage pulmonary hygiene, and help patient actively maintain health and fitness.	Regular pulmonary hygiene and overall fitness help maintain maximal functioning of the respiratory system and prevent illness.
Chest Wall		
Anteroposterior diameter increases. Thorax becomes shorter. Progressive kyphoscoliosis occurs. Chest wall compliance (elasticity) decreases. Mobility of chest wall may decrease.	Discuss the normal changes of aging.	Patients may be anxious because they must work harder to breathe.
	Discuss the need for increased rest periods during exercise.	Older patients have less tolerance for exercise.
Osteoporosis is possible, leading to chest wall abnormalities.	Encourage adequate calcium intake (especially during a woman's premenopause phase).	Calcium intake helps prevent osteoporosis by building bone in younger patients.

Respiratory disease is a major cause of illness and chronic disability in older patients. Although respiratory function normally declines with age, there is usually no problem keeping pace with the demands of ordinary activity. The sedentary older adult, however, often feels breathless during exercise (Touhy & Jett, 2014).

It is difficult to determine which respiratory changes in older adults are related to normal aging and which changes are caused by respiratory disease or exposure to pollutants. Age-related changes in the muscles and the cardiac and vascular system also may cause abnormal breathing,

even if the lungs are normal.

NCLEX Examination Challenge

Physiological Integrity

What is the effect of age-related decreased skeletal muscle strength on the effectiveness of gas exchange?

A Reduced gas exchange as a result of decreased alveolar surface

B Reduced gas exchange as a result of longer relaxation of bronchiolar smooth muscles

C Reduced gas exchange as a result of decreased changes in pressures of the chest cavity

D Reduced gas exchange as a result of failure of pulmonary circulation to fully perfuse lung tissue

Assessment Methods

Patient History

Obtaining accurate information from the patient is important for identifying the type and severity of breathing problems. Age, gender, and race can affect the physical and diagnostic findings related to breathing (Jarvis, 2016). Many of the diagnostic studies for respiratory disorders (e.g., pulmonary function tests) use these data for determining predicted normal values. As described in the Health Promotion and Maintenance section, explore the home, community, and workplace for environmental factors that could cause or worsen lung disease. Use this opportunity to teach patients about measures to protect the respiratory system.

Gender Health Considerations

Patient-Centered Care QSEN

Women, especially smokers, have greater bronchial responsiveness (i.e., bronchial hyperreactivity) and larger airways than men. This factor increases the risk for a more rapid decline in lung function as a woman ages, especially in women who were or are smokers.

Cultural Considerations

Patient-Centered Care QSEN

Compared with white people, black people and others with dark skin usually show a lower oxygen saturation (3% to 5% lower) as measured by pulse oximetry; this results from deeper coloration of the nail bed and does not reflect true oxygen status.

Ask patients about their respiratory history (Table 27-1), including smoking history, drug use, travel, and area of residence. Document the smoking history in pack-years.

TABLE 27-1

Important Aspects to Assess in A Respiratory System History

• Smoking history
• Childhood illnesses:
  • Asthma
  • Pneumonia
  • Communicable diseases
  • Hay fever
  • Allergies
  • Eczema
  • Frequent colds
  • Croup
  • Cystic fibrosis
• Adult illnesses:
  • Pneumonia
  • Sinusitis
  • Tuberculosis
  • HIV and AIDS
  • Lung disease such as emphysema and sarcoidosis
  • Diabetes
  • Hypertension
  • Heart disease
	• Influenza, pneumococcal (Pneumovax), and BCG vaccinations
	• Surgeries of the upper or lower respiratory system
	• Injuries to the upper or lower respiratory system
	• Hospitalizations
	• Date of last chest x-ray, pulmonary function test, tuberculin test, or other diagnostic tests and results
	• Recent weight loss
	• Night sweats
	• Sleep disturbances
	• Lung disease and condition of family members
	• Geographic areas of recent travel
	• Occupation and leisure activities

AIDS, Acquired immune deficiency syndrome; *BCG,* bacille Calmette-Guérin; *HIV,* human immune deficiency virus.

Drug use, both prescribed drugs and illicit drugs, can affect lung function. Some drugs affect the lungs when taken systemically. Ask about drugs taken for breathing problems and about drugs taken for other conditions. For example, a cough can be a side effect of some antihypertensive drugs (angiotensin-converting enzyme [ACE] inhibitors and angiotensin receptor blockers [ARBs]). Determine which over-the-counter drugs (e.g., cough syrups, antihistamines, decongestants, inhalants) the patient is using. Also assess the use of complementary and alternative therapies. Ask about past drug use. Some drugs for other conditions can cause permanent changes in lung function. For example, patients may have pulmonary fibrosis if they received bleomycin (Blenoxane) as chemotherapy for cancer or amiodarone (Cordarone) for cardiac problems. Marijuana and illicit drugs, such as cocaine, are often inhaled and can affect lung function.

Allergies to foods, dust, molds, pollen, bee stings, trees, grass, animal dander and saliva, or drugs can affect breathing. Ask the patient to describe specific allergic responses. For example, does he or she wheeze, have trouble breathing, cough, sneeze, or have rhinitis after exposure to the allergen? Has he or she ever been treated for an allergic response? If the patient has allergies, ask about the specific cause, treatment, and the response to treatment.

Nursing Safety Priority QSEN

Action Alert

Document any known allergies and the specific type of allergic response in a prominent place in the patient's medical record.

Travel and geographic area of residence may reveal possible exposure to certain diseases. For example, *histoplasmosis,* a fungal disease caused by inhalation of contaminated dust, is found in the central parts of the United States and Canada. *Coccidioidomycosis* is found mostly in the western and southwestern parts of the United States, in Mexico, and in portions of Central America, as is *Hantavirus*.

Nutrition Status

Assess the patient's diet history and nutrition status to determine allergic reactions to certain foods or preservatives. Manifestations range from rhinitis, chest tightness, weakness, **dyspnea** (shortness of breath), urticaria, and severe wheezing to loss of consciousness. Ask about usual food intake and whether any breathing problems occur with eating.

Family History and Genetic Risk

Obtain a family history to assess for respiratory disorders that have a genetic component, such as cystic fibrosis, some lung cancers, and emphysema. Patients with asthma often have a family history of allergy. Ask about a history of infectious disease, such as tuberculosis, because family members may have similar environmental exposures.

Current Health Problems

Whether the breathing problem is acute or chronic, the current health problem usually includes cough, sputum production, chest pain, and shortness of breath at rest or on exertion. Explore the current illness in chronologic order. Ask about the onset of the problem, how long it lasts, the location of the problem, how often it occurs, whether the problem has become worse over time, what manifestations occur with it, which actions or interventions provide relief and which ones make it worse, and what treatments have been used.

Cough is a sign of lung disease. Ask the patient how long the cough has been present and whether it occurs at a specific time of day (e.g., on awakening in the morning) or in relation to any physical activity. Ask whether the cough produces sputum or is dry, tickling, or hacking.

Sputum production is an important manifestation associated with coughing. Check the color, consistency, odor, and amount of sputum.

Describe the consistency of sputum as thin, thick, watery, or frothy. Smokers with chronic bronchitis have mucoid sputum. Excessive pink, frothy sputum is common with pulmonary edema. Bacterial pneumonia often produces rust-colored sputum, and foul-smelling sputum often occurs with a lung abscess. **Hemoptysis** (blood in the sputum) is most often seen in patients with chronic bronchitis or lung cancer. Grossly bloody sputum may occur with tuberculosis, pulmonary infarction, lung cancer, or lung abscess.

Ask the patient to quantify sputum by describing its volume in terms such as teaspoon, tablespoon, and cup. Normally, the lungs can produce up to 90 mL of sputum per day.

Chest pain can occur with other health problems as well as with lung problems. A detailed description of chest pain helps distinguish its cause. Ask the patient whether the pain is continuous or made worse by coughing, deep breathing, or swallowing. Cardiac pain is usually intense and "crushing" and may radiate to the arm, shoulder, or neck. Pulmonary pain varies depending on the cause and most often feels like something is "rubbing" inside. The pain may appear only on deep inhalation or be present at the end of inhalation and the end of exhalation. Pulmonary pain is not made worse by touching or pressing over the area.

Dyspnea (difficulty in breathing or breathlessness) is a subjective perception and varies among patients (Baker et al., 2013). A patient's feeling of dyspnea may not be consistent with the severity of the problem. Determine the type of onset (slow or abrupt); the duration; relieving factors (position changes, drug use, activity cessation); and whether wheezing or stridor occurs with dyspnea.

Try to quantify dyspnea by asking whether this manifestation interferes with ADLs and, if so, how severely. For example, does dyspnea occur after walking one block or climbing one flight of stairs? Table 27-2 classifies dyspnea with changes in ADL performance.

TABLE 27-2

Correlation of Dyspnea Classification with Performance of ADLs

CLASSIFICATION	ADLs KEY
Class I: No significant restrictions in normal activity. Employable. Dyspnea occurs only on more-than-normal or strenuous exertion.	*4:* No breathlessness, normal.
Class II: Independent in essential ADLs but restricted in some other activities. Dyspneic on climbing stairs or on walking on an incline but not on level walking. Employable only for sedentary job or under special circumstances.	*3:* Satisfactory, mild breathlessness. Complete performance is possible without pause or assistance but not entirely normal.
Class III: Dyspnea commonly occurs during usual activities, such as showering or dressing, but the patient can manage without assistance from others. Not dyspneic at rest; can walk for more than a city block at own pace but cannot keep up with others of own age. May stop to catch breath partway up a flight of stairs. Is probably not employable in any occupation.	*2:* Fair, moderate breathlessness. Must stop during activity. Complete performance is possible without assistance, but performance may be too debilitating or time consuming.
Class IV: Dyspnea produces dependence on help in some essential ADLs such as dressing and bathing. Not usually dyspneic at rest. Dyspneic on minimal exertion; must pause on climbing one flight, walking more than 100 yards, or dressing. Often restricted to home if lives alone. Has minimal or no activities outside of home.	*1:* Poor, marked breathlessness. Incomplete performance; assistance is necessary.
Class V: Entirely restricted to home and often limited to bed or chair. Dyspneic at rest. Dependent on help for most needs.	*0:* Performance not indicated or recommended; too difficult.

ADLs, Activities of daily living.

Ask about **orthopnea,** which is a shortness of breath occurring when lying down and is relieved by sitting up. Assess for paroxysmal nocturnal dyspnea (PND), which awakens the patient from sleep with the feeling of an inability to breathe. PND also occurs while lying flat and is relieved by sitting up. It often occurs with chronic lung disease and left-sided heart failure.

Physical Assessment

Assessment of the Nose and Sinuses

Inspect the patient's external nose for deformities or polyps, and inspect the nares for symmetry of size and shape. To observe the interior nose, ask the patient to tilt the head back for a penlight examination. The experienced nurse may use a nasal speculum and nasopharyngeal mirror for a more thorough inspection of the nasal cavity.

Inspect for color, swelling, drainage, and bleeding. The mucous

membrane of the nose normally appears redder than the oral mucosa, but it is pale, engorged, and bluish gray in patients with allergic rhinitis. Check the nasal septum for bleeding, perforation, or deviation. Septal deviation is common and appears as an S shape, tilting toward one side or the other. A perforated septum is present if the light shines through the perforation into the opposite side; this condition is often found in cocaine users. Nasal polyps are pale, shiny, gelatinous lumps or "bags" attached to the turbinates. Block one naris at a time to check how well air moves through the unblocked side.

NCLEX Examination Challenge

Physiological Integrity

For which problem does the nurse assess the client who cannot breathe through the nose because of a severe septal deviation?
A Dry respiratory tract membranes
B Frequent episodes of tonsillitis
C Development of nasal polyps
D Difficulty swallowing

Assessment of the Pharynx, Trachea, and Larynx

Assessment of the pharynx begins with inspection of the mouth. To examine the posterior pharynx, use a tongue depressor to press down one side of the tongue at a time (to avoid stimulating the gag reflex). As the patient says "ah," observe the rise and fall of the soft palate and inspect for color and symmetry, drainage, edema or ulceration, and enlarged tonsils.

Inspect the neck for symmetry, alignment, masses, swelling, bruises, and the use of accessory neck muscles in breathing. Palpate lymph nodes for size, shape, mobility with palpation, consistency, and tenderness.

Gently palpate the trachea for position, mobility, tenderness, and masses. The trachea should be in the midline. Many lung disorders cause the trachea to deviate from the midline. Tension pneumothorax, large pleural effusion, mediastinal mass, and neck tumors push the trachea *away* from the affected area. Pneumonectomy, fibrosis, and atelectasis pull it *toward* the affected area.

The larynx is usually examined by a specialist with a laryngoscope. An abnormal voice, especially hoarseness, may be heard when there are problems of the larynx.

Assessment of the Lungs and Thorax

Inspection.

Inspect the front and back of the thorax with the patient sitting up. Normal landmarks of the chest front (anterior) and back (posterior) are shown in Fig. 27-9. The patient should be undressed to the waist. Observe the chest, and compare one side with the other. Work from the top (apex) and move downward toward the base, going from side to side, while inspecting for discoloration, scars, lesions, masses, and spinal curvatures. Assessing from side to side allows you to compare the findings for each lung at the same level (Jarvis, 2016).

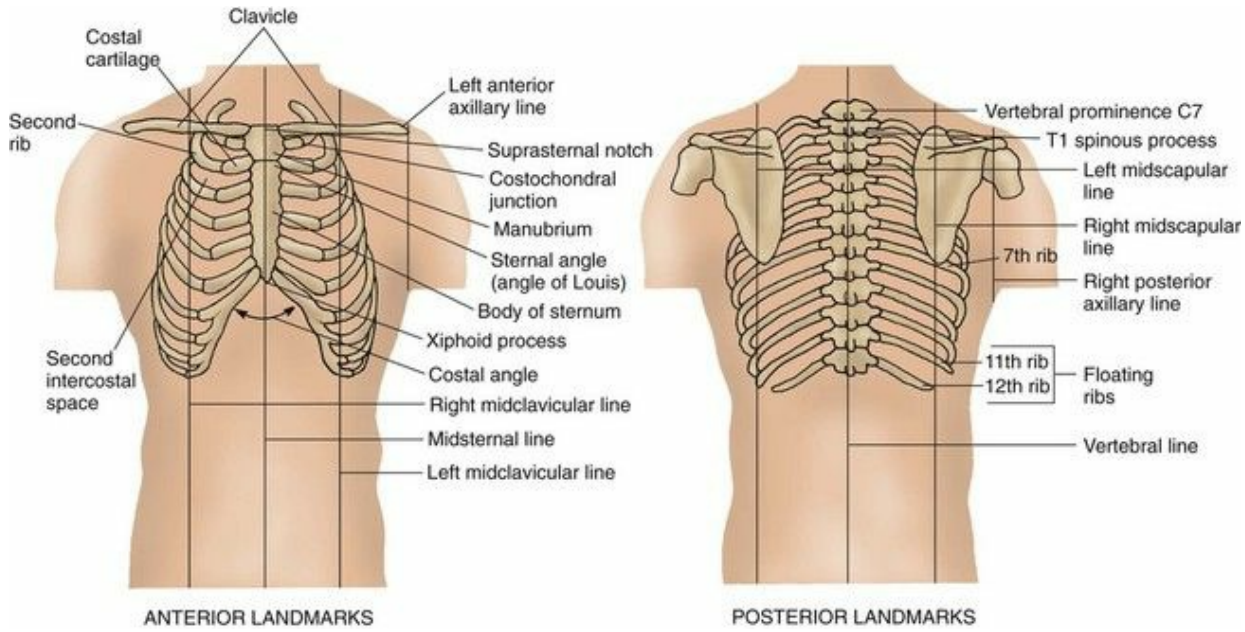

FIG. 27-9 Anterior and posterior chest landmarks.

Observe the rate, rhythm, and depth of inspirations as well as the symmetry of chest movement. Impaired movement or unequal expansion may indicate disease. Observe the type of breathing (e.g., pursed-lip or diaphragmatic breathing) and the use of accessory muscles.

Examine the shape of the patient's chest, and compare the anteroposterior (AP or front-to-back) diameter with the lateral (side-to-side) diameter. This ratio normally is about 1 : 1.5, depending on body build. The ratio increases to 1 : 1 in patients with emphysema, which results in the typical barrel-chest appearance.

Normally the ribs slope downward. Patients with air trapping in the lungs caused by emphysema have ribs that are more horizontal. Observe or palpate the distance between the ribs *(intercostal space).* This distance is usually one finger-breadth (2 centimeters). The distance increases in

disorders that cause air trapping, such as emphysema. Observe for retraction of muscle between the ribs and at the sternal notch. Retractions are areas that get sucked inward when the patient inhales. This does not occur during normal respiratory effort. Retractions may occur when the patient is working hard to inhale around an obstruction.

Palpation.

Palpate the chest after inspection to assess respiratory movement symmetry and observable abnormalities. Palpation also can help identify areas of tenderness and check vocal or tactile **fremitus** (vibration).

Assess chest expansion by placing your thumbs on the patient's spine at the level of the ninth ribs and extending the fingers sideways around the rib cage. As the patient inhales, both sides of the chest should move upward and outward together in one symmetric movement and move your thumbs apart. On exhalation, the thumbs should come back together as they return to the midline. Unequal expansion may be a result of pain, trauma, or air in the pleural cavity. Respiratory lag or slowed movement on one side indicates a pulmonary problem (Jarvis, 2016).

Palpate any abnormalities found on inspection (e.g., masses, lesions, swelling). Also palpate for tenderness, especially if the patient reports pain. **Crepitus** (air trapped in and under the skin, also known as *subcutaneous emphysema*) is felt as a crackling sensation beneath the fingertips. Document this finding and report it to the health care provider when it occurs around a wound site or a tracheostomy site or if a pneumothorax is suspected.

Tactile (vocal) fremitus is a vibration of the chest wall produced when the patient speaks. This vibration can be felt on the chest wall. Fremitus is decreased if the transmission of sound waves from the larynx to the chest wall is slowed, such as when the pleural space is filled with air (pneumothorax) or fluid **(pleural effusion)** or when the bronchus is obstructed. Fremitus is increased with pneumonia and lung abscesses because the increased density of the chest enhances transmission of the vibrations.

Percussion.

Use percussion to assess for pulmonary resonance, the boundaries of organs, and diaphragmatic excursion. Percussion involves tapping the chest wall, which sets the underlying tissues into motion and produces audible sounds (Fig. 27-10). This action produces five different sounds that help determine whether the lung tissue contains air or fluid or is

solid (Table 27-3).

TABLE 27-3

Characteristics of the Five Percussion Notes

NOTE	PITCH	INTENSITY	QUALITY	DURATION	FINDINGS
Resonance	Low	Moderate to loud	Hollow	Long	Resonance is characteristic of normal lung tissue.
Hyperresonance	Higher than resonance	Very loud	Booming	Longer than resonance	Hyperresonance indicates the presence of trapped air, so it is commonly heard over an emphysematous or asthmatic lung and occasionally over a pneumothorax.
Flatness	High	Soft	Extreme dullness	Short	An example location is the sternum. Flatness percussed over the lung fields may indicate a massive pleural effusion.
Dullness	Medium	Medium	Thudlike	Medium	Example locations are over the liver and the kidneys. Dullness can be percussed over an atelectatic lung or a consolidated lung.
Tympany	High	Loud	Musical, drumlike	Short	Examples are the cheek filled with air and the abdomen distended with air. Over the lung, a tympanic note usually indicates a large pneumothorax.

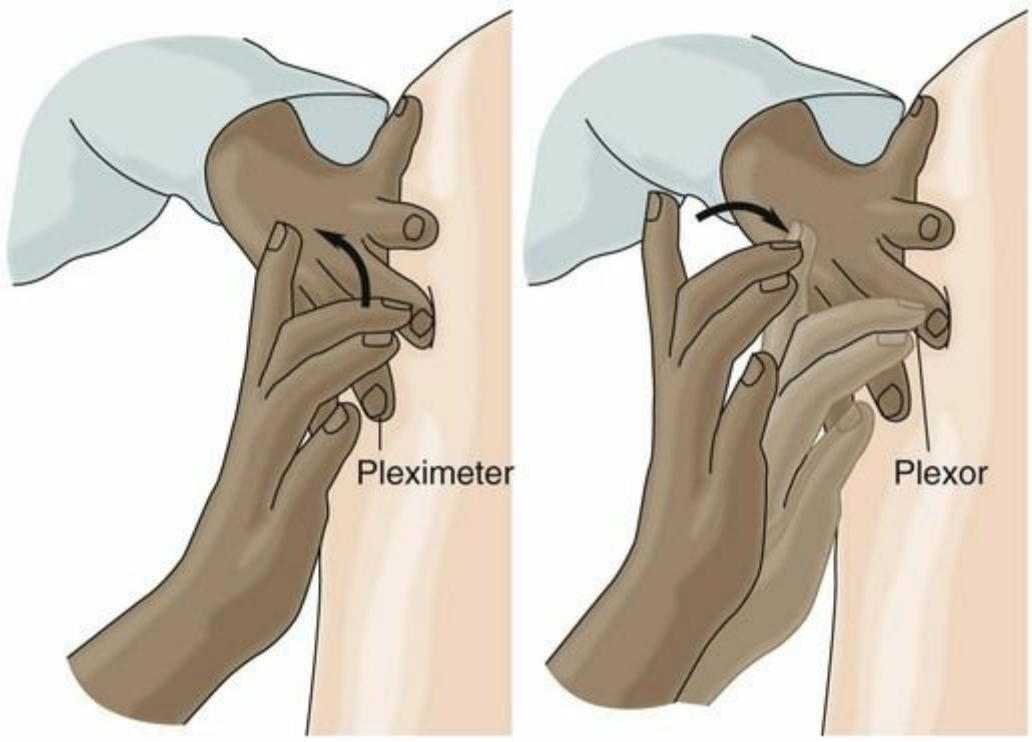

FIG. 27-10 Percussion technique.

Auscultation.

Auscultation includes listening with a stethoscope for normal breath sounds, abnormal *(adventitious)* sounds, and voice sounds. This technique provides information about the flow of air through the trachea and lungs and helps identify fluid, mucus, or obstruction in the respiratory system.

Begin auscultation with the patient sitting in an upright position. With the stethoscope pressed firmly against the chest wall (clothing can muffle

sounds), instruct the patient to breathe slowly and deeply through an open mouth. (Breathing through the nose sets up turbulent sounds that are transmitted to the lungs.) Use a systematic approach, beginning at the lung apices and moving from side to side down through the intercostal spaces to the lung bases (Fig. 27-11). Avoid listening over bony structures. Listen to a full respiratory cycle, noting the quality and intensity of the breath sounds.

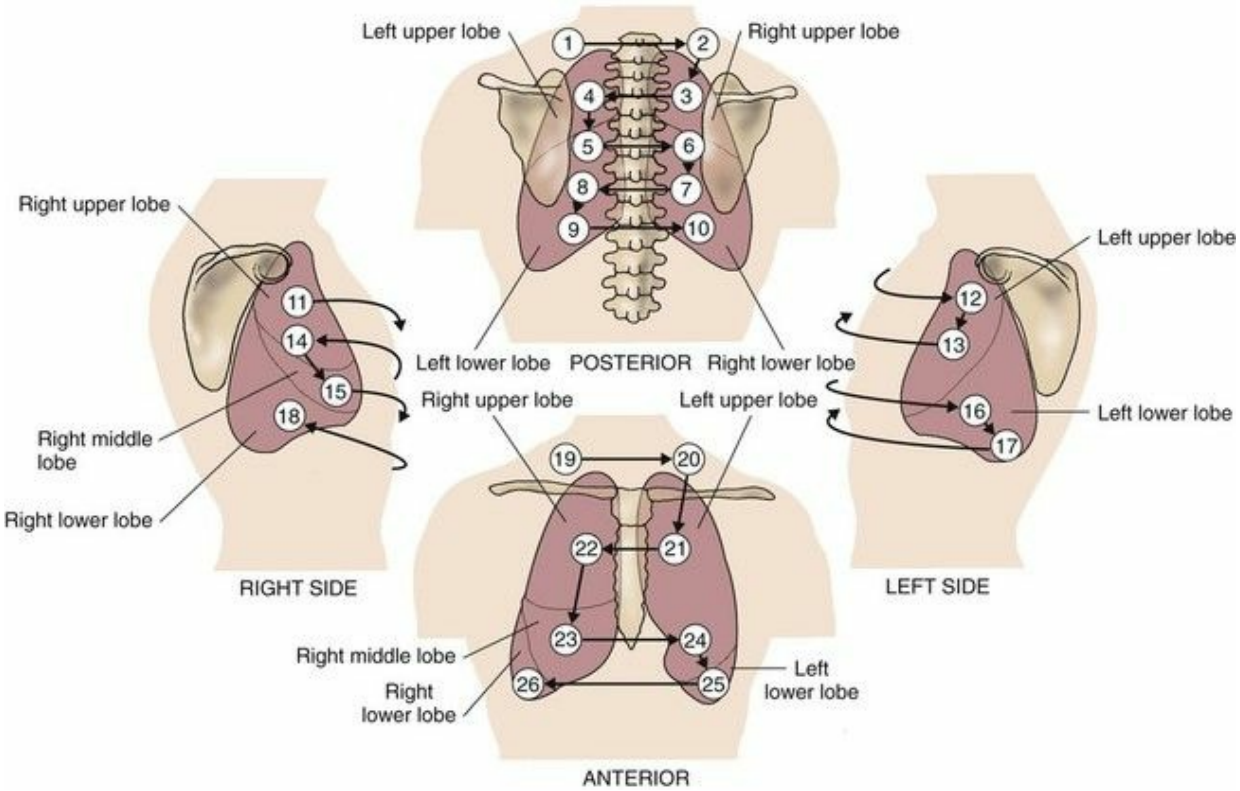

FIG. 27-11 Sequence for percussion and auscultation.

Normal breath sounds are produced as air vibrates while moving through the passages from the larynx to the alveoli. Breath sounds are identified by their location, intensity, pitch, and duration within the respiratory cycle (e.g., early or late inspiration and expiration). Normal breath sounds are known as "bronchial" or "tubular" (harsh hollow sounds heard over the trachea and mainstem bronchi), "bronchovesicular" (heard over the branching bronchi), and "vesicular" (soft rustling sounds heard in lung tissue over small bronchioles) (Table 27-4). Describe these sounds as *normal, increased, diminished,* or *absent.*

TABLE 27-4

Characteristics of Normal Breath Sounds

	PITCH	AMPLITUDE	DURATION	QUALITY	NORMAL LOCATION
Bronchial (tubular, tracheal) 	High	Loud	Inspiration < expiration	Harsh, hollow, tubular, blowing	Trachea and larynx
Bronchovesicular 	Moderate	Moderate	Inspiration = expiration	Mixed	Over major bronchi where fewer alveoli are located; posterior, between scapulae (especially on right); anterior, around upper sternum in first and second intercostal spaces
Vesicular 	Low	Soft	Inspiration > expiration	Rustling, like the sound of the wind in the trees	Over peripheral lung fields where air flows through smaller bronchioles and alveoli

From Jarvis, C. (2016). *Physical examination and health assessment* (7th ed.). St. Louis: Saunders.

Bronchial breath sounds heard at the lung edges are abnormal and occur when the bronchial sounds are transmitted to an area of increased density, such as with atelectasis, tumor, or pneumonia. When heard in an abnormal location, bronchovesicular breath sounds may indicate normal aging or an abnormality such as consolidation and chronic airway disease.

Adventitious sounds are additional breath sounds superimposed on normal sounds, and they indicate pathologic changes in the lung. Table 27-5 describes adventitious sounds: crackle, wheeze, rhonchus, and pleural friction rub. These sounds vary in pitch, intensity, and duration and can occur in any phase of the respiratory cycle. Document exactly what you hear on auscultation.

TABLE 27-5

Characteristics of Adventitious Breath Sounds

ADVENTITIOUS SOUND	CHARACTER	ASSOCIATION
Fine crackles Fine rales High-pitched rales	Popping, discontinuous sounds caused by air moving into previously deflated airways; sounds like hair being rolled between fingers near the ear "Velcro" sounds late in inspiration usually associated with restrictive disorders	Asbestosis Atelectasis Interstitial fibrosis Bronchitis Pneumonia Chronic pulmonary diseases
Coarse crackles Low-pitched crackles	Lower-pitched, coarse, rattling sounds caused by fluid or secretions in large airways; likely to change with coughing or suctioning	Bronchitis Pneumonia Tumors Pulmonary edema
Wheeze	Squeaky, musical, continuous sounds associated with air rushing through narrowed airways; may be heard without a stethoscope Arise from the small airways Usually do not clear with coughing	Inflammation Bronchospasm Edema Secretions Pulmonary vessel engorgement (as in cardiac "asthma")
Rhonchus (rhonchi)	Lower-pitched, coarse, continuous snoring sounds Arise from the large airways	Thick, tenacious secretions Sputum production Obstruction by foreign body Tumors
Pleural friction rub	Loud, rough, grating, scratching sounds caused by the inflamed surfaces of the pleura rubbing together; often associated with pain on deep inspirations Heard in lateral lung fields	Pleurisy Tuberculosis Pulmonary infarction Pneumonia Lung cancer

Voice sounds (vocal resonance) through the normally air-filled lung are muffled and unclear because sound vibrations travel poorly through air. These sounds become louder and more distinct when the sound travels through a solid tissue or liquid. The presence of pneumonia, atelectasis, pleural effusion, tumor, or abscess causes increased vocal resonance.

NCLEX Examination Challenge

Physiological Integrity

When auscultating the client's breath sounds, the nurse hears soft rustling sounds at the lung edges. What is the nurse's best action?

A Listen again with the bell of the stethoscope rather than the diaphragm.
B Ask the client to cough and spit out any collected mucus.
C Document the finding as the only action.
D Notify the health care provider.

Other Indicators of Respiratory Adequacy

Assess other indicators of respiratory adequacy, because gas exchange affects all body systems. Some indicators (e.g., cyanosis) reflect immediate gas exchange and perfusion problems. Other changes (e.g.,

clubbing, weight loss) reflect long-term oxygenation problems.

Skin and mucous membrane changes (e.g., pallor, cyanosis) may indicate inadequate gas exchange and perfusion. Assess the nail beds and the mucous membranes of the oral cavity. Examine the fingers for clubbing (see Fig. 30-10), which indicates long-term hypoxia.

General appearance includes muscle development and general body build. Long-term respiratory problems lead to weight loss and a loss of general muscle mass. Arms and legs may appear thin or poorly muscled. Neck and chest muscles may be hypertrophied, especially in the patient with chronic obstructive pulmonary disease (COPD) (McCance et al., 2014).

Endurance decreases whenever breathing is inadequate for gas exchange. Observe how easily the patient moves and whether he or she is short of breath while resting or becomes short of breath when walking 10 to 20 steps. As the patient speaks, note how often he or she pauses for breath between words.

Psychosocial Assessment

Breathing difficulty from any cause often induces anxiety. The patient may be anxious because of reduced oxygen to the brain or because the sensation of not getting enough air is frightening. The thought of having a serious respiratory problem, such as lung cancer, can also induce anxiety. Encourage the patient to express his or her feelings and fears about manifestations and their possible meaning.

Assess those aspects of the patient's lifestyle that either can affect respiratory function or are affected by it. Some respiratory problems may become worse with stress. Ask about current life stresses and usual coping mechanisms.

Chronic respiratory disease may cause changes in family roles or relationships, social isolation, financial problems, and unemployment or disability. Discuss coping mechanisms to assess the patient's reaction to these stressors and identify strengths. For example, the patient may react to stress with dependence on family members, withdrawal, or failure to adhere to interventions. Assist the patient to identify available support systems.

Clinical Judgment Challenge

Patient-Centered-Care; Teamwork and Collaboration QSEN

The patient is a 68-year-old man who has had shortness of breath

(SOB) for the past 2 to 3 days. His past medical history includes a 40–pack-year smoking history, COPD, and heart failure. He reports that he became concerned when he woke from sleep because he could not breathe. Your physical assessment reveals crackles in the lower lobes bilaterally. His oxygen saturation (Spo_2) is 84% without supplemental oxygen.

1. What are some areas of focus to assess as part of this patient's current history?
2. Whom should you contact and why?
3. What are some factors that may affect gas exchange for this patient?
4. What additional referrals might be appropriate for this patient?

Diagnostic Assessment

Laboratory Assessment

Several laboratory tests (Chart 27-3) are useful in assessing respiratory problems. A red blood cell (RBC) count provides data about the transport of oxygen. Hemoglobin, found in RBCs, transports oxygen to the tissues. A deficiency of hemoglobin could cause hypoxemia.

Chart 27-3 Laboratory Profile

Respiratory Assessment

TEST	NORMAL RANGE FOR ADULTS	SIGNIFICANCE OF ABNORMAL FINDINGS
Blood Studies		
Complete Blood Count		
Red blood cells	*Females:* 4.2-5.4 million/mm^3 *Males:* 4.7-6.1 million/mm^3	*Elevated levels* (polycythemia) often related to the excessive production of erythropoietin in response to a chronic hypoxic state, as in COPD, and from living at a high altitude. *Decreased levels* indicate possible anemia, hemorrhage, or hemolysis.
Hemoglobin, total	*Females:* 12-16 g/dL, or 7.4-9.9 mmol/L *Males:* 14-18 g/dL, or 8.7-11.2 mmol/L	Same as for red blood cells.
Hematocrit	*Females:* 37%-47%, or 0.37-0.47 SI units *Males:* 42%-52%, or 0.42-0.52 SI units	Same as for red blood cells.
White blood cell count (leukocyte count, WBC count)	*Total:* 5,000-10,000/mm^3	*Elevations* indicate possible acute infections or inflammations. *Decreased levels* may indicate an overwhelming infection, an autoimmune disorder, or immunosuppressant therapy.
Differential White Blood Cell (Leukocyte) Count		
Neutrophils	2500-8000/mm^3, or 55%-70% of total	*Elevations* indicate possible acute bacterial infection (pneumonia), COPD, or inflammatory conditions (smoking). *Decreased levels* indicate possible viral disease (influenza).
Eosinophils	50-500/mm^3, or 1%-4% of total	*Elevations* indicate possible COPD, asthma, or allergies. *Decreased levels* indicate pyogenic infections.
Basophils	25-100/mm^3, or 0.5%-1% of total	*Elevations* indicate possible inflammation; seen in chronic sinusitis, hypersensitivity reactions. *Decreased levels* may be seen in an acute infection.
Lymphocytes	1000-4000/mm^3, or 20%-40% of total	*Elevations* indicate possible viral infection, pertussis, and infectious mononucleosis. *Decreased levels* may be seen during corticosteroid therapy.
Monocytes	100-700/mm^3, or 2%-8% of total	*Elevations:* see Lymphocytes; also may indicate active tuberculosis. *Decreased levels:* see Lymphocytes.
Arterial Blood Gases		
Pa_{O_2}	80-100 mm Hg *Older adults:* values may be lower	*Elevations* indicate possible excessive oxygen administration. *Decreased levels* indicate possible COPD, asthma, chronic bronchitis, cancer of the bronchi and lungs, cystic fibrosis, respiratory distress syndrome, anemias, atelectasis, or any other cause of hypoxia.
Pa_{CO_2}	35-45 mm Hg	*Elevations* indicate possible COPD, asthma, pneumonia, anesthesia effects, or use of opioids (respiratory acidosis). *Decreased levels* indicate hyperventilation/respiratory alkalosis.
pH	*Up to 60 yr:* 7.35-7.45 *60-90 yr:* 7.31-7.42 *>90 yr:* 7.26-7.43	*Elevations* indicate metabolic or respiratory alkalosis. *Decreased levels* indicate metabolic or respiratory acidosis.
HCO_3^-	21-28 mEq/L	*Elevations* indicate possible respiratory acidosis as compensation for a primary metabolic alkalosis. *Decreased levels* indicate possible respiratory alkalosis as compensation for a primary metabolic acidosis.
Spo_2	95%-100% *Older adults:* values may be slightly lower	*Decreased levels* indicate possible impaired ability of hemoglobin to release oxygen to tissues.

COPD, Chronic obstructive pulmonary disease; HCO_3^-, bicarbonate ion; $Paco_2$, partial pressure of arterial carbon dioxide; Pao_2, partial pressure of arterial oxygen; Spo_2, peripheral oxygen saturation.

Arterial blood gas (ABG) analysis assesses gas exchange and perfusion as oxygenation (partial pressure of arterial oxygen [Pa_{O_2}]), alveolar ventilation (partial pressure of arterial carbon dioxide [Pa_{CO_2}]), and acid-base balance. Blood gas studies provide information for monitoring treatment results, adjusting oxygen therapy, and evaluating the patient's responses (Barnette & Kautz, 2013). See Chapter 12 for more details on blood gas analysis.

Sputum specimens can help identify organisms or abnormal cells. Sputum culture and sensitivity analyses identify bacterial infection and determine which specific antibiotics will be most effective. Cytologic examination can identify cancer cells. Allergic conditions may be

identified by cytologic testing. Eosinophils and Curschmann's spirals (a mucus form) are often found by cytologic study in patients with allergic asthma.

Imaging Assessment

Chest x-rays with digital images are used for patients with pulmonary problems to evaluate the status of the chest and to provide a baseline for comparison with future changes. These chest x-rays are performed from **posteroanterior** (PA; back to front) and left lateral (LL) positions.

Chest x-rays are used to assess lung pathology such as with pneumonia, atelectasis, pneumothorax, and tumor. They also can detect pleural fluid and the placement of an endotracheal tube or other invasive catheters. A computer-enhanced image can be adjusted to emphasize a specific area. These images have limitations, however, and may appear normal, even when severe chronic bronchitis, asthma, or emphysema is present.

Sinus and facial x-rays are used to assess fluid levels in the sinus cavities to assist in the diagnosis of acute or chronic sinusitis.

Computed tomography (CT) assesses soft tissues with consecutive cross-sectional views of the entire chest. This type of imaging can verify the identity of a suspicious lesion or clot. Often CT scans require a contrast agent injected IV to enhance the visibility of structures such as tumors, blood vessels, and heart chambers. These scans assist in making a diagnosis. Your role in this diagnostic test is to provide information to the patient and to determine whether the patient has any sensitivity to the contrast material. Ask the patient whether he or she has a known allergy to iodine or shellfish. In addition, IV contrast material can be nephrotoxic. Ask about his or her kidney function and whether he or she takes drugs for type 2 diabetes. If the patient usually takes metformin, the drug is stopped at least 24 hours before contrast dye is used and is not restarted until adequate kidney function has been established (see Chapter 64).

Other Noninvasive Diagnostic Assessment

Pulse Oximetry.

Pulse oximetry identifies hemoglobin saturation with oxygen. Usually hemoglobin is almost 100% saturated with oxygen in superficial tissues. The pulse oximeter uses a wave of infrared light and a sensor placed on the patient's finger, toe, nose, earlobe, or forehead (Fig. 27-12). Ideal

normal pulse oximetry values are 95% to 100%. Normal values are a little lower in older patients and in patients with dark skin. To avoid confusion with the Pa_{O_2} values from arterial blood gases, pulse oximetry readings are recorded as the Sp_{O_2} (peripheral arterial oxygen saturation) or Sa_{O_2}.

FIG. 27-12 A typical pulse oximeter.

Pulse oximetry can detect desaturation before manifestations (e.g., dusky skin, pale mucosa, pale or blue nail beds) occur. Causes for low readings include patient movement, hypothermia, decreased peripheral blood flow, ambient light (sunlight, infrared lamps), decreased hemoglobin, edema, and fingernail polish. When patients have any degree of impaired peripheral blood flow, the most accurate place to test oxygen saturation is on the forehead. Covering the sensor with a fingertip cut from a glove or changing its position may help accuracy if too much ambient light is present.

Results lower than 91% (and certainly below 86%) are an emergency and require immediate assessment and treatment. When the Sp_{O_2} is below 85%, body tissues have a difficult time becoming oxygenated. An Sp_{O_2} lower than 70% is usually life threatening, but in some cases, values below 80% may be life threatening. Pulse oximetry is less accurate at lower values.

Capnometry and Capnography.

Capnometry and capnography are methods that measure the amount of

carbon dioxide present in exhaled air, which is an indirect measurement of arterial carbon dioxide levels. These noninvasive tests measure the partial-pressure of end-tidal carbon dioxide ($PETCO_2$, also known as $ETCO_2$) levels in both intubated patients and those breathing spontaneously. With capnometry, the exhaled air sample is tested with a sensor that changes the CO_2 level into a color or number for analysis. With capnography, the CO_2 level is graphed as a specific waveform along with a number. These methods provide information about CO_2 production, pulmonary perfusion, alveolar ventilation, respiratory patterns, ventilator effectiveness, and possible rebreathing of exhaled air (Carlisle, 2014).

The normal value of the partial pressure of end-tidal carbon dioxide ($PETCO_2$) ranges between 20 and 40 mm Hg. Changes in $PETCO_2$ reflect changes in breathing effectiveness and gas exchange. These changes occur before hypoxia can be detected using pulse oximetry. The use of both pulse oximetry and $PETCO_2$ for patients at risk for respiratory problems can provide information to direct early intervention (Carlisle, 2014).

Conditions that increase $PETCO_2$ above normal levels are those that reflect inadequate gas exchange or an increase in cellular metabolism, both of which increase production of carbon dioxide (CO_2). Conditions of inadequate gas exchange include hypoventilation, partial airway obstruction, and rebreathing exhaled air. Conditions that increase cellular metabolism include fever, acidosis, and heavy exercise.

Conditions that decrease $PETCO_2$ below normal levels are those that reflect poor pulmonary ventilation, such as pulmonary embolism, apnea, total airway obstruction, and tracheal extubation. Other causes of low $PETCO_2$ include hyperventilation not based on oxygen need in which CO_2 is "blown off" faster than it is generated in the tissues.

Pulmonary Function Tests.

Pulmonary function tests (PFTs) assess lung function and breathing problems. These tests measure lung volumes and capacities, flow rates, diffusion capacity, gas exchange, airway resistance, and distribution of ventilation. The results are interpreted by comparing the patient's data with expected findings for age, gender, race, height, weight, and smoking status.

The PFTs are useful in screening patients for lung disease even before the onset of manifestations. Repeated testing over time provides data that may be used to guide management (e.g., changes in lung function

can support a decision to continue, change, or discontinue a specific therapy). Testing before surgery may identify patients at risk for lung complications after surgery. The most common reason for performing PFTs is to determine the cause of dyspnea. When performed while the patient exercises, PFTs help determine whether dyspnea is caused by lung or cardiac dysfunction or by muscle weakness.

Patient Preparation.

Explain the purpose of the tests, and advise the patient not to smoke for 6 to 8 hours before testing. Depending on the reasons for testing, bronchodilator drugs may be withheld for 4 to 6 hours before the test. The patient with breathing problems often fears further breathlessness and is anxious before these "breathing" tests. Help reduce anxiety by describing what will happen during and after the testing.

Procedure.

PFTs can be performed at the bedside or in the respiratory laboratory by a respiratory therapist or respiratory technician. The patient is asked to breathe through the mouth only. A nose clip may be used to prevent air from escaping. The patient performs different breathing maneuvers while measurements are obtained. Table 27-6 describes the most commonly used PFTs and their uses.

TABLE 27-6

Characteristics and Purposes of Pulmonary Function Tests

TEST	PURPOSE
FVC (forced vital capacity) records the maximum amount of air that can be exhaled as quickly as possible after maximum inspiration.	Indicates respiratory muscle strength and ventilatory reserve. Reduced in obstructive and restrictive diseases.
FEV_1 *(forced expiratory volume in 1 sec)* records the maximum amount of air that can be exhaled in the first second of expiration.	Is effort dependent and declines normally with age. It is reduced in certain obstructive and restrictive disorders.
FEV_1/FVC is the ratio of expiratory volume in 1 sec to FVC.	Indicates obstruction to airflow. This ratio is the hallmark of obstructive pulmonary disease. It is normal or increased in restrictive disease.
$FEF_{25\%-75\%}$ records the forced expiratory flow over the 25%-75% volume (middle half) of the FVC.	This measure provides a more sensitive index of obstruction in the smaller airways.
FRC (functional residual capacity) is the amount of air remaining in the lungs after normal expiration. FRC test requires use of the helium dilution, nitrogen washout, or body plethysmography technique.	Increased FRC indicates hyperinflation or air trapping, often from obstructive pulmonary disease. FRC is normal or decreased in restrictive pulmonary diseases.
TLC (total lung capacity) is the amount of air in the lungs at the end of maximum inhalation.	Increased TLC indicates air trapping from obstructive pulmonary disease. Decreased TLC indicates restrictive disease.
RV (residual volume) is the amount of air remaining in the lungs at the end of a full, forced exhalation.	RV is increased in obstructive pulmonary disease such as emphysema.
DLCO (diffusion capacity of the lung for carbon monoxide) reflects the surface area of the alveolocapillary membrane. The patient inhales a small amount of CO, holds for 10 sec, and then exhales. The amount inhaled is compared with the amount exhaled.	Is reduced whenever the alveolocapillary membrane is diminished (emphysema, pulmonary hypertension, and pulmonary fibrosis). It is increased with exercise and in conditions such as polycythemia and congestive heart disease.

Follow-up Care.

Because many breathing maneuvers are performed during PFTs, assess the patient for increased dyspnea or bronchospasm after these studies. Document any drugs given during testing.

Exercise Testing.

Exercise increases metabolism and increases gas transport because energy is used. Exercise testing assesses the patient's ability to work and perform ADLs, differentiates reasons for exercise limitation, evaluates disease influence on exercise capacity, and determines whether supplemental oxygen is needed during exercise. These tests are performed on a treadmill or bicycle or by a self-paced 12-minute walking test. Exercise in the patient with normal pulmonary function is limited by circulatory factors, whereas exercise in the pulmonary patient is limited by breathing capacity, gas exchange compromise, or both. Explain exercise testing, and assure the patient that he or she will be closely monitored by trained professionals throughout the test.

Skin Tests.

Skin tests are used with other diagnostic data to identify various infectious diseases (e.g., tuberculosis), viral diseases (e.g., mononucleosis, mumps), and fungal diseases (e.g., coccidioidomycosis, histoplasmosis). Allergies and the status of the immune system also can be checked through skin testing. (See Chapters 17 and 20 for further discussion of these tests.)

Other Invasive Diagnostic Assessment

Endoscopic Examinations.

Endoscopic studies to assess breathing problems include bronchoscopy, laryngoscopy, and mediastinoscopy. With *laryngoscopy,* a tube for visualization is inserted into the larynx to assess the function of the vocal cords, remove foreign bodies caught in the larynx, or obtain tissue samples for biopsy or culture. A *mediastinoscopy* is the insertion of a flexible tube through the chest wall just above the sternum into the area between the lungs. It is performed in the operating room with the patient under general anesthesia to examine for the presence of tumors and to obtain tissue samples for biopsy or culture. Most complications are related to the anesthetic agents and bleeding. The most common procedure is the bronchoscopy.

A **bronchoscopy** is the insertion of a tube in the airways, usually as far

as the secondary bronchi, to view airway structures and obtain tissue samples for biopsy or culture. It is used to diagnose and manage pulmonary diseases. Rigid bronchoscopy usually requires general anesthesia in the operating room. Flexible bronchoscopy can be performed in the intensive care unit (ICU) with low-dose sedation. A flexible bronchoscopy is used to evaluate the airway and to assist with placing or changing an endotracheal tube, collecting specimens, and diagnosing infections. It is often used for lung cancer staging and removal of secretions that are not cleared with normal suctioning procedures. Stents can be placed during bronchoscopy to open up strictures in the trachea and bronchus.

Patient Preparation.

Explain the procedure to the patient, and verify that consent for the procedure was obtained. Expected outcomes, risks, and benefits of the procedure must be discussed with the patient by the health care provider performing the procedure. Document patient allergies. Other tests before the procedure may include a complete blood count, platelet count, prothrombin time, electrolytes, and chest x-ray. The patient should be NPO for 4 to 8 hours before the procedure to reduce the risk for aspiration. Premedication with one of the benzodiazepines may be used to provide both sedation and amnesia. Opioids may also be used.

Nursing Safety Priority QSEN

Critical Rescue

In accordance with The Joint Commission's National Patient Safety Goals, verify the patient's identity with *two* types of identifiers (name and at least one person-specific number such as birth date, medical record number, or Social Security number) before a bronchoscopy.

Benzocaine spray as a topical anesthetic to numb the oropharynx is used cautiously, if at all. This agent may induce a condition called **methemoglobinemia,** which is the conversion of normal hemoglobin to methemoglobin (Wesley, 2014). Methemoglobin is an altered iron state that does not carry oxygen, resulting in tissue hypoxia. Other topical anesthetic sprays, such as lidocaine, appear less likely to induce this problem.

The normal blood level of methemoglobin is less than 1%. When this level increases, tissue gas exchange is reduced. Cyanosis occurs with

methemoglobin levels between 10% and 20%, and death can occur when levels reach 50% to 70%. Suspect methemoglobinemia if a patient becomes cyanotic after receiving a topical anesthetic, if he or she does not respond to supplemental oxygen, and if blood is a characteristic chocolate-brown in color. It can be reversed with oxygen and IV injection of 1% methylene blue (1 to 2 mg/kg).

Nursing Safety Priority QSEN

Critical Rescue

Notify the Rapid Response Team if the patient has any manifestations of methemoglobinemia (cyanosis unresponsive to oxygen therapy, chocolate-brown–colored blood) after the use of benzocaine topical anesthetic.

Procedure.

The procedure can be done in a bronchoscopy suite or at the ICU bedside. The bronchoscope is inserted through either the naris or the oropharynx. Maintain IV access, and continuously monitor the patient's pulse, blood pressure, respiratory rate, and oxygen saturation. Apply supplemental oxygen.

Follow-up Care.

Monitor the patient until the effects of the sedation have resolved and a gag reflex has returned. Continue to monitor vital signs, including oxygen saturation, and assess breath sounds every 15 minutes for the first 2 hours. Also assess for potential complications, including bleeding, infection, or hypoxemia.

Thoracentesis.

Thoracentesis is the needle aspiration of pleural fluid or air from the pleural space for diagnostic or management purposes. Microscopic examination of the pleural fluid helps in making a diagnosis. Pleural fluid may be drained to relieve blood vessel or lung compression and the respiratory distress caused by cancer, empyema, pleurisy, or tuberculosis. Drugs can also be instilled into the pleural space during thoracentesis.

Patient Preparation.

Patient preparation is essential before thoracentesis to ensure cooperation during the procedure and to prevent complications. Tell the

patient to expect a stinging sensation from the local anesthetic agent and a feeling of pressure when the needle is pushed through the posterior chest. Stress the importance of not moving, coughing, or deep breathing during the procedure to avoid puncture of the pleura or lung.

Ask the patient about any allergy to local anesthetic agents. Verify that the patient has signed an informed consent. The entire chest or back is exposed, and the hair on the skin over the aspiration site is clipped if necessary. The site depends on the volume and location of the fluid.

Fig. 27-13 shows the best position for thoracentesis, which widens the spaces between the ribs and permits easy access to the pleural fluid. Properly position and physically support the patient during the procedure. Use pillows to make the patient comfortable and to provide physical support. When the sitting position is used for the procedure, stand in front of the patient to prevent the table from moving and the patient from falling.

FIG. 27-13 Position for thoracentesis.

Procedure.

Thoracentesis is often performed at the bedside by a nurse practitioner or a physician, although CT or ultrasound may be used to guide it. The person performing the procedure and any assistants wear goggles and masks to prevent accidental eye or oral splash exposure to the pleural fluid. After the skin is prepped, a local anesthetic is injected into the selected site. Keep the patient informed of the procedure while observing

for shock, pain, nausea, pallor, diaphoresis, cyanosis, tachypnea, and dyspnea.

The short 18- to 25-gauge thoracentesis needle (with an attached syringe) is advanced into the pleural space. Fluid in the pleural space is slowly aspirated with gentle suction. A vacuum collection bottle may be needed to remove larger volumes of fluid. To prevent re-expansion pulmonary edema, usually no more than 1000 mL of fluid is removed at one time. If a biopsy is performed, a second, larger needle with a cutting edge and collection chamber is used. After the needle is withdrawn, pressure is applied to the puncture site and a sterile dressing is applied. In some cases, pigtail drain catheters may be left in place to a waterseal drainage system, rather than doing a thoracentesis aspiration on a recurring basis.

Follow-up Care.

After thoracentesis, a chest x-ray is performed to rule out possible pneumothorax and **mediastinal shift** (shift of central thoracic structures toward one side). Monitor vital signs, and listen to the lungs for absent or reduced sounds on the affected side. Check the puncture site and dressing for leakage or bleeding. Assess for complications, such as reaccumulation of fluid in the pleural space, subcutaneous emphysema, infection, and tension pneumothorax. Urge the patient to breathe deeply to promote lung expansion. Document the procedure, including the patient's response; the volume and character of the fluid removed; any specimens sent to the laboratory; the location of the puncture site; and respiratory assessment findings before, during, and after the procedure.

Teach the patient about the manifestations of a **pneumothorax** (partial or complete collapse of the lung), which can occur within the first 24 hours after a thoracentesis. Manifestations include:

- Pain on the affected side that is worse at the end of inhalation and the end of exhalation
- Rapid heart rate
- Rapid, shallow respirations
- A feeling of air hunger
- Prominence of the affected side that does not move in and out with respiratory effort
- Trachea slanted more to the unaffected side instead of being in the center of the neck
- New onset of “nagging” cough
- Cyanosis

Instruct the patient to go to the nearest emergency department

immediately if these manifestations occur.

Lung Biopsy.

A lung biopsy is performed to obtain tissue for histologic analysis, culture, or cytologic examination. The samples are used to make a definite diagnosis of inflammation, cancer, infection, or lung disease. There are several types of lung biopsies. The site and extent of the lesion determine which one is used. Transbronchial biopsy (TBB) and transbronchial needle aspiration (TBNA) are performed during bronchoscopy. Transthoracic needle aspiration is performed through the skin (percutaneous) for areas that cannot be reached by bronchoscopy.

Patient Preparation.

The patient may worry about the outcome of the biopsy and may associate the term *biopsy* with *cancer.* Explain what to expect before and after the procedure, and explore the patient's feelings. An analgesic or sedative may be prescribed before the procedure. Inform the patient undergoing percutaneous biopsy that discomfort is reduced with a local anesthetic agent but that pressure may be felt during needle insertion and tissue aspiration. Open lung biopsy is performed in the operating room with the patient under general anesthesia, and the usual preparations before surgery apply (see Chapter 14).

Procedure.

Percutaneous lung biopsy is usually performed in the radiology department after an informed consent has been obtained. Fluoroscopy or CT is often used to visualize the area and guide the procedure. The patient is usually placed in the side-lying position, depending on the location of the lesion. The skin is cleansed with an antiseptic agent, and a local anesthetic is given. Under sterile conditions, a spinal-type needle is inserted through the skin into the desired area and tissue is obtained for microscopic examination. Apply a dressing after the procedure. A CT scan or chest x-ray must follow the biopsy to confirm there is no pneumothorax.

An open lung biopsy is performed in the operating room. The patient undergoes a thoracotomy in which lung tissue is exposed and appropriate tissue specimens are taken. A chest tube is placed to remove air and fluid so the lung can re-inflate, and then the chest is closed.

Follow-up Care.

Monitor the patient's vital signs and breath sounds at least every 4 hours

for 24 hours, and assess for signs of respiratory distress (e.g., dyspnea, pallor, diaphoresis, tachypnea). Pneumothorax is a serious complication of needle biopsy and open lung biopsy. Report reduced or absent breath sounds immediately. Monitor for hemoptysis (which may be scant and transient) or, in rare cases, for frank bleeding from vascular or lung trauma.

Clinical Judgment Challenge

Safety; Patient-Centered Care; Teamwork and Collaboration

QSEN

Your patient is the 68-year-old man from the previous *Clinical Judgment Challenge* who had shortness of breath (SOB) for the past 2 to 3 days. His clinical condition deteriorated further, requiring intubation. The health care provider orders a CT scan of the chest.

1. What are your responsibilities when preparing the patient for the CT scan?
2. Why is it important to monitor your patient using capnography?
3. A large fluid collection on the left side is found during the CT scan, and a thoracentesis is planned. What are your responsibilities in preparing for and assisting with this procedure?
4. Your patient was extubated after the left thoracentesis. Within 12 hours he again develops respiratory distress, decreased breath sounds, and a trachea that appears deviated to the right. What is your assessment?

Nursing Concepts and Clinical Judgment Review

What might you NOTICE in a patient with adequate gas exchange and tissue perfusion related to respiratory function?

Vital signs:

- Respiratory rate and heart rate within normal range
- Oxygen saturation of 95% or higher

Physical assessment:

- Able to speak a sentence of 12 words without stopping for breath
- Able to walk and talk without stopping for breath
- Skin color normal (no cyanosis or pallor)
- Oral mucous membrane and nail beds pink with rapid capillary refill
- Fingertips and nails normal shape, no clubbing
- Anterior to posterior diameter of chest about two-thirds the size of the lateral diameter

- Space between each rib no larger than the breadth of the patient's finger
- Usually breathes in through the nose and out through the mouth or nose
- Breathing quiet
- Air movement heard (with a stethoscope) in all lobes of both lungs
- Sputum production minimal, clear or white
- Muscle development even with no muscle loss on arms and legs
- Weight proportionate to height; does not appear underweight

Psychological assessment:

- Oriented and not confused
- Energy level good, can engage in desired work, recreational, and personal activities

Laboratory assessment:

- Red blood cell, hemoglobin, hematocrit, and white blood cell levels within normal limits for age and gender

Health Promotion and Maintenance

- Assess any patient's geographic, home, occupational, and recreational exposure to inhalation irritants. **Patient-Centered Care** QSEN
- Encourage all people to use masks and adequate ventilation when exposed to inhalation irritants.
- Promote smoking cessation for people who smoke. **Patient-Centered Care** QSEN
- Support the person who chooses to stop smoking by assisting him or her to decide about drug therapy for smoking cessation and finding an appropriate smoking-cessation program. **Patient-Centered Care** QSEN

Psychosocial Integrity

- Allow the patient the opportunity to express fear or anxiety about tests of respiratory function or about a potential change in respiratory function. **Patient-Centered Care** QSEN
- Teach patients and family members about what to expect during tests and procedures to assess respiratory function and respiratory disease. **Patient-Centered Care** QSEN

Physiological Integrity

- Ask the patient about respiratory problems in any other members of the family, because some problems have a genetic component. **Patient-Centered Care** QSEN
- Ask the patient about current and past drug use (prescribed, over-the-counter, and illicit), and evaluate drug use for potential lung damage.
- Calculate the pack-year smoking history for the patient who smokes or who has ever smoked cigarettes. **Patient-Centered Care** QSEN
- Use concepts of anatomy and appropriate psychomotor skills to apply respiratory assessment techniques correctly.
- Distinguish between normal and abnormal (adventitious) breath sounds.
- Interpret arterial blood gas values to assess the patient's respiratory status.
- Assess the degree to which breathing problems interfere with the patient's ability to perform ADLs. **Patient-Centered Care** QSEN

- Document any known specific allergies that have respiratory manifestations. **Patient-Centered Care** QSEN
- Assess the airway and breathing effectiveness for any patient who has shortness of breath or any change in mental status. **Evidence-Based Practice** QSEN
- Assess the patient's respiratory status every 15 minutes for at least the first 2 hours after undergoing an endoscopic test for respiratory disorders. **Patient-Centered Care** QSEN
- Explain nursing care needs for the patient after bronchoscopy or open lung biopsy.

CHAPTER 28

Care of Patients Requiring Oxygen Therapy or Tracheostomy

Harry Rees

PRIORITY CONCEPTS

- Gas Exchange
- Perfusion

Learning Outcomes

Safe and Effective Care Environment

1. Act as a patient advocate for patients receiving oxygen or who have tracheostomies.
2. Protect the patient receiving oxygen or who has a tracheostomy from injury and infection.

Health Promotion and Maintenance

3. Teach the patient and family how to avoid injury and complications related to oxygen therapy or tracheostomy in the home.

Psychosocial Integrity

4. Reduce the psychological impact of oxygen therapy or tracheostomy for the patient and family.
5. Work with other members of the health care team to ensure that patient values, preferences, and expressed needs related to a tracheostomy and oxygen therapy are respected.

Physiological Integrity

6. Apply knowledge of anatomy and physiology to perform a focused respiratory assessment and re-assessment to determine adequacy of gas exchange, oxygenation, and tissue perfusion for the patient receiving oxygen therapy or who has a tracheostomy.
7. Use appropriate techniques to administer prescribed oxygen therapy.
8. Use appropriate techniques to provide tracheostomy care.

http://evolve.elsevier.com/Iggy/

Oxygen (O_2) is an essential element that serves as a nutrient for all cells to live and perform their specific jobs. For cells to receive oxygen, gas exchange must occur first in the lungs and then at the tissue level with perfusion of oxygenated blood. These processes rely on three systems—the respiratory system, the cardiovascular system, and the hematologic system—to work together to ensure sufficient oxygen for cell survival and proper function (see Fig. 27-1). Gas exchange with oxygenation and tissue perfusion needs can go unmet as a result of many problems with the lungs. When a respiratory problem interferes with adequate gas exchange, both the cardiac system and the hematologic system adjust (compensate) and work harder to restore balance and maintain oxygenation and tissue perfusion (Fig. 28-1) (McCance et al., 2014). Oxygen therapy through various delivery systems, including tracheostomy, can help improve gas exchange and tissue perfusion and reduce the burden on the cardiovascular and hematologic systems.

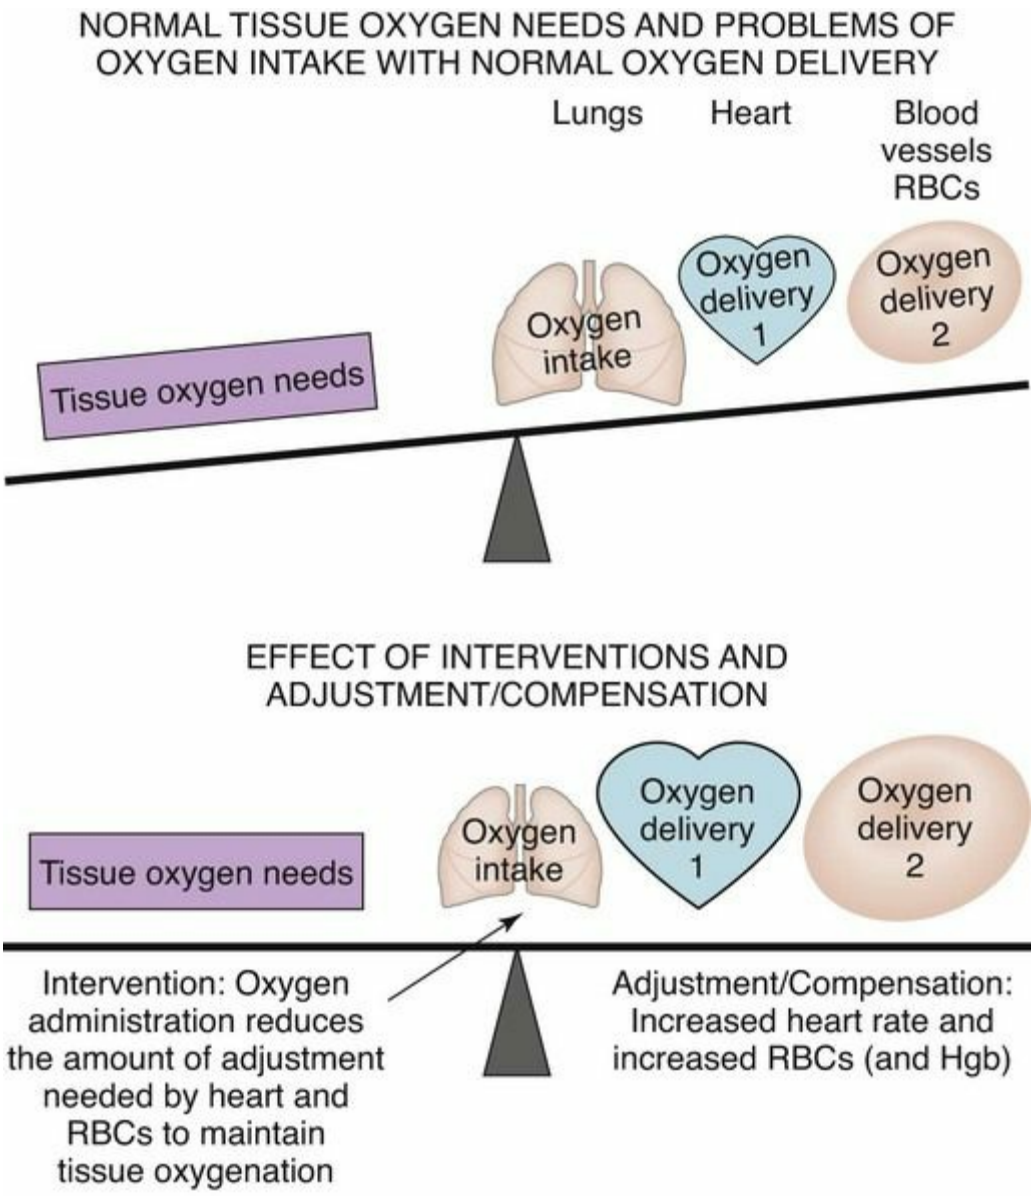

FIG. 28-1 Restoration of adequate oxygenation and tissue perfusion by oxygen delivery adjustments and oxygen therapy when respiratory problems interfere with meeting tissue oxygen needs. *Hgb,* Hemoglobin, *RBCs,* red blood cells.

Oxygen Therapy

Oxygen (O_2) is a gas used as a drug for relief of **hypoxemia** (low levels of oxygen in the blood) and **hypoxia** (decreased tissue oxygenation). The oxygen content of atmospheric air is about 21%. Oxygen therapy is prescribed for both acute and chronic breathing problems when the oxygen needs of the patient cannot be met by atmospheric or "room air" alone. Indications for use include decreased partial pressure of arterial oxygen (Pa_{O_2}) levels or decreased arterial oxygen saturation (Sa_{O_2}). Non-respiratory conditions, such as heart failure, sepsis, fever, some poisons, and decreased hemoglobin levels or poor hemoglobin quality, can affect gas exchange and oxygenation and are indications for oxygen therapy. These conditions increase oxygen demand, decrease the oxygen-carrying capability of the blood, or decrease cardiac output.

The purpose of oxygen therapy is to use the lowest *fraction of inspired oxygen (Fi_{O_2})* to have an acceptable blood oxygen level without causing harmful side effects. *Although oxygen improves the Pa_{O_2} level, it does not cure the problem or stop the disease process.* Most patients with hypoxia require an oxygen flow of 2 to 4 L/min via nasal cannula or up to 40% via Venturi mask to achieve an oxygen saturation of at least 95%. For a patient who is hypoxemic and has chronic **hypercarbia** (increased partial pressure of arterial carbon dioxide [Pa_{CO_2}] levels), the Fi_{O_2} delivered should be titrated to correct the hypoxemia to achieve generally acceptable oxygenation saturations in the range of 88% to 92% (Abdo & Heunks, 2012).

❖ Patient-Centered Collaborative Care

◆ Assessment

Arterial blood gas (ABG) analysis is the best measure for determining the need for oxygen therapy and for evaluating its effects. Oxygen need is also determined by noninvasive monitoring, such as pulse oximetry and capnography (Carlisle, 2014).

◆ Interventions

Before starting oxygen therapy and while caring for a patient receiving oxygen therapy, you must be knowledgeable about oxygen hazards and complications. Know the rationale and the expected outcome related to oxygen therapy for each patient receiving oxygen. Chart 28-1 lists best practices for patients using oxygen therapy.

Chart 28-1 Best Practice for Patient Safety & Quality Care QSEN

Oxygen Therapy

- Check the health care provider's prescription with the type of delivery system and liter flow or percentage of oxygen actually in use.
- Obtain a prescription for humidification if oxygen is being delivered at 4 L/min or more.
- Be sure the oxygen and humidification equipment are functioning properly.
- Check the skin around the patient's ears, back of the neck, and face every 4 to 8 hours for pressure points and signs of irritation.
- Ensure that mouth care is provided every 8 hours and as needed; assess nasal and oral mucous membranes for cracks or other signs of dryness.
- Pad the elastic band and change its position frequently to prevent skin breakdown.
- Pad tubing in areas that put pressure on the skin.
- Cleanse the cannula or mask by rinsing with clear, warm water every 4 to 8 hours or as needed.
- Cleanse skin under the tubing, straps, and mask every 4 to 8 hours or as needed.
- Lubricate the patient's nostrils, face, and lips with non-petroleum cream to relieve the drying effects of oxygen.
- Position the tubing so it does not pull on the patient's face, nose, or artificial airway.
- Ensure that there is no smoking and that no candles or matches are lit in the immediate area.
- Assess and document the patient's response to oxygen therapy.
- Ensure that the patient has an adequate oxygen source during any periods of transport.
- Provide the patient with ongoing teaching and reassurance to enhance his or her adherence with oxygen therapy.

Hazards and Complications of Oxygen Therapy

Combustion.

Oxygen itself does not burn, but it enhances combustion so that fire burns better in the presence of oxygen. For example, when the oxygen content of the air around a lighted cigarette is nearly 50%, the entire cigarette flames up and can catch items nearby on fire (Murabit &

Tredget, 2012). Open fires, even small ones like candles or cigarettes, should not be in the same room during oxygen therapy. Take precautions during oxygen delivery, including posting a sign on the door of the patient's room. Smoking is prohibited in the patient's room, including at home, when oxygen is in use.

All electrical equipment in rooms where oxygen is in use must have grounded plugs and be plugged into grounded outlets to prevent fires from electrical arcing sparks. Frayed cords must be repaired because they can cause a spark that can ignite a flame. Flammable solutions (containing high concentrations of alcohol or oil) are not used in rooms in which oxygen is in use. (This does not include alcohol-based hand rubs.)

Oxygen-Induced Hypoventilation.

For many years, oxygen was thought to induce hypoventilation in the patient with chronic lung disease who also had carbon dioxide retention **(hypercarbia)**. As a result, nurses and physicians were reluctant to administer oxygen to these hypoxic patients, leading to serious problems and even deaths related to inadequate gas exchange and perfusion. More recent research disproves the hypoxic drive theory and has found that patients with chronic lung disease are at risk for oxygen-induced hypercapnia but not for severely reduced respiratory effort (Makic et al., 2013). Therefore oxygen therapy is prescribed at the lowest liter flow needed to manage hypoxemia (Mac Sweeney et al., 2011). A system that delivers more precise oxygen levels (e.g., a Venturi mask) is preferred. However, some patients with chronic lung disease may not tolerate a facemask. Monitor the patient's response to therapy closely to ensure adequate gas exchange and correction of hypoxemia. Parameters to monitor include the level of consciousness, respiratory pattern and rate, and pulse oximetry. Remember, untreated or inadequately treated hypoxemia is a threat to life for any person with a breathing problem.

Oxygen Toxicity.

Oxygen toxicity is related to the concentration of oxygen delivered, duration of oxygen therapy, and degree of lung disease present. In general, an oxygen level greater than 50% given continuously for more than 24 to 48 hours may damage the lungs.

The causes and manifestations of lung injury from oxygen toxicity are the same as those for acute respiratory distress syndrome (ARDS) (see Chapter 32). Initial problems include dyspnea, nonproductive cough, chest pain beneath the sternum, GI upset, and crackles on auscultation.

As exposure to high levels of oxygen continues, the problems become more severe with decreased vital capacity, decreased compliance, and hypoxemia. With prolonged exposure to high oxygen levels, atelectasis, pulmonary edema, hemorrhage, and hyaline membrane formation may result. Surviving this critical condition depends on correcting the underlying disease process and decreasing the oxygen amount delivered.

The toxic effects of oxygen are difficult to manage, making prevention a priority. The lowest level of oxygen needed to maintain gas exchange and oxygenation and prevent oxygen toxicity is prescribed. Closely monitor arterial blood gases (ABGs) during oxygen therapy, and notify the health care provider when Pa_{O_2} levels become greater than 90 mm Hg. Also monitor the prescribed oxygen level and length of therapy to identify patients at higher risk. High oxygen levels are avoided unless absolutely necessary. The use of noninvasive positive airway pressure techniques with oxygen or the use of mechanical ventilation (see Chapter 32) may reduce the amount of oxygen needed. As soon as the patient's condition allows, the prescribed amount of oxygen is decreased.

Absorptive Atelectasis.

Normally, nitrogen in the air maintains patent airways and alveoli. Making up 79% of room air, nitrogen prevents alveolar collapse. When high oxygen levels are delivered, nitrogen is diluted, oxygen diffuses from the alveoli into the blood, and the alveoli collapse. Collapsed alveoli cause atelectasis (called *absorptive atelectasis*), which is detected as crackles and decreased breath sounds on auscultation.

Nursing Safety Priority QSEN

Action Alert

Monitor the patient receiving high levels of oxygen closely for indications of absorptive atelectasis (new onset of crackles and decreased breath sounds) every 1 to 2 hours when oxygen therapy is started and as often as needed thereafter.

Drying of the Mucous Membranes.

When the prescribed oxygen flow rate is higher than 4 L/min, humidify the delivery system (Fig. 28-2). Ensure that oxygen bubbles through the water in the humidifier.

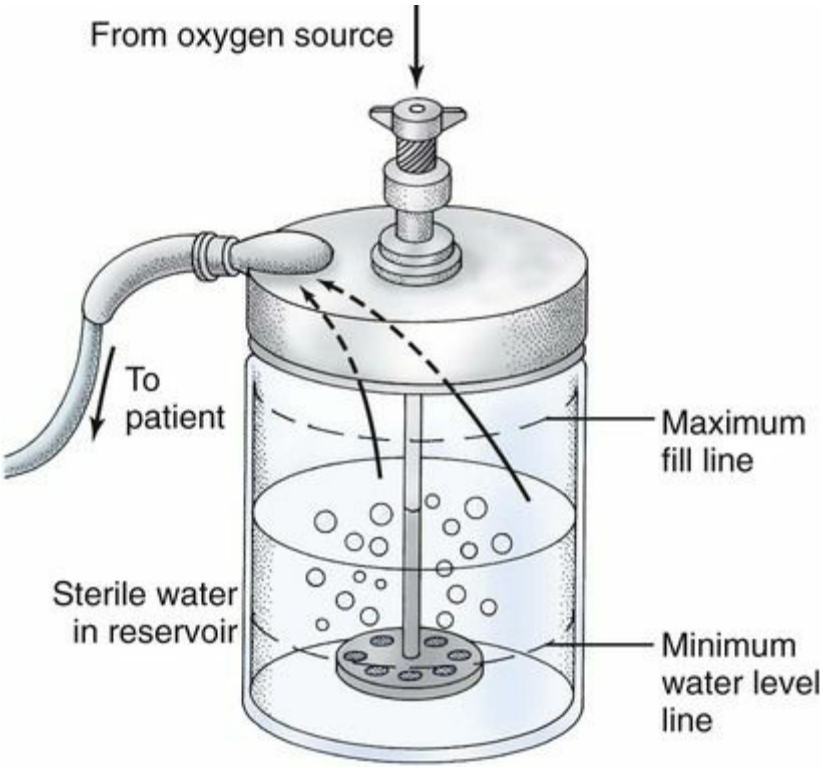

FIG. 28-2 A bubble humidifier bottle used with oxygen therapy.

Oxygen can also be humidified via a large-volume jet nebulizer in mist form (aerosol). A heated nebulizer raises the humidity even more and is used for oxygen delivery through an artificial airway. Usually the upper airway passages warm the air during breathing, but these passages are bypassed with an artificial airway, such as an endotracheal tube.

For the patient to receive properly humidified oxygen, the humidifier or nebulizer must have a sufficient amount of sterile water and the flow rate must be adequate. Condensation often forms in the tubing. Remove this condensation as it collects by disconnecting the tubing and emptying the water. Minimize the time the tubing is disconnected because the patient does not receive oxygen during this period. Some humidifiers and nebulizers have a water trap that hangs from the tubing so that the condensation can be drained without disconnecting. Check the water level and change the humidifier as needed.

Nursing Safety Priority QSEN

Action Alert

To prevent bacterial contamination of the oxygen delivery system, never drain the fluid from the water trap back into the humidifier or nebulizer.

Infection.

The humidifier or nebulizer may be a source of bacteria, especially if it is heated. Oxygen delivery equipment such as cannulas and masks can also harbor organisms. Change equipment as per agency policy, which ranges from every 24 hours for humidification systems to every 7 days or whenever necessary for cannulas and masks.

NCLEX Examination Challenge

Physiological Integrity

Which manifestations in a client receiving oxygen therapy at 60% for more than 24 hours alert the nurse to the possibility of oxygen toxicity?
A Oxygen saturation greater than 100%
B Decreased rate and depth of respiration
C Wheezing on inhalation and exhalation
D Discomfort or pain under the sternum

Oxygen Delivery Systems.

Oxygen can be delivered by many systems. Regardless of the type of delivery system used, it is important to understand its indications, advantages, and disadvantages. Use the equipment properly, and ensure appropriate equipment maintenance. Consult a respiratory therapist whenever there is a question or concern about an oxygen delivery system.

The type of delivery system used depends on:

- Oxygen concentration required by the patient
- Oxygen concentration achieved by a delivery system
- Importance of accuracy and control of the oxygen concentration
- Patient comfort
- Importance of humidity
- Patient mobility

Oxygen delivery systems are classified by the rate of oxygen delivery into either low-flow systems or high-flow systems. Low-flow systems have a low fraction of inspired oxygen (Fio_2) and therefore do not provide enough oxygen to meet the total oxygen need and air volume of the patient. So, part of the tidal volume is supplied by the patient as he or she breathes room air. The total level of oxygen inspired depends on the respiratory rate and tidal volume. High-flow systems have a flow rate that meets the entire oxygen need and tidal volume regardless of the patient's breathing pattern. These systems are used for critically ill patients and when delivery of precise levels of oxygen is needed.

If the patient needs a mask but is able to eat, request a prescription for a nasal cannula to be used at mealtimes only. Reapply the mask after the meal is completed. To increase mobility, up to 50 feet of connecting tubing can be used with connecting pieces.

Low-Flow Oxygen Delivery Systems.

Low-flow systems include the nasal cannula, simple facemask, partial rebreather mask, and non-rebreather mask (Table 28-1). These systems are inexpensive, easy to use, and fairly comfortable, but the amount of oxygen delivered varies and depends on the patient's breathing pattern. The oxygen is diluted with room air (21% oxygen), which lowers the amount actually inspired.

TABLE 28-1

Comparison of Low-Flow Oxygen Delivery Systems

Fio_2 DELIVERED	NURSING INTERVENTIONS	RATIONALES
Nasal Cannula		
24%-40% Fio_2 at 1-6 L/min ≈24% at 1 L/min ≈28% at 2 L/min ≈32% at 3 L/min ≈36% at 4 L/min ≈40% at 5 L/min ≈44% at 6 L/min	Ensure that prongs are in the nares properly.	A poorly fitting nasal cannula leads to hypoxemia and skin breakdown.
	Apply water-soluble jelly to nares PRN.	This substance prevents mucosal irritation related to the drying effect of oxygen; promotes comfort.
	Assess the patency of the nostrils.	Congestion or a deviated septum prevents effective delivery of oxygen through the nares.
	Assess the patient for changes in respiratory rate and depth.	The respiratory pattern affects the amount of oxygen delivered. A different delivery system may be needed.
Simple Facemask		
40%-60% Fio_2 at 5-8 L/min; flow rate must be set at least at 5 L/min to flush mask of carbon dioxide ≈40% at 5 L/min ≈45%-50% at 6 L/min ≈55%-60% at 8 L/min	Be sure mask fits securely over nose and mouth.	A poorly fitting mask reduces the Fio_2 delivered.
	Assess skin and provide skin care to the area covered by the mask.	Pressure and moisture under the mask may cause skin breakdown.
	Monitor the patient closely for risk for aspiration.	The mask limits the patient's ability to clear the mouth, especially if vomiting occurs.
	Provide emotional support to the patient who feels claustrophobic.	Emotional support decreases anxiety, which contributes to a claustrophobic feeling.
	Suggest to the health care provider to switch the patient from a mask to the nasal cannula during eating.	Use of the cannula prevents hypoxemia during eating.
Partial Rebreather Mask		
60%-75% at 6-11 L/min, a liter flow rate high enough to maintain reservoir bag two-thirds full during inspiration and expiration	Make sure that the reservoir does not twist or kink, which results in a deflated bag.	Deflation results in decreased oxygen delivered and increases the rebreathing of exhaled air.
	Adjust the flow rate to keep the reservoir bag inflated.	The flow rate is adjusted to meet the pattern of the patient.
Non-Rebreather Mask		
80%-95% Fio_2 at a liter flow high enough to maintain reservoir bag two-thirds full	Interventions as for partial rebreather mask; this patient requires close monitoring.	Rationales as for partial rebreather mask. Monitoring ensures proper functioning and prevents harm.
	Make sure that valves and rubber flaps are patent, functional, and not stuck. Remove mucus or saliva.	Valves should open during expiration and close during inhalation to prevent dramatic decrease in Fio_2. Suffocation can occur if the reservoir bag kinks or if the oxygen source disconnects.
	Closely assess the patient on increased Fio_2 via non-rebreather mask. Intubation is the only way to provide more precise Fio_2.	The patient may require intubation.

Fio_2, Fraction of inspired oxygen.

Nasal Cannula.

The nasal cannula (prongs) (Fig. 28-3), is used at flow rates of 1 to 6 L/min. Oxygen concentrations of 24% (at 1 L/min) to 44% (at 6 L/min) can be achieved. Flow rates greater than 6 L/min do not increase gas exchange because the **anatomic dead space** (places where air flows but the structures are too thick for gas exchange) is full. Also, high flow rates increase mucosal irritation.

FIG. 28-3 A nasal cannula (prongs).

The nasal cannula is often used for chronic lung disease and for any patient needing long-term oxygen therapy. Place the nasal prongs in the nostrils, with the openings facing the patient, following the natural anatomic curve of the nares.

Facemasks.

Facemasks can deliver a wide range of oxygen flow rates and concentrations.

Simple facemasks are used to deliver oxygen concentrations of 40% to 60% for short-term oxygen therapy or in an emergency (Fig. 28-4). A minimum flow rate of 5 L/min is needed to prevent the rebreathing of exhaled air. Ensure that the mask fits well to maintain inspired oxygen levels. Care for the skin under the mask and strap to prevent skin breakdown (Ambutas et al., 2014).

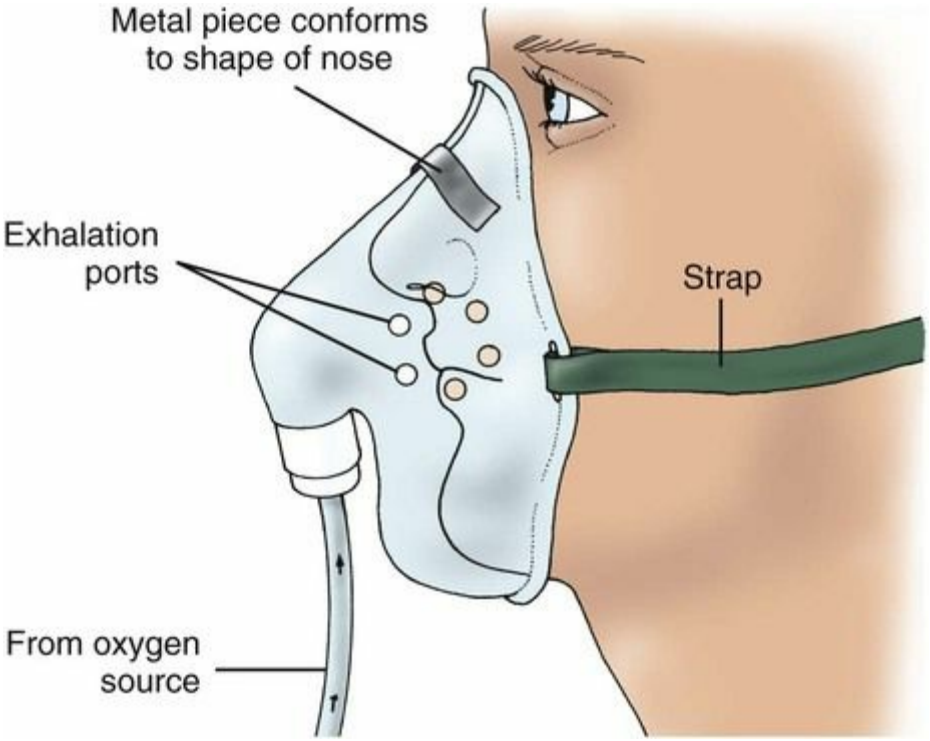

FIG. 28-4 A simple facemask used to deliver oxygen.

Partial rebreather masks provide oxygen concentrations of 60% to 75% with flow rates of 6 to 11 L/min. It is a mask with a reservoir bag but no flaps (Fig. 28-5). With each breath, the patient rebreathes one third of the exhaled tidal volume, which is high in oxygen and increases the fraction of inspired oxygen (Fio_2). For best oxygen delivery, be sure that the bag remains slightly inflated at the end of inspiration. If needed, call the respiratory therapist for assistance.

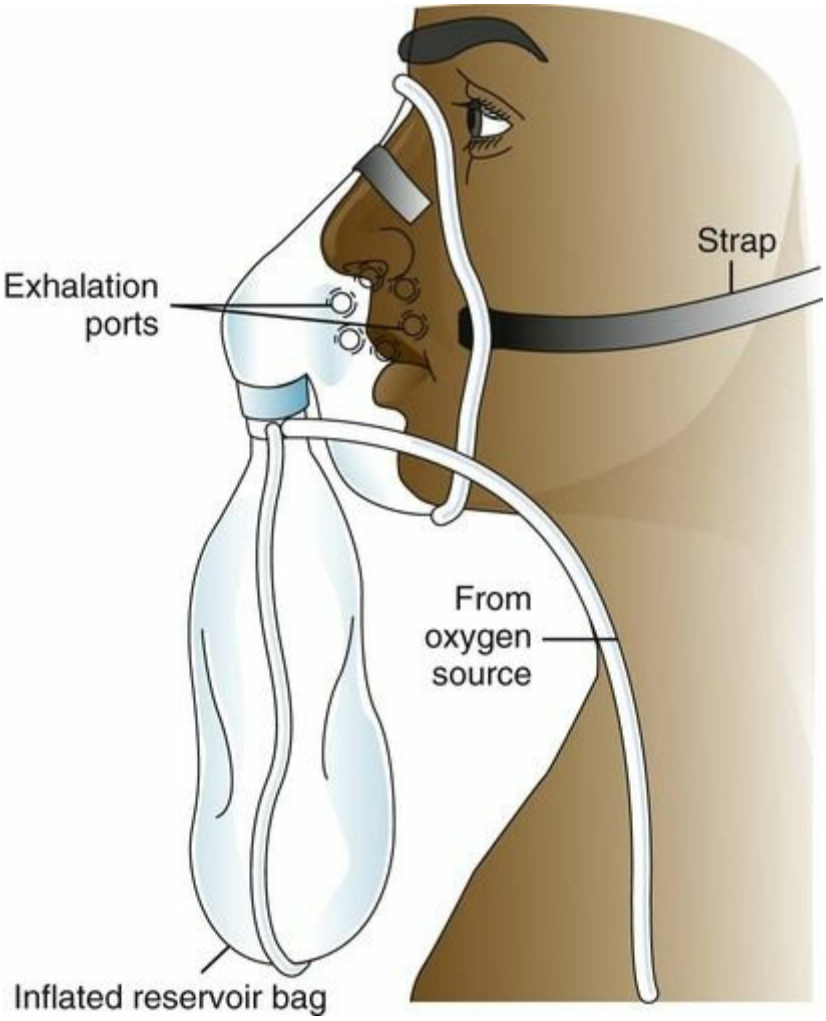

FIG. 28-5 A partial rebreather mask.

Non-rebreather masks provide the highest oxygen level of the low-flow systems and can deliver an Fio_2 greater than 90%, depending on the patient's breathing pattern. This mask is often used with patients whose respiratory status is unstable and who may require intubation.

The non-rebreather mask has a one-way valve between the mask and the reservoir and usually has two flaps over the exhalation ports (Fig. 28-6). The valve allows the patient to draw all needed oxygen from the reservoir bag, and the flaps prevent room air from entering through the exhalation ports (which would dilute the oxygen concentration). During exhalation, air leaves through these exhalation ports while the one-way valve prevents exhaled air from re-entering the reservoir bag. The flow rate is kept high (10 to 15 L/min) to keep the bag inflated during inhalation. Assess for this safety feature at least hourly.

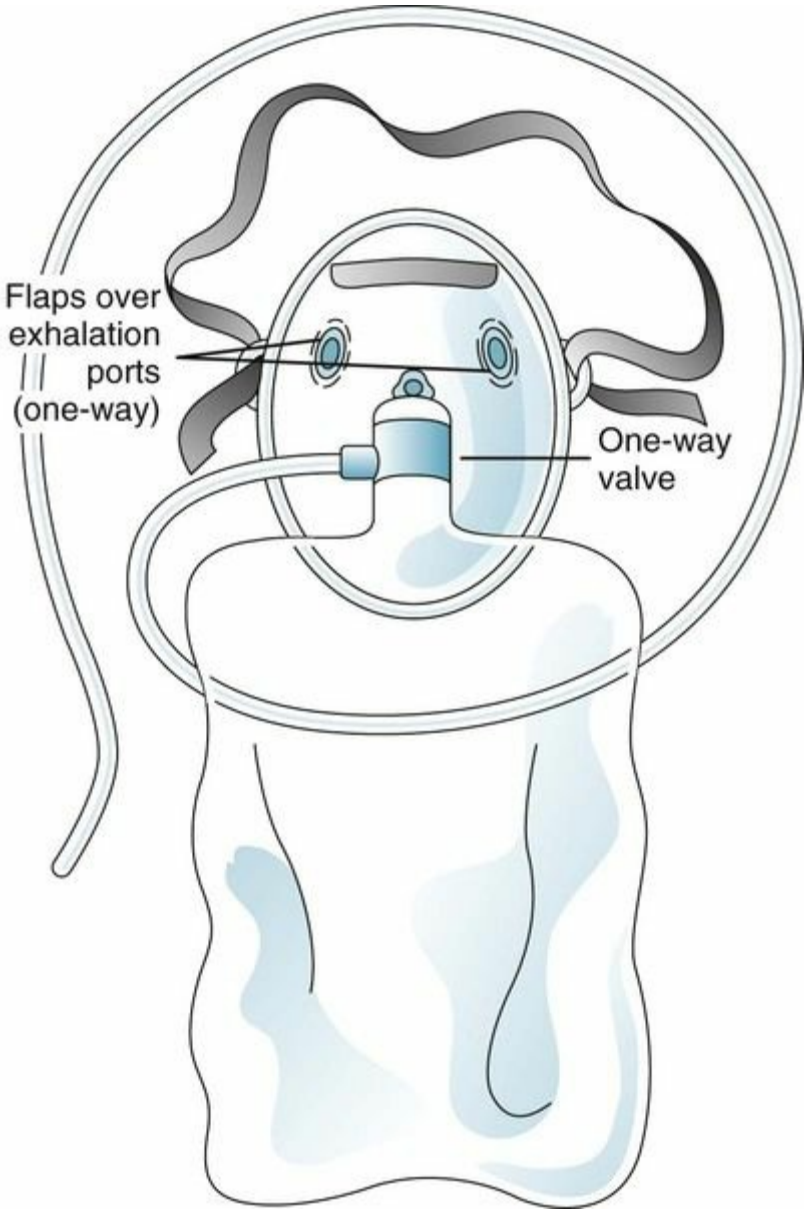

FIG. 28-6 A non-rebreather mask.

Nursing Safety Priority QSEN

Critical Rescue

Ensure that the valve and flaps on a non-rebreather mask are intact and functional during each breath. If the oxygen source should fail or be depleted when both flaps are in place, the patient would not be able to inhale room air.

High-Flow Oxygen Delivery Systems.

High-flow systems (Table 28-2) include the Venturi mask, aerosol mask, face tent, tracheostomy collar, and T-piece. These devices deliver an accurate oxygen level when properly fitted, with oxygen concentrations

from 24% to 100% at 8 to 15 L/min.

TABLE 28-2

Comparison of High-Flow Oxygen Delivery Systems

Fio_2 DELIVERED	NURSING INTERVENTIONS	RATIONALES
Venturi Mask (Venti Mask)		
24%-50% Fio_2 with flow rates as recommended by the manufacturer, usually 4-10 L/min; provides high humidity	Perform constant surveillance to ensure an accurate flow rate for the specific Fio_2.	An accurate flow rate ensures Fio_2 delivery.
	Keep the orifice for the Venturi adaptor open and uncovered.	If the Venturi orifice is covered, the adaptor does not function and oxygen delivery varies.
	Provide a mask that fits snugly and tubing that is free of kinks.	Fio_2 is altered if kinking occurs or if the mask fits poorly.
	Assess the patient for dry mucous membranes.	Comfort measures may be indicated.
	Change to a nasal cannula during mealtime.	Oxygen is a drug that needs to be given continuously.
Aerosol Mask, Face Tent, Tracheostomy Collar		
24%-100% Fio_2 with flow rates of at least 10 L/min; provides high humidity	Assess that aerosol mist escapes from the vents of the delivery system during inspiration and expiration.	Humidification should be delivered to the patient.
	Empty condensation from the tubing.	Emptying prevents the patient from being lavaged with water, promotes an adequate flow rate, and ensures a continued prescribed Fio_2.
	Change the aerosol water container as needed.	Adequate humidification is ensured only when there is sufficient water in the canister.
T-Piece		
24%-100% Fio_2 with flow rates of at least 10 L/min; provides high humidity	Empty condensation from the tubing.	Condensation interferes with flow rate delivery of Fio_2 and may drain into the tracheostomy if not emptied.
	Keep the exhalation port open and uncovered.	If the port is occluded, the patient can suffocate.
	Position the T-piece so that it does not pull on the tracheostomy or endotracheal tube.	The weight of the T-piece pulls on the tracheostomy and causes pain or erosion of skin at the insertion site.
	Make sure the humidifier creates enough mist. A mist should be seen during inspiration and expiration.	An adequate flow rate is needed to meet the inspiration effort of the patient. If not, the patient will be "air-hungry."

Fio_2, Fraction of inspired oxygen.

Venturi masks (Venti masks) deliver the most accurate oxygen concentration without intubation. It works by pulling in a proportional amount of room air for each liter flow of oxygen. An adaptor is located between the bottom of the mask and the oxygen source (Fig. 28-7). Adaptors with holes of different sizes allow specific amounts of air to mix with the oxygen, resulting in more precise delivery of oxygen. Each adaptor requires a different flow rate. For example, to deliver 24% of oxygen, the flow rate must be 4 L/min. Another type of Venturi mask has one adaptor with a dial that is used to select the amount of oxygen desired. Humidification is not needed with the Venturi mask.

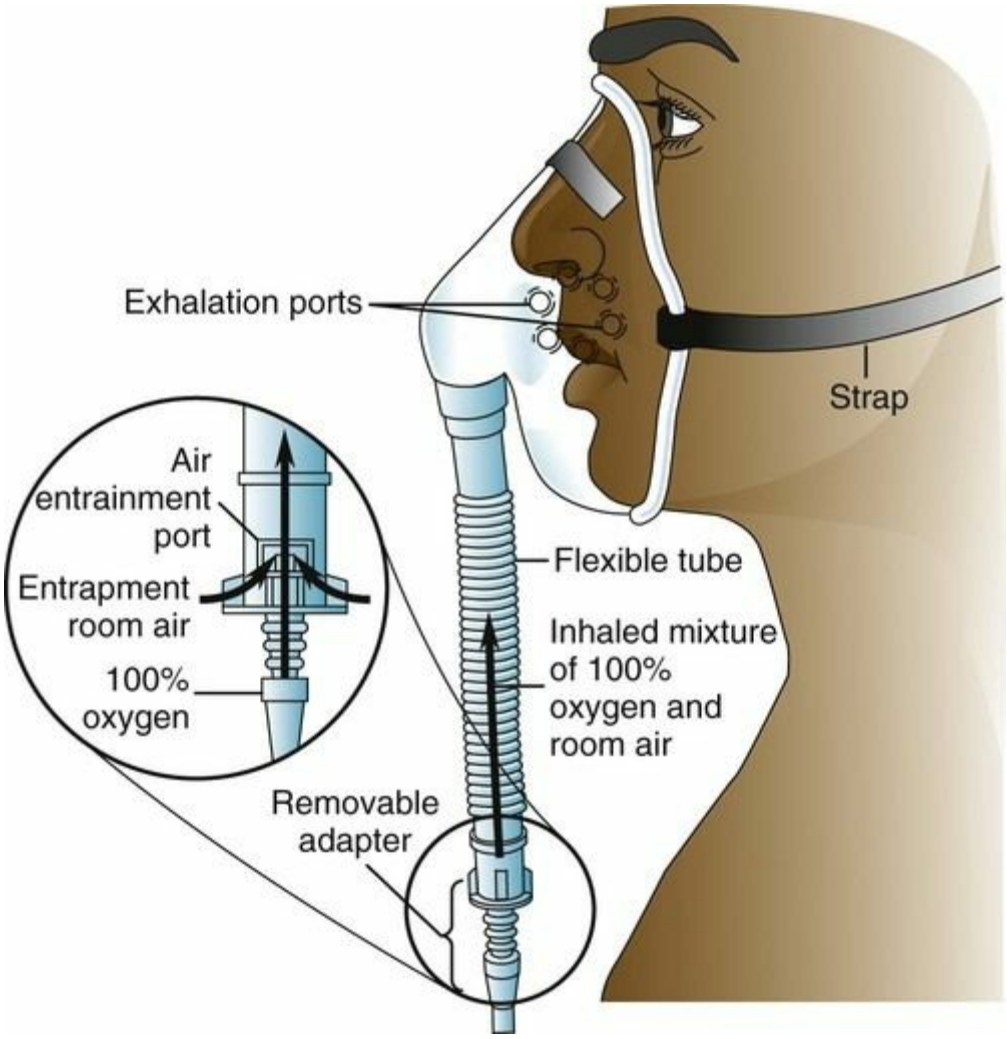

FIG. 28-7 A Venturi mask for precise oxygen delivery.

Other high-flow systems include the face tent, aerosol mask, tracheostomy collar, and T-piece. They are often used to provide high humidity with oxygen delivery. A dial on the humidity source regulates the delivered oxygen level. A face tent fits over the chin, with the top extending halfway across the face. The oxygen level delivered varies, but the face tent, instead of a tight-fitting mask, is useful for patients who have facial trauma or burns. An aerosol mask is used when high humidity is needed. The tracheostomy collar is used to deliver high humidity and the desired oxygen to the patient with a tracheostomy. A special adaptor, called the T-*piece*, is used to deliver any desired Fio_2 to the patient with a tracheostomy, laryngectomy, or endotracheal tube (Fig. 28-8). Adjust the flow rate so that the aerosol appears on the exhalation side of the T-piece.

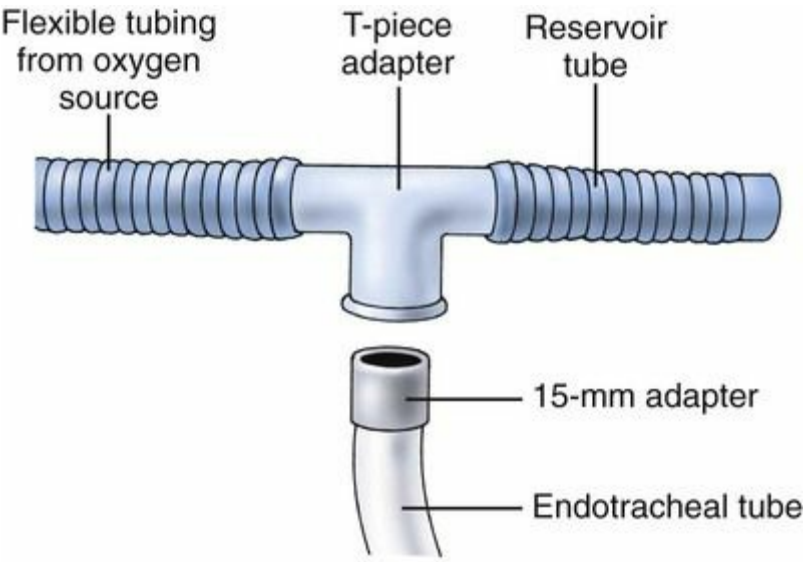

FIG. 28-8 A T-piece apparatus for attachment to an endotracheal or tracheostomy tube.

Noninvasive Positive-Pressure Ventilation.

Noninvasive positive-pressure ventilation (NPPV) is a technique using positive pressure to keep alveoli open and improve gas exchange without the need for airway intubation. It is now being used to manage dyspnea, hypercarbia, and acute exacerbations of chronic obstructive pulmonary disease (COPD), cardiogenic pulmonary edema, and acute asthma attacks. Although NPPV prevents the complications associated with intubation, including ventilator-associated pneumonia (VAP), risks and complications are associated with it. Masks must fit tightly in order to form a proper seal, which can lead to skin breakdown over the nose or other areas of the face. Leaks can cause uncomfortable pressure around the eyes, and gastric insufflation can lead to vomiting and the potential for aspiration. Thus NPPV should be used only on alert patients who have the ability to protect their airway, although a nasogastric (NG) tube may still be required for safety.

NPPV can deliver oxygen or may use just room air. A nasal mask, nasal pillows, or full-face mask delivery system allows mechanical delivery. The three most common modes of delivery for NPPV are (1) continuous positive airway pressure (CPAP), which delivers a set positive airway pressure throughout each cycle of inhalation and exhalation; (2) volume-limited or flow-limited, which delivers a set tidal volume with the patient's inspiratory effort; and (3) pressure-limited, which includes pressure support, pressure control, and bi-level positive airway pressure (BiPAP), which cycles different pressures at inspiration and at expiration.

For BiPAP, a cycling machine delivers a set inspiratory positive airway

pressure each time the patient begins to inspire. As he or she begins to exhale, the machine delivers a lower set end-expiratory pressure. Together, these two pressures improve tidal volume, can reduce respiratory rate, and may relieve dyspnea.

For CPAP, the effect is to open collapsed alveoli. Patients who may benefit from this form of oxygen or air delivery include those with atelectasis after surgery or cardiac-induced pulmonary edema or those with COPD. It is not beneficial for patients with respiratory failure following extubation. NPPV is also being used in palliative care for alleviating dyspnea, including for those patients with "do-not-intubate" orders. However, this practice is controversial. The Society of Critical Care Medicine (SCCM) recommends that goals of therapy and expected outcomes be discussed with the patient and family before initiating therapy.

NPPV is used for sleep apnea. The effect is to hold open the upper airways (Fig. 28-9). Patients using CPAP or BiPAP at home to manage sleep apnea often bring their home equipment to the hospital. They are familiar with their own machines and feel more comfortable using their own masks. The reasons for using NPPV still exist when the patient enters the hospital, and with some problems, there may be a greater need for them to continue NPPV while hospitalized.

FIG. 28-9 Nasal continuous positive airway pressure (CPAP).

The number of patients using NPPV therapy is increasing, and they are often cared for outside of the ICU setting. Nurses caring for the patient with NPPV must be knowledgeable about the equipment, the technique, and the potential complications. Adequate respiratory therapy support also is needed to safely manage a patient receiving NPPV.

Transtracheal Oxygen Therapy.

Transtracheal oxygen (TTO) is a long-term method of delivering oxygen directly into the lungs. A small, flexible catheter is passed into the trachea through a small incision with the patient under local anesthesia. TTO avoids the irritation from nasal prongs and is less visible. A TTO team provides patient education, including the purpose of TTO and care of the catheter. Flow rates are prescribed for rest and for activity. A flow rate also is prescribed for the nasal cannula, which is used when the TTO catheter is being cleaned. Most patients using this delivery method have a 55% reduction in required oxygen flow at rest and a 30% decrease with activity.

Clinical Judgment Challenge

Patient-Centered Care; Teamwork and Collaboration; Evidence-Based Practice QSEN

Your patient is an 81-year-old male with end-stage COPD who is admitted with pneumonia and COPD exacerbation. He has a 60–pack-year smoking history and has been hospitalized many times over the past year for respiratory distress. The admitting provider orders an arterial blood gas (ABG). The patient is not using supplemental oxygen.

1. Based on your understanding of his disease process (see Chapter 30), would you expect this patient to have normal or altered ABG values, especially carbon dioxide ($Paco_2$) level?
2. The results of the ABG indicate hypoxemia (Pao_2 of 40 mm Hg). Should you provide your patient with supplemental oxygen? Why or why not? If so, how much and which method would be best?
3. What areas will be the focus of your assessment and documentation? Provide a rationale for your choice(s).
4. Your patient has continually increasing oxygen requirements. He is now wearing a simple mask, and one of your colleagues would like to switch to a non-rebreather mask to deliver 100% oxygen. What are other good options for this patient?

Community-Based Care

Home Care Management.

The patient must be stable before home oxygen is considered. For Medicare to cover the cost of home oxygen therapy, the patient must have severe hypoxemia defined as a partial pressure of arterial oxygen (Pao_2) level of less than 55 mm Hg or an arterial oxygen saturation (Spo_2) of less than 88% on room air and at rest. The criteria vary when hypoxemia is caused by nonpulmonary problems or when oxygen is needed only at night or with exercise.

Self-Management Education.

When home oxygen therapy is prescribed, begin a teaching plan about oxygen therapy. The nurse or respiratory therapist teaches the patient about the equipment needed for home oxygen therapy and the safety aspects of using and maintaining the equipment. Equipment may include the oxygen source, delivery devices, and humidity sources. Work with the discharge planner to help the patient select a durable medical equipment

(DME) company to deliver oxygen equipment and select a community health nursing agency for follow-up care in the home. Re-evaluation of the need for oxygen therapy occurs on a periodic basis.

While providing discharge planning and teaching, be sensitive to the patient's emotional adjustment to oxygen therapy. Encourage the patient to share feelings and concerns. He or she may be concerned about social acceptance. Help him or her realize that adherence to oxygen therapy is important for being able to participate in ADLs and other events that bring enjoyment.

Home Care Preparation.

Home oxygen therapy is provided in one of three ways: compressed gas in a tank or a cylinder, liquid oxygen in a reservoir, or an oxygen concentrator. Compressed gas in an oxygen tank (green) is the most often used oxygen source. The large H cylinder may be used as a stationary source, and the small E tank is available for transporting the patient (Fig. 28-10). Smaller cylinders are available for the patient to carry. Teach the patient and family to check the gauge daily to assess the amount of oxygen left in the tank. As a safety precaution, the tanks must always be in a stand or rack. A tank that is accidentally knocked over could suddenly decompress and move around in an uncontrolled manner.

FIG. 28-10 Small E size oxygen tank (cylinder) for portability.

Liquid oxygen for home use is oxygen gas that has been liquefied. A concentrated amount of oxygen is available in a lightweight and easy-to-carry container similar to a Thermos bottle (Fig. 28-11). This portable tank is filled from a large stationary liquid vessel. Liquid oxygen lasts longer than gaseous oxygen; however, it is expensive and the oxygen evaporates if it is not used continuously.

FIG. 28-11 Portable liquid oxygen.

The **oxygen concentrator** or *oxygen extractor* is a machine that removes nitrogen from room air, increasing oxygen levels to more than 90%. This device is the least expensive system and does not need to be filled. It is often used in the home as a stationary system. A smaller version that can plug into DC electrical outlets can be rented for longer car or boat trips. Liquid oxygen and E tanks are used for short trips.

Regardless of the type of oxygen delivery system used, review safety issues with the patient and all family members.

Nursing Safety Priority QSEN

Action Alert

Stress to the patient the importance of not smoking when he or she is using oxygen. Teach the patient and all family members that smoking materials, candles, gas burners, and fireplaces (and other open flames) are not to be used in the same room that oxygen is being used.

NCLEX Examination Challenge

Health Promotion and Maintenance

For which activity does the nurse teach the client who is receiving oxygen by a transtracheal oxygen (TTO) delivery system to switch to a nasal cannula oxygen delivery system?

A Eating a meal
B Sleeping at night
C Cleaning the catheter
D Performing mouth care

Tracheostomy

Tracheotomy is the surgical incision into the trachea to create an airway. **Tracheostomy** is the tracheal *stoma* (opening) that results from the tracheotomy. A tracheotomy can be an emergency procedure or a scheduled surgery. Tracheostomies can be temporary or permanent. Some indications for tracheostomy include acute airway obstruction, the need for airway protection, laryngeal or facial trauma or burns, and airway involvement during head or neck surgery. Tracheostomies also are used for prolonged unconsciousness, paralysis, or the inability to be weaned from mechanical ventilation. With temporary tracheostomies, the nurse is key in evaluating patient readiness for progression toward decannulation (removal of the tracheostomy tube) (Morris et al., 2014).

Patient-Centered Collaborative Care

Analysis

The priority NANDA-I nursing diagnoses and collaborative problems for patients requiring tracheostomy include:

- Impaired Gas Exchange related to weak chest muscles, obstruction, or other physical problems that interfere with ventilation and diffusion of gases (NANDA-I)
- Impaired Verbal Communication related to tracheostomy or intubation (NANDA-I)
- Imbalanced Nutrition: Less Than Body Requirements related to presence of endotracheal tube (NANDA-I)
- Potential for infection related to invasive procedures or problems with the normal protective mechanisms of the respiratory tract
- Damaged oral mucosa related to mechanical factors (endotracheal tube)

Interventions

Preoperative Care.

The care for the patient having a tracheotomy is similar to that for a laryngectomy (see Chapter 29). Focus on his or her knowledge deficits through teaching, and discuss tracheostomy care, communication, and speech.

Operative Procedures.

Initially, the neck is extended and an endotracheal (ET) tube is placed by

the anesthesia provider to maintain the airway. Incisions are made through the neck and the tracheal rings to enter the trachea (Fig. 28-12). The types of incisions and techniques vary, depending on the surgeon's preference and the reason for the surgery.

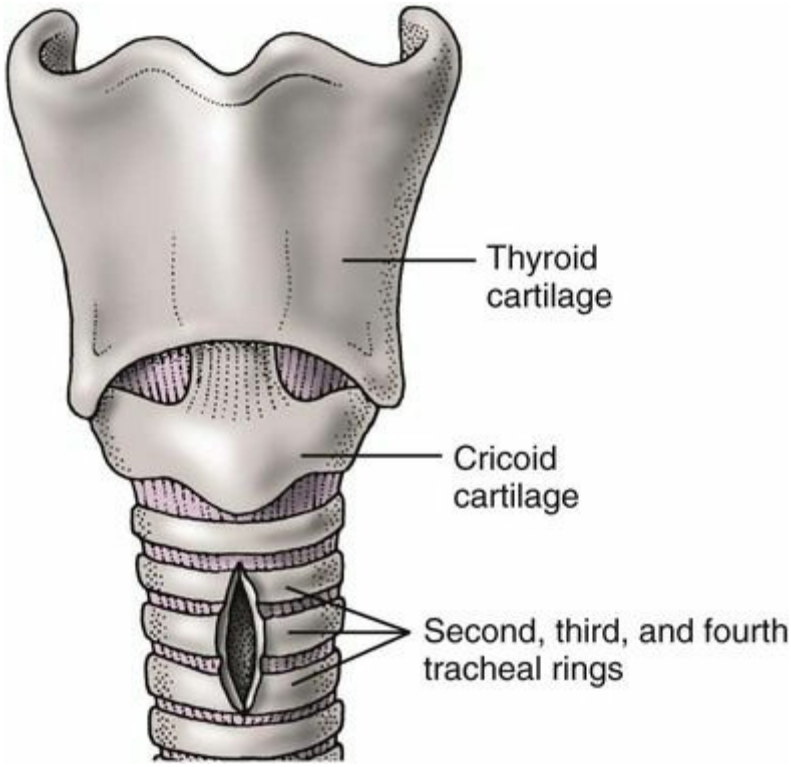

FIG. 28-12 A vertical tracheal incision for a tracheostomy.

After the trachea is entered, the ET tube is removed while the tracheostomy tube is inserted. The tracheostomy tube is secured in place with sutures and tracheostomy ties or Velcro tube holders. A chest x-ray determines proper placement of the tube.

Postoperative Care.

Immediately after surgery, focus care on ensuring a patent airway. Confirm the presence of bilateral breath sounds. Perform a respiratory assessment at least hourly. Assess the patient for complications from the procedure.

Complications.

Major complications can arise after surgery. Table 28-3 lists manifestations, management, and prevention of complications of tracheostomy.

TABLE 28-3
Complications of Tracheostomy

COMPLICATIONS AND DESCRIPTION	MANIFESTATIONS	MANAGEMENT	PREVENTION
Tracheomalacia: constant pressure exerted by the cuff causes tracheal dilation and erosion of cartilage.	An increased amount of air is required in the cuff to maintain the seal. A larger tracheostomy tube is required to prevent an air leak at the stoma. Food particles are seen in tracheal secretions. The patient does not receive the set tidal volume on the ventilator.	No special management is needed unless bleeding occurs.	Use an uncuffed tube as soon as possible. Monitor cuff pressure and air volumes closely, and detect changes.
Tracheal stenosis: narrowed tracheal lumen is due to scar formation from irritation of tracheal mucosa by the cuff.	Stenosis is usually seen after the cuff is deflated or the tracheostomy tube is removed. The patient has increased coughing, inability to expectorate secretions, or difficulty in breathing or talking.	Tracheal dilation or surgical intervention is used.	Prevent pulling of and traction on the tracheostomy tube. Properly secure the tube in the midline position. Maintain proper cuff pressure. Minimize oronasal intubation time.
Tracheoesophageal fistula (TEF): excessive cuff pressure causes erosion of the posterior wall of the trachea. A hole is created between the trachea and the anterior esophagus. The patient at highest risk also has a nasogastric tube present.	Similar to tracheomalacia: Food particles are seen in tracheal secretions. Increased air in cuff is needed to achieve a seal. The patient has increased coughing and choking while eating. The patient does not receive the set tidal volume on the ventilator.	Manually administer oxygen by mask to prevent hypoxemia. Use a small, soft feeding tube instead of a nasogastric tube for tube feedings. A gastrostomy or jejunostomy may be performed by the physician. Monitor the patient with a nasogastric tube closely; assess for TEF and aspiration.	Maintain cuff pressure. Monitor the amount of air needed for inflation, and detect changes. Progress to a deflated cuff or cuffless tube as soon as possible.
Trachea–innominate artery fistula: a malpositioned tube causes its distal tip to push against the lateral wall of the tracheostomy. Continued pressure causes necrosis and erosion of the innominate artery. ***This is a medical emergency.***	The tracheostomy tube pulsates in synchrony with the heartbeat. There is heavy bleeding from the stoma. This is a life-threatening complication.	Remove the tracheostomy tube immediately. Apply direct pressure to the innominate artery at the stoma site. Prepare the patient for immediate surgical repair.	Correct the tube size, length, and midline position. Prevent pulling or tugging on the tracheostomy tube. Immediately notify the physician of the pulsating tube.

Tube obstruction can occur as a result of secretions or by cuff displacement. Indicators include difficulty breathing; noisy respirations; difficulty inserting a suction catheter; thick, dry secretions; and unexplained peak pressures (if a mechanical ventilator is in use). Assess the patient at least hourly for tube patency. Prevent obstruction by helping the patient cough and deep breathe, providing inner cannula care, humidifying oxygen, and suctioning. If tube obstruction occurs as a result of cuff prolapse over the end of the tracheostomy tube, the health care provider repositions or replaces the tube.

Tube dislodgement and accidental decannulation can occur when the tube

is not secure. Prevent this problem by securing the tube in place to reduce movement and traction from the tubing or from accidental pulling by the patient. *Tube dislodgment in the first 72 hours after surgery is an emergency because the tracheostomy tract has not matured and replacement is difficult. The tube may end up in the subcutaneous tissue instead of in the trachea (also referred to as "false passage"). The patient will not be able to be ventilated.* Obese patients or those with short, large necks may be particularly difficult to recannulate if the tracheostomy tube is dislodged.

Nursing Safety Priority QSEN

Critical Rescue

If the tube is dislodged on an immature tracheostomy, ventilate the patient using a manual resuscitation bag and facemask while another nurse calls the Rapid Response Team.

For safety, ensure that a tracheostomy tube of the same type (including an obturator) and size (or one size smaller) is at the bedside at all times, along with a tracheostomy insertion tray. If decannulation occurs after 72 hours, extend the patient's neck and open the tissues of the stoma with a curved Kelly clamp to secure the airway. With the obturator inserted into the tracheostomy tube, quickly and gently replace the tube and remove the obturator. Check for airflow through the tube and for bilateral breath sounds. *If you cannot secure the airway, notify a more experienced nurse, respiratory therapist, or physician for assistance. Ventilate with a bag-valve mask. If the patient is in distress, call the Rapid Response Team for help.* To minimize tube dislodgment problems, many institutions have developed policies for patients with new tracheostomies and those identified at high risk (i.e., obese patients or those identified by the surgeon or anesthesiologist as high risk). One policy is to have a "difficult airway" cart available for these high-risk patients.

Pneumothorax (air in the chest cavity) can develop during the tracheotomy procedure if the chest cavity is entered. Chest x-rays after placement are used to assess for pneumothorax.

Subcutaneous emphysema occurs when there is an opening or tear in the trachea and air escapes into the fresh tissue planes of the neck. Air can progress throughout the chest and other tissues into the face. Inspect and palpate for air under the skin around the new tracheostomy.

Nursing Safety Priority QSEN

Critical Rescue

If the skin around a new tracheostomy is puffy and you can feel a crackling sensation when pressing on this skin, notify the physician immediately.

Bleeding in small amounts from the tracheotomy incision is expected for the first few days, but constant oozing is abnormal. Wrap gauze around the tube and pack gauze gently into the wound to apply pressure to the bleeding sites.

Infection can occur at any time. In the hospital, use sterile technique to prevent infection during suctioning and tracheostomy care. Assess the stoma site at least once every 8 hours for purulent drainage, redness, pain, or swelling. Tracheostomy dressings may be used to keep the stoma clean and dry. These dressings resemble a 4 × 4 gauze pad with an area removed to fit around the tube. If tracheostomy dressings are not available, fold standard sterile 4 × 4s to fit around the tube. *Do not cut the dressing because small bits of gauze could then be aspirated through the tube.* Change these dressings often because moist dressings provide a medium for bacterial growth. Careful wound care prevents most local infections.

Tracheostomy Tubes.

Many types of tracheostomy tubes are available (Fig. 28-13). The one chosen depends on the needs of the patient. Tracheostomy tubes are available in many sizes and are made of plastic or metal. Most tubes in use today are disposable. A tracheostomy tube may have a cuff and may have an inner cannula. For patients receiving mechanical ventilation, a cuffed tube is used. A noncuffed tube is used when mechanical ventilation is not required.

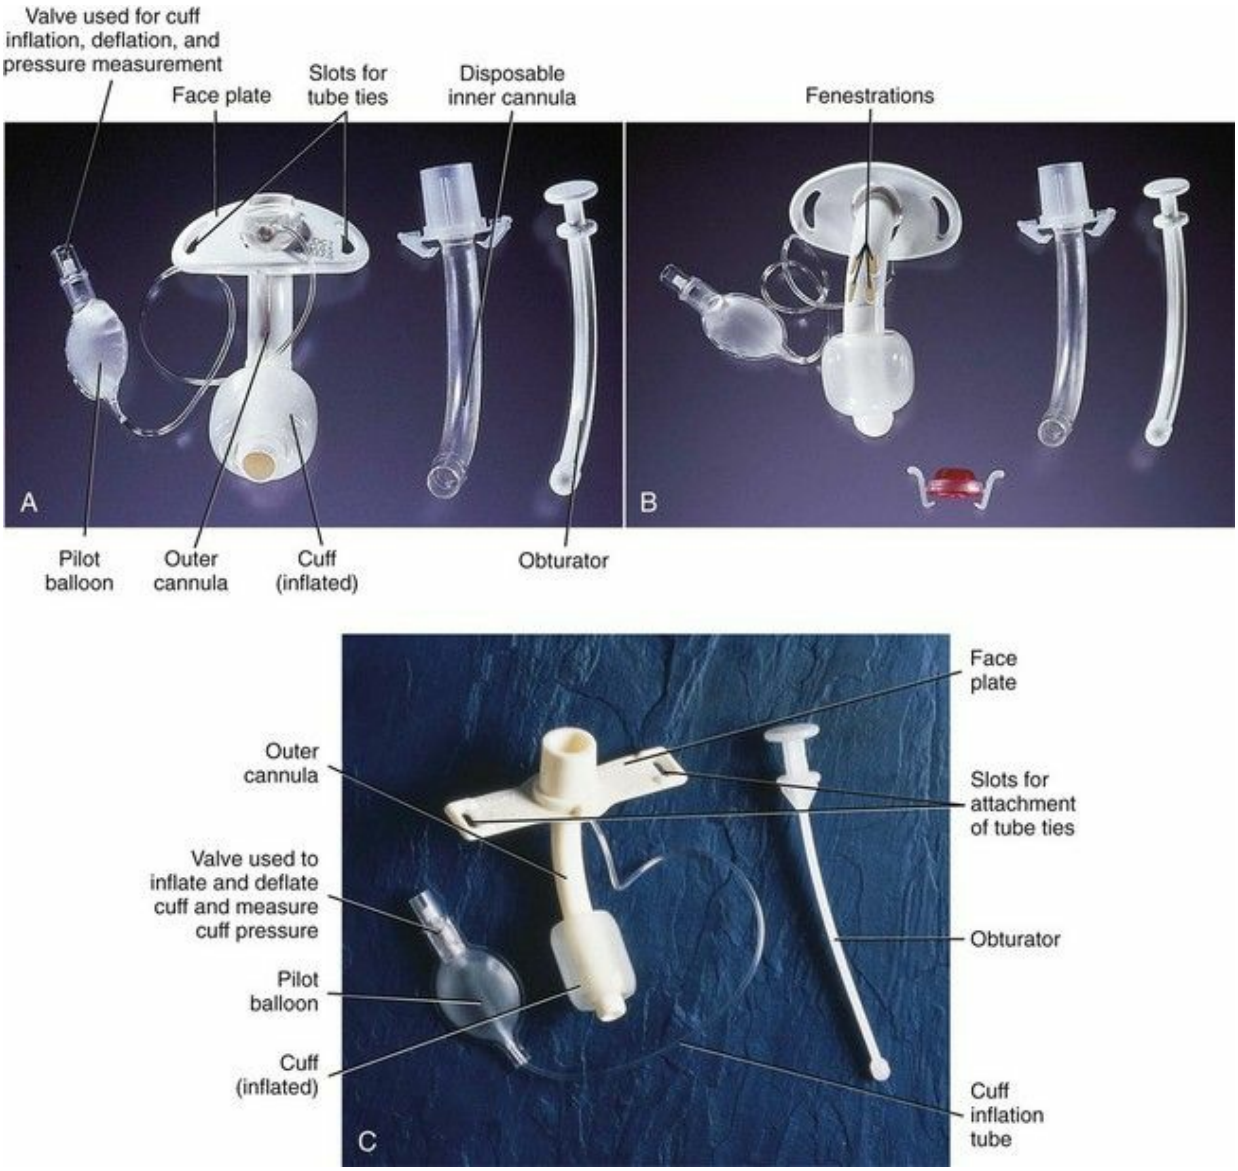

FIG. 28-13 Tracheostomy tubes. **A,** Dual-lumen cuffed tracheostomy tube with disposable inner cannula. **B,** Dual-lumen cuffed fenestrated tracheostomy tube. **C,** Single-lumen cannula cuffed tracheostomy tube.

For tubes with a reusable inner cannula, inspect, suction, and clean the inner cannula. During the first 24 hours after surgery, perform cannula care as often as needed, perhaps every 30 to 60 minutes. Thereafter, care is determined by the patient's needs and agency policy. In planning for self-care, teach the patient to remove the inner cannula and check for cleanliness. Also instruct him or her about suctioning and tracheostomy cleaning.

Because breathing and swallowing move the tube, a cuffed tube does not protect against aspiration. Having a cuffed tube inflated may give a false sense of security that aspiration cannot occur during feeding or mouth care. In addition, the pilot balloon does not reflect whether the correct amount of air is present in the cuff.

A fenestrated tube functions in many different ways. When the inner cannula is in place, the fenestration is closed and this tube works like a double-lumen tube. With the inner cannula removed and the plug or stopper locked in place, air can pass through the fenestration, around the tube, and up through the natural airway so that the patient can cough and speak. If the patient has trouble with these actions, he or she should be evaluated for proper tube placement, patency, size, and fenestration. *Do not cap the tube until the problem is identified and corrected.*

A fenestrated tube may or may not have a cuff. With a cuff, some air flows through the natural airway when the patient is not being mechanically ventilated.

Nursing Safety Priority QSEN

Action Alert

Always deflate the cuff before capping the tube with the decannulation cap; otherwise, the patient has no airway.

Patients with metal tracheostomy tubes scheduled for magnetic resonance imaging (MRI) need to change to a plastic tube. Metal tubes could be dislodged or heat up with exposure to the magnetic field during the scan.

Care Issues for the Patient with a Tracheostomy

Preventing Tissue Damage.

Tissue damage can occur at the point where the inflated cuff presses against the tracheal mucosa. Mucosal ischemia occurs when the pressure exerted by the cuff on the mucosa exceeds the capillary perfusion pressure. To reduce the risk for tracheal damage, keep the cuff pressure between 14 and 20 mm Hg or 20 and 30 cm H_2O (ideally, 25 cm H_2O or less) (Sole et al., 2011).

Most cuffs use a high volume of air while keeping low pressure on the tracheal mucosa. Inflate the cuff to form a seal between the trachea and the cuff with the least amount of pressure. If the cuff cannot be inflated to seal well enough, a larger-diameter tube may be needed. A pressure cuff inflator can be used to inflate the cuff to a specified pressure or to check the cuff pressure (Fig. 28-14).

FIG. 28-14 An aneroid pressure manometer for cuff inflation and measuring cuff pressures.

Check the cuff pressure at least once during each shift, especially with the minimal leak technique, and keep the pressure at 14 to 20 mm Hg or 20 to 30 cm H_2O. In rare situations, the cuff pressure is increased to maintain ventilator volumes when peak pressures are greater than 50 mm Hg (65 cm H_2O) and positive end-expiratory pressure (PEEP) is greater than 10 mm Hg (14 cm H_2O). High PEEP values can deflate the cuff over time, and more air may need to be added to maintain a proper seal. Manufacturers have guidelines for the specific volumes for each cuff size. Most cuffs are adequately inflated with less than 10 mL of air.

Although a high cuff pressure alone causes tracheal damage, other factors contribute to the risk for damage (Makic et al., 2013). The patient who is malnourished, dehydrated, hypoxic, older, or receiving corticosteroids is at risk for greater tissue damage. Tube friction and movement damage the mucosa and lead to tracheal stenosis. Reduce local airway damage by maintaining proper cuff pressures, stabilizing the tube, suctioning only when needed, and preventing malnutrition, dehydration, and hypoxia.

Ensuring Air Warming and Humidification.

The tracheostomy tube bypasses the nose and mouth, which normally humidify and warm the inspired air. If humidification and warming are

not adequate, tracheal damage can occur. Thick, dried secretions can occlude the airways.

To prevent these complications, humidify the air as prescribed. Continually assess for a fine mist emerging from the tracheostomy collar or T-piece during ventilation. To increase the amount of humidity delivered, a warming device can be attached to the water source with a temperature probe in the tubing circuit. Monitor the circuit temperature hourly by feeling the tubing and by checking the probe. Ensure adequate hydration, which also helps liquefy secretions. Increasing the flow rate at the flowmeter increases the amount of delivered humidity.

Nursing Safety Priority QSEN

Action Alert

Keep the temperature of the air entering a tracheostomy between 98.6° and 100.4° F (37° and 38° C) and never exceed 104° F (40° C).

Suctioning.

Suctioning maintains a patent airway and promotes gas exchange by removing secretions when the patient cannot cough adequately. Chart 28-2 lists best practices for suctioning. Assess the patient's need for suctioning (e.g., audible or noisy secretions; crackles or wheezes heard on auscultation; restlessness; increased pulse or respiratory rates; or mucus present in the artificial airway). Other indications include patient requests for suctioning or an increase in the peak airway pressure on the ventilator.

Chart 28-2 Best Practice for Patient Safety & Quality Care QSEN

Suctioning the Artificial Airway

1. Assess the need for suctioning (routine unnecessary suctioning causes mucosal damage, bleeding, and bronchospasm).
2. Wash hands. Don protective eyewear. Maintain Standard Precautions.
3. Explain to the patient that sensations such as shortness of breath and coughing are to be expected but that any discomfort will be very brief.
4. Check the suction source. Occlude the suction source, and adjust the pressure dial to between 80 and 120 mm Hg to prevent hypoxemia and trauma to the mucosa.

5. Set up a sterile field.
6. Preoxygenate the patient with 100% oxygen for 30 seconds to 3 minutes (at least three hyperinflations) to prevent hypoxemia. Keep hyperinflations synchronized with inhalation.
7. Quickly insert the suction catheter until resistance is met. *Do not apply suction during insertion.*
8. Withdraw the catheter 0.4 to 0.8 inch (1 to 2 cm), and begin to apply suction. Apply suction and use a twirling motion of the catheter during withdrawal. *Never suction longer than 10 to 15 seconds.*
9. Hyperoxygenate for 1 to 5 minutes or until the patient's baseline heart rate and oxygen saturation are within normal limits.
10. Repeat as needed for up to three total suction passes.
11. Suction mouth as needed, and provide mouth care.
12. Remove gloves, and wash hands.
13. Describe secretions, and document patient's responses.

Deep endotracheal suctioning is painful. Some unconscious or noncommunicative patients still feel pain, and this should be kept in mind during the suctioning procedure (see the Evidence-Based Practice box). At the very least, provide verbal acknowledgment of the discomfort and reassurance of when the procedure will end.

Evidence-Based Practice QSEN

How Do You Know When Suctioning is Painful to a Patient?

Rahu, M., Grap, M., Cohn, J., Munro, C., Lyon, D., & Sessler, C. (2013). Facial expression as an indicator of pain in critically ill intubated adults during endotracheal suctioning. *American Journal of Critical Care, 22*(5), 412-422.

Endotracheal suctioning is often painful, and patients may require pain medication before the procedure. Patients who are not able to communicate may still feel pain during the procedure, but often this is not addressed. The investigators sought to determine whether pain in noncommunicative critically ill patients during endotracheal suctioning could be discerned by changes in facial expression.

Fifty noncommunicative patients who had endotracheal tubes were video recorded during rest phases in which no treatments or procedures were being performed and during periods of endotracheal suctioning. The video-recorded facial changes were coded using the Facial Action Coding System of the Behavioral Pain Scale. A total of 14 different facial

expressions were present during suctioning that were seldom seen during rest phases. Five of the 14 accounted for 71% of the variance from expected responses as measured in stepwise multivariate analysis. These expression changes were brow raised, brow lowered, nose wrinkling, head turned right or left, and head turned up. The investigators suggest that such changes in upper facial expressions in noncommunicative critically ill patients could be used as a valid alternative to self-reports of procedural pain.

Level of Evidence: 3

The results of this quasi-experimental study in which patients served as their own controls provide significant evidence that noncommunicative critically ill patients feel pain during the suctioning procedure. The use of video-recording and the observer software analysis of facial changes strengthened the study by reducing observer bias and providing opportunity for re-examination. The Facial Action Coding System (FACS) is an established and reliable instrument useful for assessing behavioral responses to pain. The statistical analysis methods used were appropriate for the study design.

Commentary: Implications for Practice and Research

This study is important in that it was conducted under real clinical conditions using a variety of noncommunicative and intubated patients. The results indicate that the FACS could be used to standardize pain evaluation in this patient population. Additional research with larger sample sizes are needed to determine whether the instruments could be used to quantify the pain experienced by noncommunicative patients so that appropriate pain-relieving measures could be instituted. Although some limitations were present in this study, the nature of the question and the patient population do not lend themselves to randomized controlled clinical trials.

Suctioning is often performed through an artificial airway, but the nose or mouth also can be used. Suctioning of both routes is routine for the patient with retained secretions.

Suctioning through the nose has similar complications as suctioning through an artificial airway and can be painful. Slow, careful placement of the catheter following the nasopharyngeal anatomy reduces pain and trauma. Placing a nasopharyngeal airway and suctioning through it can prevent trauma to the nasal mucosa. Advance the catheter through the nasopharynx and into the laryngopharynx while the patient receives

oxygen by mask or nasal cannula. Once the catheter enters the larynx, the patient may cough. On inhalation, insert the catheter into the trachea. If needed, disconnect the catheter from suction and attach it to an oxygen source so that the patient receives oxygen via the catheter.

Suctioning can cause hypoxia, mucosal trauma, infection, vagal stimulation, bronchospasm, and cardiac dysrhythmias.

Hypoxia can be caused by these factors in the patient with a tracheostomy:

- Ineffective oxygenation before, during, and after suctioning
- Use of a catheter that is too large for the artificial airway
- Prolonged suctioning time
- Excessive suction pressure
- Too frequent suctioning

Prevent hypoxia by hyperoxygenating the patient with 100% oxygen using a manual resuscitation bag attached to an oxygen source. Instruct the patient to take deep breaths 3 or 4 times with the existing oxygen delivery system before suctioning. Monitor the heart rate or use a pulse oximeter while suctioning to assess tolerance of the procedure. Assess for hypoxia (e.g., increased heart rate and blood pressure, oxygen desaturation, cyanosis, restlessness, anxiety, dysrhythmias). Oxygen saturation below 90% by pulse oximetry indicates hypoxemia. If hypoxia occurs, stop the suctioning procedure. Using the 100% oxygen delivery system, reoxygenate the patient until baseline parameters return.

Use a correct-size catheter to reduce the risk for hypoxia and still remove secretions effectively. The size should not exceed half of the size of the tracheal lumen. The standard catheter size for an adult is 12 Fr or 14 Fr.

Tissue trauma results from frequent suctioning, prolonged suctioning, excessive suction pressure, and non-rotation of the catheter. Prevent trauma to the mucosa by suctioning only when needed and lubricating the catheter with sterile water or saline before insertion. *Apply suction only during catheter withdrawal*. Use a twirling motion during withdrawal to prevent grabbing of the mucosa.

Apply suction for only 10 to 15 seconds. Estimate this time frame by holding your own breath and counting to 10 or 15 during suctioning. At the end of the 15 seconds, stop suctioning. Longer suctioning can cause alveolar collapse *(suction atelectasis).*

Infection is possible because each catheter pass introduces bacteria into the trachea. In the hospital, use sterile technique for suctioning and for all suctioning equipment (e.g., suction catheters, gloves, saline or water). Suction the mouth or nose *after* suctioning the artificial airway. Clean

technique is used at home because the number of virulent organisms in the home environment is lower than in the hospital.

Nursing Safety Priority QSEN

Action Alert

Never use oral suction equipment for suctioning an artificial airway, because this can introduce oral bacteria into the lungs.

Vagal stimulation and bronchospasm are possible during suctioning. Vagal stimulation results in bradycardia, hypotension, heart block, ventricular tachycardia, or other dysrhythmias. *If vagal stimulation occurs, stop suctioning immediately and oxygenate the patient manually with 100% oxygen.* Bronchospasm may occur when the catheter passes into the airway. The patient may need a bronchodilator to relieve bronchospasm and respiratory distress. The hypoxia caused by suctioning can stimulate a variety of cardiac dysrhythmias. If the patient has cardiac monitoring in place, check the monitor during suctioning.

NCLEX Examination Challenge

Safe and Effective Care Environment

During nasotracheal suctioning, the client's heart rate changes from 78 beats/min to 48 beats/min. What is the nurse's best first action?
A Immediately stop suctioning
B Gently pinch the client's cheek
C Administer oxygen by mask at 2 L/min
D Document the change as the only action

Providing Tracheostomy Care.

Tracheostomy care keeps the tube free of secretions, maintains a patent airway, and provides wound care. It is performed whether or not the patient can clear secretions. Perform tracheostomy care according to agency policy, usually every 8 hours and as needed. Chart 28-3 outlines best practices for tracheostomy care.

Chart 28-3 Best Practice for Patient Safety & Quality Care QSEN

Tracheostomy Care

1. Assemble the necessary equipment.
2. Wash hands. Maintain Standard Precautions.
3. Suction the tracheostomy tube if necessary.
4. Remove old dressings and excess secretions.
5. Set up a sterile field.
6. Remove and clean the inner cannula. Use half-strength hydrogen peroxide to clean the cannula and sterile saline to rinse it. If the inner cannula is disposable, remove the cannula and replace it with a new one.
7. Clean the stoma site and then the tracheostomy plate with half-strength hydrogen peroxide followed by sterile saline. Ensure that none of the solutions enters the tracheostomy.
8. Change tracheostomy ties if they are soiled. Secure new ties in place before removing soiled ones to prevent accidental decannulation. If a knot is needed, tie a square knot that is visible on the side of the neck. Only one finger should be able to be placed between the tie tape and the neck.
9. Wash hands.
10. Document the type and amount of secretions and the general condition of the stoma and surrounding skin. Document the patient's response to the procedure and any teaching or learning that occurred.

Before tracheostomy care, assess the patient as described in Chart 28-4. The need for suctioning and tracheostomy care is determined by the secretions, the specific disorder, the ability of the patient to cough, the need for mechanical ventilation, and wound care. Using a penlight, inspect the inner lumen of a single-lumen tube to assess for secretions.

Chart 28-4 Focused Assessment

The Patient with a Tracheostomy

- Note the quality, pattern, and rate of breathing:
  - Within patient's baseline?
    Tachypnea can indicate hypoxia.
    Dyspnea can indicate secretions in the airway.
- Assess for any cyanosis, especially around the lips, which could indicate hypoxia.

- Check the patient's pulse oximetry reading.
- If oxygen is prescribed, is the patient receiving the correct amount, with the correct equipment and humidification?
- Assess the tracheostomy site:
  - Note the color, consistency, and amount of secretions in the tube or externally.
  - If the tracheostomy is sutured in place, is there any redness, swelling, or drainage from suture sites?
  - If the tracheostomy is secured with ties, what is the condition of the ties? Are they moist with secretions or perspiration? Are the secretions dried on the ties? Is the tie secure?
  - Assess the condition of the skin around the tracheostomy and neck. Be sure to check underneath the neck for secretions that may have drained to the back. Check for any skin breakdown related to pressure from the ties or related to excess secretions.
  - Assess behind the faceplate for the size of the space between the outer cannula and the patient's tissue. Are any secretions collected in this area?
- If the tube is cuffed, check cuff pressure.
- Auscultate the lungs.
- Are a second (emergency) tracheostomy tube and obturator available?

Secure tracheostomy tubes in place using either twill tape ties or commercial tube holders. Both devices require changing when soiled or at least daily to keep them clean, to prevent infection, and to assess for skin irritation under the ties. A properly secured tie or holder allows space for only one finger to be placed between the tie or holder and the neck (Morris et al., 2013). Tube movement causes irritation and coughing and may lead to decannulation. Keeping the tube secure while changing the ties or holder to prevent accidental decannulation is critical. Include the patient in tracheostomy care as a step toward self-care. Fig. 28-15 shows correct placement of a tracheostomy dressing.

FIG. 28-15 Placement of tracheostomy gauze dressing and Velcro tracheostomy tube holder.

Nursing Safety Priority QSEN

Critical Rescue

Prevent decannulation during tracheostomy care by keeping the old ties or holder on the tube while applying new ties or holder or by keeping a hand on the tube until it is securely stable. (This is best performed with the assistance of another person.)

Providing Bronchial and Oral Hygiene.

Bronchial hygiene promotes a patent airway and prevents infection. Turn and reposition the patient every 1 to 2 hours, support out-of-bed activities, and encourage ambulation to promote lung expansion and gas exchange and help remove secretions. Coughing and deep breathing, combined with the chest percussion, vibration, and postural drainage, promote pulmonary hygiene (see Chapter 30).

Good oral hygiene keeps the airway patent, prevents bacterial overgrowth, and promotes comfort. Avoid using glycerin swabs or mouthwash that contains alcohol for oral care because these products dry the mouth, change its pH, and promote bacterial growth. Instead, use a sponge tooth cleaner or soft-bristle toothbrush moistened in water for mouth care. Hydrogen peroxide solutions can help remove crusted matter but may break down healing tissue and should be used only with a physician's prescription. Help the patient rinse his or her mouth with

normal saline every 4 hours while awake or as often as he or she desires.

Examine the mouth for open areas or dental problems. Ulcers and infections are treated medically. Apply lip balm or water-soluble jelly to prevent cracked lips and promote comfort. Mouth care helps promote oral health, comfort, and aesthetic appearance. Offering an opportunity for the patient or family member to perform mouth care allows participation in care and increases self-esteem.

Oral secretions can move down the trachea and collect above the inflated cuff of the endotracheal tube. When the cuff is deflated, the secretions can move into the lungs. Some endotracheal tubes have an extra lumen open to the area above the cuff, which allows suctioning of the airway above the cuff before deflating and reduces the risk for aspiration.

Ensuring Nutrition.

Swallowing can be a major problem for the patient with a tracheostomy tube in place. In a normal swallow, the larynx lifts and moves forward to prevent the entering of food and saliva. The tracheostomy tube sometimes tethers the larynx in place, making it unable to move effectively. The result is difficulty in swallowing. Also, when the tracheostomy tube cuff is inflated, it can balloon backwards and interfere with food passage through the esophagus because the wall separating the back of the trachea and the front of the esophagus is thin.

Instruct the patient to keep the head of the bed elevated for at least 30 minutes after eating. Chart 28-5 outlines best practices to prevent aspiration during swallowing.

Chart 28-5 Best Practice for Patient Safety & Quality Care QSEN

Preventing Aspiration During Swallowing

- Avoid serving meals when the patient is fatigued.
- Provide smaller and more frequent meals.
- Provide adequate time; do not "hurry" the patient.
- Provide close supervision if the patient is self-feeding.
- Keep emergency suctioning equipment close at hand and turned on.
- Avoid water and other "thin" liquids.
- Thicken all liquids, including water.
- Avoid foods that generate thin liquids during the chewing process, such as fruit.

- Position the patient in the most upright position possible.
- When possible, completely (or at least partially) deflate the tube cuff during meals.
- Suction after initial cuff deflation to clear the airway and allow maximum comfort during the meal.
- Feed each bite or encourage the patient to take each bite slowly.
- Encourage the patient to "dry swallow" after each bite to clear residue from the throat.
- Avoid consecutive swallows of liquids.
- Provide controlled small volumes of liquids, using a spoon.
- Encourage the patient to "tuck" his or her chin down and move the forehead forward while swallowing.
- Allow the patient to indicate when he or she is ready for the next bite.
- If the patient coughs, stop the feeding until he or she indicates that the airway has been cleared.
- Continuously monitor tolerance to oral food intake by assessing respiratory rate, ease, pulse oximetry, and heart rate.

Maintaining Communication.

The patient can speak when there is a cuffless tube, when a fenestrated tracheostomy tube is in place, and when the fenestrated tube is capped or covered. Until natural speech is feasible, teach him or her and the family about other communication means. A writing tablet, a board with pictures and letters, communication "flash cards" on a ring, hand signals, and a computer, as well as a call light within reach, are used to promote communication and decrease frustration from not being able to speak or be understood. Phrase questions for "yes" or "no" answers to help the patient respond easily. Move the patient closer to the nurses' station, and mark the central call light system to indicate that he or she cannot speak.

The inability to talk is a stressor for the patient. Helping communication is an important nursing action and is required by The Joint Commission's National Patient Safety Goals (NPSGs). When the patient can tolerate cuff deflation, he or she places a finger over the tracheostomy tube on exhalation, forcing air up through the larynx and mouth and allowing speech.

A device to facilitate speech for the patient with a tracheostomy is a one-way valve that fits over the tube and replaces the need for finger occlusion. The valve allows him or her to breathe in through the tracheostomy tube. On exhalation, the valve closes so that air is forced through the vocal cords, allowing speech. For this valve to assist in

speech, the patient must not be connected to a ventilator, must have the cuff deflated, and must be able to breathe around the tube. Some valves have a port for supplemental oxygen without impairing the ability to speak.

Supporting Psychosocial Needs and Self-Image.

Addressing psychological concerns is an important aspect of caring for patients recovering from a tracheostomy. Always keep in mind the emotional impact of an artificial airway. Acknowledge the patient's frustration with communication, and allow sufficient time for communication. When speaking to him or her, use a normal tone of voice because hearing and comprehension are not altered by the presence of a tube.

The patient may have a change in self-image because of the presence of a stoma or artificial airway, speech changes, a change in the method of eating, or difficulty with speech. Help the patient set realistic goals, starting with involvement in self-care.

Work with the family to ease the patient into a more normal social environment. Provide encouragement and positive reinforcement while demonstrating acceptance and caring behaviors. Assess the family for the need for counseling.

After surgery, the patient may feel shy and socially isolated. He or she can wear loose-fitting shirts, decorative collars, or scarves to cover the tracheostomy tube.

Weaning.

Weaning the patient from a tracheostomy tube entails a gradual decrease in the tube size and ultimate removal of the tube. Carefully monitor this process, especially after each change. The physician or advanced practice nurse performs the steps in the process.

First, the cuff is deflated as soon as the patient can manage secretions and does not need mechanical ventilation. This change allows him or her to breathe through the tube and through the upper airway. Next, the tube is changed to an uncuffed tube. If this is tolerated, the size of the tube is gradually decreased. When a small fenestrated tube is placed, the tube is capped so that all air passes through the upper airway and the fenestra, with none passing through the tube. Assess the patient to ensure adequate airflow around the tube when it is capped. The tube may be removed after he or she tolerates more than 24 hours of capping. Place a dry dressing over the stoma (which gradually heals on its own).

Another device used for the transition from tracheostomy to natural

breathing is a *tracheostomy button.* The button maintains stoma patency and assists spontaneous breathing. The Kistner tracheostomy tube and Olympic tracheostomy button are examples of this type of device. To function, the button must fit properly. A disadvantage is the possibility of decannulation—the tube can dislodge from the trachea but remain in the neck tissues.

Clinical Judgment Challenge

Safety; Patient-Centered Care QSEN

Your patient is a 41-year-old woman with a significant closed head injury (CHI) from a motor vehicle crash (MVC). She is not anticipated to be able to be weaned from the ventilator, and the physicians have asked the patient's family for permission to create a tracheostomy. The family is concerned that the patient will not be able to speak again.

1. What is your response?
2. What are some possible concerns for patient care in the immediate postoperative period?
3. What can you do to minimize tracheal damage?
4. The patient's family is concerned that the tracheostomy will be permanent and they are worried about her image. How do you respond?

Community-Based Care

By the time of discharge, the patient should be able to provide self-care, which may include tracheostomy care, nutrition care, suctioning, and communication. Although education begins before surgery, most self-care is taught in the hospital. Teach the patient and family how to care for the tracheostomy tube. Review airway care, including cleaning and signs of infection. Teach clean suction technique, and review the plan of care.

Instruct the patient to use a shower shield over the tracheostomy tube when bathing to prevent water from entering the airway. Teach him or her to cover the airway loosely with a small cotton cloth to protect it during the day. Covering the opening filters the air entering the stoma, keeps humidity in the airway, and enhances appearance. Attractive coverings are available as cotton scarves, decorative collars, and jewelry.

Teach the patient to increase humidity in the home. Tell the patient to continue using the method of communication that began in the hospital and to wear a medical alert bracelet that identifies the inability to speak.

The health care team assesses specific discharge needs and makes

referrals to home care agencies and durable medical equipment companies (for suction equipment and tracheostomy supplies). Follow-up visits occur early after discharge, and the home care nurse also is an important resource for the patient and family. This nurse initiates and coordinates the services of dietitians, nurses, speech and language pathologists, and social workers. He or she informs the patient and family of community resources that can offer support and friendship.

Considerations for Older Adults

Patient-Centered Care QSEN

Self-managing tracheostomy care and oxygen therapy can be difficult for the older patient who has vision problems or difficulty with upper arm movement. Teach him or her to use magnifying lenses or glasses to ensure the proper setting on the oxygen gauge. Assess his or her ability to reach and manipulate the tracheostomy. If possible, work with a family member who can provide assistance during tracheostomy care.

Nursing Concepts and Clinical Judgment Review

What might you NOTICE if the patient is experiencing inadequate gas exchange with oxygenation and tissue perfusion as a result of respiratory problems?

- Respirations rapid and shallow
- Respirations noisy
- Cannot speak more than 4 or 5 words without pausing for breath
- Change in cognition, acute confusion
- Decreased oxygen saturation by pulse oximetry
- Skin cyanosis or pallor (lighter-skinned patients)
- Cyanosis or pallor of the lips and oral mucous membranes (in patients of any skin color)
- Tachycardia
- Patient appears to strain to catch breath
- Fatigue

What should you INTERPRET and how should you RESPOND to a patient experiencing inadequate gas exchange with oxygenation and tissue perfusion as a result of a respiratory problem?

Perform and interpret physical assessment, including:

- Taking vital signs

- Auscultating all lung fields
- Monitoring oxygen saturation by pulse oximetry
- Checking most recent laboratory values for hematocrit, hemoglobin, and ABG levels
- Assessing cognition (Mini-Mental State Examination [MMSE])
- Assessing for the use of accessory muscles
- Assessing for the presence of thick or excessive secretions
- Assessing the patient's ability to cough and clear the airway

Respond by:

- Applying oxygen and assessing the patient's responses to this intervention
- Keeping the patient's head elevated to about 30 degrees
- Suctioning (oral, pharyngeal, endotracheal, tracheostomy), if needed
- Notifying the physician or Rapid Response Team
- Prioritizing and pacing activities to prevent fatigue

On what should you REFLECT?

- Observe the patient for evidence of restored gas exchange (see Chapter 27).
- Think about what may have made the impaired gas exchange worse and what steps could be taken to either prevent a similar episode or identify it earlier.
- Think about what additional resources could improve the nursing response to this situation.

Get Ready for the NCLEX® Examination!

Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Never allow water condensation in an oxygen delivery system to drain back into the system. **Safety** QSEN
- Use sterile technique when performing endotracheal or tracheal suctioning. **Safety** QSEN
- Inspect the oral mucous membranes each shift for anyone who has an endotracheal tube. **Safety** QSEN
- Keep a tracheostomy tube (and obturator) and tracheostomy insertion tray at the bedside for the first 72 hours after a tracheostomy has been created. **Safety** QSEN
- Never use oral suctioning equipment to suction an artificial airway. **Safety** QSEN
- Use Aspiration Precautions for any patient with an altered level of consciousness or who has an endotracheal tube (see Chart 28-5). **Safety** QSEN
- Verify safe use of appropriate oxygen delivery systems and tracheostomy equipment. **Safety** QSEN

Health Promotion and Maintenance

- Teach the patient and family about home management of oxygen therapy, including the avoidance of smoking or open flames in rooms in which oxygen is being used. **Patient-Centered Care** QSEN
- Teach the patient and family how to perform tracheostomy care (see Chart 28-3). **Patient-Centered Care** QSEN

Psychosocial Integrity

- Provide opportunity for the patient and family to express concerns about a change in breathing status or the possibility of intubation and mechanical ventilation.
- Teach family members ways to communicate with a patient who is intubated or being mechanically ventilated. **Patient-Centered Care** QSEN
- Reassure patients who are intubated that the loss of speech is temporary. **Patient-Centered Care** QSEN

- Encourage patients with permanent tracheostomies to become involved in self-care. **Patient-Centered Care** QSEN

Physiological Integrity

- Apply oxygen to anyone who is hypoxemic. **Evidence-Based Practice** QSEN
- Ensure that oxygen therapy delivered to the patient is humidified appropriately. **Evidence-Based Practice** QSEN
- Monitor arterial blood gases (ABGs) and oxygen saturation of all patients receiving oxygen therapy. **Evidence-Based Practice** QSEN
- Assess the skin under the mask and under the plastic tubing every shift for patients receiving oxygen by mask. **Patient-Centered Care** QSEN
- Assess the skin of the nares and under the elastic band every shift for patients receiving oxygen by nasal cannula. **Patient-Centered Care** QSEN
- Observe any patient receiving oxygen at greater than a 50% concentration for early manifestations of oxygen toxicity (i.e. dyspnea, nonproductive cough, chest pain, GI upset). **Patient-Centered Care** QSEN
- Use a manual resuscitation bag to ventilate the patient if the tracheostomy tube has dislodged or become decannulated. **Safety** QSEN
- Assess the new tracheostomy stoma site at least once per shift for purulent drainage, redness, pain, and swelling as indicators of infection. **Evidence-Based Practice** QSEN
- Keep the tracheal cuff pressure between 14 and 20 mm Hg to prevent tissue injury. **Safety** QSEN

CHAPTER 29

Care of Patients with Noninfectious Upper Respiratory Problems

M. Linda Workman

PRIORITY CONCEPTS

- Gas Exchange
- Cellular Regulation

Learning Outcomes

Safe and Effective Care Environment

1. Protect patients with upper respiratory problems from hypoxia, injury, infection, and impairment in gas exchange.

Health Promotion and Maintenance

2. Teach all people measures to take to protect the upper respiratory system from damage and cancer (loss of cellular regulation), including the avoidance of known environmental causative agents.
3. Teach the patient and family how to manage a chronic lower respiratory disorder and avoid injury and complications in the home.

Psychosocial Integrity

4. Reduce the psychological impact for the patient and family experiencing an acute or chronic upper respiratory problem.
5. Work with other members of the health care team to ensure that values, preferences, and expressed needs of patients experiencing upper respiratory problems and reduced gas exchange are respected.

Physiological Integrity

6. Assess and re-assess the manifestations of patients being managed for an upper respiratory problem.
7. Use laboratory data and clinical manifestations to prioritize nursing care for the patient who has an acute or chronic upper respiratory problem.
8. Prioritize nursing care needs of a patient after a nasoseptoplasty.
9. Prioritize the nursing care needs of the patient and family experiencing head and neck cancer.
10. Work with other health care professionals who help the patient and family experiencing a chronic upper respiratory problem achieve desired health outcomes.
11. Coordinate nursing interventions for the patient with a chronic upper respiratory problem in the community.

 http://evolve.elsevier.com/Iggy/

The nose, sinuses, oropharynx, larynx, and trachea are the upper airway structures. They are important for gas exchange and perfusion by providing the entrance site for air. Problems of the upper airways, especially the larynx and trachea, can interfere with oxygen delivery. Patients with upper respiratory problems are found in the community and in all health care settings. *The nursing priority with disorders of the upper respiratory tract is to promote gas exchange by ensuring a patent airway.*

Disorders of the Nose and Sinuses

Fracture of the Nose

❖ Pathophysiology

Nasal fractures often result from injuries received during falls, sports activities, car crashes, or physical assaults and can interfere with gas exchange. If the bone or cartilage is not displaced and no complications are present, treatment may not be needed. Displacement of either the bone or cartilage, however, can cause airway obstruction or cosmetic deformity and is a potential source of infection.

❖ Patient-Centered Collaborative Care

◆ Assessment

Document any nasal problem, including deviation, malaligned nasal bridge, a change in nasal breathing, crackling of the skin *(crepitus)* on palpation, bruising, and pain. Blood or clear fluid (cerebrospinal fluid [CSF]) rarely drains from one or both nares as a result of a simple nasal fracture and, if present, indicates a serious injury (e.g., skull fracture). CSF can be differentiated from normal nasal secretions because CSF contains glucose that will test positive with a dipstick test for glucose. When CSF dries on a piece of filter paper, a yellow "halo" appears as a ring at the dried edge of the fluid. X-rays are not always useful in the diagnosis of simple nasal fractures.

◆ Interventions

The health care provider performs a simple **closed reduction** (moving the bones by palpation to realign them) of the nasal fracture using local or general anesthesia within the first 24 hours after injury. After 24 hours, the fracture is more difficult to reduce because of edema and scar formation. Then reduction may be delayed for several days until edema is gone. Simple closed fractures may not need surgical intervention. Management focuses on pain relief and cold compresses to decrease swelling.

Rhinoplasty.

Reduction and surgery may be needed for severe fractures or for those that do not heal properly. **Rhinoplasty** is a surgical reconstruction of the nose. It can be performed to repair a fractured nose and also can be performed to change the shape of the nose. The patient returns from

surgery with packing in both nostrils, which prevents bleeding and provides support for the reconstructed nose. As long as the packing is in place, the patient cannot breathe through the nose. A "moustache" dressing (or drip pad), often a folded 2 × 2 gauze pad, is usually placed under the nose (Fig. 29-1). A splint or cast may cover the nose for better alignment and protection. Change or teach the patient to change the drip pad as necessary.

FIG. 29-1 Immediate postoperative appearance of a patient who has undergone rhinoplasty. Note the splint and gauze drip pad (moustache dressing).

After surgery, observe for edema and bleeding. Check vital signs every 4 hours until the patient is discharged. The patient with uncomplicated rhinoplasty is discharged the day of surgery. Instruct him or her and the family about the routine care described below.

Nursing Safety Priority QSEN

Action Alert

Assessing how often the patient swallows after nasal surgery is a priority because repeated swallowing may indicate posterior nasal bleeding. Use a penlight to examine the throat for bleeding, and notify the surgeon if bleeding is present.

Instruct the patient to stay in a semi-Fowler's position and to move slowly. Suggest that he or she rests and uses cool compresses on the nose, eyes, and face to help reduce swelling and bruising. If a general anesthetic was used, soft foods can be eaten once the patient is alert and the gag reflex has returned. Urge the patient to drink at least 2500 mL/day.

To prevent bleeding, teach the patient to limit Valsalva maneuvers (e.g., forceful coughing or straining during a bowel movement), not to sniff upward or blow the nose, and not to sneeze with the mouth closed for the first few days after the packing is removed. Instruct the patient to avoid aspirin and other NSAIDs to prevent bleeding. Antibiotics may be prescribed to prevent infection. Recommend the use of a humidifier to prevent mucosal drying. Explain that edema lasts for weeks and that the final surgical result will be evident in 6 to 12 months.

Nasoseptoplasty.

Nasoseptoplasty, or **submucous resection (SMR),** may be needed to straighten a deviated septum when chronic "stuffy" nose, snoring, sinusitis, or discomfort occurs. Slight nasal septum deviation causes no manifestations. Major deviations may obstruct the nasal passages or interfere with airflow and sinus drainage. The deviated section of cartilage and bone is removed or reshaped as an ambulatory surgical procedure. Nursing care is similar to that for a rhinoplasty.

Epistaxis

❖ Pathophysiology

Epistaxis (nosebleed) is a common problem because of the many capillaries within the nose. Nosebleeds occur as a result of trauma, hypertension, blood dyscrasia (e.g., leukemia), inflammation, tumor, decreased humidity, nose blowing, nose picking, chronic cocaine use, and procedures such as nasogastric suctioning. Older adults tend to bleed most often from the posterior portion of the nose.

❖ Patient-Centered Collaborative Care

The patient often reports that the bleeding started after sneezing or blowing the nose. Document the amount and color of the blood, and take vital signs. Ask the patient about the number, duration, and causes of previous bleeding episodes.

Chart 29-1 lists the best practices for emergency care of the patient

with a nosebleed. An additional intervention for use at home or in the emergency department is a special nasal plug that contains an agent to promote blood clotting (sold by HemCon). The plug expands on contact with blood and compresses mucosal blood vessels.

Chart 29-1 Best Practice for Patient Safety & Quality Care QSEN

Emergency Care of a Patient with an Anterior Nosebleed

- Maintain Standard Precautions or Body Substance Precautions.
- Position the patient upright and leaning forward to prevent blood from entering the stomach and possible aspiration.
- Reassure the patient and attempt to keep him or her quiet to reduce anxiety and blood pressure.
- Apply direct lateral pressure to the nose for 10 minutes, and apply ice or cool compresses to the nose and face if possible.
- If nasal packing is necessary, loosely pack both nares with gauze or nasal tampons.
- To prevent rebleeding from dislodging clots, instruct the patient to not blow the nose for 24 hours after the bleeding stops.
- Seek medical assistance if these measures are ineffective or if the bleeding occurs frequently.

Medical attention is needed if the nosebleed does not respond to these interventions. In such cases, the affected capillaries may be cauterized with silver nitrate or electrocautery and the nose packed. Anterior packing controls bleeding from the anterior nasal cavity.

Posterior nasal bleeding is an emergency because it cannot be easily reached and the patient may lose a lot of blood quickly (Vacca & Poirier, 2013). Posterior packing, epistaxis catheters (nasal pressure tubes), or a gel tampon is used to stop bleeding that originates in the posterior nasal region. With packing, the health care provider positions a large gauze pack in the posterior nasal cavity above the throat, threads the attached string through the nose, and tapes it to the patient's cheek to prevent pack movement. Epistaxis catheters look like very short (about 6 inches) urinary catheters (Fig. 29-2, *A*). These tubes have an exterior balloon along the tube length in addition to an anchoring balloon on the end. Placement of posterior packing or pressure tubes is uncomfortable, and the airway may be obstructed and gas exchange impaired if the pack slips. Fig. 29-2, *B*, shows a patient with tubes in place for a posterior nasal

bleed.

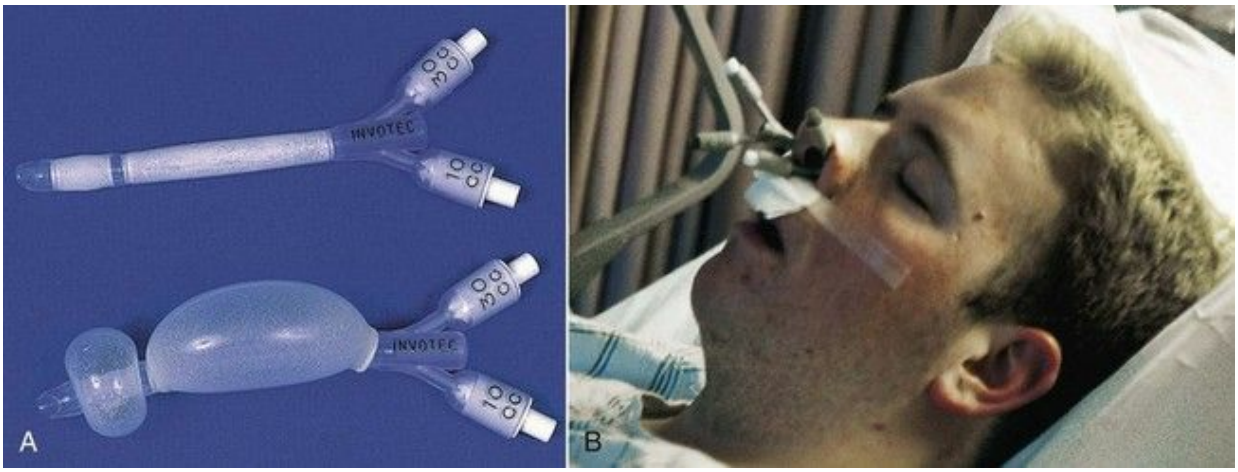

FIG. 29-2 **A,** The Ultra-Stat epistaxis catheter. **B,** Patient with epistaxis catheters in place to control a posterior nasal bleed.

Observe the patient for respiratory distress and for tolerance of the packing or tubes. Humidity, oxygen, bedrest, and antibiotics may be prescribed. Opioid drugs may be prescribed for pain. Assess patients receiving opioids at least hourly for gag and cough reflexes. Use pulse oximetry to monitor for hypoxemia. The tubes or packing is usually removed after 1 to 3 days.

For posterior bleeds that do not respond to packing or tubes, additional options include cauterizing the blood vessels, ligating the vessels, or performing an embolization of the bleeding artery with interventional radiology. Potential complications of embolization include facial pain, necrosis of skin or nasal mucosa, facial nerve paralysis, and blindness (Poetker, 2013).

After the tubes or packing is removed, teach the patient and family these interventions to use at home for comfort and safety:

- Petroleum jelly can be applied sparingly to the nares for lubrication and comfort. (Excessive application could cause inhalation of the jelly into the lungs and increase the risk for pneumonia.)
- Nasal saline sprays and humidification add moisture and prevent rebleeding.
- Avoid vigorous nose blowing, the use of aspirin or other NSAIDs, and strenuous activities such as heavy lifting for at least 1 month.

NCLEX Examination Challenge

Health Promotion and Maintenance

Which precaution is most important for the nurse to teach a client who is a secretary and just had nasal tubes removed after a posterior nasal bleed?
A "Avoid NSAIDs for at least 1 week."
B "Wait 4 weeks before returning to work."
C "If bleeding recurs, call 911 immediately."
D "Do not blow your nose for at least a month."

Cancer of the Nose and Sinuses

Tumors of the nasal cavities and sinuses are rare, the result of loss of cellular regulation, and may be either benign or malignant. This type of cancer is more common among people with chronic exposure to wood dusts, dusts from textiles, leather dusts, flour, nickel and chromium dust, mustard gas, and radium. Cigarette smoking along with these exposures increases the risk (American Cancer Society [ACS], 2014).

The onset of sinus cancer is slow, and manifestations resemble sinusitis. These include persistent nasal obstruction, drainage, bloody discharge, and pain that persists after treatment of sinusitis. Lymph node enlargement often occurs on the side with tumor mass. Tumor location is identified with x-ray, CT, or MRI. A biopsy is performed to confirm the diagnosis.

Surgical removal of all or part of the tumor is the main treatment for nasopharyngeal cancers. It is usually combined with radiation therapy, especially intensity modulated radiation therapy (IMRT) (see Chapter 22). Chemotherapy may be used in conjunction with surgery and radiation for some tumors. Problems after surgery include a change in body image or speech and altered nutrition, especially when the maxilla and floor of the nose are involved in the surgery. Patients often also have changes in taste and smell.

Provide general postoperative care (see Chapter 16), including maintaining a patent airway, monitoring for hemorrhage, providing wound care, assessing nutrition status, and performing tracheostomy care (if needed). (See Chapter 28 for tracheostomy care.) Perform careful mouth and sinus cavity care with saline irrigations using an electronic irrigation system (e.g., Waterpik, Sonicare) or a syringe. Assess the patient for pain and infection. Collaborate with the dietitian to help the patient make food selections that promote healing.

Facial Trauma

Pathophysiology

Facial trauma is described by the specific bones (e.g., mandibular, maxillary, orbital, nasal fractures) and the side of the face involved. Mandibular (lower jaw) fractures are the most common. *Le Fort I* is a nasoethmoid complex fracture. *Le Fort II* is a maxillary *and* nasoethmoid complex fracture. *Le Fort III* combines I and II plus an orbital-zygoma fracture, called "craniofacial disjunction" because the midface has no connection to the skull. The rich facial blood supply results in extensive bleeding and bruising.

Patient-Centered Collaborative Care

Assessment

The priority action when caring for a patient with facial trauma is airway assessment for gas exchange. Manifestations of airway obstruction are stridor, shortness of breath, dyspnea, anxiety, restlessness, hypoxia, **hypercarbia** (elevated blood levels of carbon dioxide), decreased oxygen saturation, cyanosis, and loss of consciousness. After establishing the airway, assess the site of trauma for bleeding and possible fractures. Check for soft-tissue edema, facial asymmetry, pain, or leakage of spinal fluid through the ears or nose, indicating a skull fracture. Assess vision and eye movement because orbital and maxillary fractures can entrap the eye nerves and muscles. Check behind the ears (mastoid area) for extensive bruising, known as the "battle sign," which is often associated with skull fracture and brain trauma. Because facial trauma can occur with spinal trauma and skull fractures, cranial CT, facial series, and cervical spine x-rays are obtained.

Interventions

The priority action is to establish and maintain an airway for adequate gas exchange. Anticipate the need for emergency intubation, **tracheotomy** (surgical incision into the trachea to create an airway), or **cricothyroidotomy** (creation of a temporary airway by making a small opening in the throat between the thyroid cartilage and the cricoid cartilage). Care at first focuses on establishing an airway, controlling hemorrhage, and assessing for the extent of injury. If shock is present, fluid resuscitation and identification of bleeding sites are started immediately.

Time is critical in stabilizing the patient who has head and neck trauma. Early response and treatment by special services (e.g., trauma

team, maxillofacial surgeon, general surgeon, otolaryngologist, plastic surgeon, dentist) optimize the patient's recovery.

Stabilizing the fractured jaw allows the teeth to heal in proper alignment and involves **fixed occlusion** (wiring the jaws together with the mouth in a closed position). The patient remains in fixed occlusion for 6 to 10 weeks. Treatment delay, tooth infection, or poor oral care may cause jaw bone infection. This condition may then require surgical removal of dead tissue, IV antibiotic therapy, and a longer period with the jaws in a fixed position.

Extensive jaw fractures may require open reduction with internal fixation (ORIF) procedures. Compression plates and reconstruction plates with screws may be applied. Plates may be made of stainless steel, titanium, or Vitallium. If the mandibular fracture is repaired with titanium plates, the plates are permanent and do not interfere with MRI studies.

Facial fractures may be repaired with microplating surgical systems that involve bone substitutes. These shaping plates hold the bone fragments in place until new bone growth occurs. Bone cells grow into the bone substitute and re-matrix into a stable bone support. The plates may remain in place permanently or may be removed after healing.

Other fixation methods include the use of resorbable devices (plates and screws) to hold tissues in place. These devices are made from a plastic-like material that retains its integrity for about 8 weeks and then slowly biodegrades. With inner maxillary fixation (IMF), the bones are realigned and then wired in place with the bite closed. Nondisplaced aligned fractures can be repaired in a clinic or office using local dental anesthesia. General anesthesia is used to repair displaced or complex fractures or fractures that occur with other facial bone fractures.

After surgery, teach the patient about oral care with an irrigating device, such as a Waterpik or Sonicare. If the patient has inner maxillary fixation, teach self-management with wires in place, including a dental liquid diet. If the patient vomits, watch for aspiration because of the patient's inability to open the jaws to allow ejection of the emesis. Teach him or her how to cut the wires if vomiting occurs to maintain gas exchange. If the wires are cut, instruct the patient to return to the surgeon for rewiring as soon as possible to reinstitute fixation.

Nursing Safety Priority QSEN

Action Alert

Instruct the patient to keep wire cutters with him or her at all times to prevent aspiration if vomiting occurs.

Nutrition is important and difficult for a patient with fractures because of oral fixation, pain, and surgery. Collaborate with the dietitian for patient teaching and support.

Obstructive Sleep Apnea

Pathophysiology

Obstructive sleep apnea (OSA) is a breathing disruption during sleep that lasts at least 10 seconds and occurs a minimum of 5 times in an hour. The most common cause of sleep apnea is upper airway obstruction by the soft palate or tongue. Factors that contribute to sleep apnea include obesity, a large uvula, a short neck, smoking, enlarged tonsils or adenoids, and oropharyngeal edema.

During sleep, the muscles relax and the tongue and neck structures are displaced. As a result, the upper airway is obstructed but chest movement is unimpaired. The apnea impairs gas exchange and increases blood carbon dioxide levels and decreases the pH. These blood gas changes stimulate neural centers. The sleeper awakens after 10 seconds or longer of apnea and corrects the obstruction, and respiration resumes. After he or she goes back to sleep, the cycle begins again, sometimes as often as every 5 minutes.

This cyclic pattern of disrupted sleep prevents the deep sleep needed for best rest. Thus the person may have excessive daytime sleepiness, an inability to concentrate, and irritability. The long-term effects of OSA include increased risk for hypertension, stroke, neurocognitive deficits, weight gain, diabetes, and pulmonary and cardiovascular disease (Woidtke, 2013).

Patient-Centered Collaborative Care

Assessment

Patients are often unaware that they have sleep apnea. The disorder should be suspected for any person who has persistent daytime sleepiness or reports "waking up tired," particularly if he or she also snores heavily. Other manifestations include irritability and personality changes. Sleep apnea may be verified by family members who observe the problem when the person sleeps. A complete assessment is performed when excessive daytime sleepiness is a problem.

A beginning assessment includes having the patient complete the Epworth Sleepiness Scale (ESS) (Simmons & Pruitt, 2012). The patient is asked to score his or her likelihood of falling asleep during eight common activities or scenarios. Each is self-scored from 0 to 3. Those patients who score 18 or above are considered at risk for severe sleep apnea.

The most accurate test for sleep apnea is an overnight sleep study. In this study, the patient is directly observed while wearing a variety of monitoring equipment to evaluate depth of sleep, type of sleep, respiratory effort, oxygen saturation, and muscle movement. Monitoring devices include an electroencephalograph (EEG), an electrocardiograph (ECG), a pulse oximeter, and an electromyograph (EMG). Home-based sleep studies also are available but often not covered by insurance (Carlucci et al., 2013).

Interventions

A change in sleeping position or weight loss may correct mild sleep apnea and improve gas exchange. Position-fixing devices may prevent subluxation of the tongue and neck structures and reduce obstruction. Severe sleep apnea requires additional methods to prevent obstruction.

A common method to prevent airway collapse is the use of noninvasive positive-pressure ventilation (NPPV) to hold open the upper airways. A nasal mask or full-face mask delivery system allows mechanical delivery of either bi-level positive airway pressure (BiPAP), autotitrating positive airway pressure (APAP), or nasal continuous positive airway pressure (CPAP). With BiPAP, a machine delivers a set inspiratory positive airway pressure at the beginning of each breath. As the patient begins to exhale, the machine delivers a lower end-expiratory pressure. These two pressures hold open the upper airways. With APAP, the machine adjusts continuously, resetting the pressure throughout the breathing cycle to meet the patient's needs. Nasal CPAP delivers a set positive airway pressure continuously during each cycle of inhalation and exhalation. For any positive-pressure ventilation delivered through a facemask during sleep, a small electric compressor is required. Proper fit of the mask over the nose and mouth or just over the nose is key to successful treatment (see Fig. 28-9 in Chapter 28). Although noisy, these methods are accepted by most patients after an adjustment period.

One drug has been approved to help manage the daytime sleepiness associated with sleep apnea. Modafinil (Attenace, Provigil) is helpful for patients who have *narcolepsy* (uncontrolled daytime sleep) from sleep apnea by promoting daytime wakefulness. This drug does *not* treat the cause of sleep apnea. Sleep-inducing sedatives also are not considered first-line therapy.

Surgical intervention may involve a simple adenoidectomy, uvulectomy, or remodeling of the entire posterior oropharynx (uvulopalatopharyngoplasty [UPP]). Both conventional and laser surgeries are used for this purpose. A tracheostomy may be needed for

very severe sleep apnea that is not relieved by more moderate interventions.

Disorders of the Larynx

Vocal Cord Paralysis

Vocal fold (cord) paralysis may result from injury, trauma, or diseases that affect the larynx, laryngeal nerves, or vagus nerve. Prolonged intubation with an endotracheal (ET) tube may cause temporary or permanent paralysis. Paralysis may occur in patients with neurologic disorders or with conditions that damage either the vagus nerve or the laryngeal nerves. Paralysis of both vocal cords may result from injury, brainstem stroke, or total thyroidectomy.

Vocal fold paralysis may affect both cords or only one. When only one vocal cord is involved (most common), the airway remains patent but the voice is affected. Manifestations of open bilateral vocal cord paralysis include hoarseness; a breathy, weak voice; and aspiration of food. *Bilateral closed vocal cord paralysis causes airway obstruction and is an emergency if the manifestations are severe and the patient cannot compensate. Stridor is the major manifestation.*

Securing an airway is the main intervention. Place the patient in a high-Fowler's position to aid in breathing and proper alignment of airway structures. Assess for airway obstruction.

Nursing Safety Priority QSEN

Critical Rescue

Immediately notify the Rapid Response Team if dyspnea with stridor occurs. Emergency endotracheal intubation or tracheotomy may be needed.

Various surgical procedures can improve the voice. One simple procedure for open vocal cord paralysis involves injecting polytef (Teflon) into the affected cord so it enlarges toward the unaffected cord. This technique improves closure during speaking and eating.

The patient with open cord paralysis is at risk for aspiration because the airway is open during swallowing. Teach him or her to hold the breath during swallowing to allow the larynx to rise, close, and push food back into the esophagus during swallowing. Teach the patient to tuck the chin down and tilt the forehead forward during swallowing. Indications of aspiration include immediate coughing on swallowing of liquids or solids, a “wet”-sounding voice, and “tearing up” or watery eyes on swallowing. Chest x-rays are used to diagnose aspiration pneumonia.

Laryngeal Trauma

Laryngeal trauma occurs with a crushing or direct blow injury, fracture, or prolonged endotracheal intubation. Manifestations include difficulty breathing **(dyspnea),** inability to produce sound **(aphonia),** hoarseness, and **subcutaneous emphysema** (air present in the subcutaneous tissue). Bleeding from the airway **(hemoptysis)** may occur, depending on the location of the trauma. The health care provider performs a direct visual examination of the larynx by laryngoscopy or fiberoptic laryngoscopy to determine the extent of the injury.

Management of patients with laryngeal injuries consists of assessing the effectiveness of gas exchange and monitoring vital signs (including respiratory status and pulse oximetry) every 15 to 30 minutes. *Maintaining a patent airway is a priority.* Apply oxygen and humidification as prescribed to maintain adequate oxygen saturation. Manifestations of respiratory difficulty include tachypnea, nasal flaring, anxiety, sternal retraction, shortness of breath, restlessness, decreased oxygen saturation, decreased level of consciousness, and stridor.

Nursing Safety Priority QSEN

Critical Rescue

If the patient has respiratory difficulty, stay with him or her and instruct other trauma team members or the Rapid Response Team to prepare for an emergency intubation or tracheotomy.

Surgical intervention is needed for lacerations of the mucous membranes, cartilage exposure, and cord paralysis. Laryngeal repair is performed as soon as possible to prevent laryngeal stenosis and to cover any exposed cartilage. An artificial airway may be needed.

Other Upper Airway Disorders

Upper Airway Obstruction

Pathophysiology

Upper airway obstruction is a life-threatening emergency in which airflow through nose, mouth, pharynx, or larynx is interrupted and gas exchange is impaired. Early recognition is essential to prevent complications, including respiratory arrest. Causes of upper airway obstruction include:

- Tongue edema (surgery, trauma, angioedema as an allergic response to a drug)
- Tongue occlusion (e.g., loss of gag reflex, loss of muscle tone, unconsciousness, coma)
- Laryngeal edema
- Peritonsillar and pharyngeal abscess
- Head and neck cancer
- Thick secretions
- Stroke and cerebral edema
- Smoke inhalation edema
- Facial, tracheal, or laryngeal trauma
- Foreign-body aspiration
- Burns of the head or neck area
- Anaphylaxis

One preventable cause of airway obstruction leading to asphyxiation is inspissated (thickly crusted) oral and nasopharyngeal secretions. In this condition, poor oral hygiene leads to thickening and hardening of secretions that can completely block the airway and lead to death. Proper nursing care can eliminate this cause of airway obstruction. Patients at highest risk are those with an altered mental status and level of consciousness, are dehydrated, are unable to communicate, are unable to cough effectively, or are at risk for aspiration.

Nurse Safety Priority QSEN

Action Alert

Assess the oral care needs of the patient with risk factors for inspissated secretions daily. Ensure that whoever provides oral care understands the importance and the correct techniques for preventing secretion buildup and airway obstruction.

Patient-Centered Collaborative Care

Assessment

Airway obstruction is frightening, and prompt care is essential to prevent a partial obstruction from progressing to a complete obstruction. Partial obstruction produces general manifestations such as diaphoresis, tachycardia, and elevated blood pressure. Persistent or unexplained manifestations must be evaluated even though vague. Diagnostic procedures include chest or neck x-rays, laryngoscopic examination, and computed tomography.

Observe for hypoxia and hypercarbia, restlessness, increasing anxiety, sternal retractions, a "seesawing" chest, abdominal movements, or a feeling of impending doom from air hunger. Use pulse oximetry or end-tidal carbon dioxide ($ETCO_2$ or $PETCO_2$) for ongoing monitoring of gas exchange. Continually assess for stridor, cyanosis, and changes in level of consciousness.

Interventions

Assess for the cause of the obstruction. When the obstruction is due to the tongue falling back or excessive secretions, slightly extend the patient's head and neck and insert a nasal or an oral airway. Suction to remove obstructing secretions. If the obstruction is caused by a foreign body, perform abdominal thrusts (Fig. 29-3).

With the conscious victim standing or sitting, place your fist between the victim's lower rib cage and navel. Wrap the palm of your hand around your fist. A quick inward, upward thrust expels the air remaining in the victim's lungs, and with it the foreign body. If the first thrust is unsuccessful, repeat several thrusts in rapid succession until the foreign body is expelled or until the victim loses consciousness.

With the unconscious victim lying supine, straddle the victim's thighs. Place one hand on top of the other as shown, with the heel of the bottom hand just above the victim's navel. Quickly thrust inward and upward, toward the victim's head.

FIG. 29-3 The abdominal thrust maneuver (formerly known as the *Heimlich maneuver*) for relief of upper airway obstruction caused by a foreign body.

Upper airway obstruction may require emergency procedures such as cricothyroidotomy, endotracheal intubation, or tracheotomy to improve gas exchange. Direct laryngoscopy may be performed before or with these procedures to determine the cause of obstruction or to remove foreign bodies.

Cricothyroidotomy is an emergency procedure performed by emergency medical personnel as a stab wound at the cricothyroid membrane between the thyroid cartilage and the cricoid cartilage (see Fig. 27-4 in Chapter 27). Any hollow tube—but preferably a tracheostomy tube—can be placed through the opening to hold this airway open until a tracheotomy can be performed. This procedure is used when it is the *only* way to secure an airway. Another emergency procedure to bypass an obstruction is the insertion of a 14-gauge needle directly into the cricoid space to allow airflow into and out of the lungs.

Endotracheal intubation is performed by inserting a tube into the trachea via the nose **(nasotracheal)** or mouth **(orotracheal)** by a physician, anesthesia provider, or other specially trained personnel.

Tracheotomy is a surgical procedure and takes about 5 to 10 minutes to perform. It is best performed in the operating room (OR) with the patient under local or general anesthesia but can be performed at the bedside. Local anesthesia is used if there is concern that the airway will

be lost during the induction of anesthesia. A tracheotomy is reserved for the patient who cannot be easily intubated with an endotracheal tube. An emergency tracheotomy can establish an airway in less than 2 minutes. See Chapter 28 for a discussion of care of the patient with a tracheotomy.

Patients receiving mechanical ventilation for upper airway obstruction or respiratory failure may require a tracheostomy after 7 or more days of continuous intubation. In such cases, a tracheotomy is performed to prevent laryngeal injury by the endotracheal tube.

NCLEX Examination Challenge

Physiological Integrity

The client is a woman with severe angioedema and tongue swelling from exposure to seafood. She has stridor, and her oxygen saturation is 70%. For which type of respiratory support does the nurse prepare?
A Nasal BiPAP
B Tracheotomy
C Cricothyroidotomy
D Endotracheal intubation

Neck Trauma

Neck injuries may be caused by any weapon or trauma. The patient with neck trauma may have other injuries, including cardiovascular, respiratory, intestinal, and neurologic damage. The final outcome of this type of injury depends on initial assessment and care. Consult a critical care textbook and see Chapter 43 for more detailed information.

The priority nursing care for a patient with neck trauma is assessing for and maintaining a patent airway. After airway patency is ensured, assess for bleeding or impending shock.

Perform a neurologic assessment for mental status, sensory level, and motor function. Injury to the carotid artery may result in death, stroke, or paralysis from disruption of blood flow to the brain (see Chapter 41). A carotid angiogram may be needed to rule out vascular injuries.

Esophagus injury may occur with neck trauma. Assess for chest pain and tenderness, oral bleeding, and **crepitus** (crackling sounds when palpating the skin). A barium or meglumine diatrizoate (Gastrografin) swallow may be needed to rule out an esophageal perforation injury.

Cervical spine injuries often occur at the same time as a neck injury (see Chapter 43). Obstruction can occur as a result of the initial injury or

from swelling after surgery to repair the injury. Health care personnel must take great care not to make these injuries worse by causing neck movement while establishing the airway using the jaw-thrust maneuver. Prepare to assist in emergency intubation, cricothyrotomy, or tracheotomy to establish a patent airway. Interventions for patients in shock are detailed in Chapter 37.

Head and Neck Cancer

❖ Pathophysiology

Head and neck cancer can disrupt breathing (gas exchange), eating, facial appearance, self-image, speech, and communication. This form of cancer can be devastating, even when cured. The care needs for patients with these problems are complex, requiring a coordinated and comprehensive team approach.

Head and neck cancers are usually squamous cell carcinomas. These slow-growing tumors are curable when treated early. The prognosis for those who have more advanced disease at diagnosis depends on the extent and location of the tumors. Untreated cancer of the head and neck is a fatal disease within 2 years of diagnosis (ACS, 2014).

The cancer begins as a loss of cellular regulation when the mucosa is chronically irritated and becomes tougher and thicker *(squamous metaplasia).* At the same time, genes controlling cell growth are damaged, allowing excessive growth of these abnormal cells, which eventually become malignant. These lesions may then be seen as white, patchy lesions **(leukoplakia)** or red, velvety patches **(erythroplakia).**

Head and neck cancer first spreads **(metastasizes)** into nearby structures, such as lymph nodes, muscle, and bone. Later spread is systemic to distant sites, usually to the lungs or liver.

The cancer type and stage are determined by cellular analysis. Earlier-stage cancers are described as *carcinoma in situ* and *well differentiated.* Without treatment, cancers progress to be *moderately differentiated* and, finally, *poorly differentiated.* Most head and neck cancers arise from the mucous membrane and skin, but they also can start from salivary glands, the thyroid, or other structures. Treatment is based on tumor cell type and degree of spread at diagnosis.

Etiology.

The two most important risk factors for head and neck cancer are tobacco and alcohol use, especially in combination. Other risk factors include voice abuse, chronic laryngitis, exposure to chemicals or dusts, poor oral

hygiene, long-term or severe gastroesophageal reflux disease, and oral infection with the human papillomavirus (ACS, 2014).

Incidence and Prevalence.

The frequency of head and neck carcinoma is increasing in North America. About 60,000 new cases of oral, pharyngeal, and laryngeal cancers are diagnosed each year and account for more than 13,000 deaths per year (ACS, 2014; Canadian Cancer Society, 2014). They affect men twice as often as women and are most common in people older than 60 years.

Patient-Centered Collaborative Care

Assessment

History.

The patient may have difficulty speaking because of hoarseness, shortness of breath, tumor bulk, and pain. Pace the interview to avoid tiring the patient.

Ask about tobacco and alcohol use, history of acute or chronic laryngitis or pharyngitis, oral sores, and lumps in the neck. Calculate the patient's pack-years of smoking history (see Chapter 27). Ask about alcohol intake (how many drinks per day and for how many years). Also ask about exposure to pollutants.

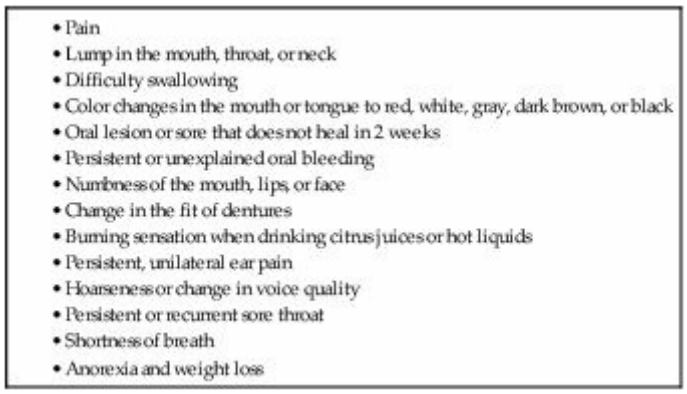
Assess problems related to risk factors. For example, nutrition may be poor because of alcohol intake and impaired liver function. Assess dietary habits and any weight loss. Ask about any chronic lung disease, which may have an impact on gas exchange.

Physical Assessment/Clinical Manifestations.

Table 29-1 lists the warning signs of head and neck cancer. With laryngeal cancer, painless hoarseness may occur because of tumor size and an inability of the vocal cords to come together for normal speech. Vocal cord lesions form early in laryngeal cancer. Any person who has a history of hoarseness, mouth sores, or a lump in the neck for 3 to 4 weeks should be evaluated for laryngeal cancer.

TABLE 29-1

Warning Signs of Head and Neck Cancer



- Pain
- Lump in the mouth, throat, or neck
- Difficulty swallowing
- Color changes in the mouth or tongue to red, white, gray, dark brown, or black
- Oral lesion or sore that does not heal in 2 weeks
- Persistent or unexplained oral bleeding
- Numbness of the mouth, lips, or face
- Change in the fit of dentures
- Burning sensation when drinking citrus juices or hot liquids
- Persistent, unilateral ear pain
- Hoarseness or change in voice quality
- Persistent or recurrent sore throat
- Shortness of breath
- Anorexia and weight loss

Inspect the head and neck for symmetry and the presence of lumps or lesions. An advanced practice nurse or physician may perform a laryngeal examination using a laryngeal mirror or fiberoptic laryngoscope. The neck is palpated to assess for enlarged lymph nodes.

Psychosocial Assessment.

Often the patient with head and neck cancer has a long-standing history of tobacco or alcohol use or both. Assess the adequacy of support systems and coping mechanisms. Document social and family support because the patient often needs extensive assistance at home after treatment. Collaborate with a social worker as needed. Assess the level of education or literacy of the patient and family to plan teaching before and after surgery.

Document any family history of cancer, as well as the patient's age, gender, occupation, and ability to perform ADLs. Ask the patient whether his or her occupation requires continual oral communication. Job retraining may be needed if treatment affects speech.

Laboratory Assessment.

Diagnostic tests include a complete blood cell count, bleeding times, urinalysis, and blood chemistries. The patient with chronic alcoholism may have low protein and albumin levels from poor nutrition. Liver and kidney function tests are performed to rule out cancer spread and to evaluate the patient's ability to metabolize drugs and chemotherapy agents.

Imaging Assessment.

Many types of imaging studies, including x-rays of the skull, sinuses, neck, and chest, are useful in diagnosing cancer spread, other tumors,

and the extent of tumor invasion. Computed tomography (CT), with or without contrast medium, helps evaluate the tumor's exact location. Magnetic resonance imaging (MRI) can help differentiate normal from diseased tissue.

The brain, bone, and liver are evaluated with nuclear imaging, bone scans, single-photon emission computerized tomography (SPECT) scans, and positron emission tomography (PET) scans. These tests locate additional tumor sites.

Other Diagnostic Assessment.

Other helpful tests include direct and indirect laryngoscopy, tumor mapping, and biopsy. *Panendoscopy* (laryngoscopy, nasopharyngoscopy, esophagoscopy, and bronchoscopy) is performed with general anesthesia to define the extent of the tumor. Tumor-mapping biopsies are performed to identify tumor location. Biopsy tissues taken at the time of the panendoscopy confirm the diagnosis, tumor type, cell features, location, and stage (see Chapter 21).

NCLEX Examination Challenge

Health Promotion and Maintenance

The 62-year-old client whose brother was just diagnosed with head and neck cancer asks the nurse what he could do to reduce his risk for also developing this cancer. What is the nurse's best response?

A "Because head and neck cancer has a strong hereditary component, participating in screening twice yearly is critical for you."
B "Always wear sunscreen with a 50% or greater protection factor whenever you are outdoors."
C "Avoid shouting and singing to prevent stress to your vocal cords and larynx."
D "Stop smoking, and drink alcohol only in moderation."

Analysis

The priority NANDA-I nursing diagnoses and collaborative problems for patients with head and neck cancer include:

1. Potential for respiratory obstruction
2. Risk for Aspiration related to edema, anatomic changes, or altered protective reflexes (NANDA-I)
3. Anxiety related to threat of death, change in role status, or change in economic status (NANDA-I)

4. Reduced self-concept related to tumor and treatment modalities

Planning and Implementation

Preventing Respiratory Obstruction.

Without treatment, head and neck cancers grow, obstruct the airway, and prevent gas exchange leading to death. Airway obstruction also can occur as a complication of treatment modalities.

Planning: Expected Outcomes.

The patient with head and neck cancer is expected to attain and maintain adequate gas exchange and tissue oxygenation. Indicators include:
- Arterial blood gas values within the normal range
- Rate and depth of respiration within the normal range
- Pulse oximetry within the normal range

Interventions.

The focus of treatment is to remove or eradicate the cancer while preserving as much normal function as possible. The physician presents the available treatment options. Surgery, radiation, chemotherapy, or biotherapy may be used alone or in combination. Considerations for treatment options include the patient's physical condition, nutrition status, and age; the effects of the tumor on body function; and the patient's personal choice. Treatment for laryngeal cancer may range from radiation therapy (for a small specific area or tumor) to total laryngopharyngectomy with bilateral neck dissections followed by radiation therapy, depending on the extent and location of the lesion. Voice-conservation procedures are used only if they do not risk incomplete removal of the tumor. Nursing care focuses on the patient's total needs, including preoperative preparation, optimal in-hospital care, discharge planning and teaching, and extensive outpatient rehabilitation.

Nonsurgical Management.

Monitor gas exchange and the respiratory system by assessing respiratory rate, breath sounds, pulse oximetry, and arterial blood gas values. Airway obstruction can occur from tumor growth, edema, or both. Teach the patient to use the Fowler's and semi-Fowler's positions for best gas exchange. Sitting upright in a reclining chair may promote more comfortable breathing. Chapters 3 and 7 provide additional information on palliation and pain control for patients who elect not to have therapy and for those whose therapy has not been effective.

Radiation therapy for treatment of small cancers in specific locations has a cure rate of at least 80%. Standard therapy uses 5000 to 7500 rad (radiation absorbed dose), usually over 6 weeks and in daily or twice-daily doses. Intensity modulated radiotherapy (IMRT) is being used increasingly to provide higher doses directly to the tumor with less damage to surrounding normal tissues. Radiation may be used alone or, more often, in combination with surgery and chemotherapy (see Chapter 22). It can be performed before or after surgery. Most patients have hoarseness, dysphagia, skin problems, and dry mouth for a few weeks after radiation therapy.

Hoarseness may become worse during therapy. Reassure the patient that voice improves within 4 to 6 weeks after completion of radiation therapy. Urge the patient to use voice rest and alternative means of communication until the effects of radiation therapy have passed.

Most patients have a sore throat and difficulty swallowing during radiation therapy to the neck. Gargling with saline or sucking ice may decrease discomfort. Mouthwashes and throat sprays containing a local anesthetic agent such as lidocaine or diphenhydramine can provide temporary relief. Analgesic drugs may be prescribed.

The skin at the site of irradiation becomes red and tender and may peel during therapy. Instruct the patient to avoid exposing this area to sun, heat, cold, and abrasive actions such as shaving. Teach the patient to wear protective clothing made of soft cotton and to wash this area gently daily with a mild soap, such as Dove (Mannix et al., 2012). Using appropriate skin care products (approved by the radiation-oncology department) can reduce the intensity of skin reactions.

If the salivary glands are in the irradiation path, the mouth becomes dry **(xerostomia)**. This side effect is long-term and may be permanent. Some of the problems from reduced saliva include increased risk for dental caries, increased risk for oral infections, halitosis (bad breath), and taste changes. Fluoride gel trays and nightly fluoride treatments can reduce the incidence of tooth deterioration. The trays can be worn during radiation therapy to prevent radiation scatter from the beam deflecting off existing metal inside the mouth. Although there is no cure for xerostomia, interventions can help reduce the discomfort. Heavy fluid intake, particularly water, and humidification can help ease the discomfort. Some patients benefit from the use of artificial saliva, such as Salivart; moisturizing sprays or gels, such as Mouth Kote; or saliva stimulants, such as Salagen and cevimeline (cholinergic drugs).

Chemotherapy can be used alone or in addition to surgery or radiation for head and neck cancer. Often, chemotherapy and radiation therapy

(chemoradiation) are used at the same time. Although the exact drugs used may vary, depending on cancer cell features, most chemotherapy regimens for head and neck cancers include cisplatin (National Comprehensive Cancer Network, 2013). The oral cavity effects of radiation are intensified with concurrent chemotherapy. These can be uncomfortable, and patients often request breaks in the treatment regimen. However, these breaks in treatment do affect the outcome of treatment and should be avoided. Intense patient education before treatment and support during treatment can improve patient adherence to the treatment plan (Mason et al., 2013). Chapter 22 discusses the general care needs of patients receiving chemotherapy.

Biotherapy in the form of epidermal growth factor receptor inhibitors (EGFRIs) may be effective for patients whose cancers overexpress the receptor. Currently, the drug approved for this purpose is cetuximab (Erbitux). Although it is a targeted therapy, this drug blocks EGFRs in normal tissues as well as those in the tumor. As a result, severe skin reactions are common and difficult for the patient (Boucher et al., 2011).

Surgical Management.

Tumor size, node number, and metastasis location (TNM classification) determines the type of surgery needed for the specific head and neck cancer (see Chapter 21). Very small, early-stage tumors may be removed by laser therapy or photodynamic therapy; however, few head and neck tumors are found at this stage and most require extensive traditional surgery. Reconstruction is also determined by the tumor size and amount of tissue to be resected and reconstructed. Surgical procedures for head and neck cancers include laryngectomy (total and partial), tracheotomy, and oropharyngeal cancer resections. The major types of surgery for laryngeal cancer include cord stripping, removal of a vocal cord **(cordectomy),** partial laryngectomy, and total laryngectomy. If cancer is in the lymph nodes in the neck, the surgeon performs a nodal neck dissection along with removal of the primary tumor ("radical neck").

Preoperative Care.

Teach the patient and family about the tumor. The surgeon explains the surgical procedure and obtains informed consent. Discuss and interpret the implications of such consent with the patient and family.

Explain about self-management of the airway, suctioning, pain-control methods, the critical care environment (including ventilators and critical care routines), nutrition support, feeding tubes, and plans for discharge. The patient will need to learn new methods of speech, at least during the

time that mechanical ventilation is used and, depending on surgery type, perhaps forever. Help him or her prepare for this change before surgery and to practice the use of the selected form of communication (see Chart 29-2 and the discussion of Maintaining Communication in Chapter 28). Determine the communication method preferred by the patient.

Chart 29-2 Best Practice for Patient Safety & Quality Care QSEN

Communicating with a Patient Who Is Unable to Speak

- Assess the patient's reading skills and cognition.
- Determine in what language (languages) the patient is most fluent.
- Collaborate with a speech and language pathologist.
- If the patient requires vision-enhancing devices or hearing-enhancing devices, be sure these are available and in use.
- Provide the patient with a variety of techniques to practice before verbal skills are lost to determine with which one(s) the patient feels most comfortable. These may include:
  - Alphabet board
  - Picture board
  - Paper and pencil
  - Magic Slate
  - Hand signals/gestures
  - Computer with e-triloquist program
  - Programmable speech-generating devices (text-to-speech communication aid)
- Reinforce to the patient the technique for esophageal speech presented by the speech and language pathologist, and provide the time for practice.
- Use a normal tone of voice to talk with the patient (unless hearing is a pre-existing problem, a change in the ability to speak does not interfere with the patient's ability to hear).
- Ensure that the call-light board at the nurses' station indicates a non-speaking patient.
- Teach the patient to make noise to indicate immediate attention is needed at the bedside when he or she signals by call light. Such noises can include tapping the siderail with a spoon, making clicking noises with the tongue, using a bell, or working a noisemaker. Be sure that whatever method is selected is listed on the call-light board.
- When face-to-face with the patient:

  - Phrase questions in a “yes” or “no” format.
  - Watch the patient's face for indications of understanding or the lack of it.
  - Listen attentively to any sound the patient makes.
- If writing is selected as the method to communicate, assess whether the patient is right-handed or left-handed and ensure appropriate writing materials are within reach. Use the other arm for IV placement.
- Ensure the preferred method of communication is documented in the patient record and is communicated to all care providers.
- Encourage the family to work with the patient in the use of the selected method.
- Provide praise and encouragement.
- Do not avoid talking with the patient.
- Allow the patient to set the pace for communication.

A team approach for planning care and rehabilitation is critical for the best outcome. The team includes nurses, physicians, speech and language pathologists, social workers, dietitians, respiratory therapists, and occupational and physical therapists. These professionals help evaluate and prepare the patient who has head and neck cancer. Chapter 14 describes general preoperative assessment and education.

Operative Procedures.

Table 29-2 lists specific information about the various surgical procedures for laryngeal cancer. Hemilaryngectomy (vertical or horizontal) and supraglottic laryngectomy are types of partial voice-conservation laryngectomies.

TABLE 29-2

Surgical Procedures for Laryngeal Cancer and their Effect on Voice Quality

PROCEDURE	DESCRIPTION	RESULTING VOICE QUALITY
Laser surgery	Tumor reduced or destroyed by laser beam through laryngoscope	Normal/hoarse
Transoral cordectomy	Tumor (early lesion) resected through laryngoscope	Normal/hoarse (high cure rate)
Laryngofissure	No cord removed (early lesion)	Normal (high cure rate)
Supraglottic partial laryngectomy	Hyoid bone, false cords, and epiglottis removed Neck dissection on affected side performed if nodes involved	Normal/hoarse
Hemilaryngectomy or vertical laryngectomy	One true cord, one false cord, and one half of thyroid cartilage removed	Hoarse
Total laryngectomy	Entire larynx, hyoid bone, strap muscles, one or two tracheal rings removed Nodal neck dissection if nodes involved	No natural voice

To protect the airway, a tracheostomy is needed. With a partial laryngectomy, the tracheostomy is usually temporary. With a total laryngectomy, the upper airway is separated from the throat and esophagus and a permanent laryngectomy stoma in the neck is created.

Neck dissection includes the removal of lymph nodes, the sternocleidomastoid muscle, the jugular vein, the 11th cranial nerve, and surrounding soft tissue. Shoulder drop is expected after extensive surgery. Physical therapy can help the patient ease the shoulder drop by using other muscle groups.

Postoperative Care.

Head and neck surgery often lasts 8 hours or longer. Usually the patient spends the immediate period after surgery in the surgical intensive care unit. Monitor airway patency, vital signs, hemodynamic status, and comfort level. Monitor for hemorrhage and other general complications of anesthesia and surgery (see Chapter 16). Take vital signs hourly for the first 24 hours and then according to agency policy until the patient is stable. After the patient is transferred from the critical care unit, monitor vital signs every 4 hours or according to agency policy.

Complications after surgery include airway obstruction, hemorrhage, wound breakdown, and tumor recurrence. *The first priorities after head and neck surgery are airway maintenance and gas exchange.* Other priorities are wound, flap, and reconstructive tissue care; pain management; nutrition;

and psychological adjustment, including speech and language therapy.

Airway Maintenance and Gas Exchange.

Immediately after surgery, the patient may need ventilatory assistance. Most patients wean easily from the ventilator after this type of surgery because the thoracic and abdominal cavities are not entered. During weaning, the patient usually uses a tracheostomy collar (over the artificial airway or open stoma) with oxygen and humidity to help move mucus secretions. Secretions may remain blood-tinged for 1 to 2 days. Use Standard Precautions, and report any increase in bleeding to the surgeon. Humidity helps remove crusts and prevents obstruction of the tube with secretions. A laryngectomy tube is used for patients who have undergone a *total laryngectomy* and need an appliance to prevent scar tissue shrinkage of the skin-tracheal border. This tube is similar to a tracheostomy tube but is shorter and wider with a larger lumen. Laryngectomy tube care is similar to tracheostomy tube care (see Chapter 28) except that the patient can change the laryngectomy tube daily or as needed. A laryngectomy button is similar to a laryngectomy tube but is softer, has a single lumen, and is very short. A button is comfortable for the patient, is easily removed for cleaning, and is available in various sizes for a custom fit. Provide alternative communication techniques because the patient cannot speak.

Coughing and deep breathing are usually effective in clearing secretions. Instruct the patient how to cough and deep breathe to clear secretions.

Oral secretions can be suctioned by the alert patient using a Yankauer or tonsillar suction or a soft red latex catheter. Teach the patient to suction *away* from the surgical side to prevent opening the wound. Using a table mirror helps the patient see the area more clearly. Provide a clean environment for the catheter.

Stoma care after a total laryngectomy is a combination of wound care and airway care. Inspect the stoma with a flashlight. Clean the suture line with sterile saline (or a prescribed solution) to prevent secretions from forming crusts and obstructing the airway. Perform suture line care every 1 to 2 hours during the first few days after surgery and then every 4 hours. The mucosa of the stoma and trachea should be bright and shiny and without crusts, similar to the appearance of the oral mucosa.

Wound, Flap, and Reconstructive Tissue Care.

Tissue "flaps" may be used to close the wound and improve appearance. Flaps are skin, subcutaneous tissue, and sometimes muscle, taken from

other body areas used for reconstruction after head and neck resection. After neck dissection, the surgeon places a split-thickness skin graft (STSG) over the exposed carotid artery before covering it with skin flaps or reconstructive flaps.

The first 24 hours after surgery are critical. Evaluate all grafts and flaps hourly for the first 72 hours. Monitor capillary refill, color, drainage, and Doppler activity of the major blood vessel to the area. Report changes to the surgeon immediately because surgical intervention may be needed. Position the patient so that the surgical flaps are not dependent.

Hemorrhage.

Hemorrhage is a possible complication after any surgery, but it is uncommon with laryngectomy. The surgeon often places a closed surgical drain in the neck area to collect blood and drainage for about 72 hours after surgery. The drain also helps maintain the position of the reconstructed skin flaps. Any drain obstruction or equipment malfunction may cause a buildup of blood or fluid under the flaps that can impair blood flow and result in flap failure. A sudden stoppage of drainage may indicate drain obstruction by a clot. Monitor and record the amount and character of drainage. Check the patency and functioning of the drainage system. Report any drain malfunction or change in flap appearance to the surgeon. Depending on the surgeon's preference and the agency's policy, you may need to empty the drainage container or "milk" the drain.

Wound Breakdown.

Wound breakdown is a complication caused by poor nutrition, a long smoking history, alcohol use, wound contamination, and radiation therapy before surgery. Manage wound breakdown with packing and local care as prescribed to keep the wound clean and to stimulate the growth of healthy granulation tissue. Wounds may be extensive, and the carotid artery may be exposed. Split-thickness skin grafts often are placed over the carotid artery for protection in the event of wound dehiscence. As the wound heals, granulation tissue covers the artery and prevents rupture. If granulation is slow and the carotid artery is at risk, another surgical flap may be made to cover the artery and close the wound.

When the carotid artery ruptures, large amounts of bright red blood spurt quickly. It is also possible for the carotid artery to have a small leak, with continuous oozing of bright red blood. Usually, a small leak leads to a complete rupture within a short time.

Nursing Safety Priority QSEN

Critical Rescue

If a carotid artery leak is suspected, call the Rapid Response Team and ***do not touch the area because additional pressure could cause an immediate rupture.*** If the carotid artery ruptures because of drying or infection, immediately place constant pressure over the site and secure the airway. Maintain direct manual, continuous pressure on the carotid artery, and immediately transport the patient to the operating room for carotid resection. Do not leave the patient. Carotid artery rupture has a high risk for stroke and death.

Pain Management.

Pain is caused by the surgical cutting or manipulation of tissue and by nerve compression. Pain should be controlled, and the patient should still be able to participate in his or her care. Morphine (Statex) often is given IV by a patient-controlled analgesia (PCA) pump for the first 1 to 2 days after surgery. As the patient progresses, liquid opioid analgesics can be given by feeding tube. Oral drugs for pain and discomfort are started only after the patient can tolerate oral intake. After discharge, the patient still requires pain management, especially if he or she is receiving radiation therapy. An adjunct to the pain regimen may be liquid NSAIDs along with opioid analgesics. Tricyclic antidepressants may also be used for the lancinating pain of nerve-root involvement.

Nutrition.

Many patients with head and neck cancer have taste changes and some degree of malnutrition before cancer treatment begins (Ardilio, 2011; McLaughlin, 2013). All patients are at risk for malnutrition during treatment for head and neck cancer. A nasogastric, gastrostomy, or jejunostomy tube is placed during surgery for nutrition support while the head and neck heal. After the intestinal tract is motile, nutrients can be given via the feeding tube. The nutrition support team or dietitian assesses the patient before surgery and is available for consultation after surgery. Replacement of calories, protein, and water loss is calculated carefully for each patient (Ardilio, 2011).

The feeding tube usually remains in place for 7 to 10 days after surgery. Before removing the tube, assess the patient's ability to swallow if nutrition is to be given by mouth. Aspiration *cannot* occur after a total laryngectomy because the airway is completely separated from the

esophagus. Stay with the patient during the first few swallowing attempts. Swallowing may be uncomfortable at first, and analgesics may be needed.

Speech and Language Rehabilitation.

The patient's voice quality and speech are altered after surgery. Although this problem has enormous effects on the patient's ability to maintain social interactions, continue employment, and maintain a desired quality of life, it is often poorly addressed while he or she is hospitalized. Working with him or her and the family toward developing an acceptable communication method during the inpatient period is essential for a satisfactory outcome (Happ et al., 2011).

Together with the speech and language pathologist (SLP), discuss the principles of speech therapy with the patient and family early in the course of the treatment plan (see Chart 29-2). Voice and speech differences depend on the type of surgical resection (see Table 29-2). Speech production varies with patient practice, amount of tissue removed, and radiation effects, but the speech can be very understandable. Patients have reported ongoing difficulties with speech and communication to be the most distressing problem for months to years after head and neck cancer therapy (Fletcher et al., 2012; Haisfield-Wolfe et al., 2012).

The speech rehabilitation plan for patients who have a total laryngectomy at first consists of writing, using a picture board, or using a computer. The patient then uses an artificial larynx and may eventually learn esophageal speech. For success, the patient needs encouragement and support from the SLP, hospital team, and family while relearning to speak. This process can be time consuming and requires concentration each time the patient speaks. Having a **laryngectomee** (a person who has had a laryngectomy) from one of the local self-help organizations visit the patient and family is often beneficial. The International Association of Laryngectomees is very supportive, as is the American Cancer Society (ACS) Visitor Program.

Esophageal speech is attempted by most patients who have a total laryngectomy. Sound can be produced this way by "burping" the air swallowed or injected into the esophageal pharynx and shaping the words in the mouth. The voice produced is a monotone; it cannot be raised or lowered and carries no pitch. If patients do not have adequate hearing, esophageal speech will be difficult because they need to use their mouth to shape the words as they hear them. Hearing-impaired patients may need hearing aids.

Mechanical devices, called *electrolarynges,* may be used for communication. Most are battery-powered devices placed against the side of the neck or cheek (Fig. 29-4). The air inside the mouth and throat is vibrated, and the patient moves his or her lips and tongue as usual. The quality of speech generated with mechanical devices is robot-like.

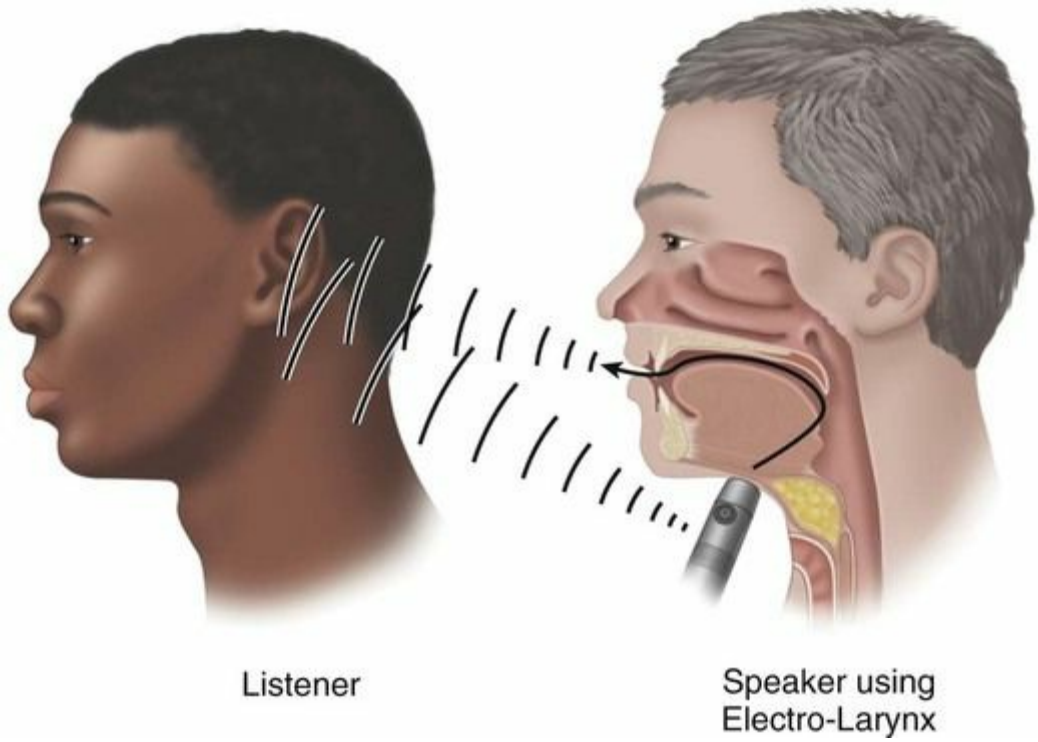


FIG. 29-4 An Electro-Larynx to generate speech after a laryngectomy.

Tracheoesophageal puncture (TEP) (formerly call a *fistula*) may be used if esophageal speech is ineffective and if the patient meets strict criteria. A small surgical puncture is created between the trachea and the esophagus using a special catheter. After the puncture heals, a silicone prosthesis (e.g., the Blom-Singer prosthesis or the Panje Voice Button) is inserted in place of the catheter. The patient covers the stoma and the opening of the prosthesis with a finger or with a special valve to divert air from the lungs, through the trachea, into the esophagus, and out of the mouth where lip and tongue movement produces speech.

Surgical Procedures for Other Head and Neck Cancers.

The major types of surgeries for other head and neck cancers are called *composite resections.* These resections are a combination of surgical procedures, including partial or total glossectomies (tongue removal), partial mandibulectomies (jaw removal), and, if needed, nodal neck

dissections. Tracheostomy may be planned to provide an adequate airway. (See Chapter 53 for more information about oral cancer.)

Tracheotomy.

A **tracheotomy** is a surgical incision into the trachea for the purpose of establishing an airway (tracheostomy). It can be performed as an emergency procedure or as a scheduled surgical procedure. A tracheostomy can be temporary or permanent. Chapter 28 discusses the nursing care of a patient with a tracheostomy.

Preventing Aspiration

Planning: Expected Outcomes.

The patient with head and neck cancer is expected to not aspirate food, gastric contents, or oral secretions into the lungs. Indicators include that the patient often or consistently demonstrates these behaviors:

- Positions self upright for eating or drinking
- Selects foods according to swallowing ability
- Chooses liquids and foods of proper consistency

Interventions.

The surgical changes in the upper respiratory tract and altered swallowing mechanisms increase the patient's risk for aspiration. Aspiration can result in pneumonia, weight loss, and prolonged hospitalization. Chart 29-3 lists actions for aspiration prevention.

Chart 29-3 Best Practice for Patient Safety & Quality Care QSEN

Prevention of Aspiration During Swallowing

- Avoid serving meals when the patient is fatigued.
- Provide smaller and more frequent meals.
- Provide adequate time; do not "hurry" the patient.
- Provide close supervision if the patient is self-feeding.
- Keep emergency suctioning equipment close at hand.
- Avoid water and other "thin" liquids.
- Thicken liquids.
- Avoid foods that generate thin liquids during the chewing process, such as fruit.
- Position the patient in the most upright position possible.

- When possible, completely (or at least partially) deflate the tube cuff during meals.
- Suction after initial cuff deflation to clear the airway and allow maximum comfort during the meal.
- Feed each bite or encourage the patient to take each bite slowly.
- Encourage the patient to "dry swallow" after each bite to clear residue from the throat.
- Avoid consecutive swallows by cup or straw.
- Provide controlled small volumes of liquids, using a spoon.
- Encourage the patient to "tuck" his or her chin down and move the forehead forward while swallowing.
- Allow the patient to indicate when he or she is ready for the next bite.
- If the patient coughs, stop the feeding until the patient indicates the airway has been cleared.
- Continuously monitor tolerance to oral food intake by assessing respiratory rate, ease, pulse oximetry, and heart rate.

A nasogastric (NG) feeding tube may further increase the risk for aspiration because it keeps the lower esophageal sphincter partially open. The one exception is the patient who has undergone a total laryngectomy. In these cases, the airway is separated from the esophagus, making aspiration impossible and the patient is *not* at risk. Most patients who need enteral feeding supplementation have a percutaneous endoscopic gastrostomy (PEG) tube placed rather than an NG tube. See Chapter 60 for care of patients receiving enteral nutrition by NG or PEG tube.

A dynamic swallow study, such as a barium swallow under fluoroscopy, evaluates a patient's ability to protect the airway from aspiration and helps determine the appropriate method of swallow rehabilitation. In many cases, enteral feedings are used either because of the patient's inability to swallow or because of continued aspiration risk.

Swallowing can be a major problem for the patient who has a tracheostomy tube. Swallowing can be normal if the cranial nerves and anatomic structures are intact. In a normal swallow, the larynx rises and moves forward to protect itself from the passing stream of food and saliva. The tracheostomy tube sometimes fixes the larynx in place, resulting in difficulty swallowing.

An inflated tracheostomy tube cuff can balloon backward into the esophagus and interfere with the passage of food. The wall between the posterior trachea and the esophagus is very thin, which allows this pushing action. The patient who is cognitively intact may adapt to eating

normal food when the tracheostomy tube is small and the cuff is not inflated.

The patient who has had a partial vertical or supraglottic laryngectomy *must* be observed for aspiration. It is critical to teach the patient to use alternate methods of swallowing without aspirating. The "supraglottic" method of swallowing is especially effective after a partial laryngectomy or base-of-tongue resection (Chart 29-4). To reinforce teaching and learning, place a chart in the patient's room detailing the steps. A dynamic swallow study is performed to guide rehabilitation for swallowing and to evaluate the patient's ability to protect the airway.

Chart 29-4 Patient and Family Education: Preparing for Self-Management

The Supraglottic Method of Swallowing

1. Place yourself in an upright, preferably out-of-bed, position.
2. Clear your throat.
3. Take a deep breath.
4. Place ½ to 1 teaspoon of food into your mouth.
5. Hold your breath, or "bear down" (Valsalva maneuver).
6. Swallow twice.
7. Release your breath, and clear your throat.
8. Swallow twice again.
9. Breathe normally.

This method exaggerates the normal protective mechanisms of cessation of respiration during the swallow. The double swallow attempts to clear food that may be pooling in the pharynx, vallecula, and piriform sinuses. This method is used only after a dynamic radiographic swallow study has demonstrated that it is appropriate and safe for the patient.

Minimizing Anxiety

Planning: Expected Outcomes.

The patient with head and neck cancer is expected to have decreased anxiety. Indicators include that the patient often or consistently demonstrates:

- Verbalization of reduced anxiety
- Absence of distress, irritability, and facial tension
- Effective use of coping strategies

Interventions.

Conferences with the physician, clinical nurse specialist, dietitian, speech and language pathologist, physical therapist, psychologist, social worker, and general nursing staff may be beneficial. Explore the reason for anxiety (e.g., fear of the unknown, lack of teaching, fear of pain, fear of death, loss of control, uncertainty). The patient and family often benefit from further information. Before the patient is scheduled for surgery (and while still at home), home care nurses or community-sponsored programs, such as the ACS, may be able to decrease fears about the disease process and surgical interventions.

Give prescribed antianxiety drugs, such as diazepam (Valium, Meval), with caution because of the risk for respiratory depression and because some of these drugs are eliminated slowly. Shorter-duration drugs, such as lorazepam (Ativan), may have fewer respiratory side effects. The location of the tumor and the presence of other lung disease may cause some degree of airway obstruction. For anxiety in these patients, drug therapy may include lorazepam (Ativan, Novo-Lorazem) rather than a sedating agent.

Supporting Self-Concept

Planning: Expected Outcomes.

The patient with head and neck cancer is expected to accept body image changes. Indicators include that the patient often or consistently demonstrates:

- Willingness to touch and care for the affected body part
- Willingness to use strategies to enhance appearance
- Interaction with visitors, staff, and family members

Interventions.

The patient with head and neck cancer usually has a change in self-concept and self-image resulting from functional and psychological issues. Common functional issues include the presence of a stoma or artificial airway, speech changes, and a change in the method of eating. Psychological issues often include guilt, regret, and uncertainty. He or she may not be able to speak at all or may have permanent speech deficits. Help the patient set realistic goals, starting with involvement in self-care. Teach the patient alternative communication methods so he or she can communicate in the hospital and after discharge (Fletcher et al., 2012; Suzuki, 2012).

Teach the family to ease the patient into a normal social environment.

Use positive reinforcement and encouragement while demonstrating acceptance and caring behaviors. The family also may benefit from counseling sessions while the patient is still in the hospital.

After surgery, the patient may feel socially isolated because of the change in voice and facial appearance. Loose-fitting, high-collar shirts or sweaters, scarves, and jewelry can be worn to cover the laryngectomy stoma, tracheostomy tube, and other changes related to surgery. Cosmetics may aid in covering disfigurement. Most surgeons try to place the incisions in the natural skinfold lines if doing so does not pose a risk for cancer recurrence.

Community-Based Care

If no complications occur, the patient is usually discharged home or to an extended-care facility within 2 weeks. At the time of discharge, he or she or a family member should be able to perform tracheostomy or stoma care and participate in nutrition, wound care, and communication methods.

The patient and family may feel more secure about discharge with a referral to support groups or a community health agency familiar with the care of patients recovering from head and neck cancer. Coordinate the efforts of the health care team in assessing the specific discharge needs and making the appropriate referrals to home care agencies. Dietitians, nurses, physical therapists, speech and language pathologists, and social workers may be needed. Coordinate the scheduling for chemotherapy or radiation therapy with the patient and family.

Home Care Management.

Extensive home care preparation is needed after a laryngectomy for cancer. The convalescent period is long, and airway management is complicated. The patient or family must be able to take an active role in care.

General cleanliness of the home is assessed by the home care nurse or case manager. For the patient with severe respiratory problems, home changes to allow for one-floor living may be needed. Increased humidity is needed. A humidifier add-on to a forced-air furnace can be obtained, or a room humidifier or vaporizer may be used. Be sure to stress that meticulous cleaning of these items is needed to prevent spread of mold or other sources of infection.

A home care nurse often is involved with care after discharge and is an important resource for the patient and family. This nurse assesses the patient and home situation for problems in self-care, complications,

adjustment, and adherence to the medical regimen. Chart 29-5 lists assessment areas for the patient in the home after a laryngectomy. This nurse reinforces health care teaching, self-care teaching, and smoking-cessation regimens.

Chart 29-5 Home Care Assessment

Patients After Laryngectomy

Assess respiratory status:
- Observe rate and depth of respiration.
- Auscultate lungs.
- Check patency of airway.
- Examine the tracheostomy drainage for amount, color, and character.
- Examine nail beds and mucous membranes for evidence of cyanosis.
- Obtain a pulse oximetry reading.

Assess condition of wound:
- Remove dressings (noting condition of dressings).
- Cleanse the wound.
- Compare with previous notations of wound condition:
  - Presence, amount, and nature of exudate
  - Presence/absence of cellulitis
  - Presence/absence of odor

Assess patient's psychosocial status:
- Ask the patient about passing the time, visitors, and trips outside the house.
- Observe whether the patient communicates responses directly or whether a family member speaks for the patient.
- Observe patient and family member interactions.
- Determine what method of communication the patient has selected, and observe the patient's skill with it.
- Observe whether the patient is wearing pajamas or is dressed in street clothes.

Take the patient's temperature at each home care visit.

Assess the patient's understanding of illness and adherence to treatment:
- Manifestations to report to the health care provider
- Medication plan (correct timing and dose)
- Ambulation or positioning schedule
- Dressing changes/skin care
- Diet modifications (24-hour diet recall)

- Skill in tracheostomy or dressing care

Assess patient's nutrition status:

- Change in muscle mass
- Lackluster nails/sparse hair
- Recent weight loss greater than 10% of usual weight
- Impaired oral intake
- Difficulty swallowing
- Generalized edema

Self-Management Education.

Education begins before surgery, and most self-care is taught in the hospital. Teach the patient and family how to care for the stoma or tracheostomy or laryngectomy tube, depending on the type of surgery performed. Review incision and airway care, including cleaning and inspecting for signs of infection. Chart 29-6 lists self-care actions for the patient after laryngeal cancer surgery. Many of these actions also apply to any surgery for head and neck cancer.

Chart 29-6 Patient and Family Education: Preparing for Self-Management

Home Laryngectomy Care

- Avoid swimming, and use care when showering or shaving.
- Lean slightly forward and cover the stoma when coughing or sneezing.
- Wear a stoma guard or loose clothing to cover the stoma.
- Clean the stoma with mild soap and water. Lubricate the stoma with a non–oil-based ointment as needed.
- Increase humidity by using saline in the stoma as instructed, a bedside humidifier, pans of water, and houseplants.
- Obtain and wear a MedicAlert bracelet and emergency care card for life-threatening situations.

Stoma care teaching is focused on protection. Use a plastic head-and-neck cut-away model or create one from Styrofoam to use as an accurate aid for teaching about the anatomic changes resulting from surgery (Zeien, 2011). Instruct the patient to use a shower shield over the tube or stoma when bathing to prevent water from entering the airway. Teach men who use electric shavers to cover the stoma while shaving to keep hair from falling into it. Suggest that the patient wear a protective cover or stoma guard to protect the stoma during the day. For those with

permanent stomas after laryngectomy or for those with permanent tracheostomies, covering the opening has two benefits: (1) to filter the air entering the stoma while keeping humidity in the airway; and (2) to enhance aesthetic appearance. Attractive coverings are available in the form of scarves, crocheted collars, and jewelry.

Instruct the patient how to increase humidity in the home. Stress the importance of keeping well hydrated to prevent secretions from thickening.

Communication involves having the patient continue the selected communication method that began in the hospital. Instruct him or her to wear a medical alert (MedicAlert) bracelet and carry a special identification card. For patients with a laryngectomy, this card is available from the local chapters of the International Association of Laryngectomees. The card instructs the reader about providing an emergency airway or resuscitating someone who has a stoma.

Smoking cessation is a difficult but important issue after head and neck cancer surgery. Stress that smoking cessation can reduce the risk for developing other cancers and can increase the rate of healing from surgery. See Chapter 27 for a detailed discussion about smoking cessation.

Psychosocial Preparation.

The many changes resulting from a laryngectomy influence physical, social, and emotional functioning. Patients may perceive changes in their quality of life. Begin preparing the patient and family by scheduling a visit from a person who has adjusted to these changes.

The patient with a permanent stoma, tracheostomy tube, NG or PEG tube, and wounds has an altered body image. Stress the importance of returning to as normal a lifestyle as possible. Most patients can resume many of their usual activities within 4 to 6 weeks after surgery. A longer time is needed after a combination of radiation therapy and surgery and for those patients who also have other chronic diseases. The patient may be frustrated at times while trying to adjust to the many changes resulting from treatment of head and neck cancer.

The patient with a total laryngectomy cannot produce sounds during laughing and crying. Mucus secretions may appear unexpectedly when these emotions arise or when coughing or sneezing occurs. The mucus can be embarrassing, and the patient needs to be prepared to cover the stoma with a handkerchief or gauze. The patient who has undergone composite resections has difficulty with speech *and* swallowing. He or she may need to deal with tracheostomy and feeding tubes in public

places.

Health Care Resources.

Inform the patient and family of community organizations (e.g., ACS) and local laryngectomee clubs, which can offer support, information, and friendships. When the patient has problems paying for health care services, equipment, and prescriptions, a visiting nurse agency and social worker may be helpful in locating available resources.

In many areas, the local unit of the ACS or Canadian Cancer Society can help provide dressing materials and nutritional supplements to patients in need. These organizations may also provide transportation to and from follow-up visits or radiation therapy.

Clinical Judgment Challenge

Patient-Centered Care; Evidence-Based Practice; Teamwork and Collaboration QSEN

A patient who had a supraglottic partial laryngectomy with a right-sided radical neck dissection 4 weeks ago is now receiving radiation therapy. He has lost 24 pounds since his surgery, which makes him 15 pounds less than his ideal weight. He tells you that he has no appetite and that what food he does eat "has no taste." In addition, although he expresses that he is glad to be alive, he does not want friends to visit because it takes so much energy to interact with them. He also says that he can no longer play the piano because of difficulty moving his right arm and shoulder.

1. What factors are contributing to his fatigue?
2. Is the weight loss a concern? If so, what should you do about it?
3. Should you further press the issue of not wanting to visit with friends? Why or why not?
4. What other health care professionals or resources would be appropriate at this time?

Evaluation: Outcomes

Evaluate the care of the patient with head and neck cancer based on the identified priority patient problems. The expected outcomes are that the patient:

- Maintains a patent airway
- Performs self-care of the artificial airway and wound
- Performs ADLs independently or with minimal assistance

- Attains or maintains adequate nutrition
- Does not aspirate gastric contents or food
- Engages in desired social interactions

Specific indicators for these outcomes are listed for priority patient problems in the Planning and Implementation section (see earlier).

Nursing Concepts and Clinical Judgment Review

What might you NOTICE if the patient is experiencing inadequate gas exchange as a result of upper airway problems?

- Voice changes (nasal quality if the problem is above the palate, "breathy" or "whispery" if the problem is in the larynx or trachea)
- Snoring or mouth breathing
- Change in cognition or level of consciousness or acute confusion
- Decreased oxygen saturation by pulse oximetry
- Skin cyanosis or pallor (lighter-skinned patients)
- Cyanosis or pallor of the lips and oral mucous membranes (patients of any skin color)
- Tachycardia and dysrhythmia

What should you INTERPRET and how should you RESPOND to a patient experiencing inadequate gas exchange as a result of an upper airway respiratory problem?

Perform and interpret physical assessment, including:

- Taking vital signs
- Monitoring oxygen saturation by pulse oximetry
- Assessing for the presence of thick or excessive secretions
- Assessing the patient's ability to cough and clear the airway
- Assessing nasal drainage and sputum for color and blood
- Checking most recent laboratory values for white blood cell and arterial blood gas (ABG) levels
- Assessing cognition
- Assessing hydration status

Respond by:

- Suctioning (oral, pharyngeal, endotracheal, tracheostomy), if needed
- Applying oxygen, and assessing the patient's responses to this intervention
- Keeping the patient's head elevated to about 30 degrees
- Notifying physician or Rapid Response Team

- Ensuring venous access

On what should you REFLECT?

- Observe patient for evidence of restored oxygenation (see Chapter 27).
- Think about what may have precipitated this episode and what steps could be taken to either prevent a similar episode or identify it earlier.
- Think about what additional resources could improve the nursing response to this situation.

Get Ready For The NCLEX® Examination!

Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Use sterile technique when performing endotracheal or tracheal suctioning. **Safety** QSEN
- Use Standard Precautions when caring for a patient with epistaxis. **Safety** QSEN
- Supervise care delegated to licensed practical nurses/licensed vocational nurses (LPNs/LVNs) or nursing assistants to patients who have risk factors for airway obstruction.
- Act as a patient advocate for patients who have tracheostomies or other issues that impair communication.

Health Promotion and Maintenance

- Assess the patient for risk factors for head and neck cancer.
- Encourage people who smoke to quit smoking or using tobacco in any way. **Patient-Centered Care** QSEN
- Encourage people who use alcohol to reduce their intake of alcoholic beverages.
- Use Aspiration Precautions for any patient with an altered level of consciousness or who has an endotracheal tube (see Chart 29-3). **Safety** QSEN
- Teach the patient and family how to perform tracheostomy care (see Chart 28-3 in Chapter 28). **Patient-Centered Care** QSEN
- Teach patients who have had radiation therapy to the oral cavity to have dental examinations at least every 6 months. **Patient-Centered Care** QSEN
- Teach the patient and family about home management of a laryngectomy stoma or tracheostomy. **Patient-Centered Care** QSEN

Psychosocial Integrity

- Allow the patient and family members the opportunity to express fear or anxiety regarding a cancer diagnosis or a change in breathing status.
- Teach family members ways to communicate with a patient who cannot speak after surgery for head and neck cancer. **Patient-Centered Care** QSEN
- Encourage patients with permanent tracheostomies or laryngectomies

to become involved in self-care and to look at the wound and touch the affected area. **Patient-Centered Care** QSEN

- Allow the patient and family to grieve the loss of function and change in body image. **Patient-Centered Care** QSEN
- Allow time to communicate with the patient who has voice loss. **Patient-Centered Care** QSEN
- Refer patients and families to local chapters of the ACS or the Canadian Cancer Society after surgery for head and neck cancer.

Physiological Integrity

- Assess the airway patency of any patient who experiences facial or nasal trauma. **Safety** QSEN
- Perform a focused upper respiratory assessment and re-assessment to determine adequacy of gas exchange and tissue perfusion. **Patient-Centered Care** QSEN
- Notify the Rapid Response Team when a patient experiences a posterior nasal bleed. **Safety** QSEN
- Check the airway and packing at least every hour for a patient who has posterior nasal packing placed after nasal surgery or posterior epistaxis. **Evidence-Based Practice** QSEN
- Instruct patients who have had mandibular immobilization or fixation after a mandibular fracture to keep wire cutters with them at all times. **Safety** QSEN
- Apply oxygen to any patient who develops stridor. **Safety** QSEN
- Use a manual resuscitation bag to ventilate the patient if the tracheostomy tube has dislodged or been decannulated. **Safety** QSEN
- Assess the new tracheostomy stoma site at least once per shift for purulent drainage, redness, pain, and swelling, as indicators of infection. **Safety** QSEN
- Keep the tracheal cuff pressure between 14 and 20 mm Hg to prevent tissue injury. **Evidence-Based Practice** QSEN
- Apply knowledge of anatomy to prevent aspiration in a patient with a tracheostomy. **Evidence-Based Practice** QSEN
- Use correct technique to suction via a tracheostomy or laryngectomy tube. **Evidence-Based Practice** QSEN
- Collaborate with physicians, speech and language pathologists, social workers, dietitians, respiratory therapists, and occupational and physical therapists to provide optimal care for the patient experiencing head and neck cancer. **Teamwork and Collaboration** QSEN

CHAPTER 30

Care of Patients with Noninfectious Lower Respiratory Problems

M. Linda Workman

PRIORITY CONCEPTS

- Gas Exchange
- Perfusion
- Inflammation
- Cellular Regulation

Learning Outcomes

Safe and Effective Care Environment

1. Ensure safe oxygen delivery to promote gas exchange.
2. Protect patients with lower respiratory problems from injury or infection.

Health Promotion and Maintenance

3. Teach all people measures to take to protect the respiratory system from damage and cancer, including the avoidance of known environmental causative agents.
4. Teach the patient and family how to manage a chronic lower respiratory disorder and avoid injury and complications in the home.
5. Use assessment information to identify people at increased genetic risk for a respiratory disease that affects gas exchange and perfusion.

Psychosocial Integrity

6. Reduce the psychological impact for the patient and family experiencing a chronic lower respiratory problem.

7. Work with other members of the health care team to ensure that values, preferences, and expressed needs of patients experiencing lower respiratory problems are respected.

Physiological Integrity

8. Assess and re-assess the manifestations of patients being managed for a lower respiratory problem.
9. Use laboratory data and clinical manifestations to prioritize nursing care for the patient who has an acute or chronic lower respiratory problem.
10. Collaborate with other health care professionals who help patients and families experiencing a chronic lower respiratory problem achieve desired health outcomes.
11. Coordinate nursing interventions for the patient with a chronic lower respiratory problem in the community.
12. Prioritize nursing care for the patient with chest tubes.

 http://evolve.elsevier.com/Iggy/

The alveoli and the smallest airways are sites for direct gas exchange. Any problem of these tissues reduces gas exchange and interferes with perfusion. Many lower airway problems are chronic and progressive, requiring changes in lifestyle, especially for older adults. Chart 30-1 lists nursing issues for the older patient with a respiratory problem.

Chart 30-1 Nursing Focus on the Older Adult

Chronic Respiratory Disorder

- Provide rest periods between activities such as bathing, meals, and ambulation.
- Place the patient in an upright position for meals to prevent aspiration.
- Encourage nutritional fluid intake after the meal to promote increased calorie intake.
- Schedule drugs around routine activities to increase adherence to drug therapy.
- Arrange chairs in strategic locations to allow the patient with dyspnea to stop and rest while walking.
- Urge the patient to notify the health care provider promptly for any manifestation of infection.

- Encourage the patient to receive the pneumococcal vaccine and to have an annual influenza vaccination.

Chronic airflow limitation (CAL) is a group of chronic lung diseases that includes asthma, chronic bronchitis, and pulmonary emphysema. More than 10% of American adults suffer from some form of CAL, and many have moderate to severe disability from it (Centers for Disease Control and Prevention [CDC], 2012). Although CAL problems are not all reversible, good management can help maintain adequate gas exchange and improve overall health.

Asthma

Pathophysiology

Asthma is often a chronic condition in which reversible airflow obstruction in the airways occurs intermittently (Fig. 30-1). Airway obstruction occurs by inflammation and by airway tissue sensitivity (hyperresponsiveness) that leads to bronchoconstriction. Inflammation obstructs the airway **lumens** (i.e., the insides) (Fig. 30-2). Airway hyperresponsiveness and constriction of bronchial smooth muscle narrow the airways from the outside. Airway inflammation and sensitivity can trigger bronchiolar constriction, and many people with asthma have both problems. Severe airway obstruction impairs gas exchange and can be fatal. At least 3400 deaths from acute asthma occur in the United States each year (CDC, 2014a).

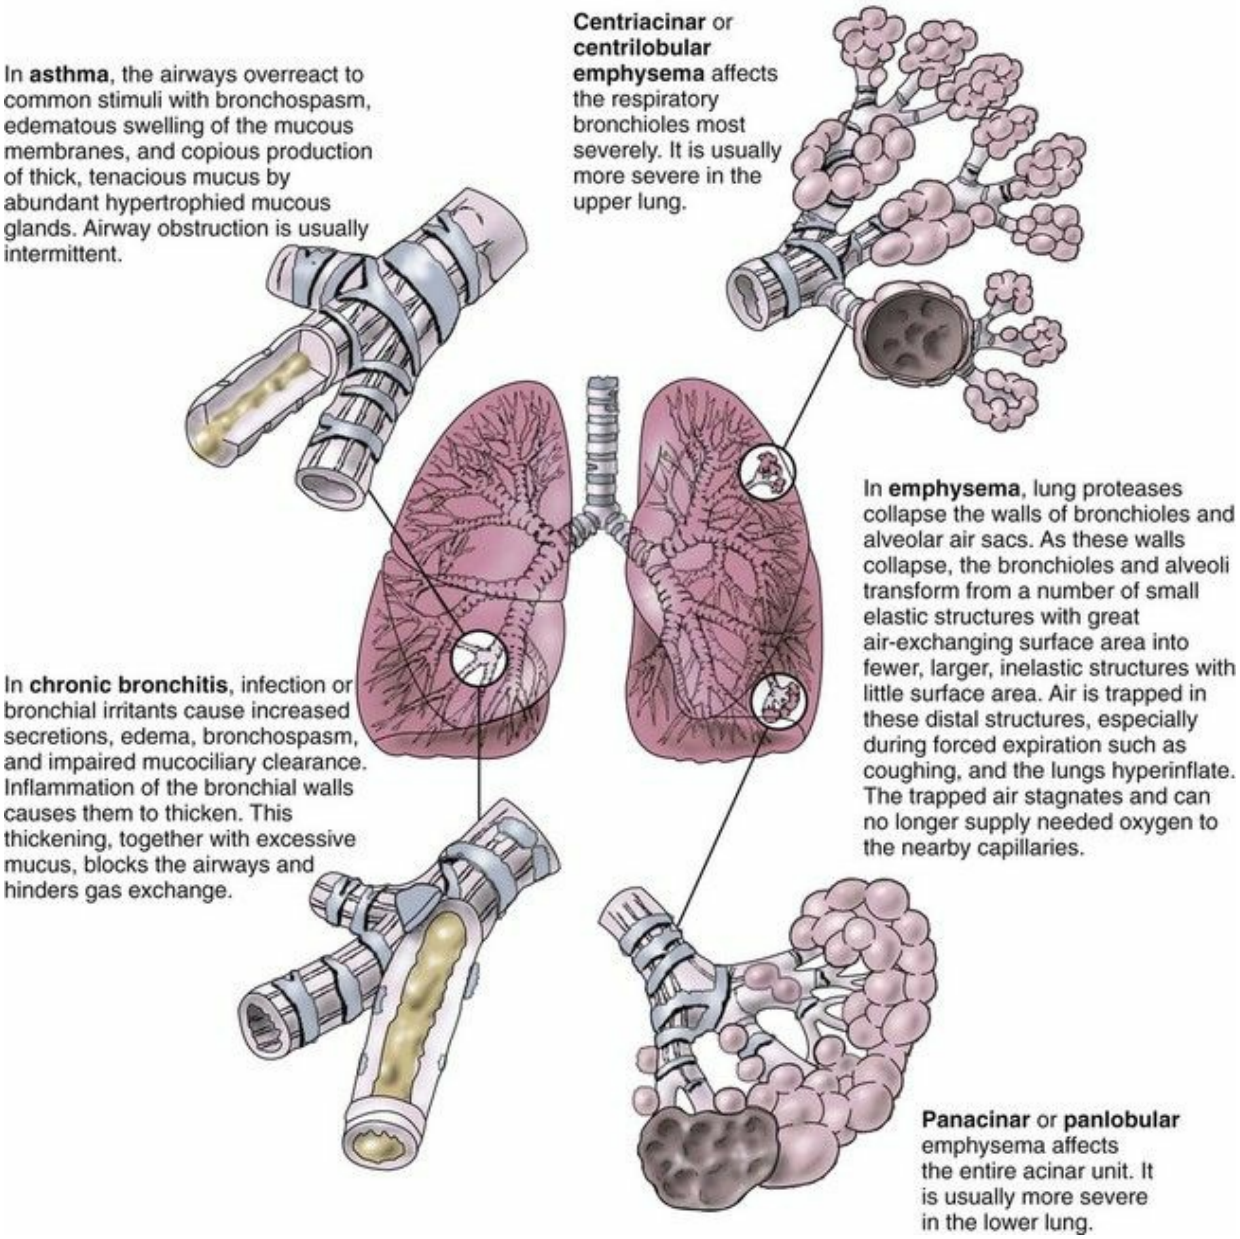

FIG. 30-1 The pathophysiology of chronic airflow limitation (CAL).

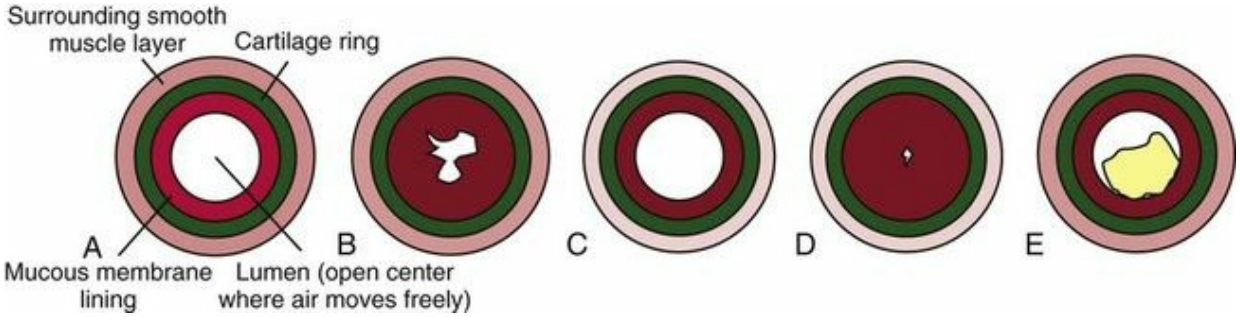

FIG. 30-2 Causes of narrowed airways. **A,** Cross section of a small airway showing the tissue layers. **B,** Mucosal swelling. **C,** Constriction of smooth muscle. **D,** Mucosal swelling and constriction of smooth muscle. **E,** Mucus plug.

Etiology and Genetic Risk

Although asthma is classified into types based on what triggers the attacks, the effect on gas exchange is the same. Inflammation of the mucous membranes lining the airways is a key event in triggering an asthma attack. It occurs in response to the presence of specific allergens; general irritants such as cold air, dry air, or fine airborne particles; microorganisms; and aspirin and other NSAIDs. Increased airway sensitivity (hyperresponsiveness) can occur with exercise, with an upper respiratory illness, and for unknown reasons.

Genetic/Genomic Considerations

Patient-Centered Care QSEN

Results of genome-wide association studies (GWAS) indicate that more than 50 gene variations are associated with asthma, although asthma is a multifactorial disorder with both genetic and environmental input required for expression (Beery & Workman, 2012; Online Mendelian Inheritance in Man [OMIM], 2013b). Some variations have a greater influence for asthma expression within certain racial or ethnic groups. Also, genetic variation in the gene that controls the synthesis and activity of beta-adrenergic receptors has an impact on drug therapy for asthma. Patients who have a mutation in this gene do not respond as expected to beta agonist drugs and need an altered therapy plan. Teaching these patients about why their drug therapies are different from standard recommendations is a nursing responsibility that can assist with therapy adherence.

When asthma is well controlled, the airway changes are temporary and

reversible. With poor control, chronic inflammation can lead to airway damage and altered cellular regulation with enlargement of the bronchial epithelial cells and changes in the bronchial smooth muscle. When asthma attacks are frequent, even exposure to low levels of the triggering agent or event may stimulate an attack.

Inflammation triggers asthma for some people when allergens bind to specific antibodies (especially immunoglobulin E [IgE]). These antibodies are attached to tissue *mast cells* and white blood cells (WBCs) called *basophils,* which are filled with chemicals that can start local inflammatory responses (see Chapters 17 and 20). Some chemicals, such as histamine, start an immediate inflammatory response, which can be blocked by drugs like diphenhydramine (Benadryl). Others, such as leukotriene and eotaxin, are slower and cause later, prolonged inflammatory responses, which can be blocked by drugs like montelukast (Singulair), zafirlukast (Accolate), and zileuton (Zyflo). Chemicals also attract more WBCs (eosinophils, macrophages, basophils) to the area, which then continue the responses of blood vessel dilation and capillary leak, leading to mucous membrane swelling and increased mucus production (McCance et al., 2014). These responses narrow the lumens even more, which then interferes with airflow and gas exchange. Inflammation can also occur through general irritation rather than allergic responses.

Bronchospasm is a narrowing of the bronchial tubes by constriction of the smooth muscle around and within the bronchial walls. It can occur when small amounts of pollutants or respiratory viruses stimulate nerve fibers, causing constriction of bronchial smooth muscle. If an inflammatory response is stimulated at the same time, the chemicals released during inflammation also trigger constriction. Severe bronchospasm alone, especially in smaller bronchioles, can profoundly limit airflow to the alveoli and greatly reduce gas exchange.

Aspirin and other NSAIDs can trigger asthma in some people, although this response is not a true allergy. It results from increased production of leukotriene when aspirin or NSAIDs suppress other inflammatory pathways.

Gastroesophageal reflux disease (GERD) can trigger asthma in some people, who then have more asthma manifestations at night (Global Initiative for Asthma [GINA], 2014). GERD allows highly acidic stomach contents to enter the airway and make the pre-existing tissue sensitivity worse.

Incidence and Prevalence

Asthma can occur at any age. About half of adults with asthma also had the disease in childhood. Asthma affects nearly 20.8 million adults in the United States and Canada (CDC, 2012). It is more common in urban settings than in rural settings.

Considerations for Older Adults

Patient-Centered Care QSEN

Asthma occurs as a new disorder in about 3% of people older than 55 years. Another 3% of people older than 60 years have asthma as a continuing chronic disorder (CDC, 2012). Lung and airway changes as a part of aging make any breathing problem more serious in the older adult. One problem related to aging is a decrease in the sensitivity of beta-adrenergic receptors. When stimulated, these receptors relax smooth muscle and cause bronchodilation. As these receptors become less sensitive, they no longer respond as quickly or as strongly to agonists (epinephrine, dopamine) and beta-adrenergic drugs, which are often used as rescue therapy during an acute asthma attack. Thus teaching older patients how to avoid asthma attacks and to correctly use preventive drug therapy is a nursing priority.

Patient-Centered Collaborative Care

Assessment

Asthma is classified on the basis of how well controlled the manifestations are, as well as on the patient's response to asthma drugs. These classes are the basis for current asthma therapy (Charts 30-2 and 30-3).

Chart 30-2 Key Features

Levels of Asthma Control

CHARACTERISTIC	CONTROLLED (ALL OF THESE CHARACTERISTICS MUST BE PRESENT)	PARTLY CONTROLLED (THE PRESENCE OF ANY ONE OF THESE CHARACTERISTICS IS CONSIDERED PARTLY CONTROLLED)	UNCONTROLLED (THE PRESENCE OF THREE OR MORE CHARACTERISTICS FROM THE PARTLY CONTROLLED LIST IS CONSIDERED UNCONTROLLED ASTHMA)
Daytime manifestations	Manifestations occur twice per week or less	Manifestations occur more than twice per week	
Activity limitations	None	Any	
Nighttime manifestations	None	Any	
Reliever drug use	Reliever used twice per week or less	Reliever used more than twice per week	
PEF or FEV_1	Normal	Less than 80% of predicted or established personal best	
Treatment action	Find and maintain lowest step level that controls manifestations	Increase step until manifestations are controlled on a regular basis and then reduce step to the lowest step level that consistently controls manifestations	Increase step (step up) until control is reached and maintained

FEV_1, Forced expiratory volume in the first second; *PEF*, peak expiratory flow.

Chart 30-3 Key Features

The Step System for Medication Use in Asthma Control

STEP 1	STEP 2	STEP 3	STEP 4	STEP 5
As-needed rapid-acting $beta_2$ agonist (relief inhaler)	As-needed rapid-acting $beta_2$ agonist (relief inhaler)	As-needed rapid-acting $beta_2$ agonist (relief inhaler)	As-needed rapid-acting $beta_2$ agonist (relief inhaler)	As-needed rapid-acting $beta_2$ agonist (relief inhaler)
No daily drugs needed	Daily treatment involves the use of *one* of these two options:	Daily treatment involves the use of *one* of these four options:	Daily treatment involves the use of the Step 3 option that provided the best degree of control and was well tolerated along with one or more of these two options:	Daily treatment involves the use of the Step 4 option(s) that provided the best degree of control and was well tolerated along with either of these two options:
	Low-dose ICS*	Low-dose ICS *and* long-acting $beta_2$ agonist	Medium-dose or high-dose ICS *and* long-acting $beta_2$ agonist	Oral glucocorticosteroid (lowest dose)
	Leukotriene modifier†	Medium-dose or high-dose ICS Low-dose ICS and leukotriene modifier Low-dose ICS and sustained-release theophylline	Leukotriene modifier and sustained-release theophylline	Anti-IgE‡ treatment

*ICS = Inhaled corticosteroid.

†Leukotriene modifier = Leukotriene receptor antagonist or leukotriene synthesis inhibitor.

‡IgE = Immunoglobulin E.

Data compiled from Global Initiative for Asthma (GINA). (2014). Pocket guide for asthma management and prevention. Retrieved June 2014, from www.ginasthma.org/Guidelines/guidelines-resources.html.

History.

The patient with asthma usually has a pattern of intermittent episodes of **dyspnea** (shortness of breath), chest tightness, coughing, wheezing, and increased mucus production. Ask whether the manifestations occur continuously, seasonally, in association with specific activities or exposures, or more frequently at night. Some patients have manifestations for 4 to 8 weeks after a cold or other upper respiratory

infection. The patient with atopic (allergic) asthma often has other allergic problems such as rhinitis, skin rash, or pruritus. Ask whether any family members have asthma or respiratory problems. Ask about current or previous smoking habits. If the patient smokes, use this opportunity to teach him or her about smoking cessation (see Chart 27-1 in Chapter 27). Wheezing in nonsmokers is important in the diagnosis of asthma.

Physical Assessment/Clinical Manifestations.

The patient with mild to moderate asthma may have no manifestations between asthma attacks. During an acute episode, common manifestations are an audible wheeze and increased respiratory rate. At first, the wheeze is louder on exhalation. When inflammation occurs with asthma, coughing may increase.

The patient may use accessory muscles to help breathe during an attack. Observe for muscle retraction at the sternum and the suprasternal notch and between the ribs. The patient with long-standing, severe asthma may have a "barrel chest," caused by air trapping (Fig. 30-3). The anteroposterior (AP) diameter (diameter between the front and the back of the chest) increases with air trapping, giving the chest a rounded rather than an oval shape. The normal chest is about 1.5 times as wide as it is deep. In severe, chronic asthma, the AP diameter may equal or exceed the lateral diameter. Compare the AP diameter of the chest with the lateral diameter. Chronic air trapping also flattens the diaphragm and increases the space between the ribs.

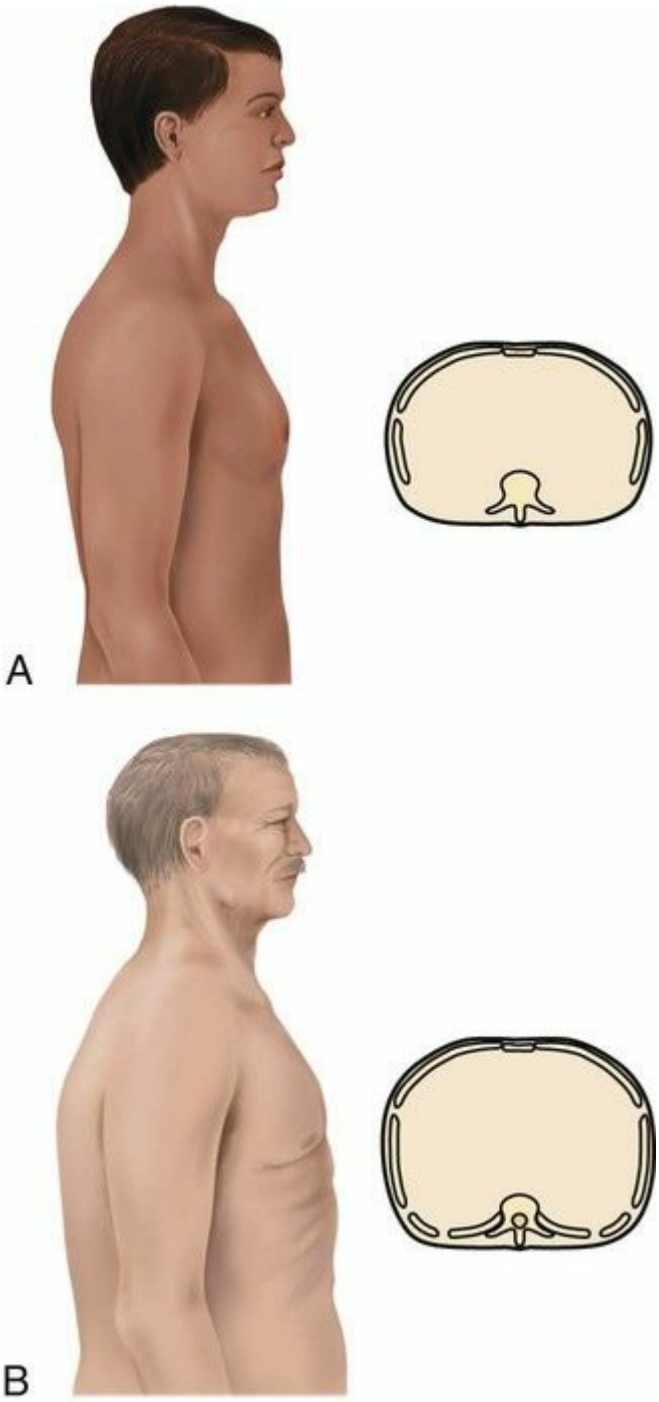

FIG. 30-3 **A,** Normal adult. The thorax has an oval shape with an anteroposterior-to-transverse diameter of 1 : 1.5 or 5 : 7. **B,** Barrel chest. Note equal anteroposterior-to-transverse diameter and that ribs are horizontal instead of the normal downward slope. This is associated with chronic obstructive pulmonary disease and severe asthma as a result of hyperinflation of the lungs.

Along with an audible wheeze, the breathing cycle is longer with prolonged exhalation and requires more effort. The patient may be unable to speak more than a few words between breaths. Hypoxia occurs with severe attacks. Pulse oximetry shows **hypoxemia** (poor blood oxygen

levels). Examine the oral mucosa and nail beds for cyanosis. Other indicators of hypoxemia include changes in the level of cognition or consciousness and tachycardia.

Laboratory Assessment.

Laboratory tests can determine asthma type and the degree of breathing impairment. Arterial blood gas (ABG) levels show the effectiveness of gas exchange (see Chapter 12 for discussion of ABGs). The arterial oxygen level (Pa_{O_2}) may decrease during an asthma attack. Early in the attack, the arterial carbon dioxide level (Pa_{CO_2}) may be decreased as the patient increases the breathing rate and depth. Later in an asthma episode, Pa_{CO_2} rises, indicating carbon dioxide retention. Allergic asthma often occurs with elevated serum eosinophil counts and immunoglobulin E (IgE) levels. The sputum may contain eosinophils and mucus plugs with shed epithelial cells (Curschmann's spirals).

Pulmonary Function Tests.

The most accurate tests for measuring airflow in asthma are the pulmonary function tests (PFTs) using spirometry (O'Laughlen & Rance, 2012). Baseline PFTs are obtained for all patients diagnosed with asthma. The most important PFTs for a patient with asthma are the forced vital capacity (FVC), the forced expiratory volume in the first second (FEV_1), and the peak expiratory flow (PEF), sometimes called *peak expiratory rate flow (PERF).* Definitions of PFTs are listed in Chapter 27. A decrease in either the FEV_1 or the PEF (PERF) of 15% to 20% below the expected value for age, gender, and size is common for the patient with asthma. Asthma is diagnosed when these values increase by 12% or more after treatment with bronchodilators. Airway responsiveness is tested by measuring the PEF and FEV_1 before and after the patient inhales the drug *methacholine,* which induces bronchospasm in susceptible people.

Interventions

The purposes of asthma therapy are to control and prevent episodes, improve airflow and gas exchange, and relieve manifestations. Asthma is best controlled when the patient is an active partner in the management plan (Pruitt, 2011). Priority nursing actions focus on patient education about implementation of the personal asthma action plan, which includes drug therapy and lifestyle management strategies to assist the patient in understanding his or her disease and its management (GINA, 2014).

Self-Management Education.

Asthma often has intermittent overt manifestations. With guided self-care, patients can co-manage this disease, increasing symptom-free periods and decreasing the number and severity of attacks (Pruitt, 2011). Good management decreases hospital admissions and increases participation in patient-chosen work and leisure activities. Self-care requires extensive education for the patient to be able to self-assess respiratory status, self-manage (by adjusting the frequency and dosage of prescribed drugs), and know when to consult the health care provider.

Ideally, a personal asthma action plan is developed by the health care provider and the patient. The plan is tailored to meet the patient's personal triggers, asthma manifestations, and drug responses. It includes:

- The prescribed daily controller drug(s) schedule and prescribed reliever drug directions
- Patient-specific daily asthma control assessment questions
  - Directions for adjusting the daily controller drug schedule
  - When to contact the health care provider (in addition to regularly scheduled visits)
  - What emergency actions to take when asthma is not responding to controller and reliever drugs

Teach the patient to assess asthma severity at least daily with a peak flow meter (Fig. 30-4) and to adjust drugs according to his or her personal asthma action plan to manage inflammation and bronchospasms to prevent or relieve manifestations. Chart 30-4 describes the correct method to use the peak flow meter. The patient first establishes a baseline or "personal best" peak expiratory flow (PEF) by measuring his or her PEF twice daily for 2 to 3 weeks when asthma is well controlled and recording the results. This way, the patient will know when his or her peak flow is reduced to the point that more drugs are needed or that emergency assistance is needed. When the patient has established a "personal best," all other readings are compared with this value. Some meters are color-coded to help the patient interpret the results. Green zone readings are at least 80% of or above the "personal best." This is the ideal range for asthma control and indicates that no increases in drug therapy are needed. Yellow is a range between 50% and 80% of personal best. When a patient has a reading in this range, he or she needs to use the prescribed reliever drug. Within a few minutes after using the reliever drug, another PEF reading should be made to determine whether the reliever drug is working. *Frequent readings in the yellow zone or increasing use of reliever drugs indicates the need to reassess the asthma plan for the need to change*

controller drugs. Red is a range below 50% of the patient's personal best, indicating serious respiratory obstruction.

Chart 30-4 Patient and Family Education: Preparing for Self-Management

Using a Peak Flow Meter

- Set the peak flowmeter at zero.
- Use a standing position, without leaning or supporting yourself on anything, if possible.
- Take as deep a breath as you can.
- Place the mouthpiece of the meter in your mouth, taking care to wrap your lips tightly around it.
- Blow your breath out through the mouthpiece as hard and as fast as you are able. (If you cough, sneeze, or have any type of interruption while you exhale, reset the meter and perform the test again.)
- Reset and perform the test two additional times.
- The highest reading of the three is your current peak flow rate.
- Keep a record or graph of your peak flow rates and examine these for trends.

FIG. 30-4 A typical peak flowmeter. This model will show faster exhalation rates in *green*, reduced exhalation rates in *yellow*, and seriously reduced exhalation rates in *red*.

Nursing Safety Priority QSEN

Action Alert

Teach the patient that if a red zone reading occurs when using the peak flowmeter to immediately use the reliever drugs and seek emergency help.

Teach the patient to keep a symptom and intervention diary to learn specific triggers of asthma, early cues for impending attacks, and personal response to drugs. Stress the importance of proper use of his or her personal asthma action plan for any severity of asthma. Chart 30-5 lists areas to emphasize when teaching the patient with asthma.

Chart 30-5 Patient and Family Education: Preparing for Self-Management

Asthma Management

- Avoid potential environmental asthma triggers, such as smoke, fireplaces, dust, mold, and weather changes of warm to cold.

- Avoid drugs that trigger your asthma (e.g., aspirin, NSAIDs, beta blockers).
- Avoid food that has been prepared with monosodium glutamate (MSG) or metabisulfite.
- If you have exercise-induced asthma, use your bronchodilator inhaler 30 minutes before exercise to prevent or reduce bronchospasm.
- Be sure you know the proper technique and correct sequence when you use metered dose inhalers.
- Get adequate rest and sleep.
- Reduce stress and anxiety; learn relaxation techniques; adopt coping mechanisms that have worked for you in the past.
- Wash all bedding with hot water to destroy dust mites.
- Monitor your peak expiratory flow rates with a flow meter at least twice daily.
- Seek immediate emergency care if you experience any of these:
  - Gray or blue fingertips or lips
  - Difficulty breathing, walking, or talking
  - Retractions of the neck, chest, or ribs
  - Nasal flaring
  - Failure of drugs to control worsening symptoms
  - Peak expiratory rate flow (PERF) declining steadily after treatment, or a flow rate 50% below your usual flow rate

Drug Therapy.

Pharmacologic management of adults with asthma is based on the step category for severity and treatment (see Charts 30-2 and 30-3) (GINA, 2014). **Control therapy drugs** are drugs used to reduce airway sensitivity (responsiveness) to prevent asthma attacks from occurring. *They are used every day, regardless of symptoms.* **Reliever drugs** (also called "rescue drugs") are those used to actually stop an attack once it has started. Some patients may need drug therapy only during an asthma episode. For others, daily drugs are needed to keep asthma episodic rather than a more frequent problem. This therapy involves the use of bronchodilators and various drug types to reduce inflammation. Some drugs reduce the asthma response, and other drugs actually prevent the response. Combination drugs are two agents from different classes combined together for better response. Chart 30-6 lists the most common preferred drugs in each class for control and relief therapy of asthma. The actions, interventions, and rationales for most drugs within a single class are similar although drug dosages may differ. Be sure to consult a pharmacology text or drug handbook for more information on a specific

drug.

Chart 30-6 Common Examples of Drug Therapy

Asthma Prevention and Treatment

DRUG/USUAL DOSAGE	NURSING INTERVENTIONS	RATIONALE
Bronchodilators Cause bronchodilation through relaxing bronchiolar smooth muscle by binding to and activating pulmonary beta$_2$ receptors.		
Short-Acting Beta$_2$ Agonist (SABA) Primary use is a fast-acting reliever (rescue) drug to be used either during an asthma attack or just before engaging in activity that usually triggers an attack.		
Albuterol (Proventil, Ventolin) 1-2 inhalations every 4-6 hr (90 mcg/ inhaled dose)	Teach patients to carry drug with them at all times.	The drug can stop or reduce life-threatening bronchoconstriction, which can occur anytime.
	Teach patient to monitor heart rate.	Excessive use causes systemic symptoms, especially tachycardia.
	When taking this drug with other inhaled drugs, teach patient to use this drug at least 5 minutes before the other inhaled drugs.	The bronchodilation effect of the drug allows better penetration of the other inhaled drugs.
	Teach patient the correct technique for using the MDI or DPI.	Correct technique is essential to getting the drug to the site of action.
Long-Acting Beta$_2$ Agonist (LABA) Causes bronchodilation through relaxing bronchiolar smooth muscle by binding to and activating pulmonary beta$_2$ receptors. Onset of action is slow with a long duration. Primary use is prevention of an asthma attack.		
Salmeterol (Serevent) 2 inhalations every 12 hr (25 mcg/inhalation with MDI) (50 mcg/inhalation with DPI)	Teach patient to shake inhaler (MDI) well before using.	Drug separates easily.
	Teach patient to not use this drug as a reliever drug.	Drug has slow onset of action and does not relieve symptoms.
	Teach patient the correct technique for using the MDI or DPI.	Correct technique is essential to getting the drug to the site of action.
Indacaterol (Arcapta Neohaler) 1 inhalation daily (75 mcg/inhalation with DPI) (COPD only)	Same as for salmeterol.	Same as for salmeterol.
Cholinergic Antagonist Causes bronchodilation by inhibiting the parasympathetic nervous system, allowing the sympathetic system to dominate, releasing norepinephrine that activates beta$_2$ receptors. Purpose is to both relieve and prevent asthma.		
Ipratropium (Atrovent, Apo-Ipravent) 2-4 inhalations 4-6 times daily (18 mcg/inhalation)	If patient is to use this as a reliever drug, teach him or her to carry it at all times.	The drug can stop or reduce life-threatening bronchoconstriction, which can occur anytime.
	Teach patient to shake MDI well before using.	Drug separates easily.
	Teach patient to increase daily fluid intake.	Drug causes mouth dryness.
	Teach patient to observe for and report blurred vision, eye pain, headache, nausea, palpitations, tremors, inability to sleep.	These are systemic symptoms of overdose and require intervention.
	Teach patient the correct technique for using the MDI or DPI.	Correct technique is essential to getting the drug to the site of action.
Anti-inflammatories All of these drugs help improve bronchiolar airflow by decreasing the inflammatory response of the mucous membranes in the airways. *They do not cause bronchodilation.*		
Corticosteroids Disrupt production pathways of inflammatory mediators. The main purpose is to prevent an asthma attack caused by inflammation or allergies (controller drug).		
Fluticasone (Flovent) 50 mcg by MDI twice daily; 100-250 mcg by DPI daily	Teach patient to use the drug daily, even when no symptoms are present.	Maximum effectiveness requires continued use for 48-72 hr and depends on regular use.
	Teach patient to use good mouth care and to check mouth daily for lesions or drainage.	Drug reduces local immunity and increases the risk for local infections, especially *Candida albicans* (yeast).
	Teach patient to not use this drug as a reliever drug.	Drug has slow onset of action and does not relieve symptoms.
	Teach patient the correct technique for using the MDI or DPI.	Correct technique is essential to getting the drug to the site of action.
Prednisone (Deltasone, Predone) 1-40 mg orally daily	Teach patient about expected side effects.	Knowing the side effects to expect reduces anxiety.
	Teach patient to avoid anyone who has an upper respiratory infection.	Drug reduces all protective inflammatory responses, increasing the risk for infection.
	Teach patient to avoid activities that lead to injury.	Blood vessels become more fragile, leading to bruising and petechiae.
	Teach patient to take drug with food.	Food helps reduce the drug side effect of GI ulceration.
	Teach patient not to suddenly stop taking the drug for any reason.	The drug suppresses adrenal production of corticosteroids, which are essential for life.
	Cromone Stabilizes the membranes of mast cells and prevents the release of inflammatory mediators. Purpose is to prevent asthma attack triggered by inflammation or allergens.	
Nedocromil (Tilade) 4 mg by MDI every 6 hr	Teach patient to use the drug daily, even when no symptoms are present.	Drug has slow onset of action for asthma prevention and is most effective when taken consistently.
	Teach patient to not use this drug as a reliever drug.	Drug does not relieve or reverse symptoms.
	Teach patient the correct technique for using the MDI.	Correct technique is essential to getting the drug to the site of action.
Leukotriene Modifier Blocks the leukotriene receptor, preventing the inflammatory mediator from stimulating inflammation. Purpose is to prevent asthma attack triggered by inflammation or allergens.		
Montelukast (Singulair) 10 mg orally daily	Teach patient to use the drug daily, even when no symptoms are present.	Drug has slow onset of action for asthma prevention and is most effective when taken consistently.
	Teach patient not to decrease the dose of or stop taking any other asthma drugs unless instructed by the health care professional.	This drug is for long-term asthma control and does not replace other drugs, especially corticosteroids and reliever (rescue) drugs.

diagnosis, management, and prevention of chronic obstructive pulmonary disease. Retrieved June 2014, from www.goldcopd.org/.

Bronchodilators.

Bronchodilators cause bronchiolar smooth muscle relaxation. They have no effect on inflammation. Thus when a patient with asthma has airflow obstruction by both bronchospasm and inflammation, at least two types of drug therapy are needed. Some bronchodilators work by stimulating the $beta_2$-adrenergic receptors on bronchial smooth muscle in the same way that the hormones *epinephrine* and *norepinephrine* do; others work by blocking the parasympathetic nervous system. Bronchodilators include $beta_2$ agonists and cholinergic antagonists.

$Beta_2$ agonists bind to the $beta_2$-adrenergic receptors and cause an increase in smooth muscle relaxation. Short-acting $beta_2$ agonists (SABAs) provide rapid but short-term relief. These inhaled drugs are most useful when an attack begins (as relief) or as premedication when the patient is about to begin an activity that is likely to induce an attack (GINA, 2014). Such agents include albuterol (Proventil, Ventolin), bitolterol (Tornalate), levalbuterol (Xopenex), pirbuterol (Maxair), and terbutaline (Brethaire). Teach the patient the correct technique for using an inhaled drug with a metered dose inhaler (MDI) (Chart 30-7). Fig. 30-5 shows a patient using a "spacer" with an MDI. Spacer use increases the amount of drug that is delivered to the lungs. Chart 30-8 describes the proper care and use of a dry powder inhaler (DPI).

Chart 30-7 Patient and Family Education: Preparing for Self-Management

How to Use an Inhaler Correctly*

With a Spacer (Preferred Technique)

1. Before each use, remove the caps from the inhaler and the spacer.
2. Insert the mouthpiece of the inhaler into the non-mouthpiece end of the spacer.
3. Shake the whole unit vigorously 3 or 4 times.
4. Place the mouthpiece into your mouth, over your tongue, and seal your lips tightly around it.
5. Press down firmly on the canister of the inhaler to release one dose of medication into the spacer.
6. Breathe in slowly and deeply. If the spacer makes a whistling sound,

you are breathing in too rapidly.
7. Remove the mouthpiece from your mouth, and, keeping your lips closed, hold your breath for at least 10 seconds and then breathe out slowly.
8. Wait at least 1 minute between puffs.
9. Replace the caps on the inhaler and the spacer.
10. At least once a day, clean the plastic case and cap of the inhaler by thoroughly rinsing in warm, running tap water; at least once a week, clean the spacer in the same manner.

Without a Spacer

1. Before each use, remove the cap and shake the inhaler according to the instructions in the package insert.
2. Tilt your head back slightly, and breathe out fully.
3. Open your mouth, and place the mouthpiece 1 to 2 inches away.
4. As you begin to breathe in deeply through your mouth, press down firmly on the canister of the inhaler to release one dose of medication.
5. Continue to breathe in slowly and deeply (usually over 5-7 sec).
6. Hold your breath for at least 10 seconds to allow the medication to reach deep into the lungs, and then breathe out slowly.
7. Wait at least 1 minute between puffs.
8. Replace the cap on the inhaler.
9. At least once a day, remove the canister and clean the plastic case and cap of the inhaler by thoroughly rinsing in warm, running tap water.

---

*Avoid spraying in the direction of the eyes.

Chart 30-8 Patient and Family Education: Preparing for Self-Management

How to Use a Dry Powder Inhaler (DPI)

For Inhalers Requiring Loading

- First load the drug by:
  - Turning the device to the next dose of drug, *or*
  - Inserting the capsule into the device, *or*
  - Inserting the disk or compartment into the device

After Loading the Drug and for Inhalers That Do Not Require

Drug Loading

- Read your doctor's instructions for how fast you should breathe for your particular inhaler.
- Place your lips over the mouthpiece, and breathe in forcefully (there is no propellant in the inhaler; only your breath pulls the drug in).
- Remove the inhaler from your mouth as soon as you have breathed in.
- *Never exhale (breathe out) into your inhaler.* Your breath will moisten the powder, causing it to clump and not be delivered accurately.
- *Never wash or place the inhaler in water.*
- *Never shake your inhaler.*
- Keep your inhaler in a dry place at room temperature.
- If the inhaler is preloaded, discard the inhaler after it is empty.
- Because the drug is a dry powder and there is no propellant, you may not feel, smell, or taste it as you inhale.

FIG. 30-5 Patient using an aerosol metered dose inhaler with a spacer.

Nursing Safety Priority QSEN

Action Alert

Teach the patient with asthma to always carry the relief drug inhaler with him or her and to ensure that enough drug remains in the inhaler to provide a quick dose when needed.

Dry powder inhalers indicate the amount of remaining drug. Some aerosol inhalers (MDIs) have meters that indicate the number of doses left in the canister, and others do not. It is recommended that the patient count the number of doses as they are used; however, many patients have difficulty keeping the dose count accurate.

Long-acting beta$_2$ agonists (LABAs) are also delivered by inhaler directly to the site of action—the bronchioles. Proper use of the long-acting agonists can decrease the need to use reliever drugs as often. Unlike short-acting agonists, long-acting drugs need time to build up an effect but the effects are longer lasting. Thus these drugs are useful in preventing an asthma attack but have no value during an acute attack. Therefore teach patients not to use LABAs alone to relieve them during an attack or when wheezing is getting worse but, instead, to use a SABA. Examples of LABAs include formoterol (Foradil) and salmeterol (Serevent). *These drugs should never be prescribed as the* ***only*** *drug therapy for asthma. Teach the patient to use these control drugs daily as prescribed, even when no manifestations are present.*

Cholinergic antagonists, also called *anticholinergic drugs,* are similar to atropine and block the parasympathetic nervous system. This action results in increased bronchodilation and decreased pulmonary secretions. The most common drug in this class is ipratropium (Atrovent), which is used as an inhalant. Most cholinergic antagonists are short acting and must be used several times a day, although long-acting agents such as tiotropium (Spiriva) are available for use once a day.

Xanthines, such as theophylline and aminophylline, are used only when other types of management are ineffective. These drugs are given systemically, and the dosage that is effective is close to the dosage that produces many dangerous side effects. Blood levels must be monitored closely to ensure the drug level is within the therapeutic range.

Anti-Inflammatory Agents.

Anti-inflammatory agents decrease inflammation in the airways. Those used as inhalants have fewer systemic side effects than those taken systemically.

Corticosteroids decrease inflammation in many ways, including by reducing the production of inflammatory chemicals. Inhaled corticosteroids (ICSs) can be helpful in controlling asthma manifestations. High-potency steroid inhalers, such as fluticasone (Flovent), budesonide (Pulmicort), and mometasone (Asmanex), may be used once per day for maintenance. Systemic corticosteroids, because of severe side effects, are avoided for mild to moderate intermittent asthma

and are used on a short-term basis for moderate asthma. For some patients with severe asthma, daily oral corticosteroids may be needed. *Both inhaled corticosteroids and those taken orally are controller drugs. They are not effective in reversing symptoms during an asthma attack and should not be used as reliever drugs. Teach patients to take corticosteroids on a scheduled basis, even when no manifestations are present.*

Cromones, both those that are inhaled and those that are taken orally, are useful as *controller* asthma therapy when taken on a scheduled basis. These agents reduce airway inflammation by either inhibiting the release of inflammatory chemicals (nedocromil [Tilade]) or preventing mast cell membranes from opening when an allergen binds to IgE (cromolyn sodium [Intal]). *Thus these drugs help prevent asthma attacks but are not effective in reversing symptoms during an asthma attack and should not be used alone as relief drugs.*

Leukotriene modifiers are oral drugs that work in several ways to control asthma when taken on a scheduled basis. Montelukast (Singulair) and zafirlukast (Accolate) block the leukotriene receptor. Zileuton (Zyflo) prevents leukotriene synthesis. *These drugs do not reverse symptoms during an asthma attack and should not be used alone as relief drugs.*

Exercise/Activity.

Regular exercise is a recommended part of asthma therapy to maintain cardiac health, strengthen muscles, and promote gas exchange and perfusion. Teach patients to examine the conditions that trigger an attack and adjust the exercise routine as needed. Some may need to use an inhaled SABA before beginning activity. For others, adjusting the environment may be needed (e.g., changing from outdoor ice-skating in cold, dry air to indoor ice-skating).

Oxygen Therapy.

Supplemental oxygen by mask or nasal cannula is often used during an acute asthma attack. High flow delivery may be needed when bronchospasms are severe and limit flow of oxygen through the bronchiole tubes. Heliox, a mixture of helium and oxygen (often 50% helium and 50% oxygen), can help improve oxygen delivery to the alveoli. This gas mixture is lower in density than oxygen alone or room air and flows even when airway resistance is high.

Nursing Safety Priority QSEN

Action Alert

Ensure that no open flames (e.g., cigarette smoking, fireplaces, burning candles) or other combustion hazards are in rooms where oxygen is in use.

Status Asthmaticus.

Status asthmaticus is a severe, life-threatening acute episode of airway obstruction that intensifies once it begins and often does not respond to usual therapy. The patient arrives in the emergency department with extremely labored breathing and wheezing. Use of accessory muscles for breathing and distention of neck veins are observed. *If the condition is not reversed, the patient may develop pneumothorax and cardiac or respiratory arrest.* IV fluids, potent systemic bronchodilators, steroids, epinephrine, and oxygen are given immediately to reverse the condition. Prepare for emergency intubation. Sudden absence of wheezing indicates complete airway obstruction and requires a tracheotomy. When breathing improves, management is similar to that for any patient with asthma.

NCLEX Examination Challenge

Safe and Effective Care Environment

Which parameter indicates to the nurse that the short-acting beta-adrenergic agonist the client took 5 minutes ago for an acute asthma attack is effective?

A Spo_2 decrease from 85% to 78%

B Peak expiratory flow rate increase from 50% to 70%

C The obvious use of accessory muscles during inhalation and exhalation

D Active bubbling in the humidifier chamber of the oxygen delivery system

Chronic Obstructive Pulmonary Disease

❖ Pathophysiology

Chronic obstructive pulmonary diseases (COPD) include emphysema and chronic bronchitis. Although these are separate disorders with different pathologic processes, many patients with emphysema also have chronic bronchitis at the same time (Fig. 30-6).

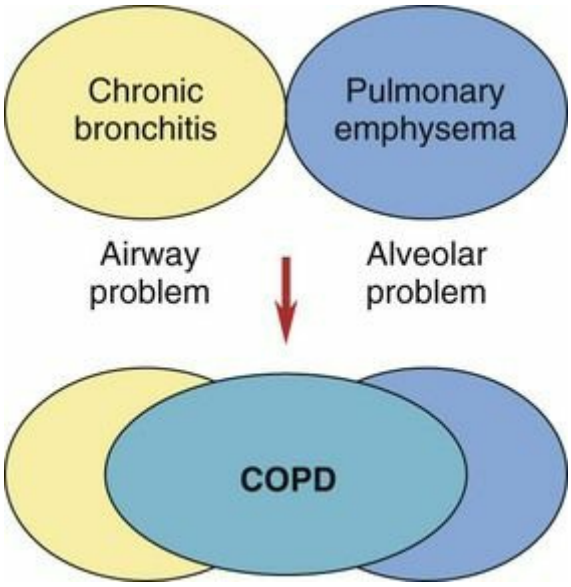

FIG. 30-6 The interaction of chronic bronchitis and emphysema in chronic obstructive pulmonary disease (COPD).

Emphysema.

The two major changes that occur with emphysema are loss of lung elasticity and hyperinflation of the lung (see Fig. 30-1). These changes result in dyspnea and the need for an increased respiratory rate.

In the healthy lung, enzymes called *proteases* are present to destroy and eliminate particulates and organisms inhaled during breathing. If these proteases are present in higher-than-normal levels, they damage the alveoli and the small airways by breaking down elastin. Over time, alveolar sacs lose their elasticity and the small airways collapse or narrow. Some alveoli are destroyed, and others become large and flabby, with less area for gas exchange.

An increased amount of air is trapped in the lungs. Causes of air trapping are loss of elastic recoil in the alveolar walls, overstretching and enlargement of the alveoli into air-filled spaces called *bullae*, and collapse of small bronchioles. These changes greatly increase the work of

breathing. The hyperinflated lung flattens the diaphragm (Fig. 30-7), weakening the effectiveness of this muscle. As a result, the patient with emphysema needs to use accessory muscles in the neck, chest wall, and abdomen to inhale and exhale. This increased effort increases the need for oxygen, making the patient have an "air hunger" sensation. Inhalation starts before exhalation is completed, resulting in an uncoordinated breathing pattern.

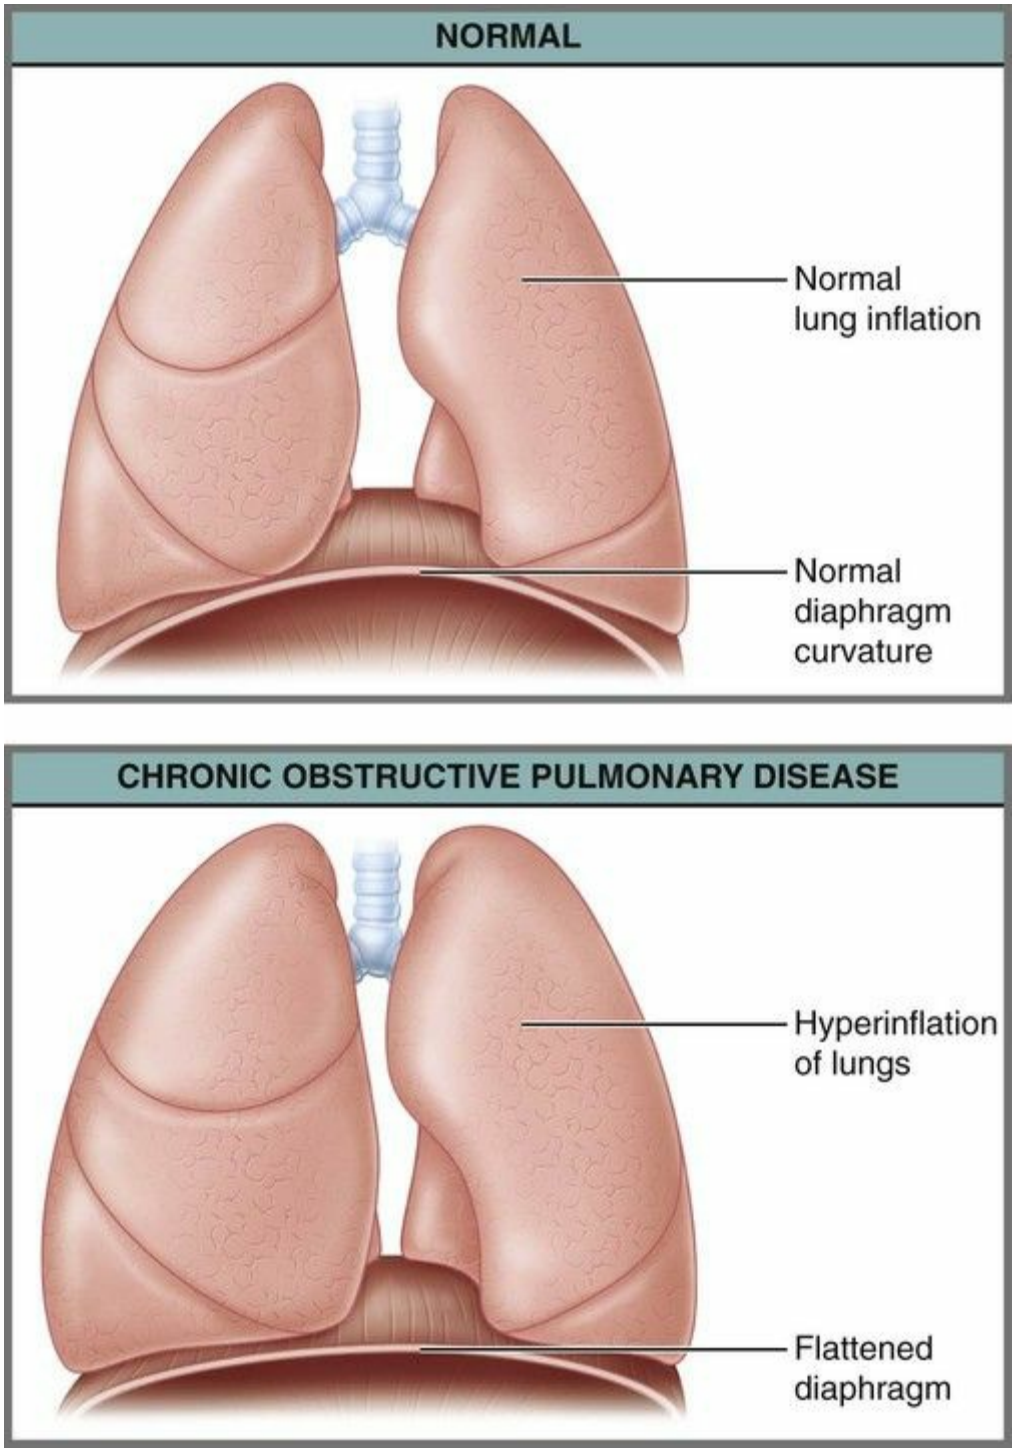

FIG. 30-7 Diaphragm shape and lung inflation in the normal patient and in the patient with chronic airflow limitation (CAL), especially chronic obstructive pulmonary disease (COPD).

Gas exchange is affected by the increased work of breathing and the loss of alveolar tissue. Although some alveoli enlarge, the curves of alveolar walls decrease and less surface area is available for gas exchange. Often the patient adjusts by increasing the respiratory rate, so arterial blood gas (ABG) values may not show gas exchange problems until the patient has advanced disease. Then carbon dioxide is produced faster than it can be eliminated, resulting in carbon dioxide retention and chronic

respiratory acidosis (see Chapter 12). The patient with late-stage emphysema also has a low arterial oxygen (Pa_{O_2}) level because it is difficult for oxygen to move from diseased alveoli into the blood.

Emphysema is classified as *panlobular, centrilobular,* or *paraseptal* depending on the pattern of destruction and dilation of the gas-exchanging units (acini) (see Fig. 30-1). Each type can occur alone or in combination in the same lung. Most are associated with smoking or chronic exposure to other inhaled particles such as wood smoke and biomass fuels (Global Initiative for Chronic Obstructive Lung Disease [GOLD], 2014).

Chronic Bronchitis.

Bronchitis is an inflammation of the bronchi and bronchioles caused by exposure to irritants, especially cigarette smoke. The irritant triggers inflammation, vasodilation, mucosal edema, congestion, and bronchospasm. Bronchitis affects only the airways, not the alveoli.

Chronic inflammation increases the number and size of mucus glands, which produce large amounts of thick mucus. The bronchial walls thicken and impair airflow. This thickening, along with excessive mucus, blocks some of the smaller airways and narrows larger ones. Mucus provides a breeding ground for organisms and leads to chronic infection.

Chronic bronchitis impairs airflow and gas exchange because mucus plugs and infection narrow the airways. As a result, the Pa_{O_2} level decreases (hypoxemia) and the arterial carbon dioxide (Pa_{CO_2}) level increases (respiratory acidosis).

Etiology and Genetic Risk.

Cigarette smoking is the greatest risk factor for COPD. The patient with a 20–pack-year history or longer often has early-stage COPD with changes in pulmonary function tests (PFTs).

The inhaled smoke triggers the release of excessive proteases in the lungs. These enzymes break down elastin, the major component of alveoli. By impairing the action of cilia, smoking also inhibits the cilia from clearing the bronchi of mucus, cellular debris, and fluid.

$Alpha_1$-antitrypsin deficiency is a less common but important risk factor for COPD. The enzyme *$alpha_1$-antitrypsin* (AAT) is normally present in the lungs. AAT inhibits excessive protease activity so that the proteases only break down inhaled pollutants and organisms and do not damage lung structures.

The production of normal amounts of AAT depends on the inheritance

of a pair of normal gene alleles for this protein. The AAT gene is recessive. Thus if one of the pair of alleles is faulty and the other allele is normal, the person makes enough AAT to prevent COPD unless there is significant exposure to cigarette smoke or other inhalation irritants. This person, however, is a carrier for AAT deficiency. When both alleles are faulty, COPD develops at a fairly young age even when the person is not exposed to cigarette smoke or other irritants.

About 100,000 Americans have severe AAT deficiency, and many more have mild to moderate deficiencies (Beery & Workman, 2012). Although an AAT deficiency also can cause problems in the skin and liver, lung diseases are more common (Kessenich & Bacher, 2014).

Genetic/Genomic Considerations

Patient-Centered Care QSEN

The gene for AAT has many known variations, and some increase the risk for emphysema. Different variations result in different levels of AAT deficiency and is a reason why the disease is more severe for some people than for others. The most serious variation for emphysema risk is the Z mutation, although others also increase the risk but to a lesser degree. Table 30-1 shows the most common AAT mutations increasing the risk for emphysema. Urge patients who have any ATT deficiency to avoid smoking and other environmental pollutants.

TABLE 30-1

Characteristics Associated with the Most Common Alpha$_1$-Antitrypsin Gene Mutations

MUTATION GENOTYPE	LEVEL OF SERUM ALPHA$_1$-ANTITRYPSIN (% OF NORMAL)	DISEASE SEVERITY
M/S	80%	No detectable disease
S/S	50%-60%	Minimal to no disease expression
M/Z	50%-55%	Minimal to no disease expression
S/Z	30%-35%	Pulmonary disease, early age
Z/Z	10%-15%	Severe COPD, extrapulmonary involvement

COPD, Chronic obstructive pulmonary disease.

From Workman, M.L., & Winkelman, C. (2008). Genetic influences in common respiratory disorders. *Critical Care Nursing Clinics of North America, 20*(2), 171-189.

In addition to genetic and environmental factors, asthma also appears to be a risk factor for COPD. The incidence of COPD is reported to be 12 times greater among adults with asthma compared with adults without asthma after adjusting for smoking history (GOLD, 2014).

Incidence and Prevalence.

The prevalence of chronic bronchitis and emphysema in the United States has been estimated at about 15.8 million, and more than 10% of nursing home residents have COPD (CDC, 2014b). COPD is the fourth leading cause of morbidity and mortality in the United States (GOLD, 2014).

Complications.

COPD affects gas exchange and the oxygenation of all tissues. Complications include hypoxemia, acidosis, respiratory infection, cardiac failure, dysrhythmias, and respiratory failure.

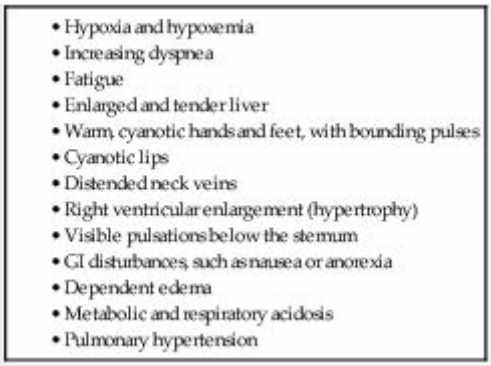
Hypoxemia and acidosis occur because the patient with COPD has reduced gas exchange, leading to decreased oxygenation and increased carbon dioxide levels. These problems reduce cellular function.

Respiratory infection risk increases because of the increased mucus and poor oxygenation. Bacterial infections are common and make COPD manifestations worse by increasing inflammation and mucus production and inducing more bronchospasm. Airflow becomes even more limited, the work of breathing increases, and dyspnea results.

Cardiac failure, especially **cor pulmonale** (right-sided heart failure caused by pulmonary disease), occurs with bronchitis or emphysema. Air trapping, airway collapse, and stiff alveolar walls increase the lung tissue pressure and narrow lung blood vessels, making blood flow more difficult. The increased pressure creates a heavy workload on the right side of the heart, which pumps blood into the lungs. To pump blood through the narrowed vessels, the right side of the heart generates high pressures. In response to this heavy workload, the right chambers of the heart enlarge and thicken, causing right-sided heart failure with backup of blood into the general venous system. Chart 30-9 lists key features of cor pulmonale.

Chart 30-9 Key Features

Cor Pulmonale



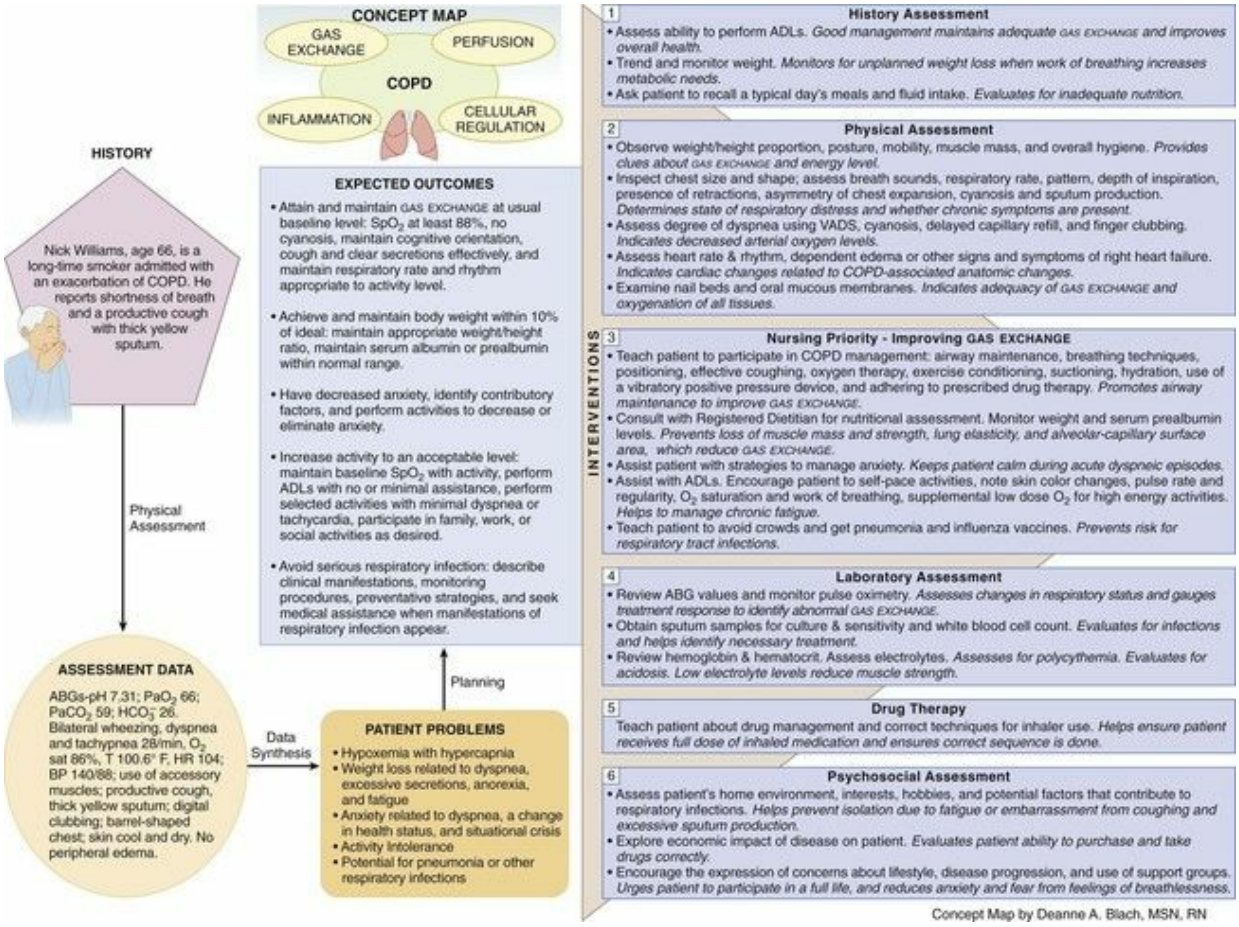
Cardiac dysrhythmias are common in patients with COPD. They result from hypoxemia (from decreased oxygen to the heart muscle), other cardiac disease, drug effects, or acidosis.

Health Promotion and Maintenance

The incidence and severity of COPD would be greatly reduced by smoking cessation. Urge all people who smoke to quit smoking. Chart 27-1 in Chapter 27 provides tips to teach people about smoking cessation. Also, as described in Chapter 27, teach all people specific actions to take to avoid exposure to other inhalation irritants.

❖ Patient-Centered Collaborative Care

The Concept Map addresses assessment and nursing care issues related to COPD.



Assessment

History.

Ask about risk factors such as age, gender, and occupational history. COPD is seen more often in older men. Some types of emphysema occur in families, especially those with alpha$_1$-antitrypsin (AAT) deficiency.

Obtain a thorough smoking history, because tobacco use is a major risk factor. Ask about the length of time the patient has smoked and the number of packs smoked daily. Use these data to determine the pack-year smoking history.

Ask the patient to describe the breathing problems, and assess whether he or she has any difficulty breathing while talking. Does he or she speak in complete sentences, or is it necessary to take a breath between every one or two words? Ask about the presence, duration, or worsening of wheezing, coughing, and shortness of breath. Determine what activities trigger these problems. Assess any cough, and ask whether sputum is clear or colored and how much is produced each day. Ask about the time of day when sputum production is greatest. Smokers often have a productive cough when they get up in the morning; nonsmokers generally do not.

Ask the patient to compare the activity level and shortness of breath now with those of a month ago and a year ago. Ask about any difficulty with eating and sleeping. Many patients sleep in a semi-sitting position because breathlessness is worse when lying down **(orthopnea).** Ask about usual daily activities and any difficulty with bathing, dressing, or sexual activity. Document this assessment to personalize the intervention plan.

Weigh the patient, and compare this weight with previous weights. Unplanned weight loss is likely when COPD severity increases, because the work of breathing increases metabolic needs. Dyspnea and mucus production often result in poor food intake and inadequate nutrition. Ask the patient to recall a typical day's meals and fluid intake. When heart failure is present with COPD, general edema with weight gain may occur.

Physical Assessment/Clinical Manifestations.

General appearance can provide clues about respiratory status and energy level. Observe weight in proportion to height, posture, mobility, muscle mass, and overall hygiene. The patient with increasingly severe COPD is thin, with loss of muscle mass in the extremities, although the neck muscles may be enlarged. He or she tends to be slow moving and slightly stooped. The person often sits in a forward-bending posture with the arms held forward, a position known as the *orthopneic* or *tripod position* (Fig. 30-8). When dyspnea becomes severe, activity intolerance may be so great that bathing and general grooming are neglected.

FIG. 30-8 Orthopnea positions that patients with chronic obstructive pulmonary disease (COPD) often assume to ease the work of breathing.

Respiratory changes occur as a result of obstruction, changes in chest size, and fatigue. Inspect the chest and assess the breathing rate and pattern. The patient with respiratory muscle fatigue breathes with rapid, shallow respirations and may have an abnormal breathing pattern in which the abdominal wall is sucked in during inspiration or may use accessory muscles in the abdomen or neck. During an acute exacerbation, the respiratory rate could be as high as 40 to 50 breaths/min and requires immediate medical attention. As respiratory muscles become fatigued, respiratory movement is jerky and appears uncoordinated.

Check the patient's chest for retractions and for asymmetric chest expansion. The patient with emphysema has limited diaphragmatic movement (excursion) because the diaphragm is flattened and below its usual resting state. Chest vibration (fremitus) is often decreased and the chest sounds hyperresonant on percussion because of trapped air.

Auscultate the chest to assess the depth of inspiration and any abnormal breath sounds. Wheezes and other abnormal sounds often occur on inspiration and expiration, although crackles are usually not present. Reduced breath sounds are common, especially with

emphysema. Note the pitch and location of the sound and the point in the respiratory cycle at which the sound is heard. A silent chest may indicate serious airflow obstruction or pneumothorax.

Assess the degree of dyspnea using a Visual Analog Dyspnea Scale (VADS), which is a straight line with verbal anchors at the beginning and end of a 100-mm line (Fig. 30-9). Ask the patient to place a mark on the line to indicate his or her perceived breathing difficulty. Document the response, and use this scale to determine the therapy effectiveness and pace the patient's activities.

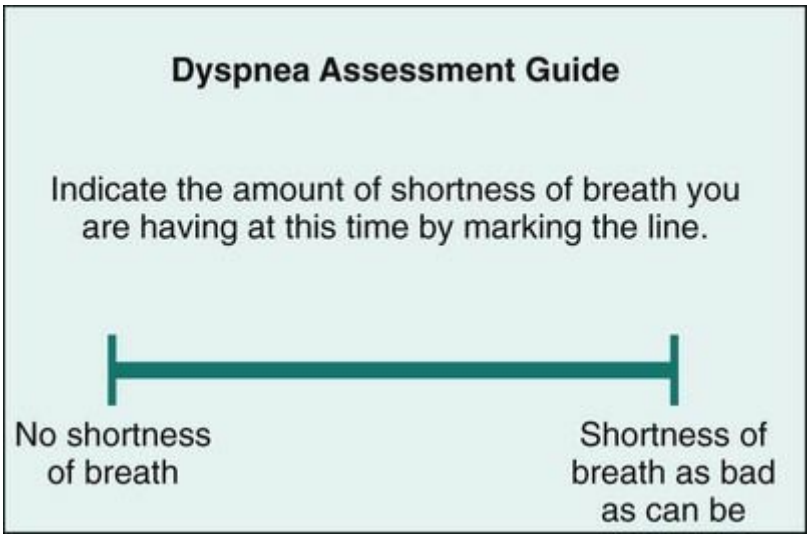


FIG. 30-9 A visual analog scale to assess dyspnea.

Examine the patient's chest for the presence of a "barrel chest" (see Fig. 30-3). With a barrel chest, the ratio between the anteroposterior (AP) diameter of the chest and its lateral diameter is 1 : 1 rather than the normal ratio of 1 : 1.5, as a result of lung overinflation and diaphragm flattening.

The patient with chronic bronchitis often has a cyanotic, or blue-tinged, dusky appearance and has excessive sputum production. Assess for cyanosis, delayed capillary refill, and finger clubbing (Fig. 30-10), which indicate chronically decreased arterial oxygen levels.

FIG. 30-10 Late digital clubbing *(on left)* compared with a normal digit *(on right).*

Cardiac changes occur as a result of the anatomic changes associated with COPD. Assess the patient's heart rate and rhythm. Check for swelling of the feet and ankles (dependent edema) or other manifestations of right-sided heart failure. Examine nail beds and oral mucous membranes. In late-stage emphysema the patient may have pallor or cyanosis and is usually underweight.

Psychosocial Assessment.

COPD affects all aspects of a person's life. The patient may be isolated because dyspnea causes fatigue or because of embarrassment from coughing and excessive sputum production.

Ask the patient about interests and hobbies to assess whether socialization has decreased or whether hobbies cause exposure to irritants. Ask about home conditions for exposure to smoke or crowded living conditions that promote transmission of respiratory infections.

Economic status may be affected by the disease through changes in income and health insurance coverage. Drugs, especially the metered dose inhalers (MDIs) and dry powder inhalers (DPIs), are expensive, and many patients with limited incomes may use them only during exacerbations and not as prescribed on a scheduled basis.

Anxiety and fear from feelings of breathlessness may reduce the patient's ability to participate in a full life. Work, family, social, and sexual roles can be affected. Encourage the patient and family to express their feelings about the limitations on lifestyle and disease progression. Assess their use of support groups and community services.

Laboratory Assessment.

Arterial blood gas (ABG) values identify abnormal gas exchange, oxygenation, ventilation, and acid-base status. Compare repeated ABG values to assess changes in respiratory status. Once baseline ABG values

are obtained, pulse oximetry can gauge treatment response. As COPD worsens, the amount of oxygen in the blood decreases **(hypoxemia)** and the amount of carbon dioxide increases **(hypercarbia).** Chronic respiratory acidosis (increased arterial carbon dioxide [$Paco_2$]) then results; metabolic alkalosis (increased arterial bicarbonate) occurs as compensation by kidney retention of bicarbonate. This change is seen on ABGs as an elevation of HCO_3^- although pH remains lower than normal. Not all patients with COPD are CO_2 retainers, even when hypoxemia is present, because CO_2 diffuses more easily across lung membranes than does oxygen. Hypercarbia is a problem in advanced emphysema (because the alveoli are affected) rather than in bronchitis (wherein the airways are affected). For more detailed information about acidosis, see Chapter 12.

Sputum samples are obtained for culture from hospitalized patients with an acute respiratory infection. The infection is treated on the basis of manifestations and the common bacterial organisms in the local community. A WBC count helps confirm the presence of infection.

Other blood tests include hemoglobin and hematocrit to determine *polycythemia* (a compensatory increase in red blood cells [RBCs] and iron in the chronically hypoxic patient). Serum electrolyte levels are examined because acidosis can change electrolyte values. Low phosphate, potassium, calcium, and magnesium levels reduce muscle strength. In patients with a family history of COPD, serum AAT levels may be drawn.

Imaging Assessment.

Chest x-rays are used to rule out other lung diseases and to check the progress of patients with respiratory infections or chronic disease. With advanced emphysema, chest x-rays show hyperinflation and a flattened diaphragm.

Other Diagnostic Assessments.

COPD is classified from mild to very severe on the basis of manifestations and pulmonary function test (PFT) changes (Table 30-2; see Table 27-6 in Chapter 27). Airflow rates and lung volume measurements help distinguish airway disease (obstructive diseases) from interstitial lung disease (restrictive diseases). PFTs determine lung volumes, flow volume curves, and diffusion capacity. Each test is performed before and after the patient inhales a bronchodilator agent. Encourage the patient to express his or her feelings about testing and the potential impact of the results. Explain the preparations for the procedures (if any), whether pain or discomfort will be involved, and any

needed follow-up care.

TABLE 30-2

Gold Classification of COPD Severity

STAGE	MANIFESTATIONS	PULMONARY FUNCTION TEST RESULTS
0 (At risk)	±Chronic cough	Normal
	±Chronic sputum production	
1 (Mild)	+Chronic cough	$FEV_1/FVC < 70\%$
	±Sputum production	$FEV_1 \geq 80\%$ of predicted
2 (Moderate)	±Dyspnea	$FEV_1/FVC < 70\%$
	±Chronic cough ±Sputum production	$FEV_1 < 80\%$ but at least 50% of predicted
3 (Severe)	+Dyspnea	$FEV_1/FVC < 70\%$
	+Chronic cough +Sputum production	$FEV_1 < 50\%$ but at least 30% of predicted
4 (Very severe)	++Dyspnea	$FEV_1/FVC < 70\%$
	++Chronic cough ++Sputum production	$FEV_1 < 30\%$ of predicted

FEV_1, Volume of air blown out as hard and fast as possible during the first second of the most forceful exhalation after the greatest full inhalation; *FVC,* functional vital capacity.

Data from Global Initiative for Chronic Obstructive Lung Disease (GOLD). (2014). *Global strategy for the diagnosis, management, and prevention of chronic obstructive pulmonary disease.* Retrieved June 2014, from www.goldcopd.org/.

The lung volumes measured for COPD are vital capacity (VC), residual volume (RV), forced expiratory volume (FEV), and total lung capacity (TLC). Although all volumes and capacities change to some degree in COPD, the RV is most affected, with increases reflecting the trapped, stale air remaining in the lungs.

A diagnosis of COPD is based mostly on the FEV_1 (the FEV in the first second of exhalation). FEV_1 can also be expressed as a percentage of the forced vital capacity (FVC). As the disease progresses, the ratio of FEV_1 to FVC becomes smaller (Smith & Tasota, 2011).

The diffusion test measures how well a test gas (carbon monoxide) diffuses across the alveolar-capillary membrane and combines with hemoglobin. In emphysema, alveolar wall destruction decreases the large surface area for diffusion of gas into the blood, leading to a decreased diffusion capacity. In bronchitis alone, the diffusion capacity is usually normal.

The patient with COPD has decreased oxygen saturation, often much lower than 90%. Changes in Spo_2 below the patient's usual saturation

require medical attention.

Peak expiratory flow meters are used to monitor the effectiveness of drug therapy to relieve obstruction. Peak flow rates increase as obstruction resolves. Teach the patient to self-monitor the peak expiratory flow rates at home and adjust drugs as needed.

Analysis

The priority NANDA-I nursing diagnoses and collaborative problems for patients with chronic obstructive pulmonary disease (COPD) include:

1. Hypoxemia with hypercapnia related to alveolar-capillary membrane changes, reduced airway size, ventilatory muscle fatigue, excessive mucus production, airway obstruction, diaphragm flattening, fatigue, and decreased energy
2. Weight loss related to dyspnea, excessive secretions, anorexia, and fatigue
3. Anxiety related to dyspnea, a change in health status, and situational crisis (NANDA-I)
4. Activity Intolerance related to fatigue, dyspnea, and an imbalance between oxygen supply and demand (NANDA-I)
5. Potential for pneumonia or other respiratory infections

Planning and Implementation

Improving Oxygenation and Reducing Carbon Dioxide Retention

Planning: Expected Outcomes.

The patient with COPD is expected to attain and maintain gas exchange at his or her usual baseline level. Indicators include that the patient:

- Maintains Spo_2 of at least 88%
- Remains free from cyanosis
- Maintains cognitive orientation
- Coughs and clears secretions effectively
- Maintains a respiratory rate and rhythm appropriate to his or her activity level

Interventions.

Most patients with COPD use nonsurgical management to improve or maintain gas exchange. Surgical management requires that the patient meet strict criteria.

Nonsurgical Management.

Nursing management for patients with COPD focuses on airway maintenance, monitoring, breathing techniques, positioning, effective coughing, oxygen therapy, exercise conditioning, suctioning, hydration, and use of a vibratory positive-pressure device. A nursing priority is to teach the patient how to be a partner in COPD management by participating in therapies to improve gas exchange and by adhering to prescribed drug therapy.

Before any intervention, assess the breathing rate, rhythm, depth, and use of accessory muscles. The accessory muscles are less efficient than the diaphragm, and the work of breathing increases. Determine whether any factors are contributing to the increased work of breathing, such as respiratory infection. *Airway maintenance is the most important focus of interventions to improve gas exchange.*

Monitoring.

Monitoring for changes in respiratory status is key to providing prompt interventions to reduce complications. Assess the hospitalized patient with COPD at least every 2 hours, even when the purpose of hospitalization is not COPD management. Apply prescribed oxygen, assess the patient's response to therapy, and prevent complications.

If the patient's condition worsens, more aggressive therapy is needed. Noninvasive ventilation (NIV) may be useful for patients with stable, very severe COPD and daytime hypercapnia (GOLD, 2014). Intubation and mechanical ventilation may be needed for patients in respiratory failure.

Breathing Techniques.

Diaphragmatic or abdominal and pursed-lip breathing may be helpful for managing dyspneic episodes. Teach the patient to use these techniques, shown in Chart 30-10, during all activities to reduce the amount of stale air in the lungs and manage dyspnea. Teach these techniques when the patient has less dyspnea.

Chart 30-10 Patient and Family Education: Preparing for Self-Management

Breathing Exercises

Diaphragmatic or Abdominal Breathing

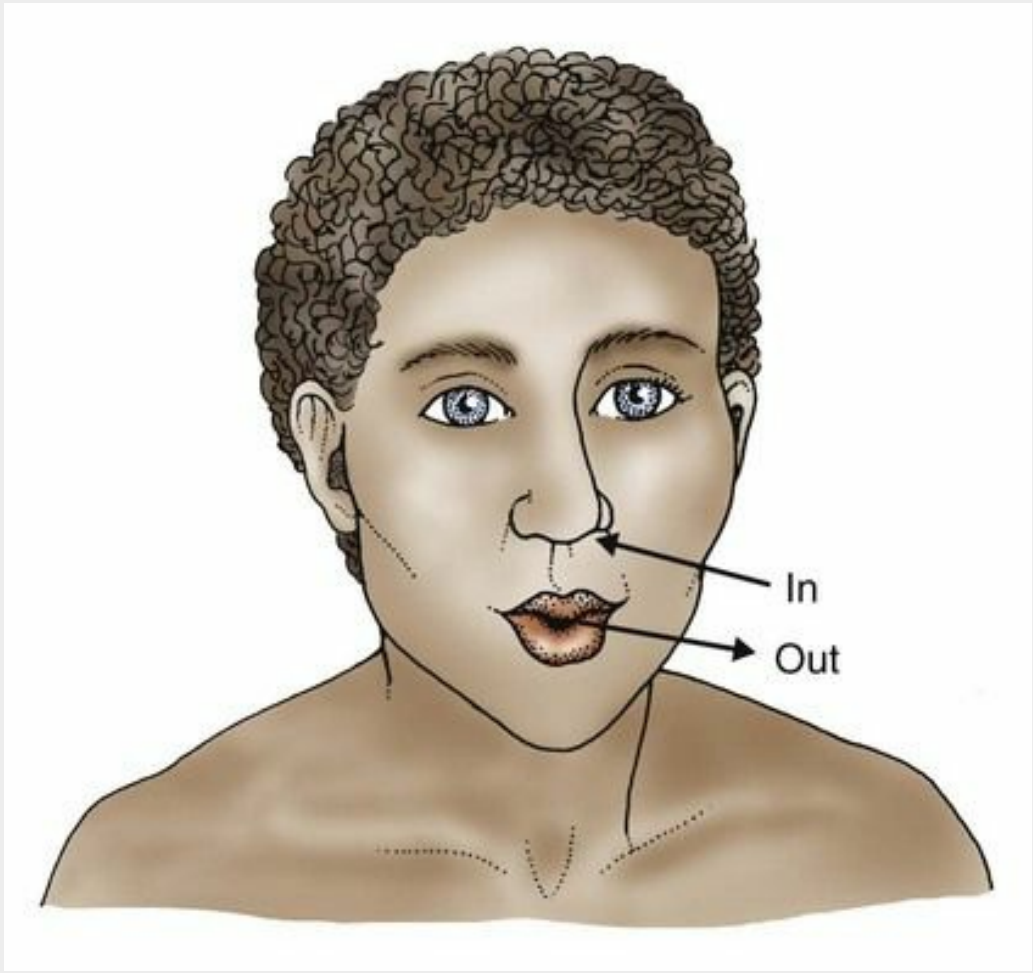
- If you can do so comfortably, lie on your back with your knees bent. If

you cannot lie comfortably, perform this exercise while sitting in a chair.

- Place your hands or a book on your abdomen to create resistance.
- Begin breathing from your abdomen while keeping your chest still. You can tell if you are breathing correctly if your hands or the book rises and falls accordingly.

Pursed-Lip Breathing

- Close your mouth, and breathe in through your nose.
- Purse your lips as you would to whistle. Breathe out slowly through your mouth, without puffing your cheeks. Spend at least twice the amount of time it took you to breathe in.
- Use your abdominal muscles to squeeze out every bit of air you can.
- Remember to use pursed-lip breathing during any physical activity. Always inhale before beginning the activity and exhale while performing the activity. Never hold your breath.



In diaphragmatic breathing, the patient consciously increases movement of the diaphragm. Lying on the back allows the abdomen to relax. Breathing through pursed lips creates mild resistance, which prolongs exhalation and increases airway pressure. This technique delays airway compression and reduces air trapping. Pursed-lip breathing can be used during diaphragmatic or abdominal breathing.

Positioning.

Placing the patient in an upright position with the head of the bed elevated can help alleviate dyspnea by increasing chest expansion and keeping the diaphragm in the proper position to contract. This position conserves energy by supporting the patient's arms and upper body. Assist the patient who can tolerate sitting in a chair out of bed for 1-hour periods 2 or 3 times a day. This position also helps move secretions.

Effective Coughing.

Coughing effectively can improve gas exchange by helping increase airflow in the larger airways. The patient with COPD often has difficulty with

removal of secretions, which results in poor gas exchange and oxygenation. Excessive mucus also increases the risk for respiratory infections.

Controlled coughing is helpful in removing excessive mucus. Teach the patient to cough on arising in the morning to eliminate mucus that collected during the night. Coughing to clear mucus before mealtimes may make meals more pleasant. Coughing before bedtime may help clear lungs for a less interrupted night's sleep.

For effective coughing, teach the patient to sit in a chair or on the side of a bed with feet placed firmly on the floor. Instruct him or her to turn the shoulders inward and to bend the head slightly downward, hugging a pillow against the stomach. The patient then takes a few breaths, attempting to exhale more fully. After the third to fifth breath (in through the nose, out through pursed lips), instruct him or her to take a deeper breath and bend forward slowly while coughing 2 or 3 times ("mini-coughs") from the same breath. On return to a sitting position, the patient takes a comfortably deep breath. The entire coughing procedure is repeated at least twice.

Oxygen Therapy.

Oxygen is prescribed for relief of hypoxemia and hypoxia. The need for oxygen therapy and its effectiveness can be determined by arterial blood gas (ABG) values and oxygen saturation by pulse oximetry. The patient with COPD may need an oxygen flow of 2 to 4 L/min via nasal cannula or up to 40% via Venturi mask. Ensure that there are no open flames or other combustion hazards in rooms in which oxygen is in use. More information on oxygen therapy is found in Chapter 28.

In the past, the patient with COPD was thought to be at risk for extreme hypoventilation with oxygen therapy because of a decreased drive to breathe as blood oxygen levels rose. However, this concern has not been shown to be evidence-based and has been responsible for ineffective management of hypoxia in patients with COPD. All hypoxic patients, even those with COPD and hypercarbia, should receive oxygen therapy at rates appropriate to reduce hypoxia and bring Spo_2 levels up between 88% and 92% (Abdo & Heunks, 2012; Burt & Corbridge, 2013; Makic et al., 2013).

Drug Therapy.

Drugs used to manage COPD are the same drugs as for asthma and include beta-adrenergic agents, cholinergic antagonists, xanthines,

corticosteroids, and cromones (see Chart 30-6). The focus is on long-term control therapy with longer-acting drugs, such as arformoterol (Brovana), indacaterol (Arcapta Neohaler), tiotropium (Spiriva), aclidinium bromide (Tudorza Pressair), and the combination drug fluticasone furoate/vilanterol (BREO ELLIPTA). The patient with COPD is more likely to be taking systemic agents (in addition to inhaled drugs) than is the patient with asthma. An additional drug class for COPD is the mucolytics, which thin the thick secretions, making them easier to cough up and expel. Nebulizer treatments with normal saline or with a mucolytic agent such as acetylcysteine (Mucosil, Mucomyst) or dornase alfa (Pulmozyme) and normal saline help thin secretions. Guaifenesin (Organidin, Naldecon Senior EX) is a systemic mucolytic that is taken orally. A combination of guaifenesin and dextromethorphan (Mucinex DM) also raises the cough threshold.

Stepped therapy, which adds drugs as COPD progresses, is recommended for patients with chronic bronchitis or emphysema, although the patient's response to drug therapy is the best indicator of when drugs or their dosages need changing. Ideally, the patient notices changes and participates in management strategies. Teach patients and family members the correct techniques for using inhalers and to care for them properly.

Many inhalers for COPD drug therapy are dry powder inhalers. These often require having the patient "load in" each dose. The steps for this process involve opening the inhaler's capsule chamber, removing the dry powder capsule from a separate blister pack, placing the capsule in the chamber, closing the inhaler until it clicks and punctures the capsule, and then using the inhaler. Often the patient with severe COPD is older, has muscle weakness, has poor manual dexterity, and may have some problems with cognition. All of these issues can be barriers to proper use of a DPI inhaler for COPD management (Lareau & Hodder, 2012).

NCLEX Examination Challenge

Health Promotion and Maintenance

A client with chronic obstructive pulmonary disease (COPD) prescribed a long-acting inhaled beta$_2$ agonist reports hating the inhaler and asks why the drug can't be taken as a pill. What is the nurse's best response?

A "Drugs taken by inhaler work more slowly and remain in the system longer."

B “Drugs taken by inhaler have no side effects and are less expensive.”
C “Drugs taken by mouth are more expensive because they must be sterile.”
D “Drugs taken by mouth have systemic side effects and are harder to control.”

Exercise Conditioning.

Exercise for conditioning and pulmonary rehabilitation can improve function and endurance in patients with COPD. Patients often respond to the dyspnea of COPD by limiting their activity, even basic ADLs. Over time, the muscles used in breathing weaken, resulting in increased dyspnea with lower activity levels.

Pulmonary rehabilitation involves education and exercise training to prevent muscle deconditioning. Each patient's exercise program is personalized to reflect his or her current limitations and planned outcomes. The simplest plan involves having the patient walk (indoors or outdoors) daily at a self-paced rate until manifestations limit further walking, followed by a rest period, and then continue walking until 20 minutes of actual walking has been accomplished. As the time during rest periods decreases, the patient can add 5 more minutes of walking time. Teach patients whose manifestations are severe to modify the exercise by using a walker with wheels or, if needed, to use oxygen while exercising. Remind patients that the exercise needs to be performed at least 2 or 3 times weekly for best improvement. Formal pulmonary rehabilitation programs can be beneficial even for patients who are severely impaired.

Additional exercise techniques to retrain ventilatory muscles include isocapneic hyperventilation and resistive breathing. Isocapneic hyperventilation, in which the patient hyperventilates into a machine that controls the levels of oxygen and carbon dioxide, increases endurance. In resistive breathing, the patient breathes against a set resistance. Resistive breathing increases respiratory muscle strength and endurance.

Suctioning.

Perform suctioning only when needed—not on a routine schedule. For the patient with a weak cough, weak pulmonary muscles, and inability to expectorate effectively, perform nasotracheal suctioning. Assess the patient for dyspnea, tachycardia, and dysrhythmias during the procedure. Assess for improved breath sounds after suctioning.

Suctioning is discussed in detail in Chapter 28.

Hydration.

Maintaining hydration may thin the thick, tenacious (sticky) secretions, making them easier to remove by coughing. Unless hydration needs to be avoided for other health problems, teach the patient with COPD to drink at least 2 to 3 L/day. Humidifiers may be useful for those living in a dry climate or those who use dry heat during the winter.

Vibratory Positive Expiratory Pressure Device.

The use of a vibratory positive expiratory pressure device can help patients remove airway secretions. The device is a small, handheld plastic pipe with a short, fat stem and a perforated lid over the bowl (Fig. 30-11). A movable steel ball is inside the bowl. The patient inhales deeply and then exhales through the device, causing the ball to move and set up vibrations that are transmitted to the chest and airways. The vibrations loosen secretions and allow them to be coughed out more easily.

FIG. 30-11 The FLUTTER® flutter valve mucus clearance device, a type of vibratory positive-pressure device.

Surgical Management.

Lung transplantation and lung reduction surgery can improve gas exchange in the patient with COPD. Transplantation is a relatively rare procedure because of cost and the scarce availability of donor lungs. The more common surgical procedure for patients with emphysema is lung reduction surgery.

The purpose of lung reduction surgery is to improve gas exchange through removal of hyperinflated lung tissues that are filled with stagnant air containing little, if any, oxygen. Instead, the level of carbon dioxide is the same as that in the capillary and no gas exchange occurs. Successful lung

reduction results in increased forced expiratory volume and decreased total lung capacity and residual volume. Activity tolerance increases, and oxygen therapy may no longer be needed.

Preoperative Care.

Patients who are selected for this procedure have end-stage emphysema, minimal chronic bronchitis, and stable cardiac function. They also must be ambulatory; not ventilator dependent; free of pulmonary fibrosis, asthma, or cancer; and not have smoked for at least 6 months. The patient must be rehabilitated to the stage that he or she is able to walk, without stopping, for 30 minutes at 1 mile/hr and maintain a 90% or better oxygen saturation level.

In addition to standard preoperative testing, tests to determine the location of greatest lung hyperinflation and poorest lung blood flow are performed. These tests include pulmonary plethysmography, gas dilution, and perfusion scans.

Operative Procedures.

Usually lung reduction is performed on both lungs, most often by the minimally invasive surgical technique of video-assisted thoracoscopic surgery (VATS) or through bronchoscopy (GOLD, 2014). Each lung is deflated separately and examined for color and texture differences. Normal lung tissue darkens to purple or gray when deflated and becomes more dense or rubbery in texture. Hyperinflated areas do not deflate and remain pink with a spongy texture. The surgeon removes as much of this tissue as possible.

Postoperative Care.

After lung reduction surgery, the patient needs close monitoring for continuing respiratory problems as well as for usual postoperative complications. Bronchodilator and mucolytic therapies are maintained. Pulmonary hygiene includes incentive spirometry 10 times per hour while awake, chest physiotherapy starting on the first day after surgery, and hourly pulmonary assessment.

Preventing Weight Loss

Planning: Expected Outcomes.

The patient with COPD is expected to achieve and maintain a body weight within 10% of ideal. Indicators include that the patient:

- Maintains an appropriate weight/height ratio

• Maintains serum albumin or prealbumin within the normal range

Interventions.

The patient with COPD often has food intolerance, nausea, *early satiety* (feeling too "full" to eat), poor appetite, and meal-related dyspnea. The increased work of breathing raises calorie and protein needs, which can lead to protein-calorie malnutrition. Malnourished patients lose muscle mass and strength, lung elasticity, and alveolar-capillary surface area, all of which reduce gas exchange.

Identify patients at risk for or who have this complication, and request that a registered dietitian perform a nutrition assessment. Monitor weight and other indicators of nutrition, such as serum prealbumin levels.

Dyspnea management is needed because shortness of breath interferes with eating. Teach the patient to plan the biggest meal of the day for the time when he or she is most hungry and well rested. Four to six small meals a day may be preferred to three larger ones. Remind patients to use pursed-lip and abdominal breathing and to use the prescribed bronchodilator 30 minutes before the meal to reduce bronchospasm.

Food selection can help prevent weight loss. Abdominal bloating and a feeling of fullness often prevent the patient from eating a complete meal. Collaborate with the dietitian to teach about foods that are easy to chew and not gas-forming. Advise the patient to avoid dry foods that stimulate coughing and caffeine-containing drinks that increase urine output and may lead to dehydration.

Urge the patient to eat high-calorie, high-protein foods. Dietary supplements, such as Pulmocare, provide nutrition with reduced carbon dioxide production. If early satiety is a problem, advise him or her to avoid drinking fluids before and during the meal and to eat smaller, more frequent meals.

Minimizing Anxiety

Planning: Expected Outcomes.

The patient with COPD is expected to have decreased anxiety. Indicators include that the patient consistently demonstrates these behaviors:

• Identifies factors that contribute to anxiety
• Identifies activities to decrease anxiety
• States anxiety is reduced or absent

Interventions.

Patients with COPD become anxious during acute dyspneic episodes, especially when excessive secretions are present. Anxiety also may cause dyspnea.

Help the patient understand that anxiety can increase dyspnea, and have a plan for dealing with anxiety. Together with the patient, develop a written plan that states exactly what he or she should do if symptoms flare. Having a plan provides confidence and control in knowing what to do, which often helps reduce anxiety. Stress the use of pursed-lip and diaphragmatic breathing techniques during periods of anxiety or panic.

Family, friends, and support groups can be helpful. Recommend professional counseling, if needed, as a positive suggestion. Stress that talking with a counselor can help identify techniques to maintain control over dyspnea and panic.

Explore other approaches to help the patient control dyspneic episodes and panic attacks, such as progressive relaxation, hypnosis therapy, and biofeedback. For some patients, antianxiety drug therapy may be needed for severe anxiety.

Improving Activity Tolerance

Planning: Expected Outcomes.

The patient with COPD is expected to increase activity to a level acceptable to him or her. Indicators include that the patient:

- Maintains his or her baseline Spo_2 with activity
- Performs ADLs with no or minimal assistance
- Performs selected activities with minimal dyspnea or tachycardia
- Participates in family, work, or social activities as desired

Interventions.

The patient with COPD often has chronic fatigue. During acute exacerbations, he or she may need extensive help with the ADLs of eating, bathing, and grooming. As the acute problem resolves, encourage the patient to pace activities and perform as much self-care as possible. Teach him or her to not rush through morning activities, because rushing increases dyspnea, fatigue, and hypoxemia. As activity gradually increases, assess the patient's response by noting skin color changes, pulse rate and regularity, oxygen saturation, and work of breathing. Suggest the use of oxygen during periods of high energy use, such as bathing or walking.

Energy conservation is the planning and pacing of activities for best tolerance and minimum discomfort. Ask the patient to describe a typical

daily schedule. Help him or her divide each activity into its smaller parts to determine whether that task can be performed in a different way or at a different time. Teach about planning and pacing daily activities with rest periods between activities. Help the patient develop a chart outlining the day's activities and planned rest periods.

Encourage the patient to avoid working with the arms raised. Activities involving the arms decrease exercise tolerance because the accessory muscles are used to stabilize the arms and shoulders rather than to assist breathing. Many activities involving the arms can be done sitting at a table leaning on the elbows. Teach the patient to adjust work heights to reduce back strain and fatigue. Remind him or her to keep arm motions smooth and flowing to prevent jerky motions that waste energy. Work with the occupational therapist to teach about the use of adaptive tools for housework, such as long-handled dustpans, sponges, and dusters, to reduce bending and reaching.

Suggest organizing work spaces so that items used most often are within easy reach. Measures such as dividing laundry or groceries into small parcels that can be handled easily, using disposable plates to save washing time, and letting dishes dry in the rack also conserve energy. Teach the patient to not talk when engaged in other activities that require energy, such as walking. In addition, teach him or her to avoid breath-holding while performing any activity.

Preventing Respiratory Infection

Planning: Expected Outcomes.

The patient with COPD is expected to avoid serious respiratory infection. Indicators include that the patient consistently demonstrates these behaviors:

- Describes clinical manifestations of respiratory infection
- Describes respiratory infection–monitoring procedures
- Uses prevention activities such as pneumonia and influenza vaccination and crowd avoidance
- Seeks medical assistance when manifestations of respiratory infection first appear

Interventions.

Pneumonia is a common complication of COPD, especially among older adults. Patients who have excessive secretions or who have artificial airways are at increased risk for respiratory tract infections. Teach patients to avoid crowds, and stress the importance of receiving a

pneumonia vaccination and a yearly influenza vaccine.

Community-Based Care

Home Care Management.

Most patients with COPD are managed in the ambulatory care setting and cared for at home. When pneumonia or a severe exacerbation develops, the patient often returns home after hospitalization. For those with advanced disease, 24-hour care may be needed for ADLs and for monitoring. If home care is not possible, placement in a long-term care setting may be needed.

Patients with hypoxemia may use oxygen at home either as needed or continually. Continuous, long-term oxygen therapy can reverse tissue hypoxia and improve cognition and well-being. For more information on home oxygen therapy, see Chapter 28.

Collaborate with the case manager to obtain the equipment needed for care at home. Patient needs may include oxygen therapy, a hospital-type bed, a nebulizer, a tub transfer bench, and scheduled visits from a home care nurse for monitoring and evaluation.

The patient with COPD faces a lifelong disease with remissions and exacerbations. Explain to the patient and family that he or she may have periods of anxiety, depression, and ineffective coping. The person who was a smoker may also have self-directed anger.

Financial concerns often increase anxiety. The disease may worsen to the point that the patient cannot work, requiring disability benefits to help ease the financial burden. Medicare or other health insurers may help pay for home oxygen therapy and nebulizer treatments. Coordinate with the social worker or case manager to help the patient make the needed arrangements.

Self-Management Education.

Patients with COPD need to know as much about the disease as possible so that they can better manage it and themselves. Patients and families should be able to discuss drug therapy, manifestations of infection, avoidance of respiratory irritants, the nutrition therapy regimen, and activity progression. Instruct them to identify and avoid stressors that can worsen the disease.

Reinforce the techniques of pursed-lip breathing, diaphragmatic breathing, positioning, relaxation therapy, energy conservation, and coughing and deep breathing. Teaching about all of the needed topics may require coordination with the home care or clinic staff.

Health Care Resources.

Provide appropriate referrals as needed. Home care visits may be needed especially when home oxygen therapy is first prescribed. Chart 30-11 lists assessment areas for the patient with COPD at home. Referral to assistance programs, such as Meals on Wheels, can be helpful. Provide a list of support groups, as well as Better Breather clubs sponsored by the American Lung Association. If the patient wants to quit smoking, make the appropriate referrals.

Chart 30-11 Home Care Assessment

The Patient with Chronic Obstructive Pulmonary Disease

Assess respiratory status and adequacy of ventilation.

- Measure rate, depth, and rhythm of respirations.
- Examine mucous membranes and nail beds for evidence of hypoxia.
- Determine use of accessory muscles.
- Examine chest and abdomen for paradoxical breathing.
- Count number of words patient can speak between breaths.
- Determine need and use of supplemental oxygen. (How many liters per minute is the patient using?)
- Determine level of consciousness and presence/absence of confusion.
- Auscultate lungs for abnormal breath sounds.
- Measure oxygen saturation by pulse oximetry.
- Determine sputum production, color, and amount.
- Ask about activity level.
- Observe general hygiene.
- Measure body temperature.

Assess cardiac status.

- Measure rate, quality, and rhythm of pulse.
- Check dependent areas for edema.
- Check neck veins for distention with the patient in a sitting position.
- Measure capillary refill.

Assess nutritional status.

- Check weight maintenance, loss, or gain.
- Determine food and fluid intake.
- Determine use of nutritional supplements.
- Observe general condition of the skin.
- Assess patient's and caregiver's adherence and understanding of illness and treatment, including:
  - Correct use of supplemental oxygen

— Correct use of inhalers
— Drug schedule and side effects
— Manifestations to report to the health care provider indicating the need for acute care
— Increasing severity of resting dyspnea
— Increasing severity of usual manifestations
— Development of new manifestations associated with poor oxygenation
— Respiratory infection
— Failure to obtain the usual degree of relief with prescribed therapies
— Unusual change in condition
— Use of pursed-lip and diaphragmatic breathing techniques
— Scheduling of rest periods and priority activities
— Participation in rehabilitation activities

Evaluation: Outcomes

Evaluate the care of the patient with COPD based on the identified priority patient problems. The expected outcomes of care are that the patient should:

- Attain and maintain gas exchange at a level within his or her chronic baseline values
- Achieve an effective breathing pattern that decreases the work of breathing
- Maintain a patent airway
- Achieve and maintain a body weight within 10% of his or her ideal weight
- Have decreased anxiety
- Increase activity to a level acceptable to him or her
- Avoid serious respiratory infections

Specific indicators for these outcomes are listed for each priority patient problem under the Planning and Implementation section (see earlier).

Clinical Judgment Challenge

Patient-Centered Care; Safety QSEN

The patient is a 64-year-old man with COPD who lives with his wife of 35 years. He retired 2 years ago when his disease interfered with his job as a carpenter. He also quit smoking about a year ago. Since then, his

disease has remained stable; however, he now reports that he thinks his wife is preparing for widowhood by taking over all the home chores that he always performed (including driving and bill paying), limiting his interaction with friends, and making all decisions. He is angry and depressed. Routine assessment with pulmonary function testing show his FEV_1 to be 40% of his predicted value, which is an improvement over the 32% value of FEV_1 last year.

1. What severity classification is his COPD? Provide a rationale for your choice.
2. How should you respond to his statement about the wife probably preparing for widowhood?
3. Should he continue to drive and pay bills? Why or why not?
4. What psychosocial assessment of this patient and his situation should you make?
5. Should you include the wife in any part of this discussion? Why or why not?

Cystic Fibrosis

Pathophysiology

Cystic fibrosis (CF) is a genetic disease that affects many organs and lethally impairs lung function. Although this disorder is present from birth and usually is first seen in early childhood, almost half of all people with cystic fibrosis in the United States are adults (Cystic Fibrosis Foundation, 2014).

The underlying problem of CF is blocked chloride transport in the cell membranes (Beery & Workman, 2012). Poor chloride transport causes the formation of mucus that has little water content and is thick. The thick, sticky mucus causes problems in the lungs, pancreas, liver, salivary glands, and testes. The mucus plugs up the airways in the lungs and the glandular tissues in nonpulmonary organs, causing atrophy and organ dysfunction. Nonpulmonary problems include pancreatic insufficiency, malnutrition, intestinal obstruction, poor growth, male sterility, and cirrhosis of the liver. Additional problems of CF in young adults include osteoporosis and diabetes mellitus. Respiratory failure is the main cause of death. Improved management has increased life expectancy even among those with severe disease to about 37 years (Cystic Fibrosis Foundation, 2014).

The pulmonary problems of CF result from the constant presence of thick, sticky mucus and are the most serious complications of the disease. The mucus narrows airways, reducing airflow and interfering with gas exchange and oxygenation. The constant presence of mucus results in chronic respiratory tract infections, chronic bronchitis, and chronic dilation of the bronchioles (bronchiectasis). Lung abscesses are common. Over time, the bronchioles distend and have increased numbers (hyperplasia) and increased size (hypertrophy) of mucus-producing cells. Complications include pneumothorax, arterial erosion and hemorrhage, and respiratory failure.

CF is most common among white people, and about 4% are carriers. It is rare among African Americans and Asians. Males and females are affected equally.

Genetic/Genomic Considerations

Patient-Centered Care QSEN

CF is an autosomal recessive disorder in which both gene alleles must be mutated for the disease to be expressed. The CF gene (*CTFR:* cystic

fibrosis transmembrane conductance regulator) produces a protein that controls chloride movement across cell membranes. The severity of CF varies greatly; however, life expectancy is always considerably reduced, with an average of 37 years. People with one mutated allele are carriers and have few or no symptoms of CF but can pass the abnormal allele on to their children. More than 1700 different mutations have been identified (OMIM, 2013c). The inheritance of different mutations is responsible for variation in disease severity. Help patients understand why their manifestations may be more or less severe than others with the disease, even within the same family.

Patient-Centered Collaborative Care

Assessment

Usually, but not always, cystic fibrosis (CF) is diagnosed in childhood. The major diagnostic test is sweat chloride analysis (Pagana & Pagana, 2014). The sweat chloride test is positive for CF when the chloride level in the sweat ranges between 60 and 200 mEq/L (mmol/L), compared with the normal value of 5 to 35 mEq/L. Genetic testing can be performed to determine which specific mutation a person may have. Different mutations result in different degrees of disease severity.

Nonpulmonary manifestations include abdominal distention, gastroesophageal reflux, rectal prolapse, foul-smelling stools, and **steatorrhea** (excessive fat in stools). The patient is often malnourished and has many vitamin deficiencies, especially of the fat-soluble vitamins (e.g., vitamins A, D, E, K). As pancreatic function decreases, diabetes mellitus develops with loss of insulin production. The adult with severe CF is usually smaller and thinner than average.

Pulmonary manifestations caused by CF are progressive. Respiratory infections are frequent or chronic with exacerbations. Patients usually have chest congestion, limited exercise tolerance, cough, sputum production, use of accessory muscles, and decreased pulmonary function (especially forced vital capacity [FVC] and forced expiratory volume in the first second of exhalation [FEV_1]). Chest x-rays show infiltrate and an increased anteroposterior (AP) diameter.

During an acute exacerbation or when the disease progresses to end stage, the patient has increased chest congestion, reduced activity tolerance, increased crackles, increased cough, increased sputum production (often with hemoptysis), and severe dyspnea with fatigue. Arterial blood gas (ABG) studies show acidosis (low pH), greatly reduced

arterial oxygen (Pa_{O_2}) levels, increased arterial carbon dioxide (Pa_{CO_2}) levels, and increased bicarbonate levels.

With infection, the patient has fever, an elevated white blood cell count, and decreased oxygen saturation. Other manifestations of infection include tachypnea, tachycardia, intercostal retractions, weight loss, and increased fatigue.

Interventions

The patient with CF needs daily therapy to slow disease progress and enhance gas exchange. There is no cure for CF.

Nonsurgical Management.

The management of the patient with CF is complex and lifelong. Nutrition management focuses on weight maintenance, vitamin supplementation, diabetes management, and pancreatic enzyme replacement. Pulmonary management focuses on preventive maintenance and management of exacerbations. Priority nursing interventions focus on teaching about drug therapy, infection prevention, pulmonary hygiene, nutrition, and vitamin supplementation.

Preventive/maintenance therapy involves the use of positive expiratory pressure, active cycle breathing technique, and an individualized exercise program. Daily chest physiotherapy with postural drainage is beneficial for the patient with CF (Fig. 30-12). This therapy uses chest percussion, chest vibration, and dependent drainage to loosen secretions and promote drainage. Increasingly the use of a chest physiotherapy (CPT) vest is recommended (Neufeld & Keith, 2012). This system uses an inflatable vest that rapidly fills and deflates, gently compressing and releasing the chest wall up to 25 times per second, a process called high-frequency chest wall oscillation (HFCWO). The action creates mini-coughs that dislodge mucus from the bronchial walls, increase mobilization, and move it toward central airways where it can be removed by coughing or suctioning. HFCWO also thins secretions, making them easier to clear. Pulmonary function tests are monitored regularly. Daily drugs include bronchodilators, anti-inflammatories, mucolytics, and antibiotics.

FIG. 30-12 Inflatable chest physiotherapy vest for high-frequency chest wall oscillation (HFCWO).

Exacerbation therapy is needed when the patient with CF has increased chest congestion, reduced activity tolerance, increased or new-onset crackles, and at least a 10% decrease in FEV_1. Other exacerbation manifestations include increased sputum production with bloody or purulent sputum, increased coughing, decreased appetite, weight loss, fatigue, decreased Spo_2, and chest muscle retractions. Often infection is present, with fever, increased lung infiltrate on x-ray, and an elevated white blood cell count.

Every attempt is made to avoid mechanical ventilation for the patient with CF. Bi-level positive airway pressure (BiPAP) may be a part of daily therapy for the patient with advanced disease (Neufeld & Keith, 2012). Management focuses on airway clearance, increased gas exchange, and antibiotic therapy. Supplemental oxygen is prescribed on the basis of Spo_2 levels. Heliox delivery of 50% oxygen and 50% helium may improve gas exchange and oxygen saturation. The respiratory therapist initiates airway clearance techniques 4 times a day. Bronchodilator and mucolytic therapies are intensified. Steroidal agents are started or increased.

Depending on the severity of the exacerbation, a 10- to 14-day course of oral antibiotics may be prescribed. For severe exacerbation, aerosolized tobramycin may be prescribed. If antibiotics are not effective or if the exacerbation is very severe, IV antibiotics are used—usually an aminoglycoside, such as tobramycin and colistin, or meropenem (Merrem).

A serious bacterial infection for patients with CF is *Burkholderia cepacia*. The organism lives in the respiratory tracts of patients with CF and is often resistant to antibiotic therapy. It is spread by casual contact from

one CF patient to another. For this reason, the Cystic Fibrosis Foundation bans infected patients from participating in any foundation-sponsored events. It is also possible for *B. cepacia* to be transmitted to a CF patient during clinic and hospital visits; thus special infection control measures that limit close contact between people with CF are needed. These measures include separating infected CF patients from noninfected CF patients on hospital units and seeing them in the clinic on different days. Strict CF Foundation–approved procedures are used to clean clinic rooms and respiratory therapy equipment. Drug therapy for this infection usually includes co-trimoxazole (a combination of trimethoprim and sulfamethoxazole [Bactrim, Septra]) along with the usual drugs used for exacerbation therapy.

Teach patients about protecting themselves by avoiding direct contact of bodily fluids such as saliva and sputum. Teach them to not routinely shake hands or kiss people in social settings. Handwashing is critical because the organism also can be acquired indirectly from contaminated surfaces, such as sinks and tissues.

As life span increases for patients with CF, other problems, such as bronchiole bleeding from lung arteries, may develop. Interventional radiology may be needed to embolize the bleeding arterial branches. Patients with CF may undergo this procedure repeatedly to control hemoptysis. See Chapter 36 for information on interventional radiology vascular procedures.

Other problems that occur with CF over time include severe gastroesophageal reflux disease (GERD), osteoporosis, and sensory hearing loss. Osteoporosis increases the risk for bone fractures.

Gene therapy for CF is available for use in patients with specific gene mutations (Nakano & Tluczek, 2014). A new drug, ivacaftor (Kalydeco) has been found to be of value to patients with CF who have any one of the following specific mutations in the *CFTR* gene: G551D, G1244E, G1349D, G178R, G551S, S1251N, S1255P, S549N, or S549R. In patients with any of these mutations, the oral drug specifically targets and potentiates the CFTR channel opening so this transporter can move chloride ions across the cell membrane. This action reduces sodium and fluid absorption so that mucus is less thick and sticky. This drug has no effect in patients whose *CFTR* gene does not have any of these mutations. The most common adverse effect of the drug is an elevation of liver enzymes.

NCLEX Examination Challenge

Health Promotion and Maintenance

Which precaution is most important for the nurse to teach a client who has cystic fibrosis?

A Report a weight change of 2 pounds to your health care provider immediately.

B Use supplemental oxygen whenever your oxygen saturation is less than 95%.

C Eat six small meals each day instead of only three larger ones.

D Avoid crowds and people who are ill.

Surgical Management.

The surgical management of the patient with CF involves lung and/or pancreatic transplantation. The patient has reduced manifestations but is at continuing risk for lethal pulmonary infections, especially with anti-rejection drug therapy. Transplantation may extend life for some years, depending on other factors, but transplant rejection rate is high among this population, possibly caused by poor intestinal absorption of anti-rejection drugs.

Fewer lung transplants are performed compared with transplantation of other solid organs because of the scarcity of available lungs. Also, many of the people who could benefit from lung transplantation have serious problems in other organs that make this procedure even more dangerous.

Lung transplant procedures include two lobes or a single lung transplantation, as well as double-lung transplantation. The type of procedure is determined by the patient's overall condition and the life expectancy after transplantation. Usually the patient with CF has a bilateral lobe transplant from either a cadaver donor or living-related donor.

Preoperative Care.

Many factors are considered before lung transplantation surgery. Recipient and donor criteria vary from one program to another, but some criteria are universal.

Recipient criteria for the patient with CF include that he or she must have severe, irreversible lung damage and still be well enough to survive the surgery. Age at transplantation is considered on an individual basis. Common exclusion criteria include a cancer diagnosis, systemic infection, human immune deficiency virus (HIV)/acquired immune deficiency syndrome (AIDS), and irreversible heart, kidney, or liver

damage/disease.

Donor criteria, regardless of whether the lung tissue is obtained from a cadaver or from a living-related donor, include that the donor be infection free and cancer free, have healthy lung tissue, be a close tissue match with the recipient, and have the same blood type as the recipient. When the donor is living-related, additional criteria include an age restriction, healthy organs, and no previous chest surgery. *The two nursing priorities before surgery are teaching the patient the expected regimen of pulmonary hygiene to be used in the period immediately after surgery and assisting the patient in a pulmonary muscle strengthening/conditioning regimen.*

Operative Procedures.

The patient may or may not need to be placed on cardiopulmonary bypass, depending on the exact procedure. Those having single-lung or lobe transplantation usually do not need bypass; those having double-lung transplantation usually do.

The most common incision used for lung transplantation is a transverse thoracotomy ("clamshell"). The diseased lung or lungs are removed. The new lobes, lung, or lungs are placed in the chest cavity with proper connections made to the trachea, bronchi, and blood vessels. Usually lung transplantation surgery is completed within 4 to 6 hours.

Postoperative Care.

The patient is intubated for at least 48 hours, and chest tubes and arterial lines are in place. The care needed is the same as that for any thoracic surgery.

Major problem areas after lung transplantation are bleeding, infection, and transplant rejection. The patient usually remains in the ICU for several days after transplantation. Postoperative chest physiotherapy often is performed with high-frequency chest wall oscillation (HFCWO) at this time (Esguerra-Gonzalez et al., 2013).

Anti-rejection drug regimens must be started immediately after surgery, which increases the risk for infection. Combination therapy with the anti-rejection drugs, described in Chapter 17, is used for the rest of the patient's life. Corticosteroids are avoided in the first 10 to 14 days after surgery because of their negative impact on the healing process.

Pulmonary Arterial Hypertension

Pathophysiology

General pulmonary hypertension can occur as a complication of other lung disorders. Primary pulmonary arterial hypertension (PAH) (also known as *idiopathic pulmonary hypertension*) occurs in the absence of other lung disorders, and its cause is unknown; however, exposure to some drugs, such as fenfluramine/phentermine (Pondimin or "Fen-Phen") or dasatinib (Sprycel), increases the risk (World Health Organization [WHO], 2011). The disorder is rare and occurs mostly in women between the ages of 20 and 40 years (McCance et al., 2014). The familial PAH form appears to be transmitted in an autosomal dominant pattern with reduced penetrance (OMIM, 2013d).

The pathologic problem in PAH is blood vessel constriction with increasing vascular resistance in the lung. Pulmonary blood pressure rises and blood flow decreases through the lungs, leading to poor perfusion and gas exchange with hypoxemia. Eventually, the right side of the heart fails *(cor pulmonale)* from the continuous workload of pumping against the high pulmonary pressures. Without treatment, death usually occurs within 2 years after diagnosis.

Genetic/Genomic Considerations

Patient-Centered Care QSEN

About 50% of patients with pulmonary arterial hypertension have a genetic mutation in the *BMPR2* gene, which codes for a growth factor receptor (Weber et al., 2011). Excessive activation of this receptor allows increased growth of arterial smooth muscle in the lungs, making these arteries thicker. Many more people have mutations in this gene than have PAH. It is thought that these mutations increase the susceptibility to PAH when other, often unknown, environmental factors also are present. Mutations in other genes, such as the *PPH1* gene and the *SMAD9* gene, are also associated with thickening of lung arteries and increased risk for PAH (OMIM, 2013d).

Often PAH is not diagnosed until late in the disease process when the lungs and heart have already been significantly damaged. Teach people, especially women, who have a first-degree relative (parent or sibling) with PAH to have regular health checks and to consult a health care provider whenever pulmonary problems are present.

❖ Patient-Centered Collaborative Care

◆ Assessment

The most common early manifestations are dyspnea and fatigue in an otherwise healthy adult. Some patients also have angina-like chest pain. Table 30-3 lists the classification of PAH.

TABLE 30-3

Severity Classification for Primary Pulmonary Arterial Hypertension

CLASS	MANIFESTATIONS
I	Pulmonary hypertension diagnosed by pulmonary function tests and right-sided cardiac catheterization
	No limitation of physical activity
	Moderate physical activity does not induce dyspnea, fatigue, chest pain, or light-headedness
II	No manifestations at rest
	Mild to moderate physical activity induces dyspnea, fatigue, chest pain, or light-headedness
III	No or slight manifestations at rest
	Mild (less than ordinary) activity induces dyspnea, fatigue, chest pain, or light-headedness
IV	Dyspnea and fatigue present at rest
	Unable to carry out any level of physical activity without manifestations
	Manifestations of right-sided heart failure apparent (dependent edema, engorged neck veins, enlarged liver)

Diagnosis is made from the results of right-sided heart catheterization showing elevated pulmonary pressures. Other test results suggesting PAH include abnormal ventilation-perfusion scans, pulmonary function tests (PFTs) showing reduced functional pulmonary volumes with reduced diffusion capacity, and computed tomography (CT).

◆ Interventions

Drug therapy can reduce pulmonary pressures and slow the development of cor pulmonale by dilating pulmonary vessels and preventing clot formation. Warfarin (Coumadin) is taken daily to achieve an international normalized ratio (INR) of 1.5 to 2.0. Calcium channel blockers have been used to dilate blood vessels. The two classes of drugs that have been shown to be most effective in the treatment of PAH are the endothelin-receptor antagonists and the prostacyclin agents.

Endothelin-receptor agonists, such as bosentan (Tracleer), induce blood vessel relaxation and decrease pulmonary arterial pressure. These agents, however, cause general vessel dilation and some degree of hypotension. A new endothelin receptor antagonist drug, macitentan (Opsumit), has been approved for management of adults with PAH. This oral drug is

taken as a 10-mg tablet once daily, with or without food. Teach patients to take the drug with a glass of water, and teach them not to break, chew, or crush the tablet.

Because macitentan can cause birth defects, its use is contraindicated for women who are pregnant or breastfeeding. Instruct women who are sexually active and within childbearing age to use at least two reliable methods of contraception while taking this drug. In addition, the drug can harm the liver, and patients should avoid drinking alcoholic beverages while taking it.

Natural and synthetic prostacyclin agents provide the best specific dilation of pulmonary blood vessels. Continuous infusion of epoprostenol (Flolan, Veletri) or treprostinil (Remodulin) through a small IV pump reduces pulmonary pressures and increases lung blood flow (Fuentes et al., 2012). Treprostinil also can be delivered by continuous subcutaneous infusion. These continuous infusions of prostacyclin drugs can be performed by the patient at home and in other settings. These drugs also are continued when the patient is hospitalized for any reason. The unusual continuous infusion, the need to keep an IV line dedicated strictly to prostacyclin infusion, and the varied dosages of the different brands of prostacyclins contribute to a high drug error rate for administration of this drug. See the Quality Improvement box for some recommendations to reduce this error rate.

Quality Improvement QSEN

Continuous Prostacyclin Therapy Error Prevention

Kingman, M., & Chin, K. (2013). Safety recommendations for administering intravenous prostacyclins in the hospital. *Critical Care Nurse, 33*(5), 32-34, 36-41.

Intravenous prostacyclin drugs are most widely prescribed for management of pulmonary arterial hypertension. These drugs are categorized as *high risk* and have some unique issues, one of which is that the patient receives them by continuous infusion 24 hours daily, 7 days a week. In the hospital setting, administration of these drugs is associated with a high error rate. Two of the most common errors were flushing the dedicated prostacyclin infusion line and administering the wrong brand of prostacyclin. Because patient lives depend on continuous and correct infusion of prostacyclins, leading experts in the field were asked to generate recommendations for IV administration to reduce the error rate.

In addition to many standard recommendations for reducing drug

errors, two unique ones were developed. The first involved safety strategies for ensuring the dedicated line is not flushed. The second unique recommendation involved including the patient in the administration of the prostacyclins. Most patients have been responsible for self-administration of the drug in the community setting and have been highly trained to do so correctly. Thus the recommendation is that the patient should be included in the administration (while in the hospital setting) to the "fullest extent possible," as an expert on drug administration and trouble-shooting.

Commentary: Implications for Practice and Research

This expert-generated set of recommendations for drug administration safety is a departure from the usual quality improvement (QI) project that is either unit-based or institution-based. It represents the next step in the QI process of standardizing procedures for an identified population-based problem across multiple institutions. Because it is a beginning project using a descriptive design rather than a randomized clinical trial, it was reasonable to first determine the justification for a practice change. A randomized clinical trial approach should be the next step in establishing the evidence to support a specific process or procedure to reduce drug administration errors.

The prostacyclin agents iloprost (Ilomedin, Ventavis) and treprostinil (Tyvaso) can be delivered by inhalation (Poms & Kingman, 2011). A drug given along with prostacyclins is sildenafil (Revatio, Viagra) administered orally or IV.

While most patients with PAH need to stay on prostacyclin drugs until lung transplantation or disease progression to death, a small percentage of patients have been successfully weaned off prostacyclin drug therapy. These patients are maintained on oral bosentan, sildenafil, and warfarin therapy (Demerouti et al., 2013). The uncertain outcome of treatment and the serious nature of the disorder have been reported to increase the levels of depression and anxiety in patients diagnosed with PAH (Roberts-Collins et al., 2013).

Nursing Safety Priority QSEN

Critical Rescue

A critical nursing priority for a patient undergoing therapy with IV prostacyclin agents is to ensure that the drug therapy is never

interrupted. Deaths have been reported if the drug delivery is interrupted even for a matter of minutes. Teach the patient to always have backup drug cassettes and battery packs. If these are not available or if the line is disrupted, the patient should go to the emergency department immediately.

Another critical priority is helping the patient receiving IV prostacyclin agents prevent sepsis. The central line IV setup provides an access for organisms to directly enter the bloodstream. Teach the patient to use strict aseptic technique in all aspects of using the drug delivery system. Also teach him or her to notify the pulmonologist at the first manifestation of any infection.

When the heart has undergone hypertrophy and cardiac output has fallen, the patient may be started on a regimen of digoxin (Lanoxin) and diuretics. Oxygen therapy is used when dyspnea is uncomfortable. This therapy improves function and reduces manifestations but does not cure PAH.

Surgical management of PAH involves lung transplantation. When cor pulmonale also is present, the patient may need a combined heart-lung transplantation. It is not known whether the process of pulmonary vasoconstriction can begin again in the transplanted lungs or if this is a "cure."

Interstitial Pulmonary Diseases

The category of interstitial pulmonary diseases contains a variety of lung disorders, also called *fibrotic lung diseases,* that have some features in common. All affect the alveoli, blood vessels, and surrounding support tissue of the lungs rather than the airways. Thus these disorders are **restrictive** (preventing good expansion and recoil of the gas exchange unit), not obstructive. With restrictive disease, the lung tissues thicken, causing reduced gas exchange and "stiff" lungs that do not expand well. Air trapping does not occur, and the patient does not develop a "barrel chest." Often the onset of these disorders is slow, and dyspnea is the most common manifestation.

Sarcoidosis

❖ Pathophysiology

Sarcoidosis is a disease of inflammation of unknown cause that can affect any organ, but the lung is involved most often. It develops over time with noncancerous inflammatory growths called **granulomas** forming in the lungs.

Pulmonary sarcoidosis involves autoimmune responses in which the normally protective T-lymphocytes increase and cause damaging actions in the alveolar cells. No single cause for T-lymphocyte activation has been identified, although infection and genetic predisposition may play a role. Alveolar inflammation **(alveolitis)** occurs from the presence of immune cells in the alveoli. Chronic inflammation causes **fibrosis** (scar tissue formation) in the lungs. The fibrosis reduces **lung compliance** (elasticity) and gas exchange. **Cor pulmonale** (right-sided cardiac failure) is often present because the heart can no longer pump effectively against the stiff, fibrotic lung.

The disease affects young adults. Manifestations include enlarged lymph nodes in the hilar area of the lungs, lung infiltrate on chest x-ray, skin lesions, and eye lesions. The first indication of disease may be an abnormal chest x-ray in an otherwise healthy patient. Common manifestations include cough, dyspnea, hemoptysis, and chest discomfort. In many patients, the illness resolves permanently. Others have progressive pulmonary fibrosis and severe systemic disease.

❖ Patient-Centered Collaborative Care

Sarcoidosis is suspected in the patient who has a cough, dyspnea, and an abnormal chest x-ray but is otherwise asymptomatic. Other conditions to

rule out before diagnosing sarcoidosis are lung infections and cancer. Bronchoscopy with biopsy may help diagnose this disorder (see Chapter 27).

Sarcoidosis is staged on the basis of x-ray findings. Higher stages have greater damage and more widespread disease. Pulmonary function studies often show a restrictive pattern of decreased lung volumes and impaired diffusing capacity. Irreversible lung changes occur in a small percentage of patients. Patients who have severe restrictive disease may develop pulmonary hypertension.

The focus of therapy is to reduce manifestations and prevent fibrosis. Management varies. If the patient is asymptomatic and has normal pulmonary function, no treatment is given. Decreased total lung capacity (TLC), diffusing capacity, or forced vital capacity (FVC); involvement of other organs; and hypercalcemia are indicators for treatment.

Corticosteroids are the main type of therapy. Dosages vary from 40 to 60 mg daily with tapering doses over 6 to 8 weeks, to a maintenance dose of 10 to 15 mg daily for 6 months. Further therapy may continue over 12 months. Drugs under study for management of this disease include thalidomide (Thalomid), infliximab (Remicade), and adalimumab (Humira). Follow-up and monitoring include assessment of symptom severity, pulmonary function studies, chest x-rays, a complete blood count, serum creatinine, serum calcium, and urinalysis. Teach the patient and family about side effects of steroid therapy, the need to avoid infection, and energy conservation strategies (see discussion of activity intolerance, p. 565 in the Chronic Obstructive Pulmonary Disease section).

Idiopathic Pulmonary Fibrosis

❖ Pathophysiology

Idiopathic pulmonary fibrosis is a common restrictive lung disease. The patient usually is an older adult with a history of cigarette smoking, chronic exposure to inhalation irritants, or exposure to the drugs *amiodarone* (Cordarone) or *ambrisentan* (Letairis, Volibris) (WHO, 2012). Most patients have progressive disease with few remission periods. Even with proper treatment, most patients usually survive less than 5 years after diagnosis.

Pulmonary fibrosis is an example of excessive wound healing with loss of cellular regulation. Once lung injury occurs, inflammation begins tissue repair. The inflammation continues beyond normal healing time, causing fibrosis and scarring. These changes thicken alveolar tissues, making gas

exchange difficult.

Patient-Centered Collaborative Care

The onset is slow, with early manifestations of mild dyspnea on exertion. Pulmonary function tests show decreased forced vital capacity (FVC). High resolution computed tomography (HRCT) shows a "honeycomb" pattern in affected lung tissue (Lewis & Scullion, 2012). As the fibrosis progresses, the patient becomes more dyspneic and hypoxemia becomes severe. Eventually, he or she needs high levels of oxygen and often is still hypoxemic. Respirations are rapid and shallow.

Therapy focuses on slowing the fibrotic process and managing dyspnea. Corticosteroids and other immunosuppressants are the mainstays of therapy. Immunosuppressant drugs include cytotoxic drugs such as cyclophosphamide (Cytoxan, Neosar, Procytox), azathioprine (Imuran), chlorambucil (Leukeran), or methotrexate (Folex). These drugs have many side effects, including increased infection risk, nausea, and lung and liver damage, and have shown limited benefit. New studies using the combination therapy of corticosteroids, azathioprine, interferon gamma 1b, and *N*-acetylcysteine show promise of slowing disease progression. Early clinical trials using drugs that help improve cellular regulation, such as those that belong to the class of mitogen-activated protein kinases inhibitors (MAPKIs), are being conducted. Starting any drug therapy early is critical, even though not all patients respond to therapy. Even among those who have a response to therapy, the disease eventually continues to progress and leads to death by respiratory failure. Lung transplantation is a curative therapy; however, the selection criteria, cost, and availability of organs make this option unlikely for most patients.

The patient and family need support and help with community resources after diagnosis. Nursing care focuses on assisting the patient and family in understanding the disease process and maintaining hope for control of the fibrosis (Lewis & Scullion, 2012). It is important to prevent respiratory infections. Teach the patient and family about the manifestations of infection and to avoid respiratory irritants, crowds, and people who are ill.

Home oxygen is needed by the time the patient has dyspnea because significant fibrosis has already occurred and gas exchange is reduced. Teach about oxygen use as a continuous therapy. Fatigue is a major problem. Teach the patient and family about energy conservation measures (see discussion of activity intolerance on p. 565 in the Chronic Obstructive

Pulmonary Disease section). These measures and rest help reduce the work of breathing and oxygen consumption. Encourage the patient to pace activities and accept assistance as needed.

In the later stages of the disease, the focus is to reduce the sensation of dyspnea. This is often accomplished with the use of oral, parenteral, or nebulized morphine. Provide information about hospice, which supports and coordinates resources to meet the needs of the patient and family when the prognosis for survival is less than 6 months (see Chapter 7).

Occupational Pulmonary Disease

Pathophysiology

Exposure to occupational or environmental fumes, dust, vapors, gases, bacterial or fungal antigens, and allergens can result in a variety of respiratory disorders. Depending on the degree, frequency, and intensity of exposure and on the specific disease, patients may have acute reversible effects or chronic lung disease. All occupational pulmonary diseases are made worse by cigarette smoking; thus smoking-cessation efforts are very important.

Many occupational diseases have an onset of manifestations long after the initial exposure to the offending agent. The patient's personal history can provide clues about the presence and cause of occupational pulmonary diseases such as occupational asthma, pneumoconiosis, diffuse interstitial fibrosis, and extrinsic allergic alveolitis. Chart 30-12 lists the key features of these disorders.

Chart 30-12 Key Features

Common Occupational Pulmonary Diseases

DISEASE AND CATEGORY	CAUSES AND MANIFESTATIONS
Occupational Asthmas	
Latency (allergic) asthma	Airway narrowing related only to workplace exposures Atopic allergic response to industrial irritants Develops after a period of exposure (from several weeks to several years) Characterized by airflow limitation Usually resolves when exposure ceases Obstructive disease
Irritant-induced asthma	Manifestations appear only in the workplace First onset usually occurs within 24 hours of exposure Common irritants are chlorine, ammonia, and phosgene Characterized by sloughing of epithelium, thickening of the basement membranes, and mucosal inflammation Early manifestations include cough, wheeze, and dyspnea High exposures can lead to pulmonary edema, ARDS, and death Most tissue changes are permanent Obstructive and restrictive disease
Pneumoconiosis	
Silicosis	Chronic fibrosis from long-term inhalation of silica dust Found among people working in mines, stone quarries, and foundries. Also found in people working in these industries: glass making, pottery, sandblasting, tile and brick making, soap and polishes, and manufacture of filters Characterized by nodule formation between alveoli leading to fibrosis Manifestations include dyspnea on exertion, fatigue, weight loss, reduced lung volume, and upper lobe fibrosis Restrictive disease
Coal Miner's Disease (Black Lung Disease)	Massive deposits of coal dust in the lungs leading to diffuse fibrosis Develops earlier among miners who smoke Early manifestations are similar to bronchitis Emphysema is a late development Restrictive disease
Diffuse Interstitial Fibrosis	
Asbestosis	Occurs among people who work in asbestos mines, building construction/remodeling, and shipyards Characterized by diffuse pleural thickening and diaphragmatic calcification Restrictive disease
Talcosis	Occurs among people who work in industries that manufacture paint, ceramics, roofing materials, cosmetics, and rubber goods Restrictive disease
Berylliosis	Occurs among people who work in industries in which metal is heated (steel mills, welding) or metal is machined, creating dust Has a genetic component for increased susceptibility to disease after beryllium exposure Restrictive disease
Extrinsic Allergic Alveolitis	
"Farmer's Lung" "Bird Fancier's Lung" "Machine Operator's Lung"	Hypersensitivity pneumonitis as an immunologic response to inhaling dust or chemical that contains bacterial or fungal antigens Characterized by formation of granulomas with central necrosis in the alveoli and surrounding blood vessels Restrictive disease

ARDS, Acute respiratory distress syndrome.

Patient-Centered Collaborative Care

Consider an occupational cause for patients with new-onset asthma or dyspnea. Ask about occupational exposure and onset of manifestations because there may or may not be a latency period between exposure and development of manifestations. Determine whether manifestations are acute or chronic. Ask about the use of inhalation protection and about cigarette smoking (see Chapter 27).

The patient who develops occupational asthma should be removed from the site of exposure, transferred to a job without exposure, and treated with asthma drugs. Nursing care is similar to the care for asthma not caused by the workplace environment. Refer the patient to a social worker, who provides information regarding compensation and pensions.

Nursing interventions for patients with occupational lung restrictive disease are the same as for those with emphysema. Hypoxemic patients

require supplemental oxygen. In addition, respiratory therapies to promote sputum clearance are essential.

Bronchiolitis Obliterans Organizing Pneumonia

Pathophysiology

Bronchiolitis obliterans organizing pneumonia (BOOP) is an inflammation that reduces cell regulation and allows connective tissue plugs to form in the lower airways and the tissue between the alveoli. Inflammation in the lumen triggers white blood cell clumping with uncontrolled fibroblast growth that occludes and eventually obliterates these airways and leads to restricted lung volume with decreased vital capacity. BOOP is not a true pneumonia, but the manifestations resemble respiratory infection.

The cause of BOOP is not known although many personal and environmental conditions are associated with it. Suggested triggers include infectious organisms, drugs (chemotherapy agents, certain antibiotics [sulfa-based drugs, cephalosporins, amphotericin B], antiseizure drugs, cocaine, and amiodarone), or the presence of a connective tissue disorder, such as rheumatoid arthritis or systemic lupus erythematosus. It is also associated with chest radiotherapy for breast or lung cancer.

BOOP is most common in people between ages 30 and 60 years and affects both genders. It is not associated with cigarette smoking. Depending on how fast the problem progresses and the degree to which it interferes with gas exchange, BOOP can lead to death.

Patient-Centered Collaborative Care

An event or condition triggers excessive inflammation in the lumens of lower airways, causing dyspnea, fever, mild cough, flu-like symptoms, and crackles on auscultation. In some patients, the problem resolves spontaneously. In others, it can rapidly progress to death within days. Usually manifestations are present for weeks or months and do not improve with antibiotic therapy.

Diagnosis of BOOP is difficult because manifestations are similar to many other respiratory problems. Chest x-rays and CT scans may show pulmonary tissue changes that only suggest BOOP, not confirm it. Biopsy with histologic findings is needed to confirm a BOOP diagnosis.

The most effective treatment for BOOP is corticosteroid therapy. A short course of the drug for acute disease can reduce manifestations, and the patient may never have a relapse. For those patients with more severe disease and those with any type of additional health problem, a year of corticosteroid therapy may be needed. In this population, BOOP is more of a chronic disease with some degree of permanent restrictive disease.

Exacerbations can occur.

Lung Cancer

Pathophysiology

Lung cancer is a leading cause of cancer-related deaths worldwide. In North America, more deaths from lung cancer occur each year than from prostate cancer, breast cancer, and colon cancer combined. The American Cancer Society estimates that more than 228,000 new cases of lung cancer are diagnosed each year and that more than 160,000 deaths occur each year from it (American Cancer Society [ACS], 2014). The overall 5-year survival for all patients with lung cancer is only 16%. This poor long-term survival is because most lung cancers are diagnosed at a late stage, when metastasis is present. Only 15% of patients have small tumors and localized disease at the time of diagnosis. The 5-year survival rate for this population is 52% (ACS, 2014).

Despite many advances in cancer treatment, the prognosis for lung cancer remains poor unless the tumor can be removed completely by surgery. Treatment often focuses on relieving symptoms **(palliation)** rather than cure because of metastasis.

Most primary lung cancers arise as a result of failure of cellular regulation in the bronchial epithelium. These cancers are collectively called *bronchogenic carcinomas.* Lung cancers are classified as small cell lung cancer (SCLC) and non–small cell lung cancer (NSCLC). Chapter 21 discusses the general mechanisms and processes of cancer development.

Metastasis (spread) of lung cancer occurs by direct extension, through the blood, and by invading lymph glands and vessels. Tumors in the bronchial tubes can grow and obstruct the bronchus partially or completely. Tumors in other areas of lung tissue can grow so large that they can compress and obstruct the airway. Compression of the alveoli, nerves, blood vessels, and lymph vessels can occur and also interfere with gas exchange. Lung cancer can spread to the lung lymph nodes, distant lymph nodes, and other tissues including bone, liver, brain, and adrenal glands.

Additional manifestations, known as *paraneoplastic syndromes,* complicate certain lung cancers. The paraneoplastic syndromes are caused by hormones secreted by tumor cells and occur most commonly with SCLC. Table 30-4 lists the endocrine paraneoplastic syndromes that may occur with lung cancer.

TABLE 30-4

Endocrine Paraneoplastic Syndromes Associated with Lung Cancer

ECTOPIC HORMONE	MANIFESTATION
Adrenocorticotropic hormone (ACTH)	Cushing's syndrome
Antidiuretic hormone	Syndrome of inappropriate antidiuretic hormone (SIADH)
	Weight gain
	General edema
	Dilution of serum electrolytes
Follicle-stimulating hormone (FSH)	Gynecomastia
Parathyroid hormone	Hypercalcemia
Ectopic insulin	Hypoglycemia

Staging of lung cancer is performed to assess the size and extent of the disease. These factors are related to survival. Lung cancer staging is based on the TNM system (T, primary **t**umor; N, number of regional lymph **n**odes; M, distant **m**etastasis). See Table 21-5 in Chapter 21 for a cancer staging system. Higher numbers represent later stages and less chance for cure or long-term survival.

Incidence and Prevalence

Lung cancers occur as a result of repeated exposure to inhaled substances that cause chronic tissue irritation or inflammation interfering with cellular regulation of cell growth. Cigarette smoking is the major risk factor and is responsible for 85% of all lung cancer deaths (ACS, 2014). The risk for lung cancer is directly related to the total exposure to cigarette smoke as determined by the number of years of smoking and number of packs of cigarettes smoked per day (pack-years). Pipe and cigar smoking also increase risk. The incidence of lung cancer decreases when smoking stops but remains higher than among people who have never smoked.

Etiology and Genetic Risk

Nonsmokers exposed to "passive," or "secondhand," smoke also have a greater risk for lung cancer than do nonsmokers who are minimally exposed to cigarette smoke. See Chapter 27 for a discussion of passive smoking risks.

Other risk factors include chronic exposure to asbestos, beryllium, chromium, coal distillates, cobalt, iron oxide, mustard gas, petroleum distillates, radiation, tar, nickel, and uranium (Held-Warmkessel & Schiech, 2014). Air pollution with hydrocarbons also increases the risk

for lung cancer.

Genetic/Genomic Considerations

Patient-Centered Care QSEN

Lung cancer development varies among people with similar smoking histories, suggesting that genetic factors can influence susceptibility. Genome-wide association studies have found specific variations in a variety of genes that increase the susceptibility to lung cancer development (OMIM, 2013a). Differences in a gene that regulates cell division, the *Tp53* gene, may be the most important genetic susceptibility link for lung cancer development. Mutations in the alleles of this gene are known to increase the susceptibility to a wide variety of cancers both with and without exposure to environmental risks, including lung cancer development among smokers and nonsmokers. Help patients understand that lung cancer susceptibility varies by genetic issues as well as by exposure to carcinogens.

Health Promotion and Maintenance

Primary prevention for lung cancer is directed at reducing tobacco smoking. Chapter 27 discusses strategies for assisting people to reduce smoking and means to protect lungs from other exposures to inhalation irritants linked to lung cancer development.

Secondary prevention by early detection involves screening of people at high risk for lung cancer development. Annual CT scans can detect cancers at stage I, when cure is probable and long-term survival (longer than 5 years) is very likely (ACS, 2014; Lehto, 2014).

Patient-Centered Collaborative Care

Assessment

History.

Ask the patient about risk factors, including smoking, hazards in the workplace, and warning signals (Table 30-5). Calculate the pack-year smoking history as described in Chapter 27.

TABLE 30-5

Warning Signals Associated with Lung Cancer

- Hoarseness
- Change in respiratory pattern
- Persistent cough or change in cough
- Blood-streaked sputum
- Rust-colored or purulent sputum
- Frank hemoptysis
- Chest pain or chest tightness
- Shoulder, arm, or chest wall pain
- Recurring episodes of pleural effusion, pneumonia, or bronchitis
- Dyspnea
- Fever associated with one or two other signs
- Wheezing
- Weight loss
- Clubbing of the fingers

Ask about the presence of lung cancer manifestations, such as hoarseness, cough, sputum production, hemoptysis, shortness of breath, or change in endurance. Assessing for and documenting these manifestations provide information about the extent of nursing care and teaching the patient needs now and can be used later to determine therapy effectiveness. Many manifestations are common and may have been present for years. Ask the patient to describe any recent changes in manifestations or if position affects them.

Assess for chest pain or discomfort, which can occur at any stage of tumor development. Chest pain may be localized or on just one side and can range from mild to severe. Ask about any sensation of fullness, tightness, or pressure in the chest, which may suggest obstruction. A piercing chest pain or pleuritic pain may occur on inspiration. Pain radiating to the arm results from tumor invasion of nerve plexuses in advanced disease.

Physical Assessment/Clinical Manifestations—Pulmonary.

Manifestations of lung cancer are often nonspecific and appear late in the disease. Specific manifestations depend on tumor location. Chills, fever, and cough may be related to pneumonitis or bronchitis that occurs with obstruction. Assess sputum quantity and character. Blood-tinged sputum may occur with bleeding from a tumor. Hemoptysis is a later finding in the course of the disease. If infection or necrosis is present, sputum may be purulent and copious.

Breathing may be labored or painful. Obstructive breathing may occur as prolonged exhalation alternating with periods of shallow breathing. Rapid, shallow breathing occurs with pleuritic chest pain and an elevated diaphragm. Look for and document abnormal retractions, the use of accessory muscles, flared nares, stridor, and asymmetric diaphragmatic

movement on inspiration. Dyspnea and wheezing may be present with airway obstruction. Ask about the level of dyspnea at rest, with activity, and in the supine position. Determine how much the dyspnea interferes with the patient's participation in ADLs, work, recreational activities, and family responsibilities. Ask him or her to compare participation in activities during the past week with that of a month ago and a year ago.

Areas of tenderness or masses may be felt when palpating the chest wall. Increased vibrations felt on the chest wall **(fremitus)** indicate areas of the lung where airspaces are replaced with tumor or fluid. Fremitus is decreased or absent when the bronchus is obstructed. The trachea may be displaced from midline if a mass is present in the area.

Lung areas with masses sound dull or flat rather than hollow or resonant on chest percussion. Breath sounds may change with the presence of a tumor. Wheezes indicate partial obstruction of airflow in passages narrowed by tumors. Decreased or absent breath sounds indicate complete obstruction of an airway by a tumor or fluid. Increased loudness or sound intensity of the voice while listening to breath sounds indicates increased density of lung tissue from tumor compression. A pleural friction rub may be heard when inflammation also is present.

Physical Assessment/Clinical Manifestations—Nonpulmonary.

Many other systems can be affected by lung cancer and have changes at the time of diagnosis. Heart sounds may be muffled by a tumor or fluid around the heart *(cardiac tamponade).* Dysrhythmias may occur as a result of hypoxemia or direct pressure of the tumor on the heart. Cyanosis of the lips and fingertips or clubbing of the fingers may be present (see Fig. 30-10).

Bones lose density with tumor invasion and break easily. The patient may have bone pain or pathologic fractures. Handle him or her carefully. Thin bones can fracture with little pressure and without trauma. Even heavy coughing can break a rib.

Late manifestations of lung cancer usually include fatigue, weight loss, anorexia, dysphagia, and nausea and vomiting. Superior vena cava syndrome may result from tumor pressure in or around the vena cava. This syndrome is an emergency (see Chapter 22) and requires immediate intervention. The patient may have confusion or personality changes from brain metastasis. Bowel and bladder tone or function may be affected by tumor spread to the spine and spinal cord, which also can change gait.

Psychosocial Assessment.

The poor prognosis for lung cancer has made it a much-feared disease. Dyspnea and pain add to the patient's fear and anxiety. The patient with a history of cigarette smoking may feel guilt and shame. Convey acceptance, and interact with the patient in a nonjudgmental way. Encourage the patient and family to express their feelings about the possible diagnosis of lung cancer.

Diagnostic Assessment.

The diagnosis of lung cancer is made by examination of cancer cells. Cytologic testing of early-morning sputum specimens may identify tumor cells; however, cancer cells may not be present in the sputum. When pleural effusion is present, fluid is obtained by thoracentesis for cytology.

Most commonly, lung lesions are first identified on chest x-rays. CT examinations are then used to identify the lesions more clearly and to guide biopsy procedures.

A thoracoscopy to directly view lung tissue may be performed through a video-assisted thoracoscope entering the chest cavity via small incisions through the chest wall. Spread to mediastinal lymph nodes is assessed with a mediastinoscopy through a small chest incision.

Other diagnostic studies may be needed to determine how widely the cancer has spread. Such tests include needle biopsy of lymph nodes, direct surgical biopsy, and thoracentesis with pleural biopsy. MRI and radionuclide scans of the liver, spleen, brain, and bone help determine the location of metastatic tumors. Pulmonary function tests (PFTs) and arterial blood gas (ABG) analysis help determine the overall respiratory status. Positron emission tomography (PET) scanning is becoming the most thorough way to locate metastases. Together, these tests help determine the extent of the cancer and the best methods to treat it.

◆ Interventions for Cure

Interventions for the patient with lung cancer can have the purposes of curing the disease, increasing survival time, and enhancing quality of life through palliation. Both nonsurgical and surgical interventions are used to achieve these purposes. Some patients with lung cancer may undergo interventions for all three purposes at different stages in the disease process. Cure is most likely for patients who undergo treatment for stage I or II disease. Cure is rare for patients who undergo treatment for stage III or IV disease, although survival time is increasing.

Nonsurgical Management.

Chemotherapy is often the treatment of choice for lung cancers, especially small cell lung cancer (SCLC). It may be used alone or as adjuvant therapy in combination with surgery for non–small cell lung cancer (NSCLC). The exact combination of drugs used depends on the response of the tumor and the overall health of the patient; however, most include platinum-based agents.

Side effects that occur with chemotherapy for lung cancer include chemotherapy-induced nausea and vomiting (CINV), **alopecia** (hair loss), open sores on mucous membranes **(mucositis),** immunosuppression with neutropenia, anemia, **thrombocytopenia** (decreased numbers of platelets), and peripheral neuropathy. Consult Chapter 22 for a thorough discussion of the nursing care needs for patients who have these side effects.

Immunosuppression with neutropenia, which greatly increases the risk for infection, is the major dose-limiting side effect of chemotherapy for lung cancer. It can be managed by the use of growth factors to stimulate bone marrow production of immune system cells. Teach the patient and family about precautions to take to reduce the patient's chances of developing an infection (see Chart 22-4 in Chapter 22). (See Chapter 22 for more information about chemotherapy and associated nursing care.)

Targeted therapy is now becoming common in the treatment of lung cancer. These agents take advantage of one or more differences in cancer cell growth or metabolism that is either not present or only slightly present in normal cells. Agents used as targeted therapies often are antibodies that work to disrupt cancer cell division in one of several ways. Some of these drugs "target" and block growth factor receptors, such as the epithelial growth factor receptor inhibitors (EGFRIs) or the vascular endothelial growth factor receptor inhibitors (VEGFRIs). When a lung cancer cell's growth depends on having the growth factors bind to their specific receptors, blocking the receptors may slow cancer cell growth. Agents most often used, along with other therapy, for targeted therapy of certain types of non–small cell lung cancer are erlotinib (Tarceva), bevacizumab (Avastin), and crizotinib (Xalkori) (Cagle & Chirieac, 2012).

Radiation therapy can be an effective treatment for locally advanced lung cancers confined to the chest. Best results are seen when radiation is used in addition to surgery or chemotherapy. Radiation may be performed before surgery to shrink the tumor and make resection easier.

Usually radiation therapy for lung cancer is performed daily for a 5- to 6-week period. Only the areas thought to have cancer are positioned in

the radiation path. The immediate side effects of this treatment are skin irritation and peeling, fatigue, nausea, and taste changes. Some patients have esophagitis during therapy, making nutrition more difficult. Collaborate with a dietitian to teach patients to eat foods that are soft, bland, and high in calories. Suggest that the patient drink liquid nutrition supplements between meals to maintain weight and energy levels.

Skin care in the radiation-treated area can be difficult. Because skin in the radiation path is more sensitive to sun damage, advise patients to avoid direct skin exposure to the sun during treatment and for at least 1 year after radiation is completed. See Chapter 22 for other nursing care issues associated with radiation therapy.

Photodynamic therapy (PDT) may be used to remove small bronchial tumors when they are accessible by bronchoscopy. The patient is first injected with an agent that sensitizes cells to light. This drug enters all cells but leaves normal cells more rapidly than cancer cells. Usually, within 48 to 72 hours, most of the drug has collected in high concentrations in cancer cells. At this time, the patient goes to the operating room where, under anesthesia and intubation, a laser light is focused on the tumor. The light activates a chemical reaction within those cells retaining the sensitizing drug that induces irreversible cell damage. Some cells die and slough immediately; others continue to slough for several days.

When PDT is used in the airways, the patient usually requires a stay in the ICU for airway management. The sloughing tissue can block the airway as can airway edema from the inflammatory response of the tissues. In addition, the patient is at risk for bronchial hemorrhage, fistula formation, and hemoptysis. Patients who have undergone bronchial PDT are very sensitive to light for days to weeks after treatment.

Surgical Management.

Surgery is the main treatment for stage I and stage II NSCLC. Total tumor removal may result in a cure. If complete resection is not possible, the surgeon removes the bulk of the tumor. The specific surgery depends on the stage of the cancer and the patient's overall health. Lung cancer surgery may involve removal of the tumor only, removal of a lung segment, removal of a lobe **(lobectomy),** or removal of the entire lung **(pneumonectomy).** These procedures can be performed by open thoracotomy or by thoracoscopy with minimally invasive surgery in select patients.

Preoperative Care.

The focus of nursing care before surgery is to relieve anxiety and promote the patient's participation (see Chapter 14 for routine preoperative care). Encourage the patient to express fears and concerns, reinforce the surgeon's explanation of the procedure, and provide education related to what is expected after surgery. Teach about the probable location of the surgical incision or thoracoscopy openings, shoulder exercises, and the chest tube and drainage system (except after pneumonectomy).

Operative Procedures.

Three types of incisions can be made depending on the location of the cancer: posterolateral, anterolateral, and median sternotomy (Fig. 30-13). The incisions are large and are held open with retractors during surgery, contributing to pain after surgery.

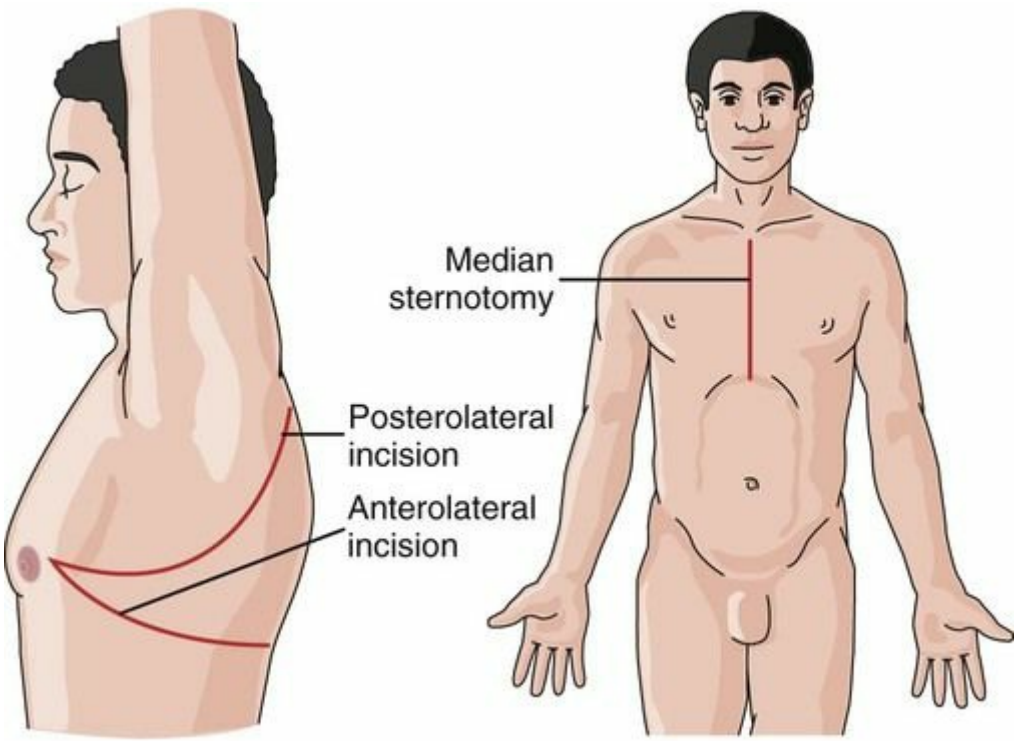


FIG. 30-13 Common incision locations for partial or total pneumonectomy.

Surgery may consist of a lobectomy, pneumonectomy, segmental resection, or wedge resection. A segmental resection is a lung resection that includes the bronchus, pulmonary artery and vein, and tissue of the involved lung segment or segments of a lobe. A **wedge resection** is removal of the peripheral portion of small, localized areas of disease.

Removal of a lobe or entire lung can be accomplished through video-assisted thoracoscopic surgery (VATS) for select patients. The procedure involves making three small incisions in the chest for placement of the instruments. These same openings are used later for placement of drains and chest tubes. The lung section, lobe, or lung is isolated from its airway, which is surgically closed. The lobe or the lung is closed off from the rest of the lung using a double-stapling technique. The tissue is sealed in a bag to prevent leakage of tumor tissue and possible seeding of the cancer and is then removed whole through one of the small incisions.

Postoperative Care.

Care after surgery for patients who have undergone thoracotomy (except for pneumonectomy) requires closed–chest drainage to drain air and blood that collect in the pleural space. A **chest tube,** a drain placed in the pleural space, allows lung re-expansion (Fig. 30-14). The chest tube also prevents air and fluid from returning to the chest. The drainage system consists of one or more chest tubes or drains, a collection container placed below the chest level, and a water seal to keep air from entering the chest. The drainage system may be a stationary, disposable, self-contained system (Fig. 30-15) or a smaller, portable, disposable, self-contained system that requires no connection to a vacuum source (Fig. 30-16). The nursing care priorities for the patient with a chest tube are to ensure the integrity of the system, promote comfort, ensure chest tube patency, and prevent complications.

FIG. 30-15 *Left,* The Pleur-evac drainage system, a commercial three-chamber chest drainage device. *Right,* Schematic of the drainage device.

FIG. 30-16 A portable chest drainage system.

Chest Tube Placement and Care.

The tip of the tube used to drain air is placed near the front lung apex (see Fig. 30-14). The tube that drains liquid is placed on the side near the base of the lung. After lung surgery, two tubes, anterior and posterior, are used. The wounds are covered with airtight dressings.

The chest tube is connected by about 6 feet of tubing to a collection device placed below the chest. The tubing allows the patient to turn and move without pulling on the chest tube. Keeping the collection device below the chest allows gravity to drain the pleural space. When two chest tubes are inserted, they are joined by a Y-connector near the patient's body; the 6 feet of tubing is attached to the Y-connector.

Stationary chest tube drainage systems use a water seal mechanism that acts as a one-way valve to prevent air or liquid from moving back into the chest cavity. The Pleur-evac system is a common device using a one-piece

disposable plastic unit with three chambers. The three chambers are connected to one another. The tube(s) from the patient is(are) connected to the first chamber in the series of three. This chamber is the drainage collection container. The second chamber is the water seal to prevent air from moving back up the tubing system and into the chest. The third chamber, when suction is applied, is the suction regulator.

In setting up the system, chamber one (nearest to the patient) does not at first have fluid in it. The tubing from the patient penetrates shallowly into this chamber, as does the tube connecting chamber one with chamber two.

Chamber one collects the fluid draining from the patient. This fluid is measured hourly during the first 24 hours. The fluid in chamber one must never fill to the point that it comes into contact with any tubes! If the tubing from the patient enters the fluid, drainage stops and can lead to a tension pneumothorax.

Chamber two is the water seal that prevents air from re-entering the patient's pleural space. As the trapped air leaves the pleural space, it will pass through chamber one (drainage collection chamber) before entering chamber two (the water seal chamber), which should always contain at least 2 cm of water to prevent air from returning to the patient. As trapped air from the patient's pleural space passes through the water seal, which serves as a one-way valve, the water will bubble. Once all the air has been evacuated from the pleural space, bubbling of the water seal stops.

Nursing Safety Priority QSEN

Action Alert

For a water seal chest tube drainage system, 2 cm of water is the minimum needed in the water seal to prevent air from flowing backward into the patient. Check the water level every shift, and add sterile water to this chamber to the level marked on the indicator (specified by the manufacturer of the drainage system).

The bubbling of the water in the water seal chamber indicates air drainage from the patient. Bubbling is seen when intrathoracic pressure is greater than atmospheric pressure, such as when the patient exhales, coughs, or sneezes. When the air in the pleural space has been removed, bubbling stops. A blocked or kinked chest tube also can cause bubbling to stop. Excessive bubbling in the water seal chamber (chamber two) may

indicate an air leak. The water in the narrow column of the water seal chamber normally rises 2 to 4 inches during inhalation and falls during exhalation, a process called *tidaling*. An absence of fluctuation may mean that the lung has fully re-expanded or can mean that there is an obstruction in the chest tube (Bauman & Handley, 2011).

Chamber three is the suction control of the system. There are different types of suction, most commonly wet or dry. With wet suction, the fluid level in chamber three is prescribed by the health care provider (usually −20 cm water). The chamber is connected to wall suction, which is turned up until there is gentle bubbling in the chamber. With dry suction, the health care provider prescribes the suction level to be dialed in on the device. When connected to wall suction, the regulator is set to the amount indicated by the device's manufacturer. For either type of suction, the amount of suction in the system is determined not by the wall suction unit but by the chest tube drainage device.

Chart 30-13 summarizes best safety practices when caring for a patient with a water seal chest tube drainage system. Check hourly to ensure the sterility and patency of the drainage system. Tape tubing junctions to prevent accidental disconnections, and keep an occlusive dressing at the chest tube insertion site. Keep sterile gauze at the bedside to cover the insertion site immediately if the chest tube becomes dislodged. Also keep padded clamps at the bedside for use if the drainage system is interrupted. Position the drainage tubing to prevent kinks and large loops of tubing, which can block drainage and prevent lung re-expansion.

Chart 30-13 Best Practice for Patient Safety & Quality Care QSEN

Management of Chest Tube Drainage Systems

Patient

- Ensure that the dressing on the chest around the tube is tight and intact. Depending on agency policy and the surgeon's preference, reinforce or change loose dressings.
- Assess for difficulty breathing.
- Assess breathing effectiveness by pulse oximetry.
- Listen to breath sounds for each lung.
- Check alignment of trachea.
- Check tube insertion site for condition of the skin. Palpate area for puffiness or crackling that may indicate subcutaneous emphysema.
- Observe site for signs of infection (redness, purulent drainage) or

excessive bleeding.
- Check to see if tube "eyelets" are visible.
- Assess for pain and its location and intensity, and administer drugs for pain as prescribed.
- Assist patient to deep breathe, cough, perform maximal sustained inhalations, and use incentive spirometry.
- Reposition the patient who reports a "burning" pain in the chest.

Drainage System

- Do not "strip" the chest tube.
- Keep drainage system lower than the level of the patient's chest.
- Keep the chest tube as straight as possible, avoiding kinks and dependent loops.
- Ensure the chest tube is securely taped to the connector and that the connector is taped to the tubing going into the collection chamber.
- Assess bubbling in the water seal chamber; should be gentle bubbling on patient's exhalation, forceful cough, position changes.
- Assess for "tidaling."
- Check water level in the water seal chamber, and keep at the level recommended by the manufacturer.
- Check water level in the suction control chamber, and keep at the level prescribed by the surgeon (unless dry suction system is used).
- Clamp the chest tube only for brief periods to change the drainage system or when checking for air leaks.
- Check and document amount, color, and characteristics of fluid in the collection chamber, as often as needed according to the patient's condition and agency policy.
- Empty collection chamber or change the system before the drainage makes contact with the bottom of the tube.
- When a sample of drainage is needed for culture or other laboratory test, obtain it from the chest tube; after cleansing chest tube, use a 20-gauge (or smaller) needle and draw up specimen into a syringe.

Immediately Notify Physician or Rapid Response Team For:

- Tracheal deviation
- Sudden onset or increased intensity of dyspnea
- Oxygen saturation less than 90%
- Drainage greater than 70 mL/hr
- Visible eyelets on chest tube
- Chest tube falls out of the patient's chest (first, cover the area with dry, sterile gauze)

- Chest tube disconnects from the drainage system (first, put end of tube in a container of sterile water and keep below the level of the patient's chest)
- Drainage in tube stops (in the first 24 hours)

Manipulation of the chest tube should be kept to a minimum. Do not vigorously "strip" the chest tube because this can create up to −400 cm of water negative pressure and damage lung tissue. If any tube manipulation is needed, gentle hand-over-hand "milking" of the tube, with stopping between each hand hold, is used to move blood clots and prevent obstruction. Follow surgeon prescriptions, as well as agency policies and guidelines on this action.

Assess the respiratory status and document the amount and type of drainage hourly on the collection chamber. Notify the surgeon if more than 100 mL/hr of drainage occurs. After the first 24 hours, assess drainage at least every 8 hours. Usually the drainage in chamber one is not emptied unless it is so full that the fluid is in danger of coming into contact with the chest drainage tube.

Check the water seal chamber for unexpected bubbling created by an air leak in the system. Bubbling is normal during forceful expiration or coughing because air in the chest is being expelled. Continuous bubbling indicates an air leak. Notify the health care provider if bubbling occurs continuously in the water seal chamber. With a prescription, gently apply a padded clamp briefly on the drainage tubing close to the occlusive dressing. If the bubbling stops, the air leak may be at the chest tube insertion site or within the chest, requiring physician intervention. Bubbling that does not stop when a padded clamp is applied indicates that the air leak is between the clamp and the drainage system. Release the clamp as soon as this assessment is made.

Mobile or portable chest tube drainage systems are "dry" chest drainage systems without a water seal to prevent air from re-entering the patient's lung through the chest tube. Instead, these light-weight devices use a dynamic control "flutter" valve that prevents backflow of air. When the patient exhales, air is forced from the chest cavity into the chest tube, under pressure. This pressure forces the soft flutter valve open and air moves into the harder surrounding tube shell (which has a vent for air). Portable units allow the patient to ambulate and go home with chest tubes still in place.

NCLEX Examination Challenge

Safe and Effective Care Environment

The chest tube of a client 16 hours postoperative from a lobectomy is accidentally pulled out by a portable x-ray machine. What is the nurse's best first action?

A Clamp the tubing with padded clamps as close as possible to the insertion site.

B Reposition the client on the nonoperative side and support the tube(s) with pillows.

C Cover the insertion site with a sterile occlusive dressing and tape down on three sides.

D Don sterile gloves and attempt to reinsert the chest tube at the original insertion site.

Pain Management.

Most patients have intense pain after an open thoracotomy. Pain is considerably less for the patient after surgery using minimally invasive techniques. However, pain control is needed in either case for patient comfort and to assist him or her to participate in techniques to reduce the risk for complications (see Chapter 16). Give the prescribed drugs for pain, and assess the patient's responses to them. Teach patients using patient-controlled analgesia (PCA) devices to self-administer the drug before pain intensity becomes too severe. Monitor vital signs before and after giving opioid analgesics, especially for the patient who is not being mechanically ventilated. Plan care activities around the timing of analgesia to reduce pain.

Respiratory Management.

Immediately after surgery the patient is mechanically ventilated. See Chapter 32 for nursing care of the patient receiving mechanical ventilation.

Once the patient is breathing on his or her own, the priorities are to maintain a patent airway, ensure adequate ventilation, and prevent complications. Assess the patient at least every 2 hours for adequacy of ventilation and gas exchange. Check the alignment of the trachea. Assess oxygen saturation and the rate and depth of respiration. Listen to breath sounds in all lobes on the nonoperative side, particularly noting the presence of crackles. Assess the oral mucous membranes for cyanosis and the nail beds for rate of capillary refill. Perform oral suctioning as necessary.

Usually the patient receives oxygen by mask or nasal cannula for the

first 2 days after surgery. Warm and humidify the oxygen. Assist the patient to a semi-Fowler's position or up in a chair as soon as possible. Encourage him or her to use the incentive spirometer every hour while awake. If coughing is permitted, help him or her cough by splinting any incision and ensuring that the chest tube does not pull with movement. Ensuring that pain is well managed increases the patient's ability to cough and deep breathe effectively.

Pneumonectomy Care.

After pneumonectomy, the pleural cavity on the affected side is an empty space. The surgeon sometimes inserts a clamped chest tube for only a day. Serous fluid collection in the empty space creates adhesions that help reduce mediastinal shift toward the affected side. Closed–chest drainage is not usually used.

Complications of a pneumonectomy include empyema (purulent material in the pleural space) and development of a bronchopleural fistula (an abnormal duct that develops between the bronchial tree and the pleura). Positioning of the patient after pneumonectomy varies according to surgeon preference and the patient's comfort. Some surgeons want the patient placed on the nonoperative side immediately after a pneumonectomy to reduce stress on the bronchial stump incision. Others prefer to place the patient on the operative side to allow fluids to fill in the now empty space.

Clinical Judgment Challenge

Patient-Centered Care; Evidence-Based Practice QSEN

The patient is a 60-year-old man who has just been diagnosed with non–small cell lung cancer. He smoked cigarettes for about 25 years starting when he was 16 years old and quit when he was 41 years old. His lung cancer is at stage I in the left lower lobe. He is distraught, saying that he can't die now because he has one child in college and two in high school. He also fears chemotherapy and seems bitter that he quit smoking and got lung cancer anyway. His next statement is: “Why couldn't I get prostate cancer like most men? At least they survive. No one beats lung cancer.”

1. What can you tell him about lung cancer survival?
2. What can you tell him about the benefits of having quit smoking?
3. For this cancer stage and type, what is/are the most likely therapy/therapies?

4. What resources could you recommend to help him at this time?

Interventions for Palliation

Oxygen therapy is prescribed when the patient is hypoxemic. Even if the hypoxemia is not severe, humidified oxygen may be prescribed to relieve dyspnea and anxiety. (See Chapter 28 for issues related to home oxygen therapy.)

Drug therapy with bronchodilators and corticosteroids is prescribed for the patient with bronchospasm to decrease bronchospasm, inflammation, and edema. Mucolytics may help ease removal of thick mucus and sputum. Bacterial infections are treated with antibiotic therapy.

Radiation therapy can help relieve hemoptysis, obstruction of the bronchi and great veins (superior vena cava syndrome), difficulty swallowing from esophageal compression, and pain from bone metastasis. Radiation for palliation uses higher doses for shorter periods. Skin care issues and fatigue are the same as those occurring with radiation therapy for cure.

Thoracentesis is performed when pleural effusion is a problem for the patient with lung cancer. The excess fluid increases dyspnea, discomfort, and the risk for infection. The purpose of treatment is to remove pleural fluid and prevent its formation. **Thoracentesis** is fluid removal by suction after the placement of a large needle or catheter into the intrapleural space. Fluid removal temporarily relieves hypoxia; however, the fluid can rapidly re-form in the pleural space. When fluid development is continuous and uncomfortable, a continuously draining catheter may be placed into the intrapleural space to collect the fluid.

Dyspnea management is needed because the patient with lung cancer tires easily and is often most comfortable resting in a semi-Fowler's position. Dyspnea is reduced with oxygen, use of a continuous morphine infusion, and positioning for comfort. The severely dyspneic patient may be most comfortable sitting in a lounge chair or reclining chair.

Pain management may be needed to help the patient be as pain-free and comfortable as possible. Pain may be present in the chest or in almost any area when bone metastasis occurs. Perform a complete pain assessment with attention to onset, intensity, quality, duration, and the patient's description of the pain.

Pharmacologic management with opioid drugs as oral, parenteral, or transdermal preparations is needed. Analgesics are most effective when given around the clock. Additional PRN analgesics are used for breakthrough pain. Ongoing evaluation of pain control effectiveness is a primary nursing responsibility.

Hospice care can be beneficial for the patient in the terminal phase of lung cancer. Hospice programs provide support to the terminally ill patient and the family, meet physical and psychosocial needs, adjust the palliative care regimen as needed, make home visits, and provide volunteers for errands and respite care. (See Chapter 7 for a more complete discussion of end-of-life issues.) The American Cancer Society may provide assistance through support groups for patients and families or through the use of equipment, such as a hospital bed or bedside commode. Family members and significant others are heavily burdened at this time. They have many needs and also require much support while performing the caregiver role during this time (Grant et al., 2013).

Nursing Concepts and Clinical Judgment Review

What might you NOTICE if the patient is experiencing inadequate gas exchange and tissue perfusion as a result of chronic obstructive respiratory problems?

- Respirations rapid and shallow
- Decreased oxygen saturation by pulse oximetry
- Skin cyanosis or pallor (in lighter-skinned patients)
- Cyanosis or pallor of the lips and oral mucous membranes (in patients of any skin color)
- Tachycardia
- Patient appears to work hard to inhale and exhale
- Patient is restless or anxious
- Patient's general appearance is thin relative to height
- Muscles of the neck appear thick
- Arm and leg muscles appear thin
- Fingers are clubbed
- Chest is barrel-shaped
- Ribs are spaced more than a fingerbreadth apart

What should you INTERPRET and how should you RESPOND to a patient experiencing inadequate gas exchange and tissue perfusion as a result of an acute critical respiratory problem?

Perform and interpret physical assessment, including:

- Taking vital signs
- Auscultating all lung fields
- Monitoring oxygen saturation by pulse oximetry
- Assessing cognition

- Assessing for the presence and characteristics of sputum production
- Assessing the patient's ability to cough and clear the airway

Interpret laboratory values, including:

- Elevated red blood cell count, hematocrit, and hemoglobin
- Elevated white blood cell count
- Arterial blood gas values: pH lower than 7.35; HCO_3^- greater than 24 mEq/L; Pa_{CO_2} greater than 45 mm Hg; Pa_{O_2} lower than 80 mm Hg

Respond by:

- Assisting the patient to an upright position, with arms resting on a table or armrests
- Performing or assisting the patient to perform chest physiotherapy/pulmonary hygiene
- Prioritizing and pacing activities to prevent fatigue
- Administering prescribed inhaled drugs
- Administering respiratory therapy treatments or collaborating with the respiratory therapist to administer these treatments
- Re-assessing respiratory status after respiratory therapy treatment
- Ensuring a fluid intake of at least 2 liters per day

On what should you REFLECT?

- Observe the patient for evidence of improved oxygenation (see Chapter 27).
- Think about what may have made the patient's dyspnea worse and what steps could be taken to prevent a similar episode.
- Think about what patient education focus could help reduce the intensity of dyspnea in the future.

Get Ready for the NCLEX® Examination!

Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Ensure there are no open flames or combustion hazards in rooms where oxygen is in use. **Safety** QSEN
- Ensure that oxygen therapy delivered to the patient is humidified. **Safety** QSEN
- Protect the patient with cystic fibrosis from hospital-acquired pulmonary infections. **Safety** QSEN
- Ensure proper function of chest tube drainage equipment. **Safety** QSEN

Health Promotion and Maintenance

- Teach patients who come into contact with inhalation irritants in their workplaces or leisure-time activities to use a mask to avoid respiratory contact with these substances. **Safety** QSEN
- Teach anyone who smokes that smoking increases the risk for development of many pulmonary problems. **Evidence-Based Practice** QSEN
- Teach patients with asthma to develop a management plan based on their identified personal best on peak expiratory rate flow testing. **Patient-Centered Care** QSEN
- Instruct patients with asthma to carry a reliever inhaler with them at all times. **Safety** QSEN
- Encourage all patients older than 50 years and anyone with a respiratory problem to receive a yearly influenza vaccination. **Patient-Centered Care** QSEN
- Teach all patients who smoke the warning signs of lung cancer. **Evidence-Based Practice** QSEN

Psychosocial Integrity

- Encourage the patient and family to express their feelings regarding the diagnosis of a chronic respiratory disease or cancer and about management/treatment regimens.
- Explain all diagnostic procedures, restrictions, and follow-up care to the patient scheduled for tests.

- Help patients use strategies to improve their appearance when alopecia occurs. **Patient-Centered Care** QSEN
- Refer patients and family members to local cancer resources and support groups. **Patient-Centered Care** QSEN
- Ensure that patient preferences are honored whenever possible. **Patient-Centered Care** QSEN

Physiological Integrity

- Assess the airway and breathing effectiveness for gas exchange for any patient who experiences shortness of breath or any change in mental status. **Evidence-Based Practice** QSEN
- Assess the degree to which breathing problems interfere with the patient's ability to perform ADLs, work, and leisure-time activities. **Patient-Centered Care** QSEN
- Apply oxygen to anyone who is hypoxemic. **Evidence-Based Practice** QSEN
- Monitor arterial blood gases and oxygen saturation of all patients receiving oxygen therapy. **Evidence-Based Practice** QSEN
- Teach patients receiving radiation therapy how to care for the skin in the radiation path (see Chart 22-2 in Chapter 22). **Patient-Centered Care** QSEN
- Collaborate with respiratory therapists, registered dietitians, and social workers to meet the hospital and home care needs of patients with chronic lower respiratory problems. **Teamwork and Collaboration** QSEN

CHAPTER 31

Care of Patients with Infectious Respiratory Problems

Meg Blair

PRIORITY CONCEPTS

- Gas Exchange
- Infection
- Inflammation

Learning Outcomes

Safe and Effective Care Environment

1. Apply principles of infection control and disease-containment activities when providing care to patients with respiratory infections.
2. Protect patients receiving mechanical ventilation from developing ventilator-associated pneumonia.

Health Promotion and Maintenance

3. Provide information to everyone about preventing respiratory infections.
4. Describe techniques for home care of the patient with active tuberculosis.

Psychosocial Integrity

5. Reduce the psychological impact of respiratory infections for the patient and family.

Physiological Integrity

6. Identify adults at highest risk for contracting influenza, pneumonia,

tuberculosis, and other respiratory infections.

7. Perform focused respiratory assessment and re-assessment.
8. Recognize manifestations of infectious respiratory diseases and inadequate gas exchange.
9. Implement appropriate interventions for the patient with a respiratory infection to ensure adequate gas exchange and oxygenation.

Disorders of the Nose and Sinuses

Rhinitis

Pathophysiology

Rhinitis, an inflammation of the nasal mucosa, is a common problem of the nose and often involves the sinuses. It can be caused by infection (viral or bacterial) or contact with allergens. An allergic rhinitis makes the mucous membranes more susceptible to bacterial invasion that may lead to infection.

Allergic rhinitis *(hay fever* or *allergies)* is triggered by hypersensitivity reactions to airborne allergens. Some episodes are "seasonal," recurring at the same time of year (Krouse & Krouse, 2014). *Perennial rhinitis* occurs intermittently with no seasonal pattern or continuously whenever the person is exposed to an offending allergen such as dust, animal dander, wool, or foods (e.g., seafood). Rhinitis also occurs as a "rebound" nasal congestion from overuse of nasal decongestant drops or sprays *(rhinitis medicamentosa)* and chronic nasal inhalation of cocaine.

Acute viral rhinitis (**coryza**, or the common cold) is caused by any of over 200 viruses. It spreads from person to person by droplets from sneezing or coughing and by direct contact. Colds are most contagious in the first 2 to 3 days after symptoms appear. Colds are self-limiting unless a bacterial infection occurs at the same time. Complications occur most often in immunosuppressed people and older adults.

Patient-Centered Collaborative Care

In allergic rhinitis, the presence of the allergen causes a release of histamine and other chemicals from basophils and mast cells in the nasal mucosa. These chemicals bind to blood vessel receptors, causing local blood vessel dilation and capillary leak, leading to local edema and swelling. Manifestations include headache, nasal irritation, sneezing, nasal congestion, **rhinorrhea** (watery drainage from the nose), and itchy, watery eyes.

Viral or bacterial invasion of the nasal passages causes the same local tissue responses as allergic rhinitis. Often the patient also has systemic manifestations, including a sore, dry throat; low-grade fever; and malaise.

Management of the patient with any type of rhinitis focuses on symptom relief and patient education. Teach him or her about correct use of the drug therapy prescribed.

Drug therapy commonly includes antihistamines, decongestants, and intranasal steroid spray (especially for chronic rhinitis). For severe

disease, immunotherapy can be used. *Antihistamines, leukotriene inhibitors,* and *mast cell stabilizers* block or reduce the amount of chemical mediators in nasal tissues and prevent local edema and itching. *Decongestants* constrict blood vessels and decrease edema. *Antipyretics* are given if fever is present. *Antibiotics* are prescribed only when a bacterial infection accompanies rhinitis. Rhinitis caused by overuse of nose drops or sprays is treated by discontinuing the drug.

Considerations for Older Adults

Patient-Centered Care QSEN

First-generation antihistamines are included as potentially inappropriate drugs for use in older adults. In this population, the drugs lead to problems with reduced clearance, higher risk for confusion, and anticholinergic effects such as dry mouth and constipation. Common drugs in this category include chlorpheniramine (Chlor-Trimeton), diphenhydramine (Benadryl), and hydroxyzine (Vistaril). Warn the older adult about these side effects.

Supportive therapy can increase the patient's comfort and help prevent spread of the infection. Instruct the patient about the importance of rest (8 to 10 hours a day) and fluid intake of at least 2000 mL/day unless other health problems require fluid restriction. Humidifying the air helps relieve congestion. Humidity can be increased with a room humidifier or by breathing steamy air in the bathroom after running hot shower water. If the condition is caused by allergies, limiting exposure to the offending agent is helpful (see Chapter 20).

Teach patients to reduce the risk for spreading colds by thoroughly washing hands, especially after nose blowing, sneezing, coughing, rubbing the eyes, or touching the face. Other precautions include staying home from work, school, or places where people gather; covering the mouth and nose with a tissue when sneezing or coughing; disposing properly of used tissues immediately; and avoiding close contact with others. Stress the need to avoid close contact with people who are more susceptible to infection, such as older adults, infants, and anyone who has a chronic respiratory problem. An uncomplicated cold typically subsides within 7 to 10 days.

Rhinosinusitis

Pathophysiology

Sinusitis is an inflammation of the mucous membranes of one or more of the sinuses and is usually associated with rhinitis. The preferred term for this condition is ***rhinosinusitis*** (Brook, 2013). Other conditions leading to rhinosinusitis include deviated nasal septum, nasal polyps or tumors, inhaled air pollutants or cocaine, facial trauma, and dental infection. Swelling can obstruct the flow of secretions from the sinuses, which may then become infected.

Most episodes of rhinosinusitis are caused by viruses and usually develop in the maxillary and frontal sinuses, although bacterial infections also can occur. Complications include cellulitis, abscess, and meningitis.

Diagnosis is made on the basis of the patient's history and manifestations. Other tests for rhinosinusitis include sinus x-rays, endoscopic examination, and computed tomography (CT). Bacterial sinusitis is usually indicated by purulent drainage from one or both nares, sometimes fever, and lack of response to decongestant therapy. Cultures are not usually necessary but may be useful in patients who do not respond to therapy or who develop complications.

Patient-Centered Collaborative Care

Assess for manifestations of rhinosinusitis. Common manifestations include pain over the cheek radiating to the teeth, tenderness to percussion over the sinuses, referred pain to the temple or back of the head, and general facial pain that is worse when bending forward. Additional manifestations that may accompany bacterial infection include purulent nasal drainage with postnasal drip, fever, erythema, swelling, fatigue, dental pain, and ear pressure.

Treatment for bacterial rhinosinusitis includes the use of broad-spectrum antibiotics (e.g., amoxicillin [Amoxil]), analgesics for pain (e.g., acetaminophen [Tylenol, Abenol, Atasol, Panadol]; ibuprofen [Advil]), decongestants (e.g., phenylephrine [Neo-Synephrine]), antipyretics, steam humidification, hot and wet packs over the sinus area, and nasal saline irrigations. In some cases, nasal steroids may be prescribed. Nasal saline irrigation is an inexpensive treatment with few side effects (Thornton et al., 2011). Sleeping with the head of the bed elevated and avoiding cigarette smoke may reduce discomfort. Teach the patient to increase fluid intake unless another medical problem requires fluid restriction. If this treatment plan is not successful (no improvement seen within 48 hours), he or she may need further evaluation. Surgical intervention with endoscopic sinus surgery to relieve obstruction and promote sinus drainage may be needed if nonsurgical management fails

to provide relief.

Disorders of the Oral Pharynx and Tonsils

Pharyngitis

Pathophysiology

Pharyngitis, or "sore throat," is a common inflammation of the pharyngeal mucous membranes that often occurs with rhinitis and sinusitis. It accounts for up to 40 million office visits each year in the United States (Aung, 2013).

Acute pharyngitis can be caused by bacteria, viruses, other organisms, trauma, irritants, dehydration, and tobacco or alcohol use. A common bacterium causing pharyngitis is group A beta-hemolytic *Streptococcus*, but most adult cases are caused by a virus (Acerra, 2014).

Patient-Centered Collaborative Care

Assessment

The patient with pharyngitis has throat soreness and dryness, throat pain, pain on swallowing *(odynophagia),* difficulty swallowing, and may have fever. Viral and bacterial pharyngitis are often difficult to distinguish on physical assessment. When inspecting a throat infected with either virus or bacteria, mild to severe redness may be seen with or without enlarged tonsils and with or without exudate. Ask about nasal discharge, which varies from thin and watery to thick and purulent. Enlargement of neck lymph nodes occurs with both viral and bacterial pharyngitis.

Bacterial infections are often associated with enlarged red tonsils, exudate, petechiae on the soft palate, purulent discharge, and local lymph node enlargement. Chart 31-1 compares the manifestations of viral and bacterial pharyngitis. Viral pharyngitis is contagious for 2 to 3 days. Symptoms usually subside within 3 to 10 days after onset, and the disease is usually self-limiting.

Chart 31-1 Key Features

Acute Viral and Bacterial Pharyngitis

FEATURE	VIRAL PHARYNGITIS	BACTERIAL PHARYNGITIS
Temperature	Low-grade or no fever	High temperature (>101° F [38.3° C] and usually 102°-104° F [38.9°-40° C])*
Ear manifestations	Retracted or dull tympanic membrane	Retracted or dull tympanic membrane
Throat manifestations	Scant or no tonsillar exudate Slight erythema of pharynx and tonsils	Severe hyperemia of pharyngeal mucosa, tonsils, tongue, and uvula Erythema of tonsils with yellow exudates Petechiae on the soft palate
Neck manifestations	Possible lymphadenopathy	Anterior cervical lymphadenopathy and tenderness
Skin manifestations	No rash	Possible scarlatiniform rash Possible petechiae on chest or abdomen or both
Dysphagia, odynophagia	Present	Present
Other symptoms	No cough Rhinitis Mild hoarseness Headache	No cough Pain on speaking and "hot potato" muffled voice Headache Arthralgia Myalgia
Laboratory data	Complete blood count usually normal White blood cell count usually ≤10,000/mm^3 Negative throat culture results	Complete blood count abnormal White blood cell count usually >12,000/mm^3* Throat culture results positive for beta-hemolytic *Streptococcus*
Onset	Gradual	Abrupt

*May not be present in adults older than 65 years.

Bacterial pharyngitis caused by group A streptococcal infection can lead to serious complications (Table 31-1), including acute glomerulonephritis and rheumatic fever. Acute glomerulonephritis may occur 7 to 10 days after the acute infection, and rheumatic fever may develop 3 to 5 weeks after the acute infection. Because rheumatic fever is rare, some experts question the need to prescribe antibiotics for all cases of pharyngitis (Acerra, 2014).

TABLE 31-1

Complications of Group A Streptococcal Infection

• Rheumatic fever • Acute glomerulonephritis • Peritonsillar abscess • Retropharyngeal abscess • Otitis media
• Sinusitis • Mastoiditis • Bronchitis • Pneumonia • Scarlet fever

Many types of rapid antigen tests (RATs) and screens for group A beta-hemolytic streptococcal antigen are available. These tests vary in specificity and sensitivity, and the results are available in less than 15 minutes. Two common tests are the Gen-Probe and the Optical Immunoassay (OIA).

In some cases, throat cultures can be important in distinguishing viral from a group A beta-hemolytic streptococcal infection. Usually 24 to 48 hours is required for results.

With either RAT or culture methods, it is essential to obtain throat specimens properly for an accurate test result. The organisms are not uniformly distributed throughout the throat and can be missed during swabbing. To obtain a specimen, rub a sterile cotton swab from a throat culture kit first over the right tonsillar area, moving across the right arch, the uvula, and then across the left arch to the left tonsillar area. Remove the swab without touching the patient's teeth, tongue, or gums. Consult with the laboratory for proper handling of the specimen. Send it to the laboratory as quickly as possible.

A complete blood count (CBC) may be performed when pharyngitis is severe or does not improve. Indications for a CBC are high fever, lethargy, or manifestations of complications.

Ask about the patient's recent contacts (within the past 10 days) with people who have been ill. Specifically ask whether he or she has been ill with manifestations of a cold or upper respiratory tract infection recently. Document any history of streptococcal infections, rheumatic fever, valvular heart disease, or penicillin allergy. Ask whether the patient has had a diphtheria immunization.

Interventions

Most sore throats in adults are viral, do not require antibiotic therapy, and respond to supportive interventions. Teach the patient to rest, increase fluid intake, humidify the air, and use analgesics for pain. Gargling several times each day with warm saline and using throat lozenges can increase comfort.

Management of bacterial pharyngitis involves antibiotics and the same supportive care as with viral pharyngitis. For streptococcal infection, an oral penicillin or cephalosporin is prescribed. Drugs from the macrolide class (e.g., azithromycin or erythromycin) are used if the patient is allergic to penicillin.

Nursing Safety Priority QSEN

Action Alert

Teach patients with any bacterial infection the importance of completing the entire antibiotic prescription, even when manifestations improve or subside. This action helps eradicate the organism and prevents development of resistant bacterial strains.

The patient should be re-evaluated if there is no improvement in 3

days or if manifestations are still present after completion of the antibiotic course. Any patient whose bacterial pharyngitis does not improve with antibiotics should consider human immune deficiency virus (HIV) testing.

A rare complication of pharyngitis is infection of the epiglottis and supraglottic structures (**epiglottitis**). The epiglottis is a flaplike structure that closes over the trachea during swallowing to prevent aspiration. An inflamed epiglottis can swell and obstruct the airway, inhibiting gas exchange and tissue perfusion.

Nursing Safety Priority QSEN

Critical Rescue

If a patient with pharyngitis develops stridor or other indications of airway obstruction, notify the Rapid Response Team. Teach patients at home to call 911 or go to the nearest emergency department if difficulty breathing, stridor, or drooling occurs.

Teach the patient with bacterial pharyngitis how to take his or her temperature every morning and evening until the infection resolves. He or she is not contagious after 24 hours of effective antibiotic therapy. Family members or close contacts who also have a sore throat should be evaluated.

Tonsillitis

Pathophysiology

Tonsillitis is an inflammation and infection of the tonsils and lymphatic tissues located on each side of the throat. The tonsils are lymphatic tissue shaped like small almonds. They are covered by mucous membranes and have small valleys *(crypts)* across their surface. Tonsils filter organisms and protect the respiratory tract from infection (McCance et al., 2014).

Tonsillitis is a contagious airborne infection that can occur in any age-group but is less common in adults. The disease usually lasts 7 to 10 days and often is caused by bacteria—most commonly *Streptococcus.* Viruses also cause tonsillitis. Chronic tonsillitis may result from an unresolved acute infection or recurrent infections.

Patient-Centered Collaborative Care

Chart 31-2 lists the manifestations of acute tonsillitis. Diagnostic tests

often used to rule out other causes of the sore throat and fever include a rapid antigen test (RAT), CBC, throat culture and sensitivity (C&S) studies, and Monospot test. If respiratory manifestations are present, chest x-rays may be needed. The white blood cell (WBC) count usually is elevated in bacterial infections and normal in viral infections.

Chart 31-2 Key Features

Acute Tonsillitis

- Sudden onset of a mild to severe sore throat
- Fever
- Muscle aches
- Chills
- Dysphagia, odynophagia (painful swallowing of food)
- Pain in the ears
- Headache
- Anorexia
- Malaise
- "Hot potato" voice (muffled voice)
- Tonsils visually swollen and red, possibly with pus
- Tonsils may be covered with a white or yellow exudate
- Purulent drainage may be expressed by pressing a tonsil
- Uvula visually edematous or inflamed
- Cervical lymph nodes usually tender and enlarged

Antibiotics, usually a non-penicillin drug, are prescribed for 7 to 10 days (Shah, 2014b). Nursing priorities include teaching the patient about supportive care and stressing the importance of completing antibiotic therapy. Teach him or her to rest, increase fluid intake, humidify the air, use analgesics for pain, gargle several times each day with warm saline, and use throat lozenges.

Surgical intervention for tonsillitis may be needed for recurrent acute or chronic infections, a peritonsillar abscess, and enlarged tonsils or adenoids that obstruct the airway. It is usually performed after the patient has recovered from an acute tonsillitis and no infection is present (except with an acute peritonsillar abscess). The procedure also may involve adenoid removal. A variety of techniques are used to remove tonsils from adults; however, the dissection and snare technique is still the most common and is performed under general anesthesia. After surgery, nursing interventions focus on assessing for airway clearance,

providing pain relief, and monitoring for excessive bleeding.

Peritonsillar Abscess

Peritonsillar abscess (PTA) is a complication of acute tonsillitis in which the infection spreads from the tonsil to the surrounding tissue and forms an abscess. The most common cause of PTA is group A beta-hemolytic *Streptococcus,* although they often contain multiple organisms (Shah, 2014a).

Manifestations include a collection of pus behind the tonsil causing one-sided swelling with deviation of the uvula toward the unaffected side. The patient may drool, have severe throat pain radiating to the ear, have a muffled voice, and have difficulty swallowing. He or she may also have a tonic contraction of the muscles of chewing (trismus) and have difficulty breathing. Bad breath is present, and lymph nodes on the affected side are swollen. An ultrasound or a CT scan may be used for diagnosis (Shah, 2014a).

Ambulatory care management with antibiotic therapy and percutaneous needle aspiration and drainage of the abscess is needed. Antibiotics alone are often ineffective. Acute management may include IV opioid analgesics for severe pain and IV steroids to reduce the swelling. *Stress the importance of completing the antibiotic regimen and of coming to the emergency department quickly if manifestations of obstruction (drooling and stridor) appear.* Hospitalization is needed when the airway is endangered or when the infection does not respond to antibiotic therapy. Incision and drainage of the abscess and additional antibiotic therapy may be needed. A tonsillectomy may be performed to prevent recurrence.

Disorders of the Lungs

Seasonal Influenza

Pathophysiology

Seasonal influenza, or "flu," is a highly contagious acute viral respiratory infection that can occur at any age. Epidemics are common and lead to complications of pneumonia or death, especially in older adults or immunocompromised patients. Between 5% and 20% of the U.S. population develop influenza each year, and up to 49,000 deaths in a single year have been attributed to it (Centers for Disease Control and Prevention [CDC], 2014b). Hospitalization may be required. Influenza may be caused by one of several virus families, referred to as *A, B,* and *C.*

The patient with influenza often has a rapid onset of severe headache, muscle aches, fever, chills, fatigue, and weakness. Adults are contagious from 24 hours before manifestations occur and up to 5 days after they begin. Sore throat, cough, and watery nasal discharge may follow the initial manifestations for a week or longer. Infection with influenza strain B also can cause nausea, vomiting, and diarrhea (Gould, 2011). Most patients feel fatigued for 1 to 2 weeks after the acute episode has resolved.

Health Promotion and Maintenance

Vaccinations for the prevention of influenza are widely available and are recommended for adults by The Joint Commission's National Patient Safety Goals (NPSGs). The vaccine is changed every year on the basis of which specific viral strains are most likely to pose a problem during the influenza season (i.e., late fall and winter in the Northern Hemisphere). Usually the vaccines contain three or four antigens for the three or four most expected viral strains (trivalent influenza vaccine [TIV]). Influenza vaccinations can be taken as an IM injection (Fluvirin, Fluzone) or as a live attenuated influenza vaccine (LAIV) by intranasal spray (FluMist). The intranasal vaccine is live, and some people develop influenza symptoms after its use. It is recommended only for healthy people up to 49 years of age. Yearly vaccination is recommended for those older than 50 years, people with chronic illness or immune compromise, those living in institutions, people living with or caring for adults with health problems that put them at risk for severe complications of influenza, and health care personnel providing direct care to patients (CDC, 2014b).

Teach the patient who is sick to reduce the risk for spreading the flu by thoroughly washing hands, especially after nose blowing, sneezing,

coughing, rubbing the eyes, or touching the face. Other precautions include staying home from work, school, or places where people gather; covering the mouth and nose with a tissue when sneezing or coughing; disposing properly of used tissues immediately; and avoiding close contact with other people. Although handwashing is a good method to prevent transmitting the virus in droplets from sneezing or coughing, many people cannot wash their hands as soon as they have coughed or sneezed. The technique recommended by the CDC for controlling flu spread is to sneeze or cough into the upper sleeve rather than into the hand (CDC, 2010a). (Respiratory droplets on the hands can contaminate surfaces and be transmitted to other people.)

Patient-Centered Collaborative Care

Viral infections do not respond to traditional antibiotic therapy. Antiviral agents may be effective for prevention and treatment of some types of influenza. Amantadine (Symmetrel) and rimantadine (Flumadine) have been effective in the prevention and treatment of some strains of influenza A. Ribavirin (Virazole) has been used for severe influenza B. Two drugs that shorten the duration of influenza A and influenza B are zanamivir (Relenza) and oseltamivir (Tamiflu). These drugs prevent viral spread in the respiratory tract by inhibiting a viral enzyme that allows the virus to penetrate respiratory cells. To be effective, they must be taken within 24 to 48 hours after the onset of manifestations. Zanamivir should be used with caution in patients who have chronic obstructive pulmonary disease (COPD) or asthma and in older adults (Dambaugh, 2012).

Advise the patient to rest for several days and increase fluid intake unless another problem requires fluid restriction. Saline gargles may ease sore throat pain. Antihistamines may reduce the rhinorrhea. Other supportive measures are the same as those for acute rhinitis.

NCLEX Examination Challenge

Safe and Effective Care Environment

The charge nurse at an assisted-living facility receives report from an emergency department (ED) nurse about one of the resident clients. The client was sent to the ED with a fever, chills, muscle aches, and headache. The ED nurse reports the client's rapid influenza report came back from the laboratory positive for influenza A. What action by the nurse at the assisted-living facility is most appropriate?

A Prepare to administer antibiotics.
B Have the resident eat meals in his room.
C Provide oseltamivir (Tamiflu) to the staff.
D Arrange a follow-up chest x-ray in 2 weeks.

Pandemic Influenza

Pathophysiology

Many viral infections among animals and birds are not usually transmitted to humans. A few notable exceptions have occurred when these animal and bird viruses mutated and became highly infectious to humans. These infections are termed **pandemic** because they have the potential to spread globally. Such pandemics include the 1918 "Spanish" influenza that resulted in 40 million to 100 million deaths worldwide. This virus, the H1N1 strain, also known as "swine flu," mutated and became highly infectious to humans. Most recently, the 2009 H1N1 influenza A resulted in a pandemic infection that spread to 215 countries. In the United States, the number of people infected with this virus during the pandemic is estimated at 61 million, resulting in more than 12,000 deaths (CDC, 2010b). A vaccine was developed in 2009 as a single antigen (monovalent) and was administered separately from the seasonal influenza vaccine. Now the trivalent seasonal vaccine contains the H1N1 antigen.

A new avian virus is the H5N1 strain, known as "avian influenza" or "bird flu," which has infected millions of birds, especially in Asia, and now has started to spread by human-to-human contact. World health officials are concerned that this strain could become a pandemic because humans have no naturally occurring immunity to this virus and it could lead to a worldwide pandemic with very high mortality rates. Another avian strain, H7N9, has appeared in China, resulting in several deaths but has not spread out of that region (CDC, 2014a).

Health Promotion and Maintenance

The prevention of a worldwide influenza pandemic of any virus is the responsibility of everyone. Health officials have been monitoring human outbreaks and testing both wild and domestic bird species throughout the world. A vaccine (Vepacel) is available but is stockpiled and not part of general influenza vaccination. The recommended early approach to disease prevention with H5N1 is early recognition of new cases and the implementation of community and personal quarantine and social-

distancing behaviors to reduce exposure to the virus.

Plans for prevention and containment in North America have been developed with the cooperation of most levels of government. When a cluster of cases is discovered in an area, the stockpiled vaccine is to be made available for immunization. Because vaccination with this vaccine is a two-step process with the first IM injection followed 28 days later by a second IM injection, additional prevention measures are needed (Medication Update, 2014; Plosker, 2012).

The antiviral drugs *oseltamivir* (Tamiflu) and *zanamivir* (Relenza) should be widely distributed. These drugs are not likely to prevent the disease but may reduce the severity of the infection and reduce the mortality rate. The infected patients must be cared for in strict isolation. All nonessential public activities in the area should be stopped, including public gatherings of any type, attendance at schools, religious services, shopping, and many types of employment. People should stay home and use the emergency preparedness food, water, and drugs they have stockpiled to last at least 2 weeks (see Chapter 10). Travel to and from this area should be stopped.

Urge all people to pay attention to public health announcements and early warning systems for disease outbreaks. Teach them the importance of starting prevention behaviors immediately upon notification of an outbreak. Teach all people to have a minimum of a 2-week supply of all their prescribed drugs and at least a 2-week supply of nonperishable food and water for each member of the household. They should also have a battery-powered radio (and batteries) to keep informed of updates in an active prevention situation. See Chapter 10 for more information on items to have ready in the home for disaster preparedness. *An influenza pandemic is a disaster, and containing it requires the cooperation of all people.*

❖ Patient-Centered Collaborative Care

The care priorities for the patient with avian or any pandemic influenza are supporting the patient and preventing spread of the disease. Both are equally important. The initial manifestations of avian influenza are similar to other respiratory infections—cough, fever, and sore throat. These progress rapidly to shortness of breath and pneumonia. In addition, diarrhea, vomiting, abdominal pain, and bleeding from the nose and gums occur. *Ask any patient with these manifestations if he or she has recently (within the past 10 days) traveled to areas of the world affected by H5N1. If such travel has occurred, coordinate with the health care team to place the patient in an airborne isolation room with negative air pressure. These precautions remain*

until the diagnosis of H5N1 is ruled out or the threat of contagion is over. Diagnosis is made based on clinical manifestations and positive testing. The most rapid test currently approved for testing of H5N1 is the AVantage A/H5N1 Flu Test. It can detect a specific protein (NS1), which indicates the presence of H5N1, from nasal or throat swabs in less than 40 minutes.

When providing care to the patient with avian influenza, personal protective equipment is essential. Coordinate the protection activity by ensuring that anyone entering the patient's room for any reason wears a fit-tested respirator or a standard surgical mask. Use other Airborne Precautions and Contact Precautions as described in Chapter 23. Teach others to self-monitor for disease manifestations, especially respiratory infection, for at least a week after the last contact with the patient. Use the antiviral drug *oseltamivir* (Tamiflu) or *zanamivir* (Relenza) within 48 hours of contact with the infected patient. All health care personnel working with patients suspected of having avian influenza should receive the vaccine in the recommended two-step process.

No effective treatment for this infection currently exists. Antibiotics and antiviral drugs cannot kill the virus or prevent its replication. Interventions are supportive to allow the patient's own immune system to fight the infection. Oxygen is given when hypoxia or breathlessness is present. Respiratory treatments to dilate the bronchioles and move respiratory secretions are used. If hypoxemia is not improved with oxygen therapy, intubation and mechanical ventilation may be needed. Antibiotics are used to treat a bacterial pneumonia that may occur with H5N1.

In addition to the need for respiratory support, the patient with H5N1 may have severe diarrhea and need fluid therapy. The Transmission Precautions may prevent the use of a scale to determine fluid needs by weight changes. Monitor the patient's hydration status, and carefully measure intake and output. The type of fluid therapy varies with the patient's cardiovascular status and blood osmolarity. The two most important areas to monitor during rehydration are pulse rate and quality and urine output.

Clinical Judgment Challenge

Prioritization, Delegation, and Supervision

The patient is a 67-year-old man with moderate emphysema. He has just been admitted to the medical unit with a diagnosis of shortness of

breath related to influenza. In the emergency department he received a chest x-ray and a nebulizer treatment with albuterol. He also had a saline lock placed, and arterial blood gases were sent to the laboratory. Vital signs before transfer were: BP, 158/92; HR, 92; RR, 32; T, 101.4° F.

The health care provider has prescribed:

- Schedule pulmonary function tests
- Obtain admission vital signs
- Tylenol 650 mg orally as needed
- Oxygen at 2 L per nasal cannula
- Nebulizer treatment with albuterol every 6 hours
- Intravenous antibiotic administration
- Use of incentive spirometer hourly
- Blood drawn for culture and sensitivity

1. Which order takes priority at this time? Provide a rationale for your choice.
2. Which action should you delegate to the unlicensed assistive personnel (UAP) who is helping you admit the patient? Provide a rationale for your choice.
3. The patient's Sa_{O_2} is 90% on admission. What action would you take at this time? Provide a rationale for your choice.
4. The patient continues to have an elevated temperature (now 102.4° F). Which actions should you delegate to the licensed practical nurse/licensed vocational nurse (LPN/LVN) working with you and why?

Pneumonia

Pathophysiology

Pneumonia is excess fluid in the lungs resulting from an inflammatory process. The inflammation is triggered by many infectious organisms and by inhalation of irritating agents. The inflammation occurs in the interstitial spaces, the alveoli, and often the bronchioles. The process begins when organisms penetrate the airway mucosa and multiply in the alveolar spaces. White blood cells (WBCs) migrate to the area of infection, causing local capillary leak, edema, and exudate. These fluids collect in and around the alveoli, and the alveolar walls thicken. Both events seriously reduce gas exchange and lead to hypoxemia, interfering with oxygenation and possibly leading to death. Red blood cells (RBCs) and fibrin move into the alveoli, and capillary leak spreads the infection to other areas of the lung. If the organisms move into the bloodstream, septicemia results; if the infection extends into the pleural cavity, **empyema** (a collection of

pus in the pleural cavity) results.

The fibrin and edema stiffen the lung, reducing compliance and decreasing the vital capacity. Alveolar collapse (atelectasis) further reduces the ability of the lung to oxygenate the blood moving through it. As a result, arterial oxygen levels fall, causing hypoxemia.

Pneumonia may occur as *lobar pneumonia* with **consolidation** (solidification, lack of air spaces) in a segment or an entire lobe of the lung or as *bronchopneumonia* with diffusely scattered patches around the bronchi. The extent of lung involvement depends on the host defenses. Bacteria multiply quickly in a person whose immune system is compromised. Tissue necrosis results when an abscess forms and perforates the bronchial wall.

Etiology

Pneumonia develops when the immune system cannot overcome the invading organisms. Organisms from the environment, invasive devices, equipment and supplies, staff, or other people can invade the body. Risk factors are listed in Table 31-2. Pneumonia can be caused by bacteria, viruses, mycoplasmas, fungi, rickettsiae, protozoa, and helminths (worms). Noninfectious causes of pneumonia include inhalation of toxic gases, chemical fumes, and smoke and aspiration of water, food, fluid (including saliva), and vomitus (Echevarria & Schwoebel, 2012). Pneumonia can be categorized as community-acquired (CAP), hospital-acquired (HAP), health care–associated (HCAP) or ventilator-associated (VAP) (Table 31-3).

TABLE 31-2

Risk Factors for Pneumonia

Community-Acquired Pneumonia

- Is an older adult
- Has never received the pneumococcal vaccination or received it more than 5 years ago
- Did not receive the influenza vaccine in the previous year
- Has a chronic health problem or other coexisting condition that reduces immune responses
- Has recently been exposed to respiratory viral or influenza infections
- Uses tobacco or alcohol or is exposed to high amounts of secondhand smoke

Health Care–Acquired Pneumonia

- Is an older adult
- Has a chronic lung disease
- Has presence of gram-negative colonization of the mouth, throat, and stomach
- Has an altered level of consciousness
- Has had a recent aspiration event
- Has presence of endotracheal, tracheostomy, or nasogastric tube
- Has poor nutritional status
- Has immunocompromised status (from disease or drug therapy)
- Uses drugs that increase gastric pH (histamine [H_2] blockers, antacids) or alkaline tube feedings
- Is currently receiving mechanical ventilation (ventilator-associated pneumonia [VAP])

TABLE 31-3

Differentiation of Types of Pneumonia

TYPE OF PNEUMONIA	DEFINITION	MANAGEMENT CONSIDERATIONS
Community acquired	Contracted outside a health care setting; acquired in the community	Most common bacterial agents: *Streptococcus pneumoniae, Haemophilus influenzae* Most common viral agents: influenza, respiratory syncytial virus (RSV) Antibiotics are often empirical based on multiple patient and environmental factors Treatment length: minimum of 5 days Prompt initiation of antibiotics required; in ED setting, first dose given before patient leaves unit for inpatient bed, or within 6 hours of presentation to the ED
Health care associated	Onset/diagnosis of pneumonia occurs <48 hours after admission in patient with specific risk factors: In hospital for >48 hours in the past 90 days Living in nursing home or assisted-living facility Received IV therapy, wound care, antibiotics, chemotherapy in the past 30 days Seen at a hospital or dialysis clinic within the past 30 days	May have multidrug-resistant organisms Hand hygiene is critical
Hospital acquired	Onset/diagnosis of pneumonia >48 hours after admission to hospital	Encourage pulmonary hygiene and progressive ambulation Provide adequate hydration Assess risk for aspiration using an evidence-based tool Monitor for early signs of sepsis Hand hygiene is critical
Ventilator associated	Onset/diagnosis of pneumonia within 48-72 hours after endotracheal intubation	Presence of ET tube increases risk for pneumonia by bypassing protective airway mechanisms and by allowing aspiration of secretions from the oropharynx and stomach; dental plaque also increases risk Initiate ventilator bundle order set, including: Elevate HOB at least 30 degrees Daily sedation "vacation" and weaning assessment DVT prophylaxis Oral care regimen Stress ulcer prophylaxis Suctioning; either as needed or continuous subglottal suction Hand hygiene is critical

DVT, Deep vein thrombosis; *ED,* emergency department; *ET,* endotracheal; *HOB,* head of bed.

Incidence and Prevalence

In the United States, 2 to 5 million cases of pneumonia occur each year and it is a major cause of death. The incidence is higher among older adults, nursing home residents, hospitalized patients, and those being mechanically ventilated. CAP is more common than HAP and occurs in late fall and winter, often as a complication of influenza.

Health Promotion and Maintenance

Patient education about vaccination is important in the prevention of pneumonia (Chart 31-3). The Joint Commission NPSGs require that nurses especially encourage people older than 65 years and those with a chronic health

problem to receive immunization against pneumonia. Antigens from 23 different types of pneumonia organisms are included in the pneumococcal polysaccharide vaccine (PPV23). This vaccine is usually given once; however, some experts believe that older adults and those with chronic health problems could benefit from a second vaccination if more than 5 years has passed since the first vaccination (American Lung Association [ALA], 2010a). Because pneumonia often follows influenza, especially among older adults, urge all people to receive the seasonal influenza vaccination yearly (Scott & Kardos, 2012).

Chart 31-3 Patient and Family Education: Preparing for Self-Management

Preventing Pneumonia

- Know whether you are at risk for pneumonia (older than 65 years, have a chronic health problem [especially a respiratory problem], or have limited mobility and are confined to a bed or chair during your waking hours).
- Have the annual influenza vaccine after discussing appropriate timing of the vaccination with your primary health care provider.
- Discuss the pneumococcal vaccine with your primary health care provider, and have the vaccination as recommended.
- Avoid crowded public areas during flu and holiday seasons.
- If you have a mobility problem, cough, turn, move about as much as possible, and perform deep-breathing exercises.
- If you are using respiratory equipment at home, clean the equipment as you have been taught.
- Avoid indoor pollutants, such as dust, secondhand (passive) smoke, and aerosols.
- If you do not smoke, do not start.
- If you smoke, seek professional help on how to stop (or at least decrease) your habit.
- Be sure to get enough rest and sleep on a daily basis.
- Eat a healthy, balanced diet.
- Drink at least 3 liters (quarts) of nonalcoholic fluids each day (unless fluid restrictions are needed because of another health problem).

Other prevention techniques include strict handwashing to avoid the spread of organisms and avoiding large gatherings of people during cold and flu season. Teach the patient who has a cold or the flu to see his or

her health care provider if fever lasts more than 24 hours, if the problem lasts longer than 1 week, or if manifestations worsen.

Respiratory therapy equipment must be well maintained and decontaminated or changed as recommended. Use sterile water rather than tap water in GI tubes, and institute Aspiration Precautions as indicated, including screening patients for aspiration risk.

VAP is on the rise, but the risk can be reduced with conscientious assessment and meticulous nursing care (Echevarria & Schwoebel, 2012; Roark, 2012; Scott & Kardos, 2012). The preventive care for VAP is discussed in detail in Chapter 32.

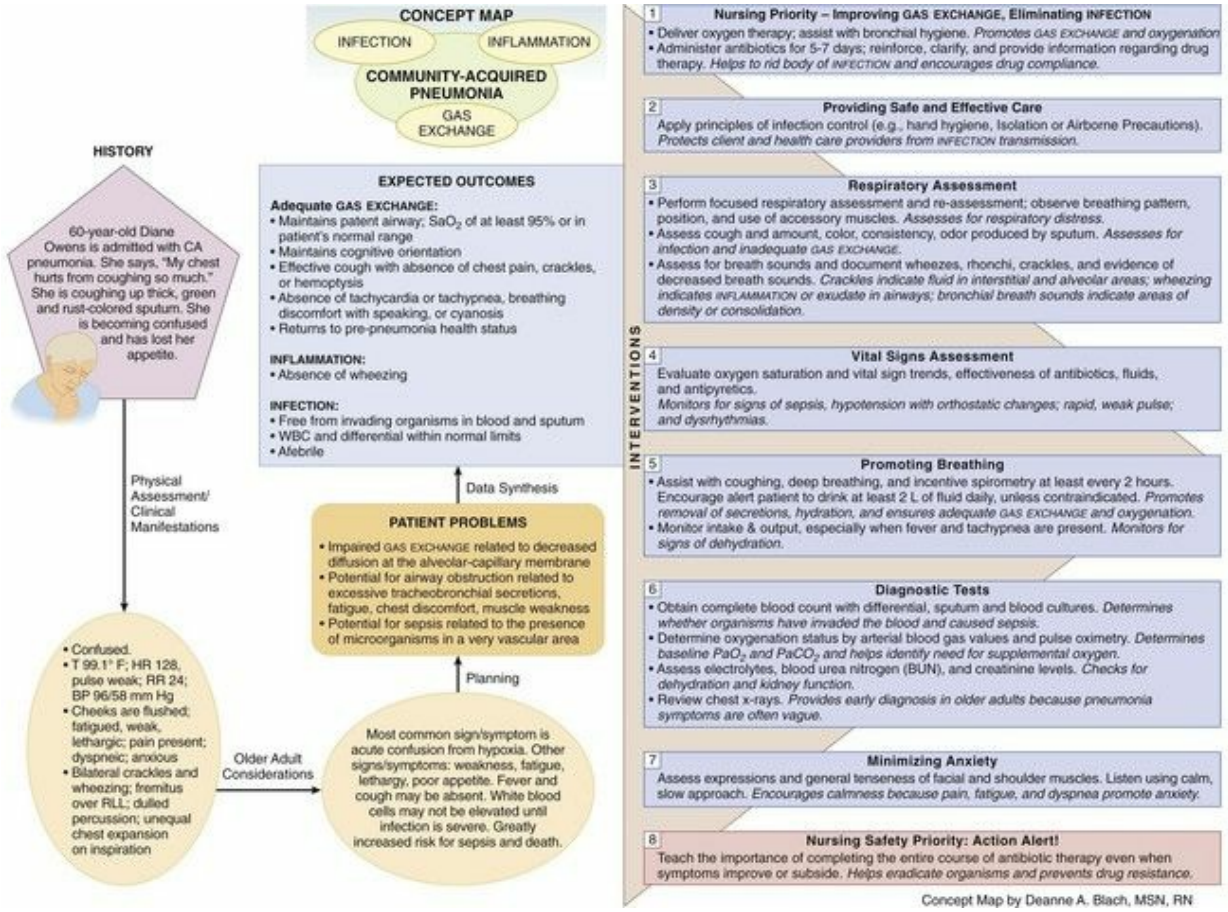
Nursing Safety Priority QSEN

Action Alert

Because pneumonia is a frequent cause of sepsis, use a sepsis screening tool to monitor patients who have pneumonia. For patients with pneumonia, always check oxygen saturation with vital signs.

Patient-Centered Collaborative Care

The Concept Map addresses assessment and nursing care issues related to patients who have pneumonia. The manifestations of pneumonia differ in older patients compared with younger patients.



Assessment

History.

Assess for the risk factors for infection (see Table 31-2). Document age; living, work, or school environment; diet, exercise, and sleep routines; swallowing problems; presence of a nasogastrointestinal tube; tobacco and alcohol use; and past and current use of or addiction to "street" drugs. Remember that often aspiration is "silent" with no manifestations. Ask about past respiratory illnesses and whether the patient has been exposed to influenza or pneumonia or has had a recent viral infection. Ask about recent skin rashes, insect bites, and exposure to animals.

If the patient has chronic respiratory problems, ask whether respiratory equipment is used in the home. Assess whether the patient's home cleaning level is adequate to prevent infection. Ask when he or she received the last influenza or pneumococcal vaccine.

Physical Assessment/Clinical Manifestations.

Observe the general appearance. Many patients with pneumonia have flushed cheeks and an anxious expression. The patient may have chest

pain or discomfort, myalgia, headache, chills, fever, cough, tachycardia, dyspnea, tachypnea, hemoptysis, and sputum production. Severe chest muscle weakness also may be present from sustained coughing.

Observe the patient's breathing pattern, position, and use of accessory muscles. The hypoxic patient may be uncomfortable in a lying position and will sit upright, balancing with the hands (“tripod position”). Assess the cough and the amount, color, consistency, and odor of sputum produced.

Crackles are heard with auscultation when fluid is in interstitial and alveolar areas, and breath sounds may be diminished. Wheezing may be heard if inflammation or exudate narrows the airways. Bronchial breath sounds are heard over areas of density or consolidation. Fremitus is increased over areas of pneumonia, and percussion is dulled. Chest expansion may be diminished or unequal on inspiration.

In evaluating vital signs, compare the results with baseline values. The patient with pneumonia is often hypotensive with orthostatic changes as a result of vasodilation and dehydration, especially the older adult. A rapid, weak pulse may indicate hypoxemia, dehydration, or impending sepsis and shock. Dysrhythmias may occur as a result of cardiac tissue hypoxia. Common pneumonia manifestations and their causes are listed in Table 31-4.

TABLE 31-4

Pathophysiology of Common Clinical Manifestations of Pneumonia

CLINICAL MANIFESTATION	PATHOPHYSIOLOGY
Increased respiratory rate/dyspnea	Stimulation of chemoreceptors Increased work of breathing as a result of decreased lung compliance Stimulation of J receptors Anxiety Pain
Hypoxemia	Alveolar consolidation Pulmonary capillary shunting
Cough	Fluid accumulation in the receptors of the trachea, bronchi, and bronchioles
Purulent, blood-tinged, or rust-colored sputum	A result of the inflammatory process in which fluid from the pulmonary capillaries and red blood cells moves into the alveoli
Fever	Phagocytes release pyrogens that cause the hypothalamus to increase body temperature
Pleuritic chest discomfort	Inflammation of the parietal pleura causes pain on inspiration

Use an evidence-based pneumonia severity scale to assist in determining what treatment site is appropriate for the patient. Two such tools are the Pneumonia Severity Index (PSI) and the CURB-65. The PSI uses four risk categories (demographics, comorbid conditions, physical examination, and selected laboratory values) to determine a score reflective of the severity of the patient's pneumonia, whereas the CURB-65 relies on laboratory values (blood urea nitrogen [BUN], age,

respirations, blood pressure, and presence of confusion (Scott & Kardos, 2012).

Considerations for Older Adults

Patient-Centered Care QSEN

The older adult with pneumonia has weakness, fatigue, lethargy, confusion, and poor appetite. Fever and cough may be absent, but hypoxemia is often present. The most common manifestation of pneumonia in the older adult patient is acute confusion from hypoxia. The WBC count may not be elevated until the infection is severe. Waiting to treat the disease until more typical manifestations appear greatly increases the risk for sepsis and death (Touhy & Jett, 2014).

Psychosocial Assessment.

The patient with pneumonia often has pain, fatigue, and dyspnea, all of which promote anxiety. Assess anxiety by looking at his or her facial expression and general tenseness of facial and shoulder muscles. Listen to the patient carefully, and use a calm approach. Because of airway obstruction and muscle fatigue, the patient with dyspnea speaks in broken sentences. Keep the interview short if severe dyspnea or breathing discomfort is present.

Laboratory Assessment.

Sputum is obtained and examined by Gram stain, culture, and sensitivity testing; however, the responsible organism often is not identified. A sputum sample is easily obtained from the patient who can cough into a specimen container. Extremely ill patients may need suctioning to obtain a sputum specimen. In these situations, a specimen is obtained by sputum trap (Fig. 31-1) during suctioning. A CBC is obtained to assess an elevated WBC count, which is a common finding except in older adults. Blood cultures may be performed to determine whether the organism has invaded the blood.

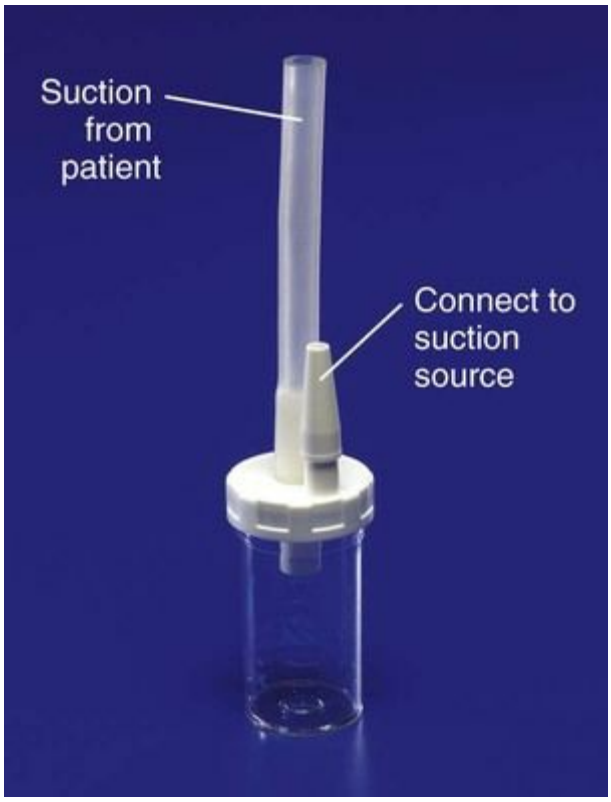


FIG. 31-1 A Lukens tube for collection of sterile sputum/mucus specimens.

In severely ill patients, arterial blood gases (ABGs) and serum lactate levels may be assessed to determine baseline arterial oxygen and carbon dioxide levels and help identify a need for supplemental oxygen. Serum electrolyte, blood urea nitrogen (BUN), and creatinine levels also are assessed. A high BUN level may occur as a result of dehydration. Hypernatremia (high blood sodium levels) occurs with dehydration.

Imaging Assessment.

Chest x-ray is the most common diagnostic test for pneumonia but may not show changes until 2 or more days after manifestations are present. It usually appears on chest x-ray as an area of increased density. It may involve a lung segment, a lobe, one lung, or both lungs. *In the older adult, the chest x-ray is essential for early diagnosis because pneumonia manifestations are often vague* (Touhy & Jett, 2014).

Other Diagnostic Assessments.

Pulse oximetry is used to assess for hypoxemia. Invasive tests such as transtracheal aspiration, bronchoscopy, or direct needle aspiration of the lung may be needed. Thoracentesis is used in patients who have an accompanying pleural effusion.

◆ Analysis

The priority NANDA-I nursing diagnoses and collaborative problems for patients with pneumonia include:
1. Impaired Gas Exchange related to decreased diffusion at the alveolar-capillary membrane (NANDA-I)
2. Potential for airway obstruction related to excessive tracheobronchial secretions, fatigue, chest discomfort, muscle weakness
3. Potential for sepsis related to the presence of microorganisms in a very vascular area

Planning and Implementation

Improving Gas Exchange

Planning: Expected Outcomes.

The patient with pneumonia is expected to have adequate gas exchange and oxygenation. Indicators of adequacy are:
- Maintenance of Sa_{O_2} of at least 95% or in the patient's normal range
- Absence of cyanosis
- Maintenance of cognitive orientation

Interventions.

Interventions to improve gas exchange and oxygenation are similar to those for the patient with chronic airflow limitation (CAL) (see Chapter 30). Nursing priorities include delivery of oxygen therapy and assisting the patient with bronchial hygiene.

Oxygen therapy is usually delivered by nasal cannula or mask unless the hypoxemia does not improve with these devices. The patient who is confused may not tolerate a facemask. Check the skin under the device and under the elastic band, especially around the ears, for areas of redness or skin breakdown. Actions for oxygen therapy are listed in Chart 28-1 in Chapter 28.

Incentive spirometry is used to improve inspiratory muscle action and to prevent or reverse atelectasis (alveolar collapse). Instruct the patient to exhale fully, then place the mouthpiece in his or her mouth, and then take a long, slow, deep breath for 3 to 5 seconds. Evaluate technique, and record the volume of air inspired. Teach the patient to perform 5 to 10 breaths per session every hour while awake.

Preventing Airway Obstruction

Planning: Expected Outcomes.

The patient with pneumonia is expected to maintain a patent airway. Indicators are:
- Effective cough
- Absence of pallor or cyanosis
- Absence of crackles and wheezes on auscultation
- Pulse oximetry at or above 95%

Interventions.

Interventions to avoid airway obstruction in pneumonia are similar to those for chronic obstructive pulmonary disease (COPD) or asthma. Because of fatigue, muscle weakness, chest discomfort, and excessive secretions, the patient often has difficulty clearing secretions. Help him or her cough and deep breathe at least every 2 hours. The alert patient may use an incentive spirometer to facilitate deep breathing and stimulate coughing. Encourage the alert patient to drink at least 2 liters of fluid daily to prevent dehydration unless another health problem requires fluid restriction. Monitor intake and output, oral mucus membranes, and skin turgor to assess hydration status, especially when fever and tachypnea are present.

Bronchodilators, especially beta$_2$ agonists (see Chart 30-6 in Chapter 30), are prescribed when bronchospasm is present. They are initially given by nebulizer and then by metered dose inhaler. Inhaled or IV steroids are used with acute pneumonia when airway swelling is present. Expectorants such as guaifenesin (Mucinex) may be used.

Preventing Sepsis

Planning: Expected Outcomes.

The patient with pneumonia is expected to be free of the invading organism and to return to a pre-pneumonia health status. Indicators are:
- Absence of fever
- Absence of pathogens in blood and sputum cultures
- WBC count and differential within normal limits

Interventions.

The key to effective treatment of pneumonia is eradication of the infecting organism. When sepsis occurs with pneumonia, the risk for death is high. Anti-infectives are given for all types of pneumonias except those caused by viruses. Which anti-infective therapy is prescribed is based on how the pneumonia was acquired (i.e., CAP, HAP, or HCAP). The exact drug or drugs and their routes of delivery are determined by

the severity of the infection, the organism suspected or identified, and whether the patient has other conditions or factors that increase the risk for complications. Drug therapy choices must reflect the degree of drug resistance in the specific geographic area and in that hospital setting.

The course of anti-infective therapy varies with the drug used and the organism(s) involved. Usually anti-infectives are used for 5 to 7 days for a patient with uncomplicated CAP and up to 21 days for an immunocompromised patient or one with HAP.

Drug resistance is becoming increasingly common, especially for infections with *Streptococcus pneumoniae* (drug-resistant *Streptococcus pneumoniae* [DRSP]). It is most common in people older than 65 years and among those who became infected as a result of exposure to young children from a day-care environment.

For pneumonia resulting from aspiration of food or stomach contents, interventions focus on preventing lung damage and treating the infection. Aspiration of acidic stomach contents can cause widespread inflammation, leading to acute respiratory distress syndrome (ARDS) and permanent lung damage. In these conditions, steroids and NSAIDs are used with antibiotics to reduce the inflammatory response.

NCLEX Examination Challenge

Physiological Integrity

A nurse is caring for an 89-year-old client admitted with pneumonia. He has an IV of normal saline running at 100 mL/hr and antibiotics that were initiated in the emergency department 3 hours ago. He has oxygen at 2 liters/nasal cannula. What assessment finding by the nurse indicates that goals for a priority diagnosis have been met for this client?

A The client is alert and oriented to person, place, and time.
B Blood pressure is within normal limits and client's baseline.
C Skin behind the ears demonstrates no redness or irritation.
D Urine output has been >30 mL/hr per Foley catheter.

Community-Based Care

The patient needs to continue the anti-infective drugs as prescribed. An important nursing role is to reinforce, clarify, and provide information to the patient and family as needed.

Home Care Management.

No special changes are needed in the home. If the home has a second

story, the patient may prefer to stay on one floor for a few weeks, because stair climbing can be tiring. Toileting needs may be met by using a bedside commode if a bathroom is not located on the level the patient is using. Home care needs depend on the patient's level of fatigue, dyspnea, and family and social support.

The long recovery phase, especially in the older adult, can be frustrating. Fatigue, weakness, and a residual cough can last for weeks. Some patients fear they will never return to a "normal" level of functioning. Prepare them for the disease course, and offer reassurance that complete recovery will occur. After discharge, a home nursing assessment may be helpful (Chart 31-4).

Chart 31-4 Focused Assessment

The Patient Recovering from Pneumonia

Ask whether the patient has had any of these:

- New-onset confusion
- Chills
- Fever
- Persistent cough
- Dyspnea
- Wheezing
- Hemoptysis
- Increased sputum production
- Chest discomfort
- Increasing fatigue
- Any other symptoms that have failed to resolve

Assess the patient for:

- Fever
- Diaphoresis
- Cyanosis, especially around the mouth or conjunctiva
- Dyspnea, tachypnea, or tachycardia
- Adventitious or abnormal breath sounds
- Weakness

Self-Management Education.

Review all drugs with the patient and family, and emphasize completing anti-infective therapy. Teach the patient to notify the health care provider if chills, fever, persistent cough, dyspnea, wheezing, hemoptysis, increased sputum production, chest discomfort, or increasing fatigue

recurs or fails to resolve. Instruct him or her to get plenty of rest and increase activity gradually.

An important aspect of education for the patient and family is the avoidance of upper respiratory tract infections and viruses. Teach him or her to avoid crowds (especially in the fall and winter when viruses are prevalent), people who have a cold or flu, and exposure to irritants such as smoke. Stress the importance of following his or her health care provider's recommendations for vaccination against influenza and pneumonia. A balanced diet and adequate fluid intake are essential.

Health Care Resources.

Inform patients who smoke that smoking is a risk factor for pneumonia. Provide them with information on local smoking-cessation classes and nicotine replacement options as required by The Joint Commission's NPSGs (see Chapter 27). Provide information booklets on pneumonia, and urge the patient who has not already been vaccinated against influenza or pneumonia to take this preventive measure after the pneumonia has resolved.

Nursing Safety Priority QSEN

Drug Alert

Warn the patient using nicotine patches or supplements of the danger of myocardial infarction if smoking is continued while using other forms of nicotine.

Evaluation: Outcomes

Evaluate the care of the patient with pneumonia based on the identified priority patient problems. The expected outcomes are that he or she:

- Attains or maintains adequate gas exchange
- Maintains patent airways
- Is free of the invading organism
- Returns to his or her pre-pneumonia health status

Specific indicators for these outcomes are listed for each priority patient problem under the Planning and Implementation section (see earlier).

Clinical Judgment Challenge

Evidence-Based Practice; Patient-Centered Care QSEN

The nurse is caring for a frail, older patient in the hospital after surgery to repair a bowel obstruction. The patient has a nasogastric (NG) tube to suction, through which all her scheduled drugs are given, oxygen at 1 liter/nasal cannula at night (home order), an indwelling urinary catheter, and a saline lock. The patient is weak and fatigued, has pain not relieved by IV opioids, and is reluctant to participate in any activities.

1. What risk factors does this patient have for developing pneumonia?
2. What actions does the nurse take to decrease the patient's risk for pneumonia?
3. Two days later, the NG tube is removed and the patient is started on ice chips and other clear liquids. The patient swallows repeatedly when given sips of water. What action does the nurse perform?
4. The nurse does hourly rounds on the patient, and the patient's daughter states, "Something is just not right with mom." What action should the nurse take first? What other actions should the nurse perform?
5. The physician orders a chest x-ray, and the results show pneumonia. What actions by the nurse are most important?

Severe Acute Respiratory Syndrome (SARS)

Severe acute respiratory syndrome (SARS) is a respiratory infection first identified in China early in November 2002. The cause of SARS is a new virus from a family of virus types known as *coronaviruses.* This family of viruses causes many forms of the common cold. The new virus, known as *SARS Co-V,* is a mutated form of the coronavirus and is very virulent. It infects cells of the respiratory tract, triggering inflammation, and stays in the respiratory passageways rather than spreading into the blood.

The virus is easily spread by airborne droplets from infected people through sneezing, coughing, and talking. People at greatest risk for SARS are those in close direct contact with an infected person. The portals of entry are the mucous membranes of the eyes, nose, and mouth.

No new cases of SARS have been reported since 2004. There is no vaccination to prevent the disease, and no known effective treatment exists at this time. If such an outbreak were to occur, the same types of precautions used to prevent infection spread for an avian influenza outbreak, discussed on p. 588, would be used. Patients diagnosed with or suspected of having SARS would be managed with supportive care under strict Airborne and Contact Precautions plus eye protection.

A disease similar in some respects to SARS, and also caused by a coronavirus *(MERS-CoV),* is MERS (Middle East respiratory syndrome).

The first U.S. case of MERS, which originates in the Arabian peninsula, appeared in May 2014. Although SARS is considered more infectious, MERS has a higher mortality rate because patients progress to respiratory failure faster with MERS than with SARS, (Barclay, 2013; CDC, 2014d; Todd, 2014).

Nursing Safety Priority QSEN

Action Alert

When performing procedures for the patient with SARS that normally induce coughing or promote aerosolization of particles (e.g., suctioning, using a positive-pressure facemask, obtaining a sputum culture, or giving aerosolized treatments), protect yourself and other health care workers. Wear a disposable particulate mask respirator and protective eyewear during the procedures. Keep the door to the patient's room closed. Avoid touching your face with contaminated gloves. Wash your hands after you remove the gown, gloves, eyewear, and face shield and whenever you leave the patient's room. Wear gloves when disinfecting contaminated surfaces or equipment.

Pulmonary Tuberculosis

Pathophysiology

Tuberculosis (TB) is a highly communicable disease caused by *Mycobacterium tuberculosis*. It is one of the most common bacterial infections worldwide (CDC, 2014c). The organism is transmitted via **aerosolization** (i.e., an airborne route) (Fig. 31-2). When a person with active TB coughs, laughs, sneezes, whistles, or sings, droplets are airborne and may be inhaled by others. Far more people are infected with the bacillus than actually develop active TB.

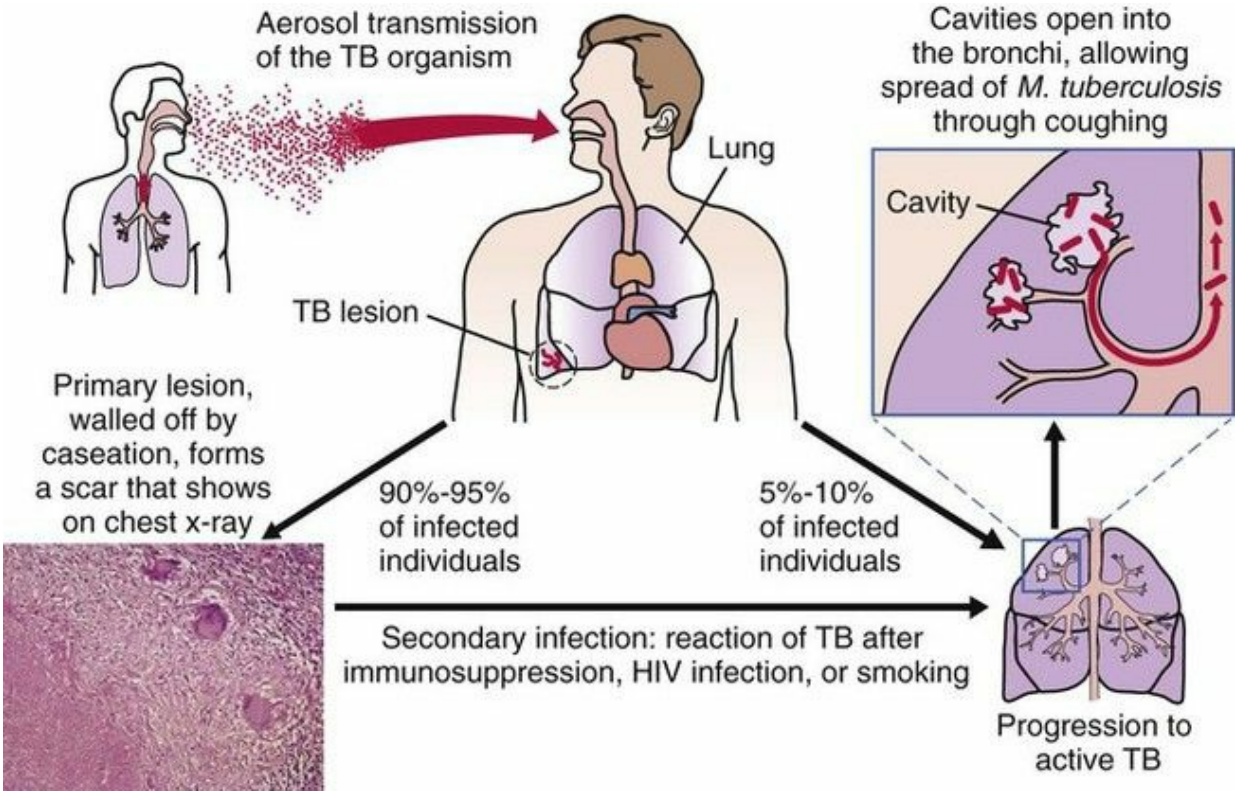

FIG. 31-2 Primary TB infection with progression to secondary infection and active disease. *HIV,* Human immune deficiency virus; *M. tuberculosis, Mycobacterium tuberculosis;* TB, tuberculosis.

The bacillus multiplies freely when it reaches a susceptible site (bronchi or alveoli). An exudative response occurs, causing pneumonitis. With the development of acquired immunity, further growth of bacilli is controlled in most initial lesions. These lesions usually resolve and leave little or no residual bacilli. Only a small percentage of people initially infected with the bacillus ever develop active TB.

Cell-mediated immunity develops 2 to 10 weeks after infection and is manifested by a positive reaction to a tuberculin test. The primary infection may be so small that it does not appear on a chest x-ray. The process of infection occurs in this order:

1. The granulomatous inflammation created by the TB bacillus in the lung becomes surrounded by collagen, fibroblasts, and lymphocytes.
2. **Caseation necrosis,** which is necrotic tissue being turned into a granular mass, occurs in the center of the lesion. If this area shows on x-ray, it is the *primary* lesion.

Areas of caseation then undergo resorption, degeneration, and fibrosis. These necrotic areas may calcify *(calcification)* or liquefy *(liquefaction).* If liquefaction occurs, this material then empties into a bronchus and the evacuated area becomes a cavity *(cavitation).* Bacilli continue to grow in the necrotic cavity wall and spread via lymph

channels into new areas of the lung.

A lesion also may progress by direct extension if bacilli multiply rapidly during inflammation. The lesions may extend through the pleura, resulting in pleural or pericardial effusion. **Miliary** or **hematogenous TB** is the spread of TB throughout the body when a large number of organisms enter the blood. Many tiny nodules scattered throughout the lung are seen on chest x-ray. Other body areas can become infected as a result of this spread.

Initial infection is seen more often in the middle or lower lobes of the lung. The local lymph nodes are infected and enlarged. An asymptomatic period usually follows the primary infection and can last for years or decades before clinical symptoms develop. *An infected person is not infectious to others until manifestations of disease occur.*

Secondary TB is a reactivation of the disease in a previously infected person. It is more likely when defenses are lowered, such as with older adults and people with HIV disease. The upper lobes are the most common site of reactivation.

Etiology

M. tuberculosis is a slow-growing, acid-fast rod transmitted via the airborne route. People most often infected are those having repeated close contact with an infectious person who has not yet been diagnosed with TB. The risk for transmission is reduced after the infectious person has received proper drug therapy for 2 to 3 weeks, clinical improvement occurs, and acid-fast bacilli (AFB) in the sputum are reduced.

Incidence and Prevalence

Worldwide, 8.7 million people were diagnosed and an additional 1.4 million people died from TB in 2012 (WHO, 2014b). The incidence of TB has been steadily decreasing in North America, although increases in incidence are seen in many other countries (ALA, 2010b). In North America, the people who are at greatest risk for development of TB are:

- Those in constant, frequent contact with an untreated person
- Those who have decreased immune function or HIV
- People who live in crowded areas such as long-term care facilities, prisons, homeless shelters, and mental health facilities
- Older homeless people
- Abusers of injection drugs or alcohol
- Lower socioeconomic groups
- Foreign immigrants (especially from Mexico, the Philippines, Vietnam, China, Japan, and Eastern Mediterranean countries [WHO, 2014b])

Patient-Centered Collaborative Care

Assessment

Early detection of TB depends on subjective findings rather than on observable manifestations. TB has a slow onset, and patients are not aware of problems until the disease is advanced. *TB should be considered for any patient with a persistent cough or other manifestations compatible with TB, such as weight loss, anorexia, night sweats, hemoptysis, shortness of breath, fever, or chills.*

History.

Assess the patient's past exposure to TB. Ask about his or her country of origin and travel to foreign countries where incidence of TB is high. It is important to ask about the results of any previous tests for TB. Also ask whether the patient has had bacille Calmette-Guérin (BCG) vaccine, which contains attenuated tubercle bacilli. *Anyone who has received BCG vaccine within the previous 10 years will have a positive skin test that can complicate interpretation* (Heavey, 2013). Usually the size of the skin response decreases each year after BCG vaccination. These patients should be evaluated for TB with a chest x-ray or the QuantiFERON-TB Gold test.

Physical Assessment/Clinical Manifestations.

The patient with TB has progressive fatigue, lethargy, nausea, anorexia, weight loss, irregular menses, and a low-grade fever. Manifestations may have been present for weeks or months. Night sweats may occur with the fever. A cough with mucopurulent sputum, which may be streaked with blood, is present. Chest tightness and a dull, aching chest pain occur with the cough. Ask about, assess for, and document the presence of any of these manifestations to help with diagnosis, to establish a baseline, and to plan nursing interventions.

Chest examination does not provide conclusive evidence of TB. Dullness with percussion may be heard over the involved lung fields, as may bronchial breath sounds, crackles, and increased transmission of spoken or whispered sounds. Partial obstruction of a bronchus from the disease or compression by lymph nodes may produce localized wheezing.

Diagnostic Assessment.

A new rapid test for tuberculosis has been developed and approved by

the World Health Organization (2014b). This test is the fully automated nucleic acid amplification (NAA) test for tuberculosis. Results are available in less than 2 hours. Widespread use of this test is recommended by the CDC to replace other diagnostic methods for patients who are suspected to have TB.

Blood analysis by an enzyme-linked immunosorbent assay using the QuantiFERON-TB Gold (QFT-G) is a relatively rapid test for the presence of *M. tuberculosis.* Results are ready in 24 hours and are still used in acute care settings to determine whether a symptomatic patient has TB.

Sputum culture confirms the diagnosis. Enhanced TB cultures and automated mycobacterial cultures require 1 to 4 weeks to determine a positive or negative result. After drugs are started, sputum samples are obtained again to determine therapy effectiveness. Cultures are usually negative after 3 months of effective treatment.

The tuberculin test (Mantoux test) is the most commonly used reliable screening test of TB infection. A small amount (0.1 mL) of purified protein derivative (PPD) is placed intradermally in the forearm. An area of **induration** (localized swelling with hardness of soft tissue), not just redness, measuring 10 mm or greater in diameter 48 to 72 hours after injection indicates exposure to and possible infection with TB (Fig. 31-3). If possible, the site is re-evaluated after 72 hours because the incidence of false-negative readings is greater at 48 hours. *A positive reaction does not mean that active disease is present but indicates exposure to TB or the presence of inactive (dormant) disease.* A reaction of 5 mm or greater is considered positive in people with HIV infection. *A reduced skin reaction or a negative skin test does not rule out TB disease or infection of the very old or anyone who is severely immunocompromised.* Failure to have a skin response because of reduced immune function when infection is present is called **anergy.**

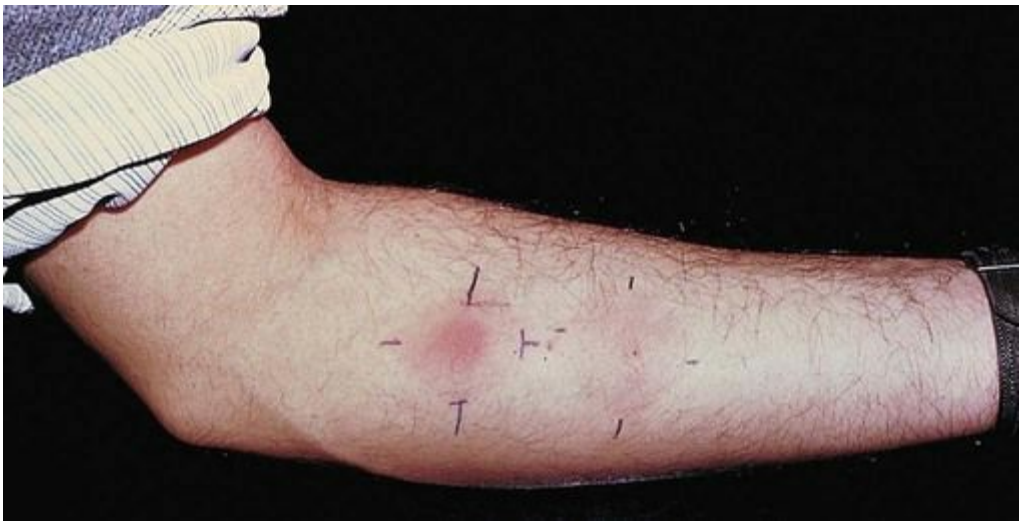

FIG. 31-3 Positive tuberculin skin test with induration.

Yearly screening is needed for anyone who comes into contact with people who may be infected with TB, including health care workers. Screening is very important for foreign-born people and migrant workers. Participation in screening programs is enhanced when programs are delivered in a culturally sensitive and nonthreatening manner. Urge anyone who is considered high risk to have an annual TB screening test.

Once a person's skin test is positive for TB, a chest x-ray is used to detect active TB or old, healed lesions. Caseation and inflammation may be seen on the x-ray if the disease is active. Instruct anyone who has manifestations of TB to seek medical attention. The chest x-rays of HIV-infected patients may be normal or may show infiltrates in any lung zone and lymph node enlargement.

Interventions

Combination drug therapy is the most effective method of treating TB and preventing transmission. Active TB is treated with a combination of drugs to which the organism is sensitive. Therapy continues until the disease is under control. The use of multiple-drug regimens destroys organisms as quickly as possible and reduces the emergence of drug-resistant organisms. First-line therapy uses isoniazid (INH) and rifampin (Rifadin) throughout the therapy; pyrazinamide is added for the first 2 months (Chart 31-5). This protocol shortens the therapy from 6 to 12 months to 6 months. Ethambutol (Myambutol) is the recommended fourth drug in first-line therapy. These drugs are now available in two-drug or three-drug combinations. One example is Rifater, which combines isoniazid, pyrazinamide, and rifampin. Variations of the first-line drugs along with other drug types are used when the patient does

not tolerate the standard first-line therapy. Nursing interventions focus on patient teaching for drug therapy adherence and infection control.

Chart 31-5 Common Examples of Drug Therapy

First-Line Treatment for Tuberculosis

DRUG/USUAL DOSAGE	PURPOSE/ACTION	NURSING INTERVENTIONS	RATIONALES
Isoniazid (INH) 200-300 mg orally daily or 600-900 mg orally twice each week	Kills actively growing mycobacteria outside the cell and inhibits the growth of dormant bacteria inside macrophages and caseating granulomas.	Teach the patient to take the drug on an empty stomach (1 hour before or 2 hours after meals) and to avoid antacids.	Food and antacids slow or prevent absorption of the drug from the GI tract.
		Teach the patient to take a daily multiple vitamin that contains the B-complex vitamins while on this drug.	Drug can deplete the body of this vitamin.
		Remind the patient to avoid drinking alcoholic beverages while on this drug.	The drug can cause liver damage. This effect is potentiated by alcohol.
		Teach the patient to report darkening of the urine, a yellow appearance to the skin or whites of the eyes, and an increased tendency to bruise or bleed.	These manifestations may indicate liver toxicity or failure.
Rifampin (RIF) 500-600 mg orally daily or twice each week	Kills slower-growing organisms, even those that reside in macrophages and caseating granulomas.	Teach the patient to expect the drug to stain the skin and urine and expect all other secretions to have a reddish orange tinge; also, soft contact lenses will become permanently stained.	This is an expected and harmless side effect of the drug and will clear some time after the patient stops taking the drug.
		Teach women using oral contraceptives to use an additional method of contraception while taking this drug and for 1 month after stopping the drug.	This drug reduces the effectiveness of oral contraceptives, increasing the risk for an unplanned pregnancy.
		Remind the patient to avoid drinking alcoholic beverages while on this drug.	The drug can cause liver damage. This effect is potentiated by alcohol.
		Teach the patient to report darkening of the urine, a yellow appearance to the skin or whites of the eyes, and an increased tendency to bruise or bleed.	These manifestations may indicate liver toxicity or failure.
		Ask the patient about all other drugs in use.	This drug interacts with many drugs.
Pyrazinamide (PZA) 1000-2000 mg orally daily or 3000-6000 mg orally twice each week	Is not inactivated by the acidic environment of macrophages and can effectively kill organisms residing within them.	Ask whether the patient has ever had gout.	This drug increases uric acid formation and will make gout worse.
		Teach the patient to drink at least 8 ounces of water when taking this tablet and to increase fluid intake.	More fluids help prevent uric acid from precipitating and causing gout or kidney problems.
		Teach the patient to wear protective clothing, a hat, and sunscreen when going outdoors in the sunlight.	The drug causes photosensitivity and greatly increases the risk for sunburn.
		Remind the patient to avoid drinking alcoholic beverages while on this drug.	The drug can cause liver damage. This effect is potentiated by alcohol.
		Teach the patient to report darkening of the urine, a yellow appearance to the skin or whites of the eyes, and an increased tendency to bruise or bleed.	These manifestations may indicate liver toxicity or failure.
Ethambutol (EMB) 750-1500 mg orally daily or 2500-5000 mg orally twice each week	Inhibits bacterial RNA synthesis, thus suppressing bacterial growth. It is slow-acting and is bacteriostatic rather than bactericidal. Thus it must be used in combination with other anti-TB drugs.	Remind the patient to avoid drinking alcoholic beverages while on this drug.	The drug induces severe nausea and vomiting when alcohol is ingested.
		Teach the patient to report any changes in vision, such as reduced color vision, blurred vision, or reduced visual fields, immediately to his or her health care provider.	The drug can cause optic neuritis, especially at high doses, and can lead to blindness. When the problem is discovered early, the eye problems are usually reversed when the drug is stopped.
		Ask whether the patient has ever had gout.	This drug increases uric acid formation and will make gout worse.
		Teach the patient to drink at least 8 ounces of water when taking this tablet and to increase fluid intake.	More fluids help prevent uric acid from precipitating and causing gout or kidney problems.

RNA, Ribonucleic acid.

Strict adherence to the prescribed drug regimen is crucial for suppressing the disease. Thus your major role is teaching the patient about drug therapy

and stressing the importance of taking each drug regularly, exactly as prescribed, for as long as it is prescribed. Provide accurate information in multiple formats, such as pamphlets, videos, and drug-schedule worksheets. To determine whether the patient understands how to take the drugs, ask him or her to describe the treatment regimen, side effects, and when to call the health care agency and physician.

Nursing Safety Priority QSEN

Drug Alert

The first-line drugs used as therapy for tuberculosis all can damage the liver. Warn the patient to not drink any alcoholic beverages for the entire duration of TB therapy. (Duration of therapy is usually 6 months but can be as long as 2 years for multidrug-resistant [MDR] TB).

The TB drugs may cause the patient to have nausea. Teach him or her to prevent nausea by taking the daily dose at bedtime. Antiemetics may also prevent this problem. Instruct him or her to eat a well-balanced diet that includes foods that are rich in iron, protein, and vitamins C and B. Collaborate with the registered dietitian for specialized needs.

The patient with TB has reduced physical stamina and also has concerns about the disease prognosis. Offer a positive outlook for the patient who adheres to the drug regimen. Tell him or her that fatigue will diminish as the treatment progresses. *With current resistant strains of TB, however, emphasize that not taking the drugs as prescribed could lead to an infection that is drug resistant.*

Some *multidrug-resistant TB* (MDR TB) strains are emerging as extensively drug-resistant (XDR TB). MDR TB is an infection that resists INH and rifampin. XDR TB is resistant not only to the first-line anti-tuberculosis drugs but also to the second-line antibiotics, including the fluoroquinolones and at least one of the aminoglycosides. In 2011, there were over 690,000 cases of MDR TB worldwide with 9% being XDR TB. The most common cause of MDR TB and XDR TB is mismanagement of drug therapy, either from inappropriate selection or use of antibiotics (WHO, 2013). Patients with acquired immune deficiency syndrome (AIDS) also often have MDR TB (CDC, 2013a). Drug therapy for MDR TB and XDR TB is more limited than standard first-line therapy and requires higher doses for longer periods. A new drug combination of bedaquiline, pyrazinamide, and moxifloxacin (Sirturo) was approved in 2012 to treat multidrug-resistant TB. Another drug, delaminid (OPC-67683), is in

clinical trials (Gler et al., 2012).

Nursing Safety Priority QSEN

Action Alert

Warn patients with extensively drug-resistant TB that absolute adherence to therapy is critical for survival and cure of the disease. These patients should receive directly observed therapy (DOT).

When teaching the patient and family with either MDR TB or XDR TB, stress that it is the organism, not the patient, that is drug resistant. So a person who acquires the infection and develops TB from a person who is infected with a resistant strain of bacillus will also have drug-resistant disease. Thus teaching infection control strategies is a priority and should be constantly reinforced.

NCLEX Examination Challenge

Health Promotion and Maintenance

A client has been admitted to the hospital with suspected TB. What drugs should the nurse plan to teach the client about before discharge? **Select all that apply.**

A Rifampin (Rifadin); contact lenses can become stained orange
B Isoniazid (INH); report yellowing of the skin or darkened urine
C Pyrazinamide (PZA); maintain a fluid restriction of 1200 mL/day
D Ethambutol (Myambutol); report any changes in vision
E Amoxicillin (Amoxil); take this drug with food or milk

Other care issues for the patient with TB include teaching about infection prevention and what to expect about disease monitoring and participating in activities. TB is often treated outside the acute care setting, with the patient convalescing in the home setting. Airborne Precautions are not necessary in this setting because family members have already been exposed; however, all members of the household need to undergo TB testing. Teach the patient to cover the mouth and nose with a tissue when coughing or sneezing, to place used tissues in plastic bags, and to wear a mask when in contact with crowds until the drugs suppress infection.

Tell the patient that sputum specimens are needed usually every 2 to 4 weeks once drug therapy is initiated. When the results of three

consecutive sputum cultures are negative, the patient is no longer infectious and may return to former employment. Remind him or her to avoid exposure to any inhalation irritants because these can cause further lung damage.

The hospitalized patient with active TB is placed on Airborne Precautions (see Chapter 23) in a well-ventilated room that has at least six exchanges of fresh air per minute. All health care workers must use a personal respirator when caring for the patient. When hand and clothing contamination is a risk, use Standard Precautions with appropriate contact protection (i.e., gowns and gloves). In accordance with The Joint Commission's NPSGs, perform handwashing before and after patient care. Precautions are discontinued when the patient is no longer infectious.

Community-Based Care

Home Care Management.

Most patients with TB are managed outside the hospital; however, patients may be diagnosed with TB while in the hospital for another problem. Discharge may be delayed if the living situation is high risk or if nonadherence is likely. Collaborate with the case manager or social service worker in the hospital or the community health nursing agency to ensure that the patient is discharged to the appropriate environment with continued supervision.

Self-Management Education.

Teach the patient to follow the drug regimen exactly as prescribed and always to have a supply on hand. Teach about side effects and ways of reducing them to promote adherence. Remind him or her that the disease is usually no longer contagious after drugs have been taken for 2 to 3 consecutive weeks and clinical improvement is seen; however, *he or she must continue with the prescribed drugs for 6 months or longer as prescribed.* **Directly observed therapy (DOT),** in which a health care professional watches the patient swallow the drugs, may be indicated in some situations. This practice leads to more treatment successes, fewer relapses, and less drug resistance.

The patient who has weight loss and severe lethargy should gradually resume usual activities. Proper nutrition is needed to prevent infection recurrence.

To help with concerns about the contagious aspect of the infection, provide the patient with information about TB. A key to preventing

transmission is identifying those in close contact with the infected person so that they can be tested and treated if needed. Identified contacts are assessed with a TB test and possibly a chest x-ray to determine infection status. Multidrug therapy may be indicated as a preventive strategy for heavily exposed individuals or for those who have other health problems that reduce the immune response.

Health Care Resources.

Teach the patient to receive follow-up care by a health care provider for at least 1 year during and after active treatment. The American Lung Association (ALA) can provide free information to the patient about the disease and its treatment. In addition, Alcoholics Anonymous (AA) and other health care resources for patients with alcoholism are available if needed. Assist the patient who uses illicit drugs to locate a drug treatment program. In accordance with The Joint Commission's NPSGs, urge smokers to quit, and assist them in finding an appropriate smoking-cessation program (see Chapter 27).

Lung Abscess

A lung abscess is a localized area of subacute infection and necrosis, which is usually related to pyogenic bacteria, and occurs most often in the lung parenchyma. Patients with an abscess often have a history of pneumonia, aspiration of stomach contents, or obstruction as a result of a tumor or foreign body. Other causes of aspiration leading to lung abscesses include any condition that alters the ability to swallow, such as alcoholic blackouts, seizure disorders, neurologic deficits, and swallowing disorders. Bronchial obstruction may cause a necrotizing process in the lung that eventually becomes an abscess (Kamanger, 2013).

Multiple abscesses and cavities form in patients with tuberculosis (TB) or fungal infections of the lung. Immunosuppressed patients, such as those receiving cancer chemotherapy or those with AIDS, are at high risk for fungal infections.

Ask the patient about any recent history of influenza, pneumonia, febrile illness, cough, and foul-smelling sputum production. Ask about the sputum color and odor and about any **pleuritic chest pain** (a stabbing pain upon taking a deep breath). Often the patient is febrile, pale, fatigued, and cachectic. Auscultation may reveal decreased breath sounds and dullness on percussion in the involved area. Bronchial breath sounds and crackles may be heard over the site of the lesion. A chest x-ray, sputum sample, and CBC are needed for diagnosis. TB testing should

be considered for patients at risk for or with this problem (Zwanger, 2013).

Problems and interventions for the patient with pneumonia also apply to the patient with a lung abscess. Management involves a long course of antibiotics that target organisms acquired by aspiration (Zwanger, 2013).

Pulmonary Empyema

Pulmonary empyema is a collection of pus in the pleural space most commonly caused by pulmonary infection, lung abscess, or infected pleural effusion (Zwanger, 2013). Infections in other body areas also can spread to the lungs by flow of infected lymph into the pleural space. Chest surgery or trauma can introduce bacteria directly into the pleural space, leading to empyema. Blood from trauma may collect in the pleural space, promoting infection.

History findings include febrile illness, pneumonia, chest pain, dyspnea, cough, and trauma. Document the character of the sputum. Chest wall motion may be reduced. If a pleural effusion is present, fremitus may be reduced or absent, percussion is flat, and breath sounds are decreased. Abnormal breath sounds, including bronchial breath sounds, egophony, and whispered pectoriloquy, also may be present. Often the patient has a fever, chills, night sweats, and weight loss.

A chest x-ray or CT scan and a sample of the pleural fluid (obtained via thoracentesis) are needed for diagnosis. Empyema fluid is thick, opaque, exudative, and foul smelling. The fluid is analyzed for color, red blood cell (RBC) count, white blood cell (WBC) count, glucose and protein levels, lactate dehydrogenase (LDH), and pH. Gram stains, acid-fast stains, culture and sensitivity, and cytology studies are also performed.

Therapy involves emptying the empyema cavity, re-expanding the lung, and controlling the infection. Appropriate antibiotics are prescribed. A chest tube(s) to closed-chest drainage is used to promote lung expansion and drainage. The tube is removed when the lung is fully expanded and the infection is under control. Chest surgery may be needed for thick pus or excessive pleural thickening. Nursing interventions are similar to those for patients with a pleural effusion, pneumothorax, or infection. Chapters 30 and 32 discuss these interventions in more detail.

Inhalation Anthrax

❖ Pathophysiology

Inhalation anthrax (respiratory anthrax) is a bacterial infection caused by

the gram-positive organism *Bacillus anthracis,* which lives as a spore in soil where grass-eating animals live and graze. Most cases of anthrax are on the skin (cutaneous). Inhalation anthrax accounts for only about 5% of cases, and GI anthrax accounts for about 1% of cases of the disease. When infection occurs through the lungs, the disease is nearly 100% fatal without treatment (Cunha, 2014). Inhalation anthrax is a rare natural occurrence in North America and is not spread by person-to-person contact. It is an occupational hazard of veterinarians, farmers, taxidermists, and others who come into frequent contact with animal wool, hides, bone meal, and skin (Cunha, 2014).

Nursing Safety Priority QSEN

Action Alert

Because inhalation anthrax is so rare, any occurrence in a person who does not have an occupational risk is considered an intentional act of bioterrorism. Report the presence of manifestations consistent with inhalation anthrax to hospital authorities immediately.

This organism first forms a **spore**—an encapsulated organism that is inactive. When many spores are inhaled deeply into the lungs, macrophages engulf them. Once inside the macrophage, the organism leaves its capsule and replicates. The active bacteria produce several toxins that are released into the infected tissues and the blood that make the infection worse. Massive edema occurs along with hemorrhage and destruction of lung cells. Infected macrophages carry the organisms to the lymph nodes, and the organism spreads rapidly, causing bacteremia, sepsis, and meningitis. Lethal toxins produced by the bacteria are the most common cause of death (Cunha, 2014).

Patient-Centered Collaborative Care

Inhalation anthrax is a two-stage illness—prodromal and fulminant. Manifestations may not begin until as long as 8 weeks after exposure to the organism (Chart 31-6).

Chart 31-6 Key Features

Inhalation Anthrax

Prodromal Stage (Early)	Fulminant Stage (Late)
• Fever • Fatigue • Mild chest pain • Dry cough • No manifestations of upper respiratory infection • Mediastinal "widening" on chest x-ray	• Sudden onset of breathlessness • Dyspnea • Diaphoresis • Stridor on inhalation and exhalation • Hypoxia • High fever • Mediastinitis • Pleural effusion • Hypotension • Septic shock

The prodromal stage is early and difficult to distinguish from influenza or pneumonia. Manifestations include low-grade fever, fatigue, mild chest pain, and a dry, harsh cough. *A special feature of inhalation anthrax is that it is* ***not*** *accompanied by upper respiratory manifestations of sore throat or rhinitis.* Usually the patient starts to feel better and manifestations improve in 2 to 4 days.

If the patient begins appropriate antibiotic therapy at this stage, the likelihood of survival is high. Diagnostic indicators are positive Gram stain of the serum and a mediastinal "widening" on chest x-ray as the local lymph nodes greatly enlarge. After several days, blood cultures may be positive for the organism and the genetic material of the bacteria may be detected through the amplification process of the polymerase chain reaction (PCR). Positive results for these definitive diagnostic tests may not be evident until the disease has progressed to the fulminant stage.

The fulminant stage begins after the patient feels a little better. Usually there is a sudden onset of severe illness, including respiratory distress, hematemesis (bloody vomit), dyspnea, diaphoresis, stridor, chest pain, and cyanosis. The patient has a high fever. Hemorrhagic mediastinitis and pleural effusions develop. The patient may be admitted with a decreased level of consciousness or frank shock. As the disease spreads through the blood, causing septic shock and hemorrhagic meningitis, death often occurs within 24 to 36 hours even if antibiotics are started in this stage (Cunha, 2014).

The naturally occurring organism is sensitive to common antibiotics; however, organisms grown for bioterrorism may have been altered to be resistant to these antibiotics. Therefore the antibiotics used for suspected or diagnosed inhalation anthrax include combination therapy (Chart 31-7). The same drugs are used for prophylaxis when people have been exposed to inhalation anthrax but do not yet have manifestations. A vaccine is available, but distribution is limited.

Chart 31-7 Common Examples of Drug Therapy

Prophylaxis and Treatment of Inhalation Anthrax

PROPHYLAXIS	TREATMENT
Ciprofloxacin (Cipro) 500 mg orally twice daily	Ciprofloxacin (Cipro IV) 400 mg IV every 12 hr
Or	*Or*
Doxycycline (Vibramycin) 100 mg orally twice daily	Doxycycline (Doxy 100) 100 mg IV every 12 hr
Or *(if organism is proven susceptible to penicillin)*	**Plus** *one or two of the following secondary agents (parenteral form (IV); dosage based on patient's weight and age):*
Amoxicillin (Amoxil, Trimox) 500 mg orally every 8 hr or 875 mg orally twice daily	Rifampin (RIF)
	Clindamycin (Cleocin)
	Vancomycin (Vancocin, Vancoled)
Prophylaxis must continue for 60 days (or longer if exposure was heavy).	Treatment with IV drugs continues for at least 7 days. When the response is good and the patient improves, IV drugs are changed to oral agents and are continued for at least 60 days.

Teach patients with any type of lower respiratory infection to be especially vigilant for changes after they think they are getting well. They need to seek medical attention immediately upon having a setback that starts with breathlessness.

Pertussis

Pertussis is a respiratory infection caused by the bacterium *Bordetella pertussis.* It is highly contagious and spreads easily from person to person via respiratory droplets. Once considered a childhood disease, a resurgence is occurring in adults, perhaps due to waning vaccination effectiveness (Bocka, 2014; CDC, 2012). In 2010, there were 27,550 new cases in the United States (CDC, 2012).

The disease occurs in three distinct phases. During the first *(catarrhal)* phase, the patient has manifestations resembling the common cold, including a mild cough. After 1 to 2 weeks, the *paroxysmal* stage begins and the patient has severe coughing "fits" lasting several minutes, during which the coughing spasms are accompanied by turning red and/or vomiting. The patient is frequently exhausted by the coughing. The distinct "whooping" sound common in children at the end of a cough may not be present in adults. This stage can last up to 10 weeks. The recovery *(convalescent)* stage can last for months. During the course of the disease, there is a bloody, purulent, mucinous exudate in the small airways that can lead to atelectasis and pneumonia (Bocka, 2014; Schweon, 2011).

The diagnosis of pertussis can be made clinically, but sputum cultures (obtained by deep suctioning) and PCR laboratory testing are available to aid the diagnosis. Blood cultures will be negative. The CDC recommends testing for anyone who has a cough lasting longer than 3 weeks (Bocka,

2014).

Coccidioidomycosis

Coccidioidomycosis is a fungal infection caused by the *Coccidioides* organism that is common in the desert southwest regions of the United States, Mexico, and Central and South America. It is also known as "valley fever," and the incidence is on the rise. The organism is present in the soil as inactive and non-reproducing microfilaments. When the soil is disturbed by excavation or dust storms, the microfilaments become airborne. As the microfilaments are inhaled, they change into the reproductively active spore form of the organism, which can lead to development of an actual pulmonary infection within 1 to 4 weeks after exposure (Buhrow, 2013).

Manifestations of the infection resemble other respiratory viral or bacterial infections with fever, cough, headache, muscle aches, chest pain, and night sweats. The presence of bone and joint pain indicates more severe infection. Often the disorder is misdiagnosed and mistreated as influenza or pneumonia. Neither antibacterial drugs nor antiviral drugs are effective in managing this infection. The disease can become widespread and cause manifestations of hemoptysis, meningitis, and involvement of the skin, adrenal glands, liver, and spleen. It also can become chronic and debilitating with low-grade fever, weight loss, fatigue, chronic cough, and chest pain.

Depending on the health of the infected person and the number of spores present in the respiratory tract, the resulting infection can be mild, moderate, severe, or widely disseminated. Most younger healthy people recover from the infection without treatment. For moderate infection, oral therapy with antifungal agents from the azole class (e.g., fluconazole [Diflucan], ketoconazole [Nizoral], voriconazole [Vfend]) is needed. For those with severe disease or women who are pregnant, IV amphotericin B may be needed. Because the infection is not spread from person to person, Isolation Precautions are not required.

In endemic areas, people working in the soil, such as farm workers or construction workers, are at highest risk for the infection. Older adults and anyone who has reduced immune competence, as well as pregnant women, also are at increased risk for developing more severe disease. Because the areas that naturally harbor this organism are often winter vacation destinations, always ask anyone with respiratory infection manifestations whether they have visited endemic regions so that the possibility of coccidioidomycosis is considered.

What might you NOTICE if the patient is experiencing inadequate gas exchange and oxygenation as a result of a respiratory infection?

- Respirations rapid and shallow
- Decreased oxygen saturation by pulse oximetry
- Tachycardia
- Skin cyanosis or pallor (in lighter-skinned patients)
- Cyanosis or pallor of the lips and oral mucous membranes (in patients of any skin color)
- Patient appears to work hard to breathe
- Patient is restless, anxious, or confused

What should you INTERPRET and how should you RESPOND to a patient experiencing inadequate gas exchange and oxygenation as a result of a respiratory infection?

Perform and interpret physical assessment, including:

- Taking vital signs
- Monitoring oxygen saturation by pulse oximetry
- Auscultating all lung fields
- Checking the accuracy of pulse oximetry readings
- Assessing cognition
- Assessing for the presence and characteristics of sputum production
- Assessing the patient's ability to cough and clear the airway

Interpret laboratory values:

- Elevated white blood cell count
- Arterial blood gas values: pH lower than 7.35, HCO_3^- at or below 24 mEq/L, Pa_{CO_2} at or below 45 mm Hg; Pa_{O_2} below 90 mm Hg; serum lactate levels above 8 mg/dL

Respond by:

- Administering oxygen
- Assisting the patient to an upright position, with arms resting on a table or armrests
- Prioritizing and pacing activities to prevent fatigue
- Administering prescribed IV, oral, or inhaled drugs
- Ensuring respiratory therapy treatments are administered
- Re-assessing respiratory status after respiratory therapy treatment

- Ensuring a fluid intake of at least 2 liters per day (unless contraindicated)

On what should you REFLECT?

- Observe patient for evidence of improved gas exchange and oxygenation (see Chapter 27).
- Think about what patient teaching focus could help reduce the occurrence of a respiratory infection in the future.

Get Ready for the NCLEX® Examination!

Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Limit transmission of respiratory infection spread by washing hands after blowing the nose or using a tissue. **Safety** QSEN
- Receive a yearly influenza vaccination because you are more likely to care for infected people and because you could spread influenza to people who are immunocompromised. **Safety** QSEN
- Use Airborne Precautions and Isolation Precautions for any patient who has TB manifestations until proven otherwise. **Safety** QSEN
- If possible, place the patient with a respiratory infection in a private room. **Safety** QSEN
- Keep the door to the room of any patient with a respiratory infection closed until the cause of the infection is identified. **Safety** QSEN

Health Promotion and Maintenance

- Teach everyone the "etiquette" of sneezing or coughing into the upper sleeve rather than the hand when a tissue is not available. **Evidence-Based Practice** QSEN
- Urge all adults older than 50 years, anyone who has a chronic respiratory problem, anyone who is immunocompromised, and anyone who lives with a person who is older or immunocompromised or has a chronic respiratory disease to receive the pneumonia vaccine and yearly influenza vaccinations. **Evidence-Based Practice** QSEN
- Urge patients to complete the anti-infective drug therapy course for any respiratory infection. **Patient-Centered Care** QSEN
- Urge all people to quit smoking or using tobacco in any form. **Patient-Centered Care** QSEN
- Teach people living with patients who have TB to ensure good ventilation of the home with open windows whenever possible.
- Educate the family and the patient with tuberculosis who lives at home about the side effects of anti-tuberculosis (TB) therapy and when to notify the health care provider. **Patient-Centered Care** QSEN
- Teach all people to be prepared for an emergency or disaster by having sufficient food, water, and prescribed drugs for at least 2 weeks (see Chapter 10). **Patient-Centered Care** QSEN
- Teach all people to follow community infection containment procedures if

there is a possible outbreak of any pandemic influenza virus. **Patient-Centered Care** QSEN

Psychosocial Integrity

- Assess older patients with acute confusion for pneumonia (cough and fever may not be present).
- Assure the family of an older adult patient with pneumonia who is confused that the new-onset confusion is temporary. **Patient-Centered Care** QSEN
- Teach people who may be afraid of contracting inhalation anthrax that this disease is not transmitted by person-to-person contact. **Patient-Centered Care** QSEN
- Inform patients who have a positive TB test that far more people are infected with the bacillus than have active TB disease. Assess the likelihood of adherence to the drug regimen for patients with TB. **Patient-Centered Care** QSEN
- Identify patients who may require a directly observed therapy (DOT) program in which they must be directly observed by a health care professional while swallowing the drug. **Safety** QSEN

Physiological Integrity

- Assess the respiratory status of anyone suspected of having a respiratory infection by taking vital signs, noting color of nail beds and mucous membranes, measuring oxygen saturation, determining ease of ventilation, determining cognition, and auscultating lung fields. **Evidence-Based Practice** QSEN
- Administer humidified oxygen therapy to patients with inadequate gas exchange and hypoxemia. **Evidence-Based Practice** QSEN
- Assess the skin under and around a facemask or nasal cannula for evidence of skin breakdown at least every 8 hours. **Patient-Centered Care** QSEN
- Ask any patient with a respiratory infection if he or she is from a foreign country or has recently visited a foreign country. Ask patients from other countries whether they have had BCG as a vaccination against TB. For patients who have had BCG, the PPD skin test is a less reliable indicator of TB. **Safety** QSEN
- Assess the patient receiving first-line drug therapy for TB for any manifestation of liver impairment (dark urine, clay-colored stools, anorexia, jaundiced sclera or hard palate). **Patient-Centered Care**

QSEN

- Teach women taking rifampin or rifapentine as drug therapy for TB that these drugs reduce the effectiveness of oral contraceptives and that an additional form of birth control should be used while on this therapy.

Patient-Centered Care QSEN

CHAPTER 32

Care of Critically Ill Patients with Respiratory Problems

Meg Blair

PRIORITY CONCEPTS

- Gas Exchange
- Perfusion
- Clotting

Learning Outcomes

Safe and Effective Care Environment

1. Protect the critically ill patient with respiratory problems from injury, infection, and bleeding.
2. Ensure safe management of endotracheal tubes, tracheostomy tubes, and mechanical ventilators.

Health Promotion and Maintenance

3. Teach people at risk for pulmonary embolism techniques to reduce the risk.
4. Teach patients and family members how to avoid injury during therapy to reduce clotting.

Psychosocial Integrity

5. Reduce the psychological impact for the patient and family experiencing a serious respiratory problem.

Physiological Integrity

6. Assess the respiratory status of any patient who develops sudden-onset respiratory difficulty or acute confusion.
7. Use laboratory data and clinical manifestations to evaluate the adequacy of gas exchange with oxygenation and ventilatory interventions.
8. Prioritize nursing care for the patient experiencing a serious or critical respiratory disorder or event.
9. Work with other members of the health care team to coordinate care for the patient being mechanically ventilated.

http://evolve.elsevier.com/Iggy/

Any respiratory problem can interfere with gas exchange, oxygenation, and tissue perfusion, progressing to an emergency and death, even with prompt treatment. These problems may overwhelm the adaptive responses of the cardiac and blood oxygen delivery systems (Fig. 32-1). *Thus prompt recognition and interventions are needed to prevent serious complications and death.*

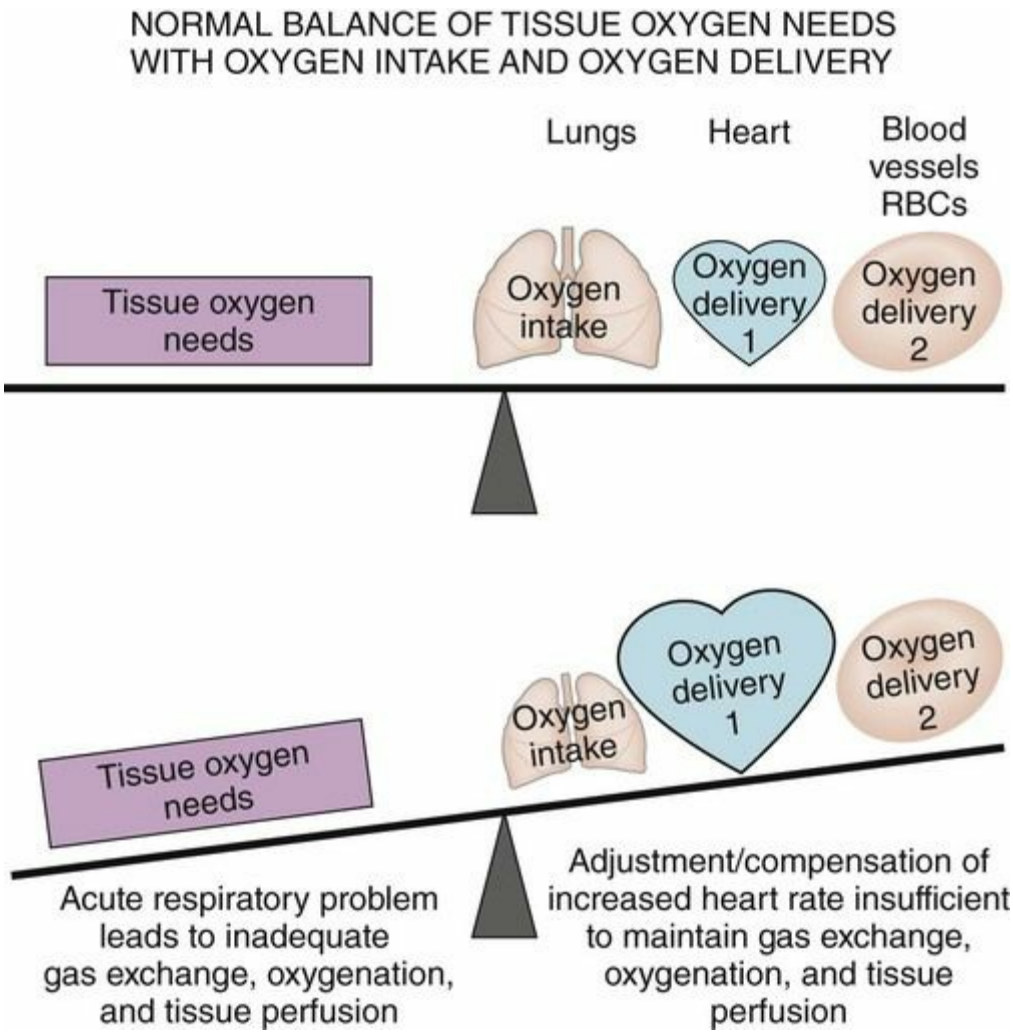

FIG. 32-1 Rapid-onset acute respiratory problems overwhelm the ability of the cardiac oxygen delivery system to adapt and restore balance. The red blood cell (RBC) oxygen delivery system cannot begin to adapt to the acute respiratory problem.

An acute injury or problem that results in severe respiratory impairment can occur at any age. Older adults, however, are more at risk for developing critical respiratory problems. The patient who is short of breath is also anxious and fearful. Be prepared to manage both the physical and emotional needs of the patient during any respiratory emergency.

Pulmonary Embolism

❖ Pathophysiology

A **pulmonary embolism (PE)** is a collection of particulate matter (solids, liquids, or air) that enters venous circulation and lodges in the pulmonary vessels. Large emboli obstruct pulmonary blood flow, leading to reduced gas exchange, reduced oxygenation, pulmonary tissue hypoxia, decreased perfusion, and potential death. Any substance can cause an embolism, but a blood clot is the most common (McCance et al., 2014). PE is common and may account for as many as 100,000 deaths each year in the United States (Smithburger et al., 2013). It may be the most common preventable death in hospitalized patients but is often misdiagnosed, and patients at risk may not be provided the appropriate preventive measures (Duff et al., 2013; Hussey, 2013).

Most often, a PE occurs when inappropriate blood clotting forms a venous thromboembolism (VTE) (also known as a *deep vein thrombosis* [DVT]) in a vein in the legs or the pelvis and a clot breaks off and travels through the vena cava into the right side of the heart. The clot then lodges in the pulmonary artery or within one or more of its branches. Platelets collect on the embolus, triggering the release of substances that cause blood vessel constriction. Widespread pulmonary vessel constriction and pulmonary hypertension impair gas exchange and tissue perfusion. Deoxygenated blood moves into arterial circulation, causing **hypoxemia** (low arterial blood oxygen level), although some patients with PE do *not* have hypoxemia.

Major risk factors for VTE leading to PE are:

- Prolonged immobility
- Central venous catheters
- Surgery
- Obesity
- Advancing age
- Conditions that increase blood clotting
- History of thromboembolism

Smoking, pregnancy, estrogen therapy, heart failure, stroke, cancer (particularly lung or prostate), and trauma increase the risk for VTE and PE (Hussey, 2013).

Fat, oil, air, tumor cells, amniotic fluid and fetal debris, foreign objects (e.g., broken IV catheters), injected particles, and infected clots can enter a vein and cause PE. Fat emboli from fracture of a long bone and oil emboli from diagnostic procedures do not impede lung blood flow; instead, they injure blood vessels and cause acute respiratory distress

syndrome (ARDS) (Powers & Talbot, 2011). Septic clots often arise from a pelvic abscess, an infected IV catheter, and injections of illegal drugs. The effects of sepsis are more serious than the venous blockage.

Health Promotion and Maintenance

Although pulmonary embolism (PE) can occur in healthy people without warning, it occurs more often in some situations. Thus prevention of conditions that lead to PE is a major nursing concern. Preventive actions for PE are those that also prevent venous stasis and VTE. Best nursing practices for PE prevention are outlined in Chart 32-1. Also see Chapter 14 for more information about core measures during the surgical experience for VTE prevention.

Chart 32-1 Best Practice for Patient Safety & Quality Care QSEN

Prevention of Pulmonary Embolism

- Start passive and active range-of-motion exercises for the extremities of immobilized and postoperative patients.
- Ambulate patients soon after surgery.
- Use antiembolism and pneumatic compression stockings and devices after surgery.
- Evaluate patient for criteria indicating the need for anticoagulant therapy.
- Avoid the use of tight garters, girdles, and constricting clothing.
- Prevent pressure under the popliteal space (e.g., do not place a pillow under the knee, use alternating pressure mattress).
- Perform a comprehensive assessment of peripheral circulation.
- Elevate the affected limb 20 degrees or more above the level of the heart to improve venous return, as appropriate.
- Change patient position every 2 hours, or ambulate as tolerated.
- Prevent injury to the vessel lumen by preventing local pressure, trauma, infection, or sepsis.
- Refrain from massaging leg muscles.
- Instruct patient not to cross legs.
- Administer prescribed prophylactic low-dose anticoagulant and antiplatelet drugs.
- Teach the patient to avoid activities that result in the Valsalva maneuver (e.g., breath-holding, bearing down for bowel movements, coughing).
- Administer prescribed drugs, such as stool softeners, that will prevent

episodes of the Valsalva maneuver.
- Teach the patient and family about precautions.
- Encourage smoking cessation.

Lifestyle changes can help reduce the risk for PE. Tobacco use narrows blood vessels and increases the risk for clot formation. Hormone-based contraceptives also increase blood clotting. Urge patients to stop smoking cigarettes, especially women who use hormone-based contraceptives. Reducing weight and becoming more physically active can reduce risk for PE. Teach patients who are traveling for long periods to drink plenty of water, change positions often, avoid crossing their legs, and get up from the sitting position at least 5 minutes out of every hour to prevent stasis and clot formation.

For patients known to be at risk for PE, small doses of heparin or low–molecular-weight heparin (enoxaparin [Lovenox]), an indirect thrombin inhibitor, may be prescribed every 8 to 12 hours. Oral direct thrombin inhibitors may be used instead of heparin for VTE prevention in patients who have non-valvular atrial fibrillation (Golembiewski, 2011).

Patient-Centered Collaborative Care

Assessment

Physical manifestations range from vague, non-specific discomforts to hemodynamic collapse and death. *It is important to remember that many patients with PE do not have the "classic" manifestations*. This variability in manifestations often leads to PEs being overlooked (Hussey, 2013; Smithburger et al., 2013).

Physical Assessment/Clinical Manifestations.

Respiratory manifestations are outlined in Chart 32-2 and are mostly related to decreased gas exchange. Assess the patient for difficulty breathing (dyspnea) and pleuritic chest pain (sharp, stabbing-type pain on inspiration). Other manifestations vary depending on the size and the type of embolism. Breath sounds may be normal or include crackles, wheezes, or a pleural friction rub. A dry or productive cough may be present; **hemoptysis** (bloody sputum) may result from pulmonary infarction.

Chart 32-2 Key Features

Pulmonary Embolism

Classic Manifestations

- Dyspnea, sudden onset
- Sharp, stabbing chest pain
- Apprehension, restlessness
- Feeling of impending doom
- Cough
- Hemoptysis

Signs

- Tachypnea
- Crackles
- Pleural friction rub
- Tachycardia
- S_3 or S_4 heart sound
- Diaphoresis
- Fever, low-grade
- Petechiae over chest and axillae
- Decreased arterial oxygen saturation (Sa_{O_2})

Cardiac manifestations related to decreased tissue perfusion include tachycardia, distended neck veins, **syncope** (fainting or loss of consciousness), cyanosis, and hypotension. Systemic hypotension results from acute pulmonary hypertension and reduced forward blood flow. Abnormal heart sounds, such as an S_3 or S_4, may occur.

Electrocardiogram (ECG) changes are nonspecific and transient. T-wave and ST-segment changes may occur as can left-axis or right-axis deviations. Right ventricular dysfunction and failure are extreme manifestations. The patient may have cardiac arrest or frank shock.

Nursing Safety Priority QSEN

Critical Rescue

Any patient who has shortness of breath, chest pain, and or/hypotension without an obvious cause should be assessed for PE and the Rapid Response Team notified. If PE is strongly suspected, prompt categorization and management are started before diagnostic studies have been completed (McLenon, 2012; Ouellette, 2014).

Psychosocial Assessment.

Manifestations of PE often occur abruptly, and the patient is anxious. Hypoxemia may stimulate a sense of impending doom and cause increased restlessness. The life-threatening nature of PE and admission to an ICU increase the patient's anxiety and fear.

Laboratory Assessment.

The hyperventilation triggered by hypoxia and pain first leads to respiratory alkalosis, indicated by low partial pressure of arterial carbon dioxide (Pa_{CO_2}) on arterial blood gas (ABG) analysis. The Pa_{O_2}-Fi_{O_2} (fraction of inspired oxygen) ratio falls as a result of "shunting" of blood from the right side of the heart to the left without picking up oxygen from the lungs. Shunting causes the Pa_{CO_2} level to rise, resulting in respiratory acidosis (McCance et al., 2014). Later, metabolic acidosis results from buildup of lactic acid due to tissue hypoxia. (See Chapter 12 for a more detailed discussion of acidosis.)

Even if ABG studies and pulse oximetry show hypoxemia, these results alone are not sufficient for the diagnosis of PE (McCance et al., 2014). A patient with a small embolus may not be hypoxemic, and PE is not the only cause of hypoxemia.

Other laboratory studies performed when PE is suspected include a general metabolic panel, troponin, brain natriuretic peptide (BNP), and a d-dimer. The d-dimer, a fibrin split product, rises with fibrinolysis. When the value is normal or low, it can rule out a PE. However, even if the value is high, other diagnostic testing is needed to determine whether a PE has occurred (Pagana & Pagana, 2014; Smithburger et al., 2013).

Genetic/Genomic Considerations

Patient-Centered Care QSEN

Factor V Leiden is an inherited thrombophilia (abnormal tendency to develop blood clots) in which the gene coding for blood clotting factor V (the *F5* gene) has a mutation that changes the nature of the factor V produced. With this genetic alteration, factor V functions normally but is not degraded as quickly as it should be. Thus clotting activity continues longer than usual, increasing the chance for developing abnormal blood clots (Lee, 2014). People can inherit either one or both abnormal gene alleles. The risk for developing clots is 8 times greater in those who inherit only one abnormal allele. The risk for developing DVT, PE, or thrombotic strokes increases greatly for people who inherit both abnormal gene alleles (one from each parent), especially if the person

also smokes or uses hormone-based contraceptives. This disorder is also known as *activated protein C resistance*. Be aware that testing for factor V Leiden is recommended for people who have developed a VTE without a precipitating event and for those who have a first-degree relative with the disorder (Online Mendelian Inheritance in Man [OMIM], 2013).

Imaging Assessment.

Pulmonary angiography is the "gold standard" diagnostic test but is not available in all settings. Computed tomography pulmonary angiography (CT-PA) or helical CT may also be used, which has the added advantage of diagnosing other pulmonary abnormalities causing the patient's manifestations. Ventilation-perfusion ($\dot{V}/\dot{Q}$) scans are not as widely used anymore but may be considered in certain circumstances (e.g., allergy to contrast dye). A chest x-ray may diagnose other conditions that mimic acute PE. Doppler ultrasound may be used to document the presence of VTE and to support a diagnosis of PE (Drumright et al., 2013; Kessenich & Erigo-Backman, 2012).

Analysis

The priority NANDA-I nursing diagnoses and collaborative problems for patients with PE include:
1. Hypoxemia related to mismatch of lung perfusion and alveolar gas exchange with oxygenation
2. Hypotension related to inadequate circulation to the left ventricle
3. Potential for inadequate clotting and bleeding related to anticoagulation or fibrinolytic therapy
4. Anxiety related to hypoxemia and life-threatening illness (NANDA-I)

Planning and Implementation

Managing Hypoxemia.

When a patient has a sudden onset of dyspnea and chest pain, immediately notify the Rapid Response Team. Reassure the patient, and elevate the head of the bed. Prepare for oxygen therapy and blood gas analysis while continuing to monitor and assess for other changes.

Planning: Expected Outcomes.

The patient with PE is expected to have adequate tissue perfusion in all major organs. Indicators of adequate perfusion are that the patient has:
• ABGs within normal limits

- Pulse oximetry above 95%
- Cognitive status unimpaired compared with baseline
- Absence of pallor and cyanosis

Interventions.

Nonsurgical management of PE is most common. In some cases, invasive procedures also may be needed. Best nursing care practices for the patient with PE are listed in Chart 32-3. Rapid categorization of PE severity and prompt management are required (Table 32-1).

Chart 32-3 Best Practice for Patient Safety & Quality Care QSEN

Care of the Patient with a Pulmonary Embolism

- Apply oxygen by nasal cannula or mask.
- Reassure patient that the correct measures are being taken.
- Place patient in high-Fowler's position.
- Apply telemetry monitoring equipment.
- Obtain an adequate venous access.
- Assess oxygenation continuously with pulse oximetry.
- Assess respiratory status at least every 30 minutes by:
  - Listening to lung sounds.
  - Measuring the rate, rhythm, and ease of respirations.
  - Checking skin color and capillary refill.
  - Checking position of trachea.
- Assess cardiac status by:
  - Comparing blood pressures in right and left arms.
  - Checking pulse for quality.
  - Checking cardiac monitor for dysrhythmias.
  - Checking for distention of neck veins.
- Ensure prescribed chest imaging and laboratory tests are obtained immediately (may include complete blood count with differential, platelet count, prothrombin time, partial thromboplastin time, d-dimer level, arterial blood gases).
- Examine the thorax for presence of petechiae.
- Administer prescribed anticoagulants.
- Assess for bleeding.
- Handle patient gently.
- Institute Bleeding Precautions.

TABLE 32-1

Pulmonary Embolism (PE) Severity and Management Options

CATEGORY	POSSIBLE MANIFESTATIONS	MANAGEMENT OPTIONS
Massive PE Mortality may be as high as 65%	Severe hypotension (SBP <90 mm Hg for at least 15 minutes) Cardiac arrest/cardiopulmonary collapse Severe bradycardia Shock Severe dyspnea/respiratory distress	CPR Inotropic and/or vasopressor support; fluids Fibrinolytic therapy Tissue plasminogen activator (tPA) Alteplase (Activase) Unfractionated heparin initial treatment
Submassive PE	Normotension RV dysfunction on echocardiography RV dilation on echocardiography or CT Right bundle branch block ST elevation or depression T-wave inversion Elevated BNP or troponin	Treatment is controversial; some agents not approved for this group Must weigh benefits of thrombolytic therapy against risk for bleeding Thrombolytics may be preferred if patient appears to be decompensating or if there is RV dysfunction (hypokinesis) or elevation in BNP or troponin LMWH preferred agent Fondaparinux (Arixtra) Unfractionated heparin
Low-risk PE Mortality ranges from 1% to 8%	Normotension No RV dysfunction No elevation in BNP or troponin	Thrombolytics not warranted due to risk for bleeding LMWH Rivaroxaban (Xarelto)

BNP, Brain natriuretic peptide; *CPR,* cardiopulmonary resuscitation; *CT,* computed tomography; *LMWH,* low–molecular-weight heparin; *RV,* right ventricle; *SBP,* systolic blood pressure.

Adapted from Jaff, M.R., McMurtry, M.S., & Archer, S.L. (2011). The use of fibrinolytics in patients with acute pulmonary embolism. *Circulation, 123,* 1788-1830.

Nonsurgical Management.

Management activities for PE focus on increasing gas exchange and oxygenation, improving lung perfusion, reducing risk for further clot formation, and preventing complications. Priority nursing interventions include implementing oxygen therapy, administering anticoagulation or fibrinolytic therapy to improve tissue perfusion, monitoring the patient's responses to the interventions, and providing psychosocial support.

Oxygen therapy is critical for the patient with PE. The severely hypoxemic patient may need mechanical ventilation and close monitoring with ABG studies. In less severe cases, oxygen may be applied by nasal cannula or mask. Use pulse oximetry to monitor oxygen saturation and hypoxemia.

Monitor the patient continually for any changes in status. Check vital signs, lung sounds, and cardiac and respiratory status at least every 1 to 2 hours. Document increasing dyspnea, dysrhythmias, distended neck veins, and pedal or sacral edema. Assess for crackles and other abnormal lung sounds along with cyanosis of the lips, conjunctiva, oral mucosa, and nail beds.

Drug therapy begins immediately with anticoagulants to prevent embolus enlargement and to prevent more clotting. Unfractionated heparin, low–molecular-weight heparin (enoxaparin [Lovenox]), or fondaparinux (Arixtra) is usually used unless the PE is massive or occurs

with hemodynamic instability. Review the patient's partial thromboplastin time (PTT)—also called *activated partial thromboplastin time* (aPTT)—before therapy is started and thereafter according to facility policy. Therapeutic PTT values usually range between 1.5 and 2.5 times the control value for this health problem. Factor anti-Xa levels may be used instead of PTT or aPTT (Riley, 2013).

Fibrinolytic drugs, such as alteplase (Activase, tPA), are used for treatment of PE when specific criteria are met such as shock, hemodynamic collapse, or instability. Fibrinolytic drugs are used to break up the existing clot. (See Chapter 38 for a discussion of fibrinolytic therapy.)

Both heparin and fibrinolytic drugs are *high alert drugs*. These drugs have a high risk to cause harm if given at too high a dose, too low a dose, or to the wrong patient.

Nursing Safety Priority QSEN

Drug Alert

Heparin comes in a variety of concentrations in vials that have differing amounts, which contributes to possible medication errors. In accordance with The Joint Commission's National Patient Safety Goals (NPSGs), check the prescribed dose carefully and ensure the correct concentration is being used to prevent overdosing or underdosing.

Heparin therapy usually continues for 5 to 10 days. Most patients are started on an oral anticoagulant, such as warfarin (Coumadin, Jantoven, Warfilone), on the third day of heparin use. Therapy with both heparin and warfarin continues until the international normalized ratio (INR) reaches 2.0 to 3.0. Monitor the platelet count and INR during this time. A low–molecular-weight heparin (e.g., dalteparin [Fragmin], enoxaparin [Lovenox]) or a direct thrombin inhibitor (rivaroxaban [Xarelto]) is often used instead of warfarin. Oral anticoagulant use continues for 3 to 6 weeks, but some patients may take it indefinitely. Charts 32-4 and 32-5 list common drugs used and the laboratory tests to monitor in a patient with PE. These drugs and the associated nursing care are discussed in Chapters 36, 38, and 39.

Chart 32-4 Common Examples of Drug Therapy

Pulmonary Embolism

DRUG AND USUAL DOSAGE	PURPOSE	NURSING INTERVENTIONS	RATIONALES
Heparin sodium (Hepalean) 5000-10,000 units as a bolus by IV push initially; then dose adjustment is based on PTT, often at 1300 units/hr on continuous infusion or by intermittent infusion **note:** Some institutions use a weight-based algorithm.	To begin anticoagulation to minimize growth of existing clots and to prevent the development of additional clots	Monitor PTT (or factor anti-Xa) and know expected therapeutic PTT range for each patient.	Ongoing assessment helps detect side effects and prevent complications.
		Report PTT (or factor anti-Xa) results. Monitor patient for bleeding or bruising.	Reporting and monitoring enable early management of a prolonged PTT and excessive bleeding.
		Adjust infusion based on PTT (or factor anti-Xa) results and institutional protocol.	To maintain anticoagulation within consistent therapeutic levels.
		Do not use with salicylates.	An increased anticoagulation effect can occur with salicylates.
		Monitor platelets daily for thrombocytopenia.	Heparin-induced thrombocytopenia (HIT), a type of adverse reaction, can occur.
		Have the antidote *protamine sulfate* available.	Being prepared for an emergency helps prevent further complications.
		Avoid puncturing the skin, and apply pressure to venipuncture and IM injection sites.	Pressure at puncture sites helps promote clotting.
		Avoid use of firm toothbrushes, razors, and rectal manipulation.	Safety measures help prevent bleeding.
Enoxaparin (Lovenox) usually 1 mg/kg subcutaneously every 12 hr	To allow for hospital discharge before complete switch to oral anticoagulants	Monitor platelet count.	Heparin-induced thrombocytopenia (HIT), a type of adverse reaction, can occur.
		Have the antidote *protamine sulfate* available.	This drug is the only antidote for enoxaparin.
		Safety precautions are the same as for heparin.	Safety precautions are the same as for heparin.
Warfarin sodium (Coumadin, Jantoven, Warfilone sodium) 10-15 mg orally once daily for 3 days initially; then dose adjustment is based on INR, usually 5-10 mg orally daily Now available as a parenteral drug for use in hospitalized patients. Dosage is the same as with the oral form of the drug.	To allow for long-term anticoagulation in at-risk patients to prevent the development of future clots	Monitor INR, and know expected therapeutic INR range for each patient.	Ongoing assessment helps detect side effects and prevent complications.
		Report INR results. Monitor the patient for bleeding or bruising.	Reporting enables early management of a prolonged INR.
		Monitor for fever and skin rash.	Adverse drug reaction can occur.
		Consult the pharmacist about potential drug interactions, and teach the patient to avoid interacting drugs.	There are many drug interactions with warfarin.
		Have the antidote *vitamin K (phytonadione)* available.	Being prepared for an emergency helps prevent further complications.
		Avoid puncturing the skin, and apply pressure to venipuncture and IM injection sites.	Pressure at puncture sites helps promote clotting.
		Avoid use of firm toothbrushes, razors, and rectal manipulation.	Safety measures help prevent bleeding.
		Teach the patient which foods are high in vitamin K (e.g., leafy dark green vegetables, herbs, spring onions, Brussels sprouts, broccoli, cabbage, asparagus).	Food sources of vitamin K will alter INR.
Alteplase (tissue plasminogen activator, recombinant; tPA; Activase) 100 mg IV infusion over 2 hr	To promote lysis of large pulmonary emboli in those patients who are hemodynamically unstable	Assess for internal and external bleeding.	Bleeding is the most common adverse effect.
		Reconstitute with sterile water without preservative immediately before use.	Recommended preparation ensures drug stability.
		Administer with caution to patients who have been receiving aspirin, dipyridamole, heparin, or other anticoagulants.	Other drugs with anticoagulation effects increase the risk for bleeding.

INR, International normalized ratio; *PTT,* partial thromboplastin time.

Chart 32-5 Laboratory Profile

Blood Tests Used to Monitor Anticoagulation Therapy

TEST	NORMAL RANGE	SIGNIFICANCE OF ABNORMAL FINDINGS
Partial thromboplastin time (PTT, aPTT [APTT])	Normal values for each local laboratory may vary. When activator reagents are used by the laboratory, the normal clotting time is shortened. Common normal ranges are 20-30 sec in some laboratories and 30-40 sec in others. Therapeutic range for PE is 1.5-2.5 times the normal value (e.g., if normal is 20-30 sec, then therapeutic range is 40-75 sec).	*Subtherapeutic times* may signify that the patient is not receiving enough heparin to prevent extension of the blood clot. An increase in the dosage or rate of infusion is usually indicated. *Therapeutic times* mean that the clotting time is increased from normal but this increase is indicated in the case of PE. *Prolonged times* in patients with PE (i.e., >75 sec) indicate that the patient is at risk for serious spontaneous bleeding. Heparin is usually held or decreased until the PTT drops back into the therapeutic range.
Prothrombin time (pro time, PT)	Common normal range is 11-12.5 sec. Therapeutic range for anticoagulant therapy in PE is 1.5-2.0 times the normal or control value in seconds. Control values can vary day to day because reagents used may vary.	*Subtherapeutic values* may signify that the patient is not receiving enough warfarin. An increase in the dosage is usually indicated. *Therapeutic values* mean that the pro time is increased from normal but this increase is indicated in the case of PE. *Prolonged values* in the treatment of PE indicate that the patient is at risk for bleeding. The warfarin dose is usually decreased or held, the patient is instructed to eat foods high in vitamin K, or an injection of vitamin K may be given.
International Normalized Ratio (INR)	The common normal range is 0.8-11. The therapeutic range for PE is 2.5-3.0, or 3.0-4.5 for recurrent PE.	*Subtherapeutic values* may signify that the patient is not receiving enough warfarin. An increase in the dosage is usually indicated. *Therapeutic values* mean that the INR is increased from normal but this increase is indicated in the case of PE. *Prolonged values* (higher than 4.5) in the treatment of PE indicate that the patient is at risk for bleeding. The warfarin dose is usually decreased or held, the patient is instructed to eat foods high in vitamin K, or an injection of vitamin K may be given.

aPTT or *APTT*, Activated partial thromboplastin time; *INR*, international normalized ratio; *PE*, pulmonary embolism.

Genetic/Genomic Considerations

Patient-Centered Care QSEN

Many agencies perform genetic tests before starting warfarin therapy to check for variation in two specific genes. One gene, *VKORC1*, produces an enzyme that alters vitamin K so it can help activate the vitamin K–dependent clotting factors. Warfarin interferes with the activity of this enzyme. Patients who have a variation in the enzyme are resistant to the effects of warfarin, and much higher doses are needed to achieve coagulation. On the other hand, the gene *CYP2C19* produces an enzyme that metabolizes warfarin and prepares it for elimination. Patients who have a variation in this gene do not metabolize warfarin well, so higher blood levels remain and more severe side effects are possible. The dosage of warfarin needs to be much lower in patients with this gene variation. When a patient's response to warfarin therapy is either greater than expected or much less than expected, consider the possibility of a gene mutation.

Anticoagulation and fibrinolytic therapy can lead to excessive bleeding. *The antidote for heparin is protamine sulfate; the antidote for warfarin is vitamin K_1, which is available as an injectable drug, phytonadione (AquaMEPHYTON, Mephyton). Antidotes for fibrinolytic therapy include clotting factors, fresh frozen plasma, and aminocaproic acid (Amicar).* Keep antidotes to anticoagulant drugs and fibrinolytic drugs on the unit for patients undergoing these therapies.

NCLEX Examination Challenge

Safe and Effective Care Environment

While assessing a client who has been receiving heparin intravenously for the past 3 days, the nurse notes the IV pump is set at twice the required setting. What orders does the nurse anticipate from the prescriber? **Select all that apply.**

A Activated partial thromboplastin time
B International normalized ratio
C Prothrombin time
D Vitamin K
E Protamine sulfate

Surgical Management.

Two surgical procedures for the management of PE are embolectomy and inferior vena cava filtration.

Embolectomy is the surgical or percutaneous removal of the embolus. It may be performed when fibrinolytic therapy cannot be used for a patient who has massive or multiple large pulmonary emboli with shock or bleeding complications. Special thrombectomy catheters that mechanically break up clots, such as the AngioJet, allow effective reduction of clots with or without the use of thrombolytic drugs (Drumright et al., 2013).

Inferior vena cava filtration with placement of a vena cava filter prevents further emboli from reaching the lungs in patients with ongoing risk for PE. Some filters can be removed when the risk for clot formation decreases, or they can be left in place permanently. Patients for whom filter placement is considered less risky than drug therapy include those with recurrent or major bleeding while receiving anticoagulants, those with septic PE, and those undergoing pulmonary embolectomy (Drumright et al., 2013). Placement of a vena cava filter is detailed in Chapter 36.

Managing Hypotension

Planning: Expected Outcomes.

The patient with PE is expected to have adequate circulation and tissue perfusion. Indicators of adequate circulation are:

- Maintenance of pulse rate and blood pressure within the normal ranges
- Maintenance of a urine output of at least 30 mL/hr

• Absence of cyanosis

Interventions.

In addition to the interventions used for hypoxemia, IV fluid therapy and drug therapy are used to increase cardiac output and maintain blood pressure.

IV fluid therapy involves giving crystalloid solutions to restore plasma volume and prevent shock (see Chapter 37). Continuously monitor the ECG and pulmonary artery and central venous/right atrial pressures of the patient receiving IV fluids because increased fluids can worsen pulmonary hypertension and lead to right-sided heart failure. Also monitor indicators of fluid adequacy including urine output, skin turgor, and moisture of mucous membranes.

Drug therapy with vasopressors is used when hypotension persists despite fluid resuscitation. Commonly used agents include norepinephrine (Levophed), epinephrine (adrenalin), or dopamine (Intropin). Agents that increase myocardial contractility **(positive inotropic agents)**, including milrinone (Primacor) and dobutamine (Dobutrex), may be considered. Vasodilators, such as nitroprusside (Nipride, Nitropress), may be used to decrease pulmonary artery pressure if it is impeding cardiac contractility. Assess the patient's cardiac status hourly during therapy with any of these drugs.

Minimizing Bleeding

Planning: Expected Outcomes.

The patient with PE is expected to have appropriate clotting and remain free from bleeding. Indicators include that the patient:

• Does not have bruising or petechiae
• Maintains hematocrit, hemoglobin, and platelet count within the normal range

Interventions.

Drug therapy that disrupts clots or prevents their formation impairs the patient's ability to start and continue the blood-clotting cascade when injured, increasing the risk for bleeding. Priority nursing actions are ensuring appropriate antidotes are present on the nursing unit, protecting the patient from situations that could lead to bleeding, ensuring correct drug therapy, assessing laboratory values, and monitoring the amount of bleeding that occurs.

Assess for evidence of bleeding (e.g., oozing, bruises that cluster,

petechiae, or purpura) at least every 2 hours. Examine all stools, urine, drainage, and vomitus for gross blood, and test for occult blood. Measure any blood loss as accurately as possible. Measure the patient's abdominal girth every 8 hours (increasing girth can indicate internal bleeding). Best practices to prevent bleeding are listed in Chart 32-6.

Chart 32-6 Best Practice for Patient Safety & Quality Care QSEN

Prevention of Injury for the Patient Receiving Anticoagulant, Fibrinolytic, or Antiplatelet Therapy

- Handle the patient gently.
- Use and teach UAP to use a lift sheet when moving and positioning the patient in bed.
- Avoid IM injections and venipunctures.
- When injections or venipunctures are necessary, use the smallest-gauge needle for the task.
- Apply firm pressure to the needle stick site for 10 minutes or until the site no longer oozes blood.
- Apply ice to areas of trauma.
- Test all urine, vomitus, and stool for occult blood.
- Assess IV sites at least every 4 hours for bleeding.
- Instruct alert patients to notify nursing personnel immediately if any trauma occurs and if bleeding or bruising is noticed.
- Avoid trauma to rectal tissues:
  - Do not administer enemas.
  - If suppositories are prescribed, lubricate liberally and administer with caution.
- Instruct the patient and UAP to use an electric shaver rather than a razor.
- When providing mouth care or supervising others in providing mouth care:
  - Use a soft-bristled toothbrush or tooth sponges.
  - Do not use floss.
  - Check to make certain that dentures fit and do not rub.
- Instruct the patient not to blow the nose forcefully or insert objects into the nose.
- Ensure the patient wears shoes with firm soles whenever he or she is ambulating.
- Ensure that antidotes to anticoagulation therapy are on the unit.

UAP, Unlicensed assistive personnel.

Monitor laboratory values daily. Review the complete blood count (CBC) results to determine the risk for impaired clotting and whether actual blood loss has occurred. If the patient has severe blood loss, packed red blood cells may be prescribed (see Transfusion Therapy in Chapter 40). Monitor the platelet count. A decreasing count may indicate ongoing clotting or heparin-induced thrombocytopenia (HIT) caused by the formation of anti-heparin antibodies.

Minimizing Anxiety

Planning: Expected Outcomes.

The patient with PE is expected to have anxiety reduced to an acceptable level. Indicators include that he or she consistently demonstrates these behaviors:

- States that anxiety is reduced
- Has no distress, irritability, or facial tension
- Uses coping strategies effectively

Interventions.

The patient with PE is anxious and fearful and often has pain. Interventions for reducing anxiety in those with PE include oxygen therapy (see Interventions discussion on pp. 605-606 in the Managing Hypoxemia section), communication, and drug therapy.

Communication is critical in allaying anxiety. Acknowledge the anxiety and the patient's perception of a life-threatening situation. Stay with him or her, and speak calmly and clearly, providing assurances that appropriate measures are being taken. Explain the rationale and share information when giving drugs, changing position, taking vital signs, or assessing the patient.

Drug therapy with an antianxiety drug may be prescribed if the patient's anxiety interferes with diagnostic testing, management, or adequate rest. Unless he or she is mechanically ventilated, sedating agents are avoided to reduce the risk for hypoventilation. Pharmacologic therapy is used for pain management. Care is taken to avoid suppressing the respiratory response.

Clinical Judgment Challenge

Patient-Centered Care; Safety; Evidence-Based Practice QSEN

The patient is a 70-year-old retiree who had a hip replacement 2 days ago. His hip pain kept him from participating in his usual exercise program for the past 6 months. He is a former two-pack a day smoker. At home he decreased his fluid intake because ambulating to the bathroom was so painful. He resisted getting out of bed with physical therapy yesterday. When you assess him this morning, he reports nausea, some chest pain, mild shortness of breath, and anxiety.

1. What should be your first actions? Provide a rationale for your choice(s).
2. Which of his manifestations are associated with PE, and what risk factors does he have for a PE?
3. What are the common manifestations of PE?
4. The patient is requesting something for his anxiety. Is antianxiety drug therapy appropriate at this time? Why or why not? How else might you be able to reduce his anxiety?
5. What other actions should you take?

Community-Based Care

The patient with a PE is discharged when hypoxemia and hemodynamic instability are resolved and adequate anticoagulation has been achieved. Anticoagulation therapy usually continues after discharge.

Home Care Management.

Some patients are discharged to home with minimal risk for recurrence and no permanent physiologic changes. Others have heart or lung damage that requires home and lifestyle modification.

Patients with extensive lung damage may have activity intolerance from reduced gas exchange and become fatigued easily. The living arrangements may need to be modified so that patients can spend most of the time on one floor and avoid climbing stairs. Depending on the degree of impairment, patients may require varying amounts of assistance with ADLs.

Self-Management Education.

The patient with a PE may continue anticoagulation therapy for weeks, months, or years after discharge, depending on the risks for PE, and have impaired clotting. Teach him or her and the family about Bleeding Precautions, activities to reduce the risk for venous thromboembolism (VTE) and recurrence of PE, complications, and the need for follow-up

care (Chart 32-7).

Chart 32-7 Patient and Family Education: Preparing for Self-Management

Preventing Injury and Bleeding

During the time you are taking anticoagulants:

- Use an electric shaver.
- Use a soft-bristled toothbrush, and do not floss.
- Do not have dental work performed without consulting your health care provider.
- Do not take aspirin or any aspirin-containing products. Read the label to be sure that the product does not contain aspirin or salicylates.
- Do not participate in contact sports or any activity likely to result in your being bumped, scratched, or scraped.
- If you are bumped, apply ice to the site for at least 1 hour.
- Avoid hard foods that would scrape the inside of your mouth.
- Eat warm, cool, or cold foods to avoid burning your mouth.
- Check your skin and mouth daily for bruises, swelling, or areas with small, reddish purple marks that may indicate bleeding.
- Notify your health care provider if you:
  - Are injured and persistent bleeding results
  - Have excessive menstrual bleeding
  - See blood in your urine or bowel movement
- Avoid anal intercourse.
- Take a stool softener to prevent straining during a bowel movement.
- Do not use enemas or rectal suppositories.
- Do not wear clothing or shoes that are tight or that rub.
- Avoid blowing your nose forcefully or placing objects in your nose. If you must blow your nose, do so gently without blocking either nasal passage.
- Avoid playing musical instruments that raise the pressure inside your head, such as brass wind instruments and woodwinds or reed instruments.
- Keep all appointments for laboratory tests.

Health Care Resources.

Patients using anticoagulation therapy with warfarin are usually seen in a clinic or health care provider's office frequently for blood tests. Those who are homebound may have a visit from a home care nurse to perform

these tests. Newer anticoagulation agents (dabigatran [Pradaxa] and enoxaparin [Lovenox]) do not require laboratory monitoring. Patients with severe dyspnea may need home oxygen therapy. Respiratory therapy treatments can be performed in the home. The nurse or case manager coordinates arrangements for oxygen and other respiratory therapy equipment to be available if needed at home. See Chart 32-8 for a focused assessment guide.

Chart 32-8 Home Care Assessment

The Patient After Pulmonary Embolism

Assess respiratory status:

- Observe rate and depth of ventilation.
- Auscultate lungs.
- Examine nail beds and mucous membranes for evidence of cyanosis.
- Take a pulse oximetry reading.
- Ask the patient if chest pain or shortness of breath is experienced in any position.
- Ask the patient about the presence of sputum and its color and character.

Assess cardiovascular status:

- Take vital signs, including apical pulse, pulse pressure; assess for presence or absence of orthostatic hypotension and quality and rhythm of peripheral pulses.
- Note presence or absence of peripheral edema.
- Examine hand vein filling in the dependent position.
- Examine neck vein filling in the recumbent and sitting positions.

Assess lower extremities for deep vein thrombosis:

- Examine lower legs and compare with each other for:
  - General edema
  - Calf swelling
  - Surface temperature
  - Presence of red streaks or cordlike, palpable structure
- Measure calf circumference:

Assess for evidence of bleeding:

- Examine the mouth and gums for oozing or frank bleeding.
- Examine all skin areas, especially old puncture sites and wounds, for bleeding, bruising, or petechiae.
- If the patient voids during the visit, test the urine for occult blood.

Assess cognition and mental status:

■ Check level of consciousness.
■ Check orientation to time, place, and person.
■ Can the patient accurately read a seven-word sentence containing no words with more than three syllables?

Assess the patient's understanding of illness and adherence to treatment:

■ Manifestations to report to health care provider
■ Drug therapy plan (correct timing and dose)
■ Bleeding Precautions
■ Prevention of venous thromboembolism

Evaluation: Outcomes

Evaluate the care of the patient with PE on the basis of the identified priority patient problems. The expected outcomes are that he or she:

• Attains and maintains adequate gas exchange and oxygenation
• Does not experience hypovolemia and shock
• Remains free from bleeding episodes
• States the level of anxiety is reduced
• Uses effective coping strategies

Specific indicators for these outcomes are listed for each patient problem under the Planning and Implementation section (see earlier).

Acute Respiratory Failure

❖ Pathophysiology

A near match in the lungs between air movement or ventilation ($\dot{V}$) and blood flow or perfusion ($\dot{Q}$) is needed for adequate pulmonary gas exchange. When either ventilation or perfusion is mismatched with the other in a lung or lung area, gas exchange is reduced and respiratory failure can result.

Acute respiratory failure (ARF) can be *ventilatory failure, oxygenation (gas exchange) failure*, or a *combination of both ventilatory and oxygenation failure* and is classified by abnormal blood gas values. The critical values are:

- Partial pressure of arterial oxygen (Pa_{O_2}) less than 60 mm Hg (hypoxemic/oxygenation failure)
- OR partial pressure of arterial carbon dioxide (Pa_{CO_2}) more than 45 mm Hg occurring with acidemia (pH <7.35) (hypercapnic/ventilatory failure)
- AND arterial oxygen saturation (Sa_{O_2}) less than 90% in both cases

Whatever the underlying problem, the patient in acute respiratory failure is always **hypoxemic** (has low arterial blood oxygen levels) (Bekken, 2011; McLean, 2012).

Ventilatory Failure.

Ventilatory failure is a problem in oxygen intake (air movement or ventilation) and blood flow (perfusion) that causes a ventilation-perfusion ($\dot{V}/\dot{Q}$) mismatch in which blood flow (perfusion) is normal but air movement (ventilation) is inadequate. It occurs when the chest pressure does not change enough to permit air movement into and out of the lungs. As a result, too little oxygen reaches the alveoli and carbon dioxide is retained. Perfusion is wasted in this area of no air movement from either inadequate oxygen intake or excessive carbon dioxide retention leading to poor gas exchange and hypoxemia (McLean, 2012).

Ventilatory failure usually results from any of these problems: a physical problem of the lungs or chest wall; a defect in the respiratory control center in the brain; or poor function of the respiratory muscles, especially the diaphragm. The problem is defined by a Pa_{CO_2} level above 45 mm Hg plus acidemia (pH < 7.35) in patients who have otherwise healthy lungs.

Many disorders can result in ventilatory failure. Causes are either

extrapulmonary (involving nonpulmonary tissues but affecting respiratory function) or **intrapulmonary** (disorders of the respiratory tract). Table 32-2 lists causes of ventilatory failure.

TABLE 32-2

Common Causes of Ventilatory Failure

EXTRAPULMONARY CAUSES	INTRAPULMONARY CAUSES

• Neuromuscular disorders:
  • Myasthenia gravis
  • Guillain-Barré syndrome
  • Poliomyelitis
• Spinal cord injuries affecting nerves to intercostal muscles
• Central nervous system dysfunction:
  • Stroke
  • Increased intracranial pressure
  • Meningitis
• Chemical depression:
  • Opioid analgesics, sedatives, anesthetics
• Kyphoscoliosis
• Massive obesity
• Sleep apnea
• External obstruction/constriction
	• Airway disease:
	  • Chronic obstructive pulmonary disease (COPD), asthma
	• Ventilation-perfusion ($\dot{V}/\dot{Q}$) mismatch:
	  • Pulmonary embolism
	  • Pneumothorax
	  • Acute respiratory distress syndrome (ARDS)
	  • Amyloidosis
	  • Pulmonary edema
	  • Interstitial fibrosis

Oxygenation (Gas Exchange) Failure.

In oxygenation (gas exchange) failure, chest pressure changes are normal and air moves in and out without difficulty but does not oxygenate the pulmonary blood sufficiently. It occurs in the type of $\dot{V}/\dot{Q}$ mismatch in which air movement and oxygen intake (ventilation) are normal but lung blood flow (perfusion) is decreased.

Many lung disorders can cause oxygenation failure. Problems include impaired diffusion of oxygen at the alveolar level, right-to-left shunting of blood in the pulmonary vessels, $\dot{V}/\dot{Q}$ mismatch, breathing air with a low oxygen level, and abnormal hemoglobin that fails to bind oxygen. In one type of $\dot{V}/\dot{Q}$ mismatch, areas of the lungs still have perfusion but gas exchange does not occur, which leads to hypoxemia. An extreme example of $\dot{V}/\dot{Q}$ mismatch is when systemic venous blood (oxygen-poor) passes through the lungs without being oxygenated and is "shunted" to the left side of the heart and into the systemic arterial system. Normally, less than 5% of cardiac output contains venous blood that has bypassed oxygenation. With poor oxygenation in the lungs or a shunt that allows venous blood to bypass the lungs, even more arterial blood is not oxygenated and applying 100% oxygen does not correct the problem. A

classic cause of such a $\dot{V}/\dot{Q}$ mismatch is acute respiratory distress syndrome (ARDS). Table 32-3 lists specific causes of oxygenation failure.

TABLE 32-3
Common Causes of Oxygenation Failure

- Low atmospheric oxygen concentration:
  - High altitudes, closed spaces, smoke inhalation, carbon monoxide poisoning
- Pneumonia
- Congestive heart failure with pulmonary edema
- Pulmonary embolism (PE)
- Acute respiratory distress syndrome (ARDS)
- Interstitial pneumonitis-fibrosis
- Abnormal hemoglobin
- Hypovolemic shock
- Hypoventilation
- Complications of nitroprusside therapy:
  - Thiocyanate toxicity, methemoglobinemia

Combined Ventilatory and Oxygenation Failure.

Combined ventilatory and oxygenation failure involves **hypoventilation** (poor respiratory movements). Impaired gas exchange at the alveolar-capillary membrane results in poor diffusion of oxygen into arterial blood and carbon dioxide retention. The condition may or may not include poor lung perfusion. When lung perfusion is not adequate, $\dot{V}/\dot{Q}$ mismatch occurs and both ventilation and perfusion are inadequate. This type of respiratory failure leads to a more profound hypoxemia than either ventilatory failure or oxygenation failure alone.

A combination of ventilatory failure and oxygenation (gas exchange) failure occurs in patients who have abnormal lungs, such as those who have any form of chronic bronchitis, have emphysema, have cystic fibrosis, or are having an asthma attack. The bronchioles and alveoli are diseased (causing oxygenation failure), and the work of breathing increases until the respiratory muscles cannot function effectively (causing ventilatory failure) leading to acute respiratory failure (ARF). ARF can also occur in patients who have cardiac failure along with respiratory failure and is made worse by the fact that the cardiac system cannot adapt to the hypoxia by increasing the cardiac output.

❖ Patient-Centered Collaborative Care

◆ Assessment

The manifestations of ARF are related to the systemic effects of hypoxia, hypercapnia, and acidosis (Bekken, 2011). Assess for **dyspnea**

(perceived difficulty breathing)—the hallmark of respiratory failure. Evaluate dyspnea on the basis of how breathless the patient becomes while performing common tasks. Depending on the nature of the underlying problem, the patient might not be aware of changes in the work of breathing.

Dyspnea is more intense when it develops rapidly. Slowly progressive respiratory failure may first be noticed as dyspnea on exertion (DOE) or when lying down. The patient may have **orthopnea**, finding it easier to breathe in an upright position (Bull, 2014). With chronic respiratory problems, a minor increase in dyspnea may represent severe gas exchange problems.

Assess for a change in the patient's respiratory rate or pattern and changes in lung sounds. Pulse oximetry (Spo_2) may show decreased oxygen saturation, but end-tidal CO_2 ($ETCO_2$ or $PETCO_2$) monitoring may be more valuable for monitoring the patient with ARF (Carlisle, 2014). His or her pulse oximetry may show adequate oxygen saturation but because of increased $ETCO_2$ the patient may be close to respiratory failure. Arterial blood gas (ABG) studies are reviewed to most accurately identify the degree of hypoxia and hypercarbia.

Other manifestations of hypoxic respiratory failure include restlessness, irritability or agitation, confusion, and tachycardia. Manifestations of hypercapnic failure include decreased level of consciousness (LOC), headache, drowsiness, lethargy, and possible seizures. The effects of acidosis may lead to decreased LOC, drowsiness, confusion, hypotension, bradycardia, and weak peripheral pulses.

Interventions

Oxygen therapy is appropriate for any patient with acute hypoxemia. It is used in acute respiratory failure to keep the arterial oxygen (Pao_2) level above 60 mm Hg while treating the cause of the respiratory failure. Oxygen therapy is discussed in detail in Chapter 28. If oxygen therapy does not maintain acceptable Pao_2 levels, mechanical ventilation (invasive or noninvasive) may be needed.

Drugs given systemically or by metered dose inhaler (MDI) may be prescribed to dilate the bronchioles and decrease inflammation to promote gas exchange. Corticosteroids may be used, but their benefit has not been conclusively demonstrated. Analgesics are needed if the patient has pain. If the patient requires mechanical ventilation, he or she may need neuromuscular blockade drugs for optimal ventilator effect. Other management strategies depend on the underlying condition(s) that

predisposed the patient to ARF development.

Help the patient find a position of comfort that allows easier breathing —usually a more upright position. To decrease the anxiety occurring with dyspnea, assist him or her to use relaxation, diversion, and guided imagery. Start energy-conserving measures, such as minimal self-care and no unnecessary procedures. Encourage deep breathing and other breathing exercises.

Acute Respiratory Distress Syndrome

❖ Pathophysiology

Acute respiratory distress syndrome (ARDS) is acute respiratory failure with these features:

- Hypoxemia that persists even when 100% oxygen is given (**refractory hypoxemia**, a cardinal feature)
- Decreased pulmonary compliance
- Dyspnea
- Noncardiac-associated bilateral pulmonary edema
- Dense pulmonary infiltrates on x-ray (ground-glass appearance)

Often ARDS occurs after an *acute lung injury (ALI)* in people who have no pulmonary disease as a result of other conditions such as sepsis, burns, pancreatitis, trauma, and transfusion. The mortality rate is about 60% depending on the underlying cause (Carroll et al., 2013). Other terms for ARDS include *adult respiratory distress syndrome* and *shock lung.*

Despite different causes of ALI in ARDS, the trigger is a systemic inflammatory response. As a result, ARDS manifestations are similar regardless of the cause. The main site of injury in the lung is the alveolar-capillary membrane, which normally is permeable only to small molecules. It can be injured during sepsis, pulmonary embolism, shock, aspiration, or inhalation injury. When injured, this membrane becomes more permeable to large molecules, which allows debris, proteins, and fluid into the alveoli. Lung tissue normally remains relatively dry, but in patients with ARDS, lung fluid increases and contains more proteins.

Other changes occur in the alveoli and respiratory bronchioles. Normally, the type II pneumocytes produce surfactant, a substance that increases lung **compliance** (elasticity) and prevents alveolar collapse. Surfactant activity is reduced in ARDS because type II pneumocytes are damaged and because the surfactant is diluted by excess lung fluids. As a result, the alveoli become unstable and tend to collapse unless they are filled with fluid. These fluid-filled and collapsed alveoli cannot participate in gas exchange. As a result, edema forms around terminal airways, which are compressed and closed and can be destroyed. Lung volume and compliance are further reduced. As fluid continues to leak in more lung areas, fluid, protein, and blood cells collect in the alveoli and in the spaces between the alveoli. Lymph channels are compressed, and more fluid collects. Poorly inflated alveoli receive blood but cannot oxygenate it, increasing the shunt. Hypoxemia and ventilation-perfusion $\dot{V}/\dot{Q}$ mismatch result.

Transfusion-related acute lung injury (TRALI) is the sudden onset (within 6 hours of a transfusion) of hypoxemic lung disease along with infiltrates on x-ray without cardiac problems. TRALI is associated with the activation of the inflammatory response due to a recent transfusion of plasma-containing blood products such as packed red blood cells (PRBCs), platelets, and fresh frozen plasma (Benson, 2012). Other lung complications of transfusion include transfusion-associated circulatory overload (TACO) and transfusion-related immunomodulation (TRIM) (Benson, 2012).

Etiology and Genetic Risk.

ALI leading to ARDS has many causes (Table 32-4). Some causes result in direct injury to lung tissue; other causes do not directly involve the lungs. As a result of sepsis, pancreatitis, trauma, and other conditions, inflammatory mediators spread to the lungs causing damage (Carroll et al., 2013; McCance et al., 2014).

TABLE 32-4

Common Causes of Acute Lung Injury

- Shock
- Trauma
- Serious nervous system injury
- Pancreatitis
- Fat and amniotic fluid emboli
- Pulmonary infections
- Sepsis
- Inhalation of toxic gases (smoke, oxygen)
- Pulmonary aspiration (especially of stomach contents)
- Drug ingestion (e.g., heroin, opioids, aspirin)
- Hemolytic disorders
- Multiple blood transfusions
- Cardiopulmonary bypass
- Submersion in water with water aspiration (especially in fresh water)

ARDS also can occur from direct lung injury. Aspiration of acidic gastric contents, pneumonia, drowning, and inhaling toxic fumes are examples of conditions causing direct lung injury. With such events, surfactant production is impaired and the remaining surfactant is diluted. This situation leads to atelectasis, decreased lung compliance, and shunting (movement of blood in the lungs without gas exchange and oxygenation) (Carroll et al., 2013; Dechert et al., 2012).

Genetic/Genomic Considerations

Patient-Centered Care QSEN

An increased genetic risk is suspected in the development and progression of ARDS. Variations in the genes responsible for surfactant production appear to increase the predisposition to developing ARDS as does variation in the genes responsible for cytokine production during inflammatory events associated with sepsis (Dechert et al., 2012). Ask about the patient's previous responses to infection or injury. If the patient has consistently had greater-than-expected inflammatory responses, he or she may be at increased risk for ARDS after ALI and should be monitored for manifestations of the disorder.

Incidence and Prevalence.

The actual incidence of ARDS is unknown because it is part of other health problems and is not systematically reported as a separate disorder. According to the ARDS Foundation, about 150,000 cases of ARDS occur yearly in North America (ARDS Foundation, 2013) although many health care professionals believe this estimate to be low.

Health Promotion and Maintenance

The nursing priority in the prevention of ARDS is early recognition of patients at high risk for the syndrome. Because patients who aspirate gastric contents are at great risk, closely assess and monitor those receiving tube feedings (because the tube keeps the gastric sphincter open) and those with problems that impair swallowing and gag reflexes. As required by The Joint Commission's NPSGs to prevent ARDS, follow meticulous infection control guidelines, including handwashing, invasive catheter and wound care, and Contact Precautions. Teach unlicensed assistive personnel (UAP) the importance of always adhering to infection control guidelines. Carefully observe patients who are being treated for any health problem associated with ARDS.

❖ Patient-Centered Collaborative Care

◆ Assessment

Physical Assessment/Clinical Manifestations.

Assess the breathing of any patient at increased risk for ARDS. Determine whether increased work of breathing is present, as indicated by hyperpnea, noisy respiration, cyanosis, pallor, and retraction **intercostally** (between the ribs) or **substernally** (below the ribs). Document sweating, respiratory effort, and any change in mental status.

Abnormal lung sounds are ***not*** *heard on auscultation because the edema occurs first in the interstitial spaces and not in the airways.* Assess vital signs at least hourly for hypotension, tachycardia, and dysrhythmias.

Diagnostic Assessment.

The diagnosis of ARDS is established by a lowered partial pressure of arterial oxygen (Pa_{O_2}) value (decreased gas exchange and oxygenation), determined by arterial blood gas (ABG) measurements. Because a widening alveolar oxygen gradient (increased fraction of inspired oxygen [Fi_{O_2}] that does not lead to increased Pa_{O_2} levels) develops with increased shunting of blood, the patient has a progressive need for higher levels of oxygen. He or she develops refractory hypoxemia and often needs intubation and mechanical ventilation. Sputum cultures obtained by bronchoscopy and by transtracheal aspiration are used to determine if a lung infection also is present.

The chest x-ray may show diffuse haziness or a "whited-out" (ground-glass) appearance of the lung. An ECG rules out cardiac problems and usually shows no specific changes. Hemodynamic monitoring with a pulmonary artery catheter helps diagnose ARDS. In ARDS, the pulmonary capillary wedge pressure (PCWP) is low to normal, whereas in cardiac-induced pulmonary edema, the PCWP is above 18 mm Hg. Chapter 38 explains hemodynamic monitoring in detail.

Interventions

The patient with ARDS often needs intubation and mechanical ventilation with positive end-expiratory pressure (PEEP) or continuous positive airway pressure (CPAP). Best practice involves using "open lung" and lung protective ventilation strategies. Low tidal volumes (6 mL/kg of body weight) have been shown to prevent lung injury. PEEP is started at 5 cm H_2O and increased to keep oxygen saturation adequate. PEEP levels may need to be high. Pressure-controlled ventilation is preferred over volume-controlled ventilation to promote the non-functional alveoli to participate in gas exchange.

Airway pressure-release ventilation (APRV) and high-frequency oscillatory ventilation are alternative modes of mechanical ventilation that improve gas exchange with oxygenation and ventilation in patients with moderate to severe ARDS (Bortolotto & Makic, 2012). Sedation and paralysis may be needed for adequate ventilation and to reduce tissue oxygen needs. Because one of the side effects of PEEP is tension pneumothorax, assess lung sounds hourly and suction as often as needed

to maintain a patent airway.

Positioning may be important in promoting gas exchange, but the exact position is controversial. Some patients do better in the prone position, especially if it is started early in the disease course. Prone positioning may be achieved using a mechanical turning device, although the turning equipment is awkward and care in the prone position is more difficult. Automated kinetic beds are available to assist with turning. Manually turning the patient every 2 hours has been shown to improve perfusion; however, this intervention often is not performed as frequently as needed. Early progressive mobility also has demonstrated benefit in reducing ventilator needs, days on the ventilator, and mortality (Morris et al., 2011; Wright & Flynn, 2011).

For severe ARDS, extracorporeal membrane oxygenation (ECMO) using heart-lung bypass equipment has been a successful life support technique when the patient does not improve with more traditional management. However, the proper timing of ECMO and standardization of this therapy for best outcomes have not been established (Williams, 2013).

Drug and Fluid Therapy.

Antibiotics are used to treat infections when organisms are identified. Other drugs are used to manage any underlying cause. Currently, no treatments reverse the pathologic changes in the lungs, although many interventions are under investigation. These include agents that modify the inflammatory responses and reduce oxidative stress, such as vitamins C and E, *N*-acetylcysteine, and nitric oxide, as well as surfactant replacement (Carroll et al., 2013).

Research shows that patients with ARDS who receive conservative fluid therapy have improved lung function and a shorter duration of mechanical ventilation and ICU length of stay compared with those who receive more liberal fluid therapy. Conservative fluid therapy involves infusing smaller amounts of IV fluid and the use of diuretics to maintain fluid balance, whereas liberal fluid therapy often results in an increasingly positive fluid balance and more edema (Ferri, 2013).

Nutrition Therapy.

The patient with ARDS is at risk for malnutrition, which further reduces respiratory muscle function and the immune response. Consultation with a dietitian is needed, and enteral nutrition (tube feeding) or parenteral nutrition is started as soon as possible.

Case Management.

Case management of the patient with ARDS focuses on the phases of ARDS rather than on day-to-day care. The course of ARDS and its management are divided into three phases:

- *Exudative phase.* This phase includes early changes of dyspnea and tachypnea resulting from the alveoli becoming fluid-filled and from pulmonary shunting and atelectasis. Early interventions focus on supporting the patient and providing oxygen.
- *Fibroproliferative phase*. Increased lung damage leads to pulmonary hypertension and fibrosis. The body attempts to repair the damage, and increasing lung involvement reduces gas exchange and oxygenation. Multiple organ dysfunction syndrome (MODS) can occur. Interventions focus on delivering adequate oxygen, preventing complications, and supporting the lungs.
- *Resolution phase.* Usually occurring after 14 days, resolution of the injury can occur; if not, the patient either dies or has chronic disease. Fibrosis may or may not occur. Research indicates that patients surviving ARDS often have neuropsychological deficits and poor quality-of-life scores (Dechert et al., 2012; Mathay & Zemans, 2011).

Clinical Judgment Challenge

Patient-Centered Care; Teamwork and Collaboration QSEN

A 50-year-old patient is admitted to the medical-surgical floor from the emergency department with severe abdominal pain thought to be from acute pancreatitis. He has a history of drinking at least a case of beer a day. He also smokes and appears cachectic. His old chart indicates a history of COPD, but he does not take drugs for this. He does have a new productive cough. At change of shift, the nurse finds the patient dyspneic and slightly confused. Lung sounds have wheezes, and he is mildly febrile. Pulse is 120 beats/min, respirations are 32 breaths/min, and blood pressure is 118/64 mm Hg (baseline). Oximetry shows an Spo_2 of 91%.

1. What risk factors for ARDS does this patient have?
2. Explain the relationship between the lung sounds and the oximetry reading.
3. What diagnostic testing should you be prepared to obtain?

Two hours after applying oxygen at 3 liters/nasal cannula, the patient's Spo_2 is now 89%.

4. What additional measures do you anticipate for this patient?

The Patient Requiring Intubation and Ventilation

Pathophysiology

With mechanical ventilation, the patient who has severe problems of gas exchange may be supported until the underlying problem improves or resolves. Usually mechanical ventilation is a temporary life-support technique. The need for this support may be lifelong for those with severe restrictive lung disease or chronic progressive neuromuscular disease that reduces ventilation.

Mechanical ventilation is most often used for patients with hypoxemia and progressive alveolar hypoventilation with respiratory acidosis. The hypoxemia is usually due to pulmonary shunting of blood when other methods of oxygen delivery do not provide a sufficiently high fraction of inspired oxygen (Fio_2). Mechanical ventilation may be used for patients who need ventilatory support after surgery, those who expend too much energy with breathing and barely maintain adequate gas exchange, or those who have general anesthesia or heavy sedation.

Patient-Centered Collaborative Care

Assess the patient to be intubated in the same way as for other breathing problems. Once mechanical ventilation has been started, assess the respiratory system on an ongoing basis. Monitor and assess for problems related to the artificial airway or ventilator.

Endotracheal Intubation

The patient who needs mechanical ventilation must have an artificial airway. The most common type of airway for a short-term basis is the endotracheal (ET) tube. To reduce tracheal and vocal cord damage, a tracheostomy is considered if an artificial airway is needed for longer than 10 to 14 days (see Chapter 28). The expectations of intubation are to maintain a patent airway, provide a means to remove secretions, and provide ventilation and oxygen.

Endotracheal Tube.

An ET tube is a long polyvinyl chloride tube that is passed through the mouth or nose and into the trachea (Fig. 32-2). When properly positioned, the tip of the ET tube rests about 2 cm above the **carina** (the point at which the trachea divides into the right and left mainstem bronchi). Oral intubation is a fast and easy way to establish an airway and is often performed as an emergency procedure. The nasal route is used

for oral surgeries and when oral intubation is not possible but should be avoided with midface trauma or possible basilar skull fracture. This route is not used if the patient has a blood clotting problem. An anesthesiologist, nurse anesthetist, or respiratory therapist usually performs the intubation.

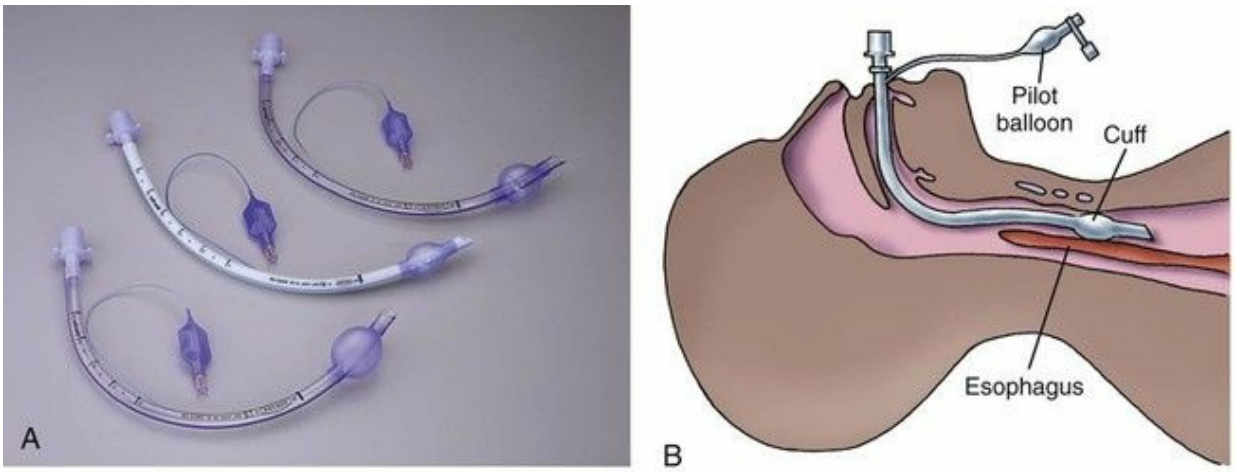

FIG. 32-2 **A,** Endotracheal tubes. **B,** Correct placement of an oral endotracheal tube.

The shaft of the tube has a radiopaque line running the length of the tube. This line shows on x-ray and is used to determine correct tube placement. Short horizontal lines (depth markings) are used to place the tube correctly at the naris or mouth (at the incisor tooth) and to identify how far the tube has been inserted.

The cuff at the distal end of the tube is inflated after placement and creates a seal between the trachea and the cuff. The seal ensures delivery of a set tidal volume when mechanical ventilation is used. The cuff is inflated using a minimal-leak technique: when the cuff is inflated to an adequate sealing volume, a minimal amount of air can pass around the cuff to the vocal cords, nose, or mouth. The patient cannot talk when the cuff is inflated.

The pilot balloon with a one-way valve permits air to be inserted into the cuff and prevents air from escaping. This balloon is a guide for determining whether air is present in the cuff, but it does not show how much or how little air is present.

The adaptor connects the ET tube to ventilator tubing or an oxygen delivery system. The endotracheal tube size is listed on the shaft of the tube. Adult tube sizes range from 7 to 9 mm. Tube size selected is based on the size of the patient.

Preparing for Intubation.

Know the proper procedure for summoning intubation personnel in the facility to the bedside in an emergency situation. Explain the procedure to the patient as clearly as possible. *Basic life support measures, such as obtaining a patent airway and delivering 100% oxygen by a manual resuscitation bag with a facemask, are crucial to survival until help arrives.*

Nursing Safety Priority QSEN

Critical Rescue

For the patient requiring emergency intubation and ventilation, bring the code (or "crash") cart, airway equipment box, and suction equipment (often already on the code cart) to the bedside. Maintain a patent airway through positioning (head-tilt, chin-lift) and the insertion of an oral or nasopharyngeal airway until the patient is intubated. Delivering manual breaths with a bag-valve-mask may also be required.

During intubation, the nurse coordinates the rescue response and continuously monitors the patient for changes in vital signs, signs of hypoxia or hypoxemia, dysrhythmias, and aspiration. Ensure that each intubation attempt lasts no longer than 30 seconds, preferably less than 15 seconds. After 30 seconds, provide oxygen by means of a mask and manual resuscitation bag to prevent hypoxia and cardiac arrest. Suction as necessary (Morton & Fontaine, 2013; Urden et al., 2012).

Verifying Tube Placement.

Immediately after an ET tube is inserted, placement should be verified. The most accurate ways to verify placement are by checking end-tidal carbon dioxide levels and by chest x-ray. Assess for breath sounds bilaterally, sounds over the gastric area, symmetric chest movement, and air emerging from the ET tube. If breath sounds and chest wall movement are absent on the left side, the tube may be in the right mainstem bronchus. The person intubating the patient should be able to reposition the tube without repeating the entire intubation procedure.

If the tube is in the stomach, the abdomen may be distended and must be decompressed with a nasogastric (NG) tube after the ET tube is replaced. Monitor chest wall movement and breath sounds until tube placement is verified by chest x-ray.

Stabilizing the Tube.

The nurse, respiratory therapist, or anesthesia provider stabilizes the ET tube at the mouth or nose. The tube is marked at the level where it touches the incisor tooth or naris. Two people working together use a head halter technique to secure the tube. An oral airway also may be inserted or a commercial bite block placed to keep the patient from biting an oral endotracheal tube. One person stabilizes the tube at the correct position and prevents head movement while a second person applies the tube holding device. Commercial tube holders are preferred over securing the tube with tape. After the procedure is completed, verify and document the presence of bilateral and equal breath sounds and the level of the tube.

Nursing Care.

The priority nursing action when caring for an intubated patient is maintaining a patent airway. Assess tube placement, cuff leak, breath sounds, indications of adequate gas exchange and oxygenation, and chest wall movement regularly.

Nursing Safety Priority QSEN

Critical Rescue

If an intubated patient shows manifestations of decreased oxygenation, check for DOPE: displaced tube, obstructed tube (most often with secretions), pneumothorax, and equipment problems (Dennison et al., 2011).

Prevent the patient from pulling or tugging on the tube to avoid tube dislodgment, and check the pilot balloon to ensure that the cuff is inflated. Suctioning, coughing, and speaking can cause dislodgment. Neck flexion, neck extension, and rotation of the head also can cause the tube to move. Tongue movement also can change the tube's position. When other measures fail, obtain a prescription for soft wrist restraints and apply these for the patient who is pulling on the tube. *Restraints are used as a last resort to prevent accidental extubation.* Adequate sedation (chemical restraint) may be needed to decrease agitation or prevent extubation. Obtain permission for restraints from the patient or family. More information on airway management is found in Chapter 28.

Complications of an ET or nasotracheal tube can occur during placement, while in place, during extubation, or after extubation (either early or late). Common complications include tube obstruction,

dislodgment, pneumothorax, tracheal tears, bleeding, and infection. Trauma and other problems can occur to the face; eye; nasal and paranasal areas; oral, pharyngeal, bronchial, tracheal, and pulmonary areas; esophageal and gastric areas; and cardiovascular, musculoskeletal, and neurologic systems.

NCLEX Examination Challenge

Safe and Effective Care Environment

The nurse caring for a client who is intubated and receiving mechanical ventilation notes that her oxygen saturation is 89%, her heart rate is 120 beats/min, and she is increasingly agitated and restless. On auscultation, the nurse finds that the lung sounds are diminished on one side. Which action does the nurse perform first?

A Notify the provider, and prepare for re-intubation or repositioning the tube.
B Document the findings, and request sedation from the provider.
C Call respiratory therapy to obtain a set of arterial blood gases.
D Reposition the tube, and call radiology for a stat chest x-ray.

Mechanical Ventilation

Mechanical ventilation to support and maintain gas exchange is used in many settings, not just in critical care units. The nurse plays a pivotal role in the coordination of care and the prevention of problems. Chart 32-9 lists best practices for patient care during mechanical ventilation.

Chart 32-9 Best Practice for Patient Safety & Quality Care QSEN

Care of the Patient Receiving Mechanical Ventilation

- Assess the patient's respiratory status at least every 4 hours for the first 24 hours and then as needed:
  - Take vital signs at least every 4 hours.
  - Assess the patient's color (especially lips and nail beds).
  - Observe the patient's chest for bilateral expansion.
  - Assess the placement of the nasotracheal or endotracheal tube.
  - Obtain pulse oximetry reading.
  - Evaluate ABGs as available.
  - Maintain head of the bed more than 30 degrees when patient is

supine to prevent aspiration and ventilator-associated pneumonia.

- Document pertinent observations in the patient's medical record.
- Check at least every 8 hours to be sure the ventilator setting is as prescribed.
- Check to be sure alarms are set (especially low-pressure and low-exhaled volume).
- If the patient is on PEEP, observe the peak airway pressure dial to determine the proper level of PEEP.
- Check the exhaled volume digital display to be sure the patient is receiving the prescribed tidal volume.
- Empty ventilator tubings when moisture collects. *Never empty fluid in the tubing back into the cascade.*
- Ensure humidity by keeping delivered air temperature maintained at body temperature.
- Be sure the tracheostomy cuff (or endotracheal cuff) is adequately inflated to ensure tidal volume.
- Auscultate the lungs for crackles, wheezes, equal breath sounds, and decreased or absent breath sounds.
- Check the patient's need for tracheal, oral, or nasal suctioning every 2 hours, and suction as needed.
- Assess the patient's mouth around the ET tube for pressure ulcers.
- Perform mouth care every 2 hours.
- Change tracheostomy tube holder or tape or endotracheal tube holder or tape as needed:
  - Carefully move the oral endotracheal tube to the opposite side of the mouth once daily to prevent ulcers.
  - Provide tracheostomy care every 8 hours.
- Assess ventilated patients for GI distress (diarrhea, constipation, tarry stools).
- Maintain accurate intake and output records to monitor fluid balance.
- Turn the patient at least every 2 hours, and get the patient out of bed as prescribed to promote pulmonary hygiene and prevent complications of immobility.
- Schedule treatments and nursing care at intervals for rest.
- Monitor the patient's progress on current ventilator settings, and make appropriate changes, as indicated.
- Monitor the patient for the effectiveness of mechanical ventilation in terms of his or her physiologic and psychological status.
- Monitor for adverse effects of mechanical ventilation: infection, barotrauma, reduced cardiac output.

- Position the patient to facilitate ventilation-perfusion ($\dot{V}/\dot{Q}$) matching ["good lung down"], as appropriate.
- Monitor the effects of ventilator changes on oxygenation and the patient's subjective response.
- Monitor readiness to wean.
- Explain all procedures and treatments; provide access to a call light; visit the patient frequently.
- Provide a method of communication. Request consultation with a speech-language pathologist for assistance, if necessary.
- Initiate relaxation techniques, as appropriate.
- Administer muscle-paralyzing agents, sedatives, and narcotic analgesics, as prescribed.
- Include the patient and family whenever possible (especially during suctioning and tracheostomy care).

ABGs, Arterial blood gases; *ET,* endotrachel; *PEEP,* positive end-expiratory pressure.

The purposes of mechanical ventilation are to improve gas exchange and to decrease the work needed for effective breathing. It is used to support the patient until lung function is adequate or until the acute episode has passed. *A ventilator does not cure diseased lungs; it provides ventilation until the patient can resume the process of breathing on his or her own.* Remember *why* the patient is using the ventilator so that management efforts also focus on correcting the causes of the respiratory failure. If normal gas exchange with oxygenation, ventilation, and respiratory muscle strength is achieved, mechanical ventilation can be discontinued.

Types of Ventilators.

Many types of ventilators are available. The ventilator selected depends on the severity of the breathing problem and the length of time ventilator support is needed. Most ventilators are positive-pressure ventilators. During inspiration, pressure is generated that pushes air into the lungs and expands the chest. Usually an endotracheal (ET) tube or tracheostomy is needed. Positive-pressure ventilators are classified by the mechanism that ends inspiration and starts expiration. Inspiration is cycled in three major ways: pressure-cycled, time-cycled, or volume-cycled.

Pressure-cycled ventilators push air into the lungs until a preset airway pressure is reached. Tidal volumes and inspiratory time vary. These ventilators are used for short periods, such as just after surgery and for

respiratory therapy. Bi-level positive airway pressure (Bi-PAP) ventilators are a newer form of pressure-cycled ventilator in which the ventilator provides a preset inspiratory pressure and an expiratory pressure similar to positive end-expiratory pressure (PEEP).

Time-cycled ventilators push air into the lungs until a preset time has elapsed. Tidal volume and pressure vary, depending on the needs of the patient and the type of ventilator.

Volume-cycled ventilators push air into the lungs until a preset volume is delivered. A constant tidal volume is delivered regardless of the pressure needed to deliver the tidal volume. A set pressure limit, however, prevents excessive pressure from being exerted on the lungs. The advantage of this type of ventilator is that a constant tidal volume is delivered regardless of changes in lung or chest wall compliance or in airway resistance.

Microprocessor ventilators are computer-managed positive-pressure ventilators. A computer is built into the ventilator to allow ongoing monitoring of ventilatory functions, alarms, and patient conditions. It often has components of volume-, time-, and pressure-cycled ventilators. This type of ventilator is more responsive to patients who have severe lung disease and those who need prolonged weaning trials. Examples include the Draeger Evita XL (Fig. 32-3) and Puritan-Bennett 840.

FIG. 32-3 Display signals, alarms, and control panel of a typical volume-cycled ventilator.

Modes of Ventilation.

The mode of ventilation is the way in which the patient receives breaths from the ventilator. The most common modes are assist-control ventilation, synchronized intermittent mandatory ventilation, and bi-level positive airway pressure ventilation.

Assist-control (AC) ventilation is the mode used most often as a resting mode. The ventilator takes over the work of breathing for the patient. The tidal volume and ventilatory rate are preset. If the patient does not trigger spontaneous breaths, a ventilatory pattern is established by the ventilator. It is programmed to respond to the patient's inspiratory effort if he or she begins a breath. In this case, the ventilator delivers the preset tidal volume while allowing the patient to control the rate of breathing.

A disadvantage of the AC mode is that the ventilator continues to deliver a preset tidal volume even when the patient's spontaneous breathing rate increases. This can cause hyperventilation and respiratory alkalosis. Investigate and correct causes of hyperventilation, such as pain, anxiety, or acid-base imbalances.

Synchronized intermittent mandatory ventilation (SIMV) is similar to AC ventilation in that tidal volume and ventilatory rate are preset. If the patient does not breathe, a ventilatory pattern is established by the

ventilator. Unlike the AC mode, SIMV allows spontaneous breathing at the patient's own rate and tidal volume between the ventilator breaths. It can be used as a main ventilatory mode or as a weaning mode. When used for weaning, the number of mechanical breaths (SIMV breaths) is gradually decreased (e.g., from 12 to 2) as the patient resumes spontaneous breathing. The mandatory ventilator breaths are delivered when the patient is ready to inspire. This action coordinates breathing between the ventilator and the patient.

Bi-level positive airway pressure (BiPAP) provides noninvasive pressure support ventilation by nasal mask or facemask. It is most often used for patients with sleep apnea but also may be used for patients with respiratory muscle fatigue or impending respiratory failure to avoid more invasive ventilation methods.

Other modes of ventilation, such as pressure support and continuous flow (flow-by), are part of most microprocessor ventilators. Both types decrease the work of breathing and are used for weaning patients from mechanical ventilation. Other modes are maximum mandatory ventilation (MMV), inverse inspiration-expiration (I/E) ratio, permissive hypercarbia, airway pressure–release ventilation (APRV), proportional assist ventilation, and high-frequency oscillation. Most modes use special ventilators, tubing, or airways.

Ventilator Controls and Settings.

The volume-cycled ventilator is the most widely used type in the acute care setting. Regardless of the type of volume-cycled ventilator used, the controls and types of settings are universal (see Fig. 32-3). The physician prescribes the ventilator settings, and usually the ventilator is readied or set up by the respiratory therapy department. The nurse assists in connecting the patient to the ventilator and monitors the ventilator settings in conjunction with respiratory therapy.

Tidal volume (V_T) is the volume of air the patient receives with each breath, as measured on either inspiration or expiration. The average prescribed V_T ranges between 7 and 10 mL/kg of body weight. Adding a zero to a patient's weight in kilograms gives an estimate of tidal volume.

Rate, or breaths/min, is the number of ventilator breaths delivered per minute. The rate is usually set between 10 and 14 breaths/min.

Fraction of inspired oxygen (Fio_2) is the oxygen level delivered to the patient. The prescribed Fio_2 is based on the ABG values and the patient's condition. The range is 21% to 100% oxygen.

The oxygen delivered to the patient is warmed to body temperature

(98.6° F [37° C]) and humidified to 100%. This is needed because upper air passages of the respiratory tree, which normally warm and humidify air, are bypassed. Humidifying and warming prevent mucosal damage.

Peak airway (inspiratory) pressure (PIP) is the pressure used by the ventilator to deliver a set tidal volume at a given lung compliance. The PIP value appears on the display of the ventilator. It is the highest pressure reached during inspiration. Monitoring trends in PIP that reflect changes in resistance of the lungs and resistance in the ventilator. An increased PIP reading means increased airway resistance in the patient or in the ventilator tubing (bronchospasm or pinched tubing), increased secretions, pulmonary edema, or decreased pulmonary compliance (the lungs or chest wall is "stiffer" and harder to inflate). An upper pressure limit is set to prevent barotrauma. When the limit is reached, the high-pressure alarm sounds and the remaining volume is not given.

Continuous positive airway pressure (CPAP) applies positive airway pressure throughout the entire respiratory cycle for spontaneously breathing patients. Sedating drugs are given lightly or not at all when the patient is receiving CPAP so that respiratory effort is not suppressed. CPAP keeps the alveoli open during inspiration and prevents alveolar collapse during expiration. This process increases functional residual capacity (FRC) and improves gas exchange and oxygenation.

CPAP is commonly used to help in the weaning process. During CPAP, no ventilator breaths are delivered. The ventilator just delivers oxygen and provides monitoring and an alarm system. The respiratory pattern is determined by the patient's efforts. Normal levels of CPAP are 5 to 15 cm H_2O to promote adequate gas exchange and oxygenation. If no pressure is set, the patient receives no positive pressure. The patient is then using the ventilator as a T-piece with alarms. Modifications of CPAP include nasal CPAP and BiPAP, which are used on a temporary basis for select problems.

Positive end-expiratory pressure (PEEP) is positive pressure exerted during expiration. PEEP improves oxygenation by enhancing gas exchange and preventing atelectasis. It is used to treat persistent hypoxemia that does not improve with an acceptable oxygen delivery level. It may be added when the arterial oxygen pressure (Pa_{O_2}) remains low with an Fi_{O_2} of 50% to 70% or greater.

The need for PEEP indicates a severe gas exchange problem. *It is important to lower the Fi_{O_2} delivered whenever possible because prolonged use of a high Fi_{O_2} can damage lungs from the toxic effects of oxygen.* PEEP prevents alveoli

from collapsing because the lungs are kept partially inflated so that alveolar-capillary gas exchange is promoted throughout the ventilatory cycle. The effect should be an increase in arterial blood oxygenation so that the Fi_{O_2} can be decreased.

PEEP is "dialed in" on the control panel. The amount of PEEP is usually 5 to 15 cm H_2O (although higher PEEP can be used) and is monitored on the peak airway pressure dial, the same dial used to read the PIP. When PEEP is added, the dial does not return to zero at the end of exhalation; rather, it returns to a baseline that is increased from zero by the amount of PEEP applied.

Flow rate is how fast each breath is delivered and is usually set at 40 L/min. *If a patient is agitated or restless, has a widely fluctuating inspiratory pressure reading, or has other signs of air hunger, the flow may be set too low. Increasing the flow should be tried before using chemical restraints.*

Other settings may be used, depending on the type of ventilator and mode of ventilation. Examples include inspiratory and expiratory cycle, waveform, expiratory resistance, and plateau.

Nursing Management.

The use of mechanical ventilation involves a collaborative and complex decision-making process for the patient and family and the health care team. Address the physical and psychological concerns of the patient and family because the mechanical ventilator often causes them anxiety. Explain the purpose of the ventilator, and acknowledge the patient's and family's feelings. Encourage the patient and family to express their concerns. Act as the coach to help and support them through this experience. Patients undergoing mechanical ventilation in ICUs often experience delirium, or "ICU psychosis." These patients need frequent, repeated explanations and reassurance.

When caring for a ventilated patient, be concerned with the patient first and the ventilator second. If the ventilator alarm sounds, examine the patient for breathing, color, and oxygen saturation before assessing the ventilator. It is vital to understand why mechanical ventilation is needed. Some problems requiring ventilation, such as excessive secretions, sepsis, and trauma, require different interventions to successfully wean from the ventilator. The patient's chronic health problems, especially chronic obstructive pulmonary disease (COPD), left-sided heart failure, anemia, and malnutrition, may slow weaning from mechanical ventilation and require close monitoring and intervention.

Nursing Safety Priority QSEN

Action Alert

The nursing priorities in caring for the patient during mechanical ventilation are monitoring and evaluating patient responses, managing the ventilator system safely, and preventing complications.

Monitoring the Patient's Response.

Monitor, evaluate, and document the patient's response to the ventilator. Assess vital signs and listen to breath sounds every 30 to 60 minutes at first. Monitor respiratory parameters (e.g., capnography, pulse oximetry), and check ABG values (Carlisle, 2014). Monitoring provides information to guide the patient's activities, such as weaning, physical or occupational therapy, and self-care. Pace activities to ensure effective ventilation with adequate gas exchange and oxygenation. Interpret ABG values to evaluate the effectiveness of ventilation and determine whether ventilator settings need to be changed (Lian, 2013).

Assess the breathing pattern in relation to the ventilatory cycle to determine whether the patient is tolerating or fighting the ventilator. Patient asynchrony with mechanical ventilation has many causes and reduces the effectiveness of gas exchange (Mellott et al., 2014). Assess and record breath sounds, including bilateral equal breath sounds to ensure proper endotracheal (ET) tube placement. Determine the need for suctioning by observing secretions for type, color, and amount. Assess the area around the ET tube or tracheostomy site at least every 4 hours for color, tenderness, skin irritation, and drainage, and document the findings.

The nurse spends the most time with the patient and is most likely to be the first person to recognize changes in vital signs or ABG values, fatigue, or distress. Promptly coordinate with the physician and respiratory therapist to implement the appropriate interventions.

Nursing Safety Priority QSEN

Critical Rescue

If the patient develops respiratory distress during mechanical ventilation, immediately remove the ventilator and provide ventilation with a bag-valve-mask device. This action allows quick determination of whether the problem is with the ventilator or with the patient.

Serve as a resource for the psychological needs of the patient and family. Anxiety can reduce tolerance for mechanical ventilation. Skilled and sensitive nursing care promotes emotional well-being and synchrony with the ventilator. The patient cannot speak, and communication can be frustrating and anxiety-producing. The patient and family may panic because they believe that the voice has been lost. Reassure them that the ET tube prevents speech only temporarily.

Plan methods of communication to meet the patient's needs, such as a picture board, pen and paper, alphabet board, electronic tablet computer, or programmable speech-generating device (Grossbach et al., 2011). Finding a successful means for communication is important because the patient often feels isolated by the inability to speak. (See Chart 29-2 in Chapter 29.) Anticipate his or her needs, and provide easy access to frequently used belongings. Visits from family, friends, and pets and keeping a call light within reach are some ways of giving patients a sense of control over the environment. Urge them to participate in self-care.

Managing the Ventilator System.

Ventilator settings are prescribed by the health care provider in conjunction with the respiratory therapist. Settings include tidal volume, respiratory rate, fraction of inspired oxygen (Fio_2), and mode of ventilation (assist-control [AC] ventilation, synchronized intermittent mandatory ventilation [SIMV], and adjunctive modes, such as positive end-expiratory pressure [PEEP], pressure support, or continuous flow).

Perform and document ventilator checks according to the standards of the unit or facility. Respond promptly to alarms. During a ventilator check, compare the prescribed ventilator settings with the actual settings. Check the level of water in the humidifier and the temperature of the humidifying system to ensure that they are not too high. Temperature extremes damage the airway mucosa. Remove any condensation in the ventilator tubing by draining water into drainage collection receptacles, and empty them every shift.

Nursing Safety Priority QSEN

Action Alert

To prevent bacterial contamination, do not allow moisture and water in the ventilator tubing to enter the humidifier.

Mechanical ventilators have alarm systems that warn of a problem with

either the patient or the ventilator. *As required by The Joint Commission's NPSGs, alarm systems must be activated and functional at all times. If the cause of the alarm cannot be determined, ventilate the patient manually with a resuscitation bag until the problem is corrected by another health care professional*. The major alarms on a ventilator indicate either a high pressure or a low exhaled volume. Table 32-5 lists interventions for causes of ventilator alarms.

TABLE 32-5

Nursing Interventions for Various Causes of Ventilator Alarms

CAUSE	NURSING INTERVENTIONS
High-Pressure Alarm (sounds when peak inspiratory pressure reaches the set alarm limit [usually set 10-20 mm Hg above the patient's baseline PIP])	
An increased amount of secretions or a mucus plug is in the airways.	Suction as needed.
The patient coughs, gags, or bites on the oral ET tube.	Insert oral airway to prevent biting on the ET tube.
The patient is anxious or fights the ventilator.	Provide emotional support to decrease anxiety. Increase the flow rate. Explain all procedures to the patient. Provide sedation or paralyzing agent per the health care provider's prescription.
Airway size decreases related to wheezing or bronchospasm.	Auscultate breath sounds. Collaborate with respiratory therapy to provide prescribed bronchodilators.
Pneumothorax occurs.	Alert the health care provider or Rapid Response Team about a new onset of decreased breath sounds or unequal chest excursion, which may be due to pneumothorax. Auscultate breath sounds.
The artificial airway is displaced; the ET tube may have slipped into the right mainstem bronchus.	Assess the chest for unequal breath sounds and chest excursion. Obtain a chest x-ray as ordered to evaluate the position of the ET tube. After the proper position is verified, secure the tube in place.
Obstruction in tubing occurs because the patient is lying on the tubing or there is water or a kink in the tubing.	Assess the system, beginning with the artificial airway and moving toward the ventilator.
There is increased PIP associated with deliverance of a sigh.	Empty water from the ventilator tubing, and remove any kinks. Coordinate with respiratory therapist or physician to adjust the pressure alarm.
Decreased compliance of the lungs is noted; a trend of gradually increasing PIP is noted over several hours or a day.	Evaluate the reasons for the decreased compliance of the lungs. Increased PIP occurs in ARDS, pneumonia, or any worsening of pulmonary disease.
Low Exhaled Volume (or Low-Pressure) Alarm (sounds when there is a disconnection or leak in the ventilator circuit or a leak in the patient's artificial airway cuff)	
A leak in the ventilator circuit prevents breath from being delivered.	Assess all connections and all ventilator tubing for disconnection.
The patient stops spontaneous breathing in the SIMV or CPAP mode or on pressure support ventilation.	Evaluate the patient's tolerance of the mode.
A cuff leak occurs in the ET or tracheostomy tube.	Evaluate the patient for a cuff leak. A cuff leak is suspected when the patient can talk (air escapes from the mouth) or when the pilot balloon on the artificial airway is flat (see Tracheostomy Tubes section in Chapter 28).

ARDS, Acute respiratory distress syndrome; *CPAP,* continuous positive airway pressure; *ET,* endotracheal; *PIP,* peak inspiratory pressure; *SIMV,* synchronized intermittent mandatory ventilation.

Assess and care for the ET or tracheostomy tube. Maintain a patent airway by suctioning when any of these conditions are present:

- Secretions
- Increased peak airway (inspiratory) pressure (PIP)
- Rhonchi
- Decreased breath sounds

Proper care of the ET or tracheostomy tube also ensures a patent airway. Assess tube position at least every 2 hours, especially when the

airway is attached to heavy ventilator tubing that may pull on the tube. Position the ventilator tubing so that the patient can move without pulling on the ET or tracheostomy tube, possibly dislodging it. To detect changes in tube position, mark it where the tube touches the patient's teeth or nose. Give oral care per facility policy. Standardized oral care has been shown to reduce ventilator-associated pneumonia (VAP), specifically using chlorhexidine oral rinses twice daily (Kiyoshi-Teo et al., 2014; Morton & Fontaine, 2013; Urden et al., 2012).

Special attention is needed for the patient being transported while receiving mechanical ventilation. Monitor Spo_2 during transport to assess adequacy of ventilation. Assess lung sounds each time the patient is moved, transferred, or turned.

NCLEX Examination Challenge

Safe and Effective Care Environment

A student nurse is working with a client in the ICU who is intubated and being mechanically ventilated. What action by the student causes the registered nurse to intervene?
A Repositioning the client every 2 hours
B Providing oral care with chlorhexidine rinse
C Checking tube placement at the client's incisor
D Turning off ventilator alarms while working in the room

Preventing Complications.

Most problems are caused by the positive pressure from the ventilator. Nearly every body system is affected.

Cardiac problems from mechanical ventilation include hypotension and fluid retention. Hypotension is caused by positive pressure that increases chest pressure and inhibits blood return to the heart. The decreased blood return reduces cardiac output, causing hypotension, especially in patients who are dehydrated or need high PIP for ventilation. Teach the patient to avoid a **Valsalva maneuver** (bearing down while holding the breath).

Fluid is retained because of decreased cardiac output. The kidneys receive less blood flow, which stimulates the renin-angiotensin-aldosterone system to retain fluid. Humidified air in the ventilator system contributes to fluid retention. Monitor the patient's fluid intake and output, weight, hydration status, and manifestations of hypovolemia.

Lung problems from mechanical ventilation include:

- **Barotrauma** (damage to the lungs by positive pressure)
- **Volutrauma** (damage to the lung by excess volume delivered to one lung over the other)
- **Atelectrauma** (shear injury to alveoli from opening and closing)
- **Biotrauma** (inflammatory response–mediated damage to alveoli)
- **Ventilator-associated lung injury/Ventilator-induced lung injury (VALI/VILI)** (damage from prolonged ventilation causing loss of surfactant, increased inflammation, fluid leakage, and noncardiac pulmonary edema)
- Acid-base imbalance

Barotrauma includes pneumothorax, subcutaneous emphysema, and pneumomediastinum. Patients at highest risk for barotrauma have chronic airflow limitation (CAL), have blebs or bullae, are on PEEP, have dynamic hyperinflation, or require high pressures to ventilate the lungs (because of "stiff" lungs, as seen in acute respiratory distress syndrome [ARDS]). Ventilator-induced lung injury can be prevented by using low tidal volumes combined with moderate levels of PEEP, especially in patients with acute lung injury (ALI) or ARDS (Bortolotto & Makic, 2012). Blood gas problems can be corrected by ventilator changes and adjustment of fluid and electrolyte imbalances.

GI and nutrition problems result from the stress of mechanical ventilation. Stress ulcers occur in many patients receiving mechanical ventilation. These ulcers complicate the nutrition status and, because the mucosa are not intact, increase the risk for systemic infection. Antacids, sucralfate (Carafate, Sulcrate), and histamine blockers such as ranitidine (Zantac) or proton-pump inhibitors such as esomeprazole (Nexium) may be prescribed as soon as the patient is intubated. Because many other acute or life-threatening events occur at the same time, nutrition is often neglected. Malnutrition is an extreme problem for these patients and is a cause of failing to wean from the ventilator. In malnutrition, the respiratory muscles lose mass and strength. The diaphragm, the major muscle of inspiration, is affected early. When it and other respiratory muscles are weak, ineffective breathing results, fatigue occurs, and the patient cannot be weaned.

Balanced nutrition, whether by diet, enteral feedings, or parenteral feeding, is essential during ventilation and should be started within 48 hours of intubation (Morton & Fontaine, 2013). Also, nutrition for the patient with chronic obstructive pulmonary disease (COPD) requires a reduction of dietary carbohydrates. During metabolism, carbohydrates are broken down to glucose, which then produces energy, carbon dioxide, and water. Excessive carbohydrate loads increase carbon dioxide

production, which the patient with COPD may be unable to exhale. Hypercarbic respiratory failure results. Nutrition formulas with a higher fat content (e.g., Pulmocare, Nutri-Vent, Intralipid) are calorie sources to combat this problem.

Electrolyte replacement is also important because electrolytes influence muscle function. Monitor potassium, calcium, magnesium, and phosphate levels, and replace them as prescribed.

Infections are a threat for the patient using a ventilator, especially ventilator-associated pneumonia (VAP). The ET or tracheostomy tube bypasses the body's filtering process and provides a direct access for bacteria to enter the lower respiratory system. The artificial airway is colonized with bacteria within 48 hours, which promotes pneumonia development and increases morbidity. Aspiration of colonized fluid from the mouth or the stomach can be a source of infection. *Infection prevention through strict adherence to infection control, especially handwashing during suctioning and care of the tracheostomy or ET tube, is essential* (*Kiyoshi-Teo et al., 2014*).

To prevent VAP, implement "ventilator bundle" order sets, which typically include these actions (Morton & Fontaine, 2013; Munro & Ruggiero, 2014; Urden et al., 2012):

- Keeping the head of the bed elevated at least 30 degrees
- Performing oral care per agency policy (usually brushing teeth every 8 hours and antimicrobial rinse [chlorhexidine] every 2 hours)
- Ulcer prophylaxis
- Preventing aspiration
- Pulmonary hygiene including chest physiotherapy, postural drainage, and turning and positioning

Using the ventilator bundle has greatly reduced the overall incidence of VAP. Vigilant oral care is a key component of the VAP prevention strategy although there is considerable variation in actual practice for timing, products used, and specific application methods (Booker et al., 2013; Hiller et al., 2013; Kiyoshi-Teo et al., 2014). (See the Evidence-Based Practice box.) Additional information on pneumonia can be found in Chapter 31.

Evidence-Based Practice QSEN

What is the Best Method and Timing of Oral Hygiene to Prevent Ventilator-Associated Pneumonia?

Hiller, B., Wilson, C., Chamberlain, D., & King, L. (2013). Preventing

ventilator-associated pneumonia through oral care, product selection, and application method. *AACN Advanced Critical Care, 24*(1), 38-58.

Ventilator-associated pneumonia (VAP) is a common, costly, and preventable complication of patients receiving mechanical ventilation. During the past decade, implementation of a "ventilator bundle" care approach focusing on prevention of aspiration and prevention of oral bacterial translocation to the lower respiratory tract has been instrumental in reducing the incidence of VAP. At first, more effort was placed on preventing aspiration; however, many studies showed that improved oral care contributed significantly to VAP reduction.

The literature abounds with different methods of oral care and products used. Some methods include toothbrushing, whereas others used sponge swabs. The most commonly used product was chlorhexidine rinse, although the concentration of this solution varied. Some studies also saw a reduction in VAP using sodium chloride solutions combined with mouth swabbing or tooth brushing. Frequency of oral care ranged from twice daily to every 2 hours. Although more vigilant oral care is key to VAP prevention, a clear best practice protocol for frequency, method of care application, and specific product use has yet to be identified. In addition, the qualifications of the person performing the oral assessment and the actual oral care vary among the studies.

Level of Evidence: 1

The results are based on a systematic review and meta-analysis of previous studies related to the outcomes of implementing oral hygiene protocols to help prevent VAP among patients receiving mechanical ventilation. Results of this analysis do indicate that education for nurses and unlicensed assistive personnel (UAP) about oral care needs for the patient receiving mechanical ventilation is needed for optimal outcomes, although no particular practice methods or products emerged as superior in reducing the incidence of VAP.

Commentary: Implications for Practice and Research

For best practice, a protocol must be both effective at preventing VAP and not harmful to the patient. Thus it must demonstrate clear positive outcomes and a lack of harmful outcomes. In addition, the protocol must be viewed as valuable by the people who are supposed to be implementing it. The previous studies analyzed showed that many nurses and UAP did not understand the link between poor oral hygiene and VAP. Thus nursing education needs to stress to students and

practicing nurses that good oral hygiene is not just an optional comfort measure but is actually a critical health promotion strategy. In addition, more research is needed into which solutions and solution concentrations provide adequate control of oral flora without causing harm. Chlorhexidine is a drug, and its use requires a health care provider's prescription. In some states, UAP would not be permitted to apply this topical solution in oral care. Thus studies are needed to determine the optimum frequency of chlorhexidine oral hygiene provided by nurses coupled with UAP-implemented sessions of oral hygiene using nonprescription solutions as part of the overall protocol.

Muscle deconditioning and weakness can occur because of immobility. Getting the patient out of bed and having him or her ambulate with help and perform exercises not only improves muscle strength but also boosts morale, enhances gas exchange, and promotes oxygen delivery to all muscles. Early progressive mobility decreases ventilator days and ICU stays (Morris et al., 2011). Early passive exercise may also be beneficial (Amidei & Sole, 2013).

Ventilator dependence is the inability to wean off the ventilator and can have both a physiologic basis and psychological basis. The longer a patient uses a ventilator, the more difficult the weaning process is because the respiratory muscles fatigue and cannot assume breathing. The health care team uses every method of weaning before a patient is declared "unweanable."

Collaborate with the physician, social worker or psychologist, and a member of the clergy to discuss with the patient and family the patient's quality of life, goals, and values. As a result of this discussion, arrange for home ventilation, nursing home placement, or withdrawal of life support (in terminal cases). Special units and facilities can maximize the rehabilitation and weaning of ventilator-dependent patients.

Weaning.

Weaning is the process of going from ventilatory dependence to spontaneous breathing. The process is prolonged by complications. Many problems can be avoided with good nursing care. For example, turning and positioning the patient not only promote comfort and prevent skin breakdown but also improve gas exchange and prevent pneumonia and atelectasis. Table 32-6 lists various weaning techniques.

TABLE 32-6

Weaning Methods

Synchronous Intermittent Mandatory Ventilation
• The patient breathes between the machine's preset breaths/min rate. • The machine is initially set on an SIMV rate of 12, meaning the patient receives a minimum of 12 breaths/min by the ventilator. • The patient's respiratory rate will be a combination of ventilator breaths and spontaneous breaths. • As the weaning process ensues, the health care provider prescribes gradual decreases in the SIMV rate, usually at a decrease of 1 to 2 breaths/min.
T-Piece Technique
• The patient is taken off the ventilator for short periods (initially 5 to 10 minutes) and allowed to breathe spontaneously. • The ventilator is replaced with a T-piece (see Chapter 28) or CPAP, which delivers humidified oxygen. • The prescribed F_{IO_2} may be higher for the patient on the T-piece than on the ventilator. • Weaning progresses as the patient can tolerate progressively longer periods off the ventilator. • Nighttime weaning is not usually attempted until the patient can maintain spontaneous respirations most of the day.
Pressure Support Ventilation
• PSV allows the patient's respiratory effort to be augmented by a predetermined pressure assist from the ventilator. • As the weaning process ensues, the amount of pressure applied to inspiration is gradually decreased. • Another method of weaning with PSV is to maintain the pressure but gradually decrease the ventilator's preset breaths/min rate.

CPAP, Continuous positive airway pressure; *Fio_2,* fraction of inspired oxygen; *PSV,* pressure support ventilation; *SIMV,* synchronized intermittent mandatory ventilation.

Considerations for Older Adults

Patient-Centered Care QSEN

The older patient, especially one who has smoked or who has a chronic lung problem such as COPD, is at risk for ventilator dependence and failure to wean. Age-related changes, such as chest wall stiffness, reduced ventilatory muscle strength, and decreased lung elasticity, reduce the likelihood of weaning. The usual manifestations of ventilatory failure—hypoxemia and hypercarbia—may be less obvious in the older adult. Use other clinical measures of gas exchange and oxygenation, such as a change in mental status, to determine breathing effectiveness.

Extubation.

Extubation is the removal of the endotracheal (ET) tube. The tube is removed when the need for intubation has been resolved. Before removal, explain the procedure. Set up the prescribed oxygen delivery system at the bedside, and bring in the equipment for emergency reintubation. Hyperoxygenate the patient, and thoroughly suction both the ET tube and the oral cavity. Then rapidly deflate the cuff of the ET tube and remove the tube at peak inspiration. Immediately instruct the patient to cough. It is normal for large amounts of oral secretions to collect. Give oxygen by facemask or nasal cannula. The fraction of

inspired oxygen (Fio_2) is usually prescribed at 10% higher than the level used while the ET tube was in place.

Monitor vital signs after extubation every 5 minutes at first, and assess the ventilatory pattern for manifestations of respiratory distress. It is common for patients to be hoarse and have a sore throat for a few days after extubation. Teach the patient to sit in a semi-Fowler's position, take deep breaths every half-hour, use an incentive spirometer every 2 hours, and limit speaking. These measures help improve gas exchange, decrease laryngeal edema, and reduce vocal cord irritation. Observe closely for respiratory fatigue and airway obstruction.

Early manifestations of obstruction are mild dyspnea, coughing, and the inability to expectorate secretions. **Stridor** is a high-pitched, crowing noise during inspiration caused by laryngospasm or edema around the glottis. It is a late manifestation of a narrowed airway and requires prompt attention. Racemic epinephrine, a topical aerosol vasoconstrictor, is given, and reintubation may be needed.

Nursing Safety Priority QSEN

Critical Rescue

When stridor or other manifestations of obstruction occur after extubation, immediately call the Rapid Response Team before the airway becomes completely obstructed.

Chest Trauma

Chest injuries are responsible for about 25% of traumatic deaths in the United States each year and are a contributing factor in about 50% of deaths related to trauma (Mancini, 2012a). Many of the injured die before arriving at the hospital. A few types of chest injury require thoracotomy. Most can be treated with basic resuscitation, intubation, or chest tube placement. *The first emergency approach to all chest injuries is ABC (**a**irway, **b**reathing, **c**irculation), a rapid assessment and treatment of life-threatening conditions.* See Chapter 8 for more information on care of the trauma patient.

Pulmonary Contusion

Pulmonary contusion, a potentially lethal injury, is a common chest injury and occurs most often by rapid deceleration during car crashes. After a contusion, respiratory failure can develop immediately or over time. Hemorrhage and edema occur in and between the alveoli, reducing both lung movement and the area available for gas exchange. The patient becomes hypoxemic and dyspneic.

Patients may be asymptomatic at first and can later develop various degrees of respiratory failure. These patients often have decreased breath sounds or crackles and wheezes over the affected area. Other manifestations include bruising over the injury, dry cough, tachycardia, tachypnea, and dullness to percussion. At first, the chest x-ray may show no abnormalities. A hazy opacity in the lobes or parenchyma may develop over several days. If there is no disruption of the parenchyma, bruise resorption often occurs without treatment (Dennison et al., 2011; Mancini, 2012a).

Management includes maintenance of ventilation and oxygenation. Provide oxygen, give IV fluids as prescribed, and place the patient in a moderate-Fowler's position. When side-lying, the “good lung down” position may be helpful. The patient in obvious respiratory distress may need mechanical ventilation with positive end-expiratory pressure (PEEP) to inflate the lungs.

A vicious cycle occurs in which more muscle effort is needed for ventilating a lung with a contusion and the patient becomes progressively hypoxemic. This situation causes him or her to tire easily, have reduced gas exchange, and become more fatigued and hypoxemic. This condition often leads to acute respiratory distress syndrome (ARDS).

Rib Fracture

Rib fractures are a common injury to the chest wall, often resulting from direct blunt trauma to the chest. The force applied to the ribs fractures them and drives the bone ends into the chest. Thus there is a risk for deep chest injury, such as pulmonary contusion, pneumothorax, and hemothorax.

The patient has pain on movement and splints the chest defensively. Splinting reduces breathing depth and clearance of secretions. If the patient has pre-existing lung disease, the risk for atelectasis and pneumonia increases. Those with injuries to the first or second ribs, flail chest, seven or more fractured ribs, or expired volumes of less than 15 mL/kg often have a deep chest injury and a poor prognosis.

Management of uncomplicated rib fractures is simple because the fractured ribs reunite spontaneously. The chest is usually not splinted by tape or other materials. The main focus is to decrease pain so that adequate ventilation is maintained. An intercostal nerve block may be used if pain is severe. Analgesics that cause respiratory depression are avoided.

Flail Chest

Flail chest is the result of fractures of at least two neighboring ribs in two or more places causing **paradoxical chest wall movement** (inward movement of the thorax during inspiration, with outward movement during expiration) (Fig. 32-4). It usually involves one side of the chest and results from blunt chest trauma—often high-speed car crashes. Because the force required to produce a flail chest is great, it is important to assess for other possible underlying injuries (Bjerke, 2012; Poirier & Vacca, 2013).

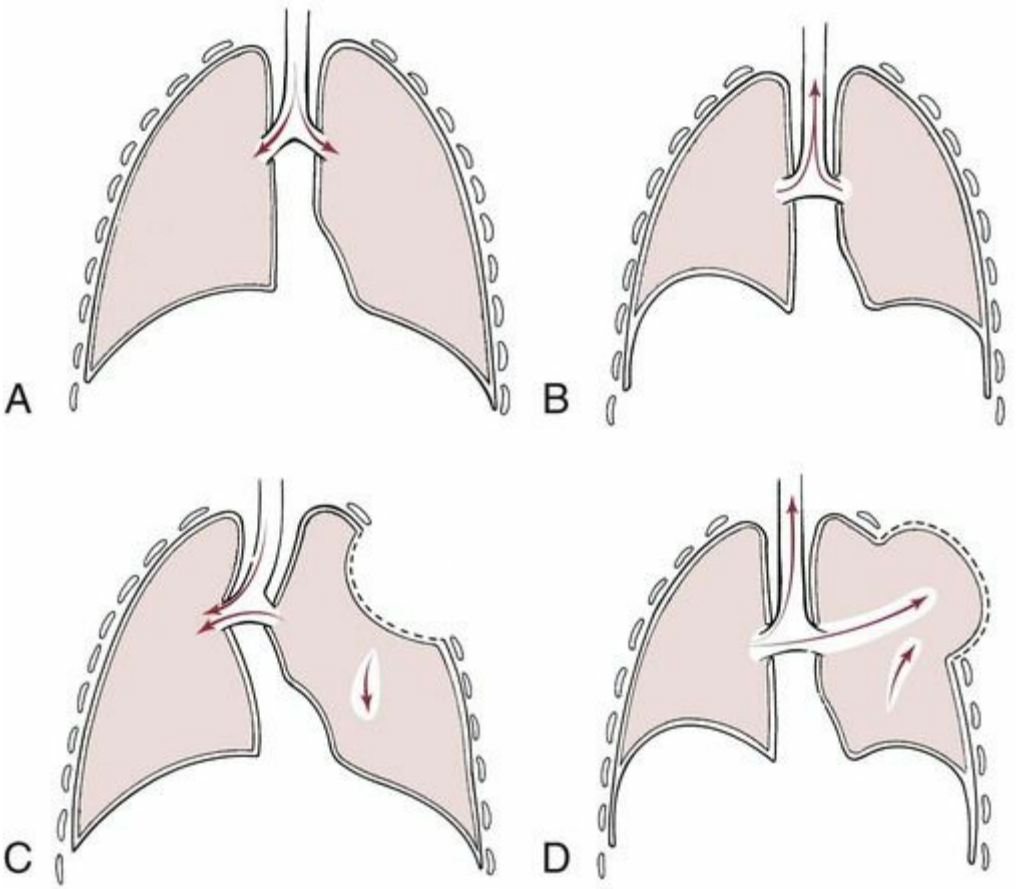

FIG. 32-4 Flail chest. Normal respiration: **A,** Inspiration; **B,** Expiration. Paradoxic motion: **C,** Inspiration—area of the lung underlying unstable chest wall sucks in on inspiration; **D,** Expiration—unstable area balloons out. Note movement of mediastinum toward opposite lung during inspiration.

Flail chest can also occur from bilateral separations of the ribs from their cartilage connections to each other anteriorly, without an actual rib fracture. This condition can occur as a complication of cardiopulmonary resuscitation. Other injuries to the lung tissue under the flail segment may be present. Gas exchange, coughing, and clearance of secretions are impaired. Splinting further reduces the patient's ability to exert the extra effort to breathe and may contribute later to failure to wean.

Assess the patient with a flail chest for paradoxical chest movement, dyspnea, cyanosis, tachycardia, and hypotension. The patient is often anxious, short of breath, and in pain. Work of breathing is increased from the paradoxical movement of the involved segment of the chest wall (Bjerke, 2012).

Interventions include humidified oxygen, pain management, promotion of lung expansion through deep breathing and positioning, and secretion clearance by coughing and tracheal suction.

The patient with a flail chest may be managed with vigilant respiratory care. Mechanical ventilation is needed if respiratory failure or shock

occurs. Monitor ABG values and vital capacity closely. With severe hypoxemia and hypercarbia, the patient is intubated and mechanically ventilated with PEEP. With lung contusion or an underlying pulmonary disease, the risk for respiratory failure increases. Usually flail chest is stabilized by positive-pressure ventilation. Surgical stabilization is used only in extreme cases of flail chest (Messing et al., 2014).

Monitor the patient's vital signs and fluid and electrolyte balance closely so that hypovolemia or shock can be managed immediately. If he or she has a lung contusion, provide oxygen as needed and give IV fluids as prescribed. Assess for and relieve pain with prescribed analgesic drugs by IV, epidural, or nerve block route. Give psychosocial support to the anxious patient by explaining all procedures, talking slowly, and allowing time for expression of feelings and concerns.

Pneumothorax

Any chest injury that allows air to enter the pleural space results in a rise in chest pressure and a reduction in vital capacity. Severity depends on the amount of lung collapse produced. Pneumothorax is often caused by blunt chest trauma and may occur with some degree of hemothorax. It can also occur as a complication of medical procedures (Day, 2011; Ruiz, 2011). The pneumothorax can be *open* (pleural cavity is exposed to outside air, as through an open wound in the chest wall) or *closed* (such as when a patient with chronic obstructive pulmonary disease [COPD] experiences a spontaneous pneumothorax). Assessment findings commonly include:

- Reduced breath sounds on auscultation
- Hyperresonance on percussion
- Prominence of the involved side of the chest, which moves poorly with respirations
- Deviation of the trachea *away* from the side of injury (tension pneumothorax)

In addition, the patient may have pleuritic pain, tachypnea, and **subcutaneous emphysema** (air under the skin in the subcutaneous tissues (Daley, 2014).

A chest x-ray is used for diagnosis. Chest tubes may be needed to allow the air to escape and the lung to re-inflate. Other care includes pain control, pulmonary hygiene, and continued assessment for respiratory failure.

Tension Pneumothorax

Tension pneumothorax, a rapidly developing and life-threatening

complication of blunt chest trauma, results from an air leak in the lung or chest wall. Air forced into the chest cavity causes complete collapse of the affected lung. Air that enters the pleural space during inspiration does not exit during expiration. As a result, air collects under pressure, compressing blood vessels and limiting blood return. This process leads to decreased filling of the heart and reduced cardiac output. *If not promptly detected and treated, tension pneumothorax is quickly fatal.* Causes include blunt chest trauma, mechanical ventilation with positive end-expiratory pressure (PEEP), closed–chest drainage (chest tubes), and insertion of central venous access catheters.

Assessment findings with tension pneumothorax include:

- Asymmetry of the thorax
- Tracheal movement *away* from midline toward the *unaffected* side
- Extreme respiratory distress
- Absence of breath sounds on one side
- Distended neck veins
- Cyanosis
- Hypertympanic sound on percussion over the affected side
- Hemodynamic instability

Pneumothorax is detectable on a chest x-ray but also can be diagnosed by the patient's manifestations. ABG assays show hypoxia and respiratory alkalosis.

Initial management is an immediate **needle thoracostomy**, with a large-bore needle inserted by the health care provider into the second intercostal space in the midclavicular line of the affected side. Then a chest tube is placed into the fourth intercostal space and the other end is attached to a water seal drainage system until the lung re-inflates. Chest tubes are discussed in detail in Chapter 30.

Nursing care also involves pain control and pulmonary hygiene.

Hemothorax

Hemothorax is a common problem occurring after blunt chest trauma or penetrating injuries. A *simple* hemothorax is a blood loss of less than 1000 mL into the chest cavity; a *massive* hemothorax is a blood loss of more than 1000 mL (Mancini, 2012b).

Bleeding is caused by injury to the lung tissue, such as lung contusions or lacerations, that can occur with rib and sternal fractures. Massive internal chest bleeding in blunt chest trauma may stem from the heart, the great vessels, or the intercostal arteries.

Assessment findings vary with the size of the hemothorax. If the

hemothorax is small, the patient may not have manifestations. With a large hemothorax, the patient may have respiratory distress with breath sounds reduced on auscultation. Percussion on the involved side produces a dull sound. Blood in the pleural space is visible on a chest x-ray and is confirmed by thoracentesis.

Interventions focus on removing the blood in the pleural space to normalize breathing and to prevent infection. Chest tubes are inserted to empty the pleural space; multiple chest tubes may be needed. Closely monitor the chest tube drainage. Serial chest x-rays are used to determine treatment effectiveness. Aggressive pain management and pulmonary hygiene are also part of care.

An open thoracotomy is needed when there is initial blood loss of 1000 mL from the chest or persistent bleeding at the rate of 150 to 200 mL/hr over 3 to 4 hours (Mancini, 2012b). Monitor the vital signs, blood loss, and intake and output. Assess the patient's response to the chest tubes, and infuse IV fluids and blood as prescribed. The blood lost through chest drainage can be infused back into the patient after processing if needed.

Tracheobronchial Trauma

Most tears of the tracheobronchial tree result from severe blunt trauma or rapid deceleration and often involve the mainstem bronchi. These injuries are rare, and patients often die before reaching the hospital. Injuries to the trachea usually occur at the junction of the trachea and cricoid cartilage, often by striking the neck against the dashboard or steering wheel during a car crash. Patients with tracheal lacerations develop massive air leaks, which cause air to enter the mediastinum and lead to extensive subcutaneous emphysema. Upper airway obstruction may occur, causing severe respiratory distress and stridor.

Airway management is the priority. If possible, an ET tube is placed distal to the injury. Cricothyroidotomy or tracheotomy below the level of injury may be required. A patient with a torn mainstem bronchus may develop a tension pneumothorax rapidly when intubated and ventilated with positive pressure (Dennison et al., 2011; Mancini, 2012a).

Assess for hypoxemia by ABG assays. Apply oxygen as needed. Depending on the degree of injury, the patient may need mechanical ventilation or surgical repair. Assess vital signs every 15 minutes because hypotension and shock are likely. Assess for subcutaneous emphysema and listen to the lungs every 1 to 2 hours. Decreased breath sounds or wheezing may indicate further obstruction, atelectasis, or pneumothorax.

Care of the patient with a tracheostomy is discussed in Chapter 28.

Nursing Concepts and Clinical Judgment Review

What might you NOTICE if the patient is experiencing inadequate gas exchange and tissue perfusion as a result of a critical respiratory problem?

- Respirations rapid and shallow
- Change in cognition, acute confusion (especially in older adults)
- Decreased oxygen saturation by pulse oximetry
- Cyanosis or pallor of the lips and oral mucous membranes
- Tachycardia
- Patient appears to strain to catch breath
- Patient is restless or anxious

What should you INTERPRET and how should you RESPOND to a patient experiencing inadequate gas exchange and tissue perfusion as a result of a critical respiratory problem?

Perform and interpret physical assessment, including:

- Taking vital signs
- Auscultating all lung fields
- Monitoring oxygen saturation by pulse oximetry
- Checking the accuracy of pulse oximetry readings
- Checking most recent laboratory values for ABG levels
- Assessing chest symmetry
- Assessing accessory muscle use
- Assessing cognition
- Assessing for the presence of hemoptysis
- Assessing the patient's ability to cough and clear the airway
- Asking the patient if he or she has chest pain
- Checking for the presence of petechiae, especially over the chest

Respond by:

- Applying oxygen and assessing the patient's responses
- Keeping the patient's head elevated to about 30 degrees (unless the potential for cervical spine trauma exists)
- Suctioning (oral, pharyngeal, endotracheal, tracheostomy), if needed
- Notifying the physician or Rapid Response Team
- Staying with the patient
- Calling for the emergency cart to be brought to the patient's bedside
- Reassuring the patient that appropriate interventions are being

instituted
- Preparing for intubation
- Using a manual resuscitation bag if the patient's Spo_2 falls below 60% while receiving oxygen by mask
- Starting an IV

On what should you REFLECT?

- Observe patient for evidence of restored gas exchange and oxygenation (see Chapter 27).
- Think about what may have precipitated this episode and what steps could be taken to either prevent a similar episode or identify it earlier.
- Think about what additional resources might improve the nursing response to this situation.

Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Use aseptic technique when caring for a patient requiring pulmonary suctioning. **Safety** QSEN
- Identify patients in your setting who are at risk for developing a pulmonary embolism. **Safety** QSEN
- Use Bleeding Precautions for patients receiving anticlotting therapy (see Chart 32-6). **Safety** QSEN
- Keep antidotes available when patients are receiving heparin (antidote is protamine) or warfarin (antidote is phytonadione). **Safety** QSEN
- Inspect the mouth and perform oral care every 2 hours for anyone who has an endotracheal tube or is being mechanically ventilated. **Safety** QSEN
- Check and document ventilator settings hourly. **Safety** QSEN
- Ensure that alarm systems on mechanical ventilators are activated and functional at all times. **Safety** QSEN
- Ensure that bag-valve-mask device and suction equipment are at the bedside at all times. **Safety** QSEN
- Evaluate the need for chemical restraint or soft wrist restraints.

Health Promotion and Maintenance

- Teach patients ways to promote venous return and avoid venous thromboembolism (VTE), especially when traveling long distances (see Chart 32-1). **Patient-Centered Care** QSEN
- Teach patients ways to prevent injury when taking drugs that reduce clotting (see Chart 32-7). **Patient-Centered Care** QSEN

Psychosocial Integrity

- Allow the patient and family members the opportunity to express feelings and concerns about a change in breathing status or the possibility of intubation and mechanical ventilation. **Patient-Centered Care** QSEN
- Use alternate ways to communicate with a patient who is intubated or being mechanically ventilated. **Patient-Centered Care** QSEN
- Reassure intubated patients that speech loss is temporary. **Patient-**

Centered Care QSEN

- Remember that patients who are receiving mechanical ventilation and are being chemically paralyzed usually can hear and can feel pain. **Patient-Centered Care** QSEN
- Provide appropriate pain management. **Patient-Centered Care** QSEN

Physiological Integrity

- Use Aspiration Precautions for any patient with an altered level of consciousness, poor gag reflex, or neurologic impairment or who has an endotracheal tube. **Evidence-Based Practice** QSEN
- Check the patient with ARDS hourly for oxygen saturation, vital sign changes, or any indication of increased work of breathing such as cyanosis, pallor, and retractions. **Patient-Centered Care** QSEN
- Assess all patients with blunt chest trauma for tracheal position and bilateral breath sounds. **Patient-Centered Care** QSEN
- Notify the physician immediately for any patient who develops sudden-onset respiratory difficulty. **Safety** QSEN
- Check oxygen saturation by pulse oximetry for any patient who has trouble breathing or who develops acute confusion. **Patient-Centered Care** QSEN
- Evaluate ABG values to assess the severity of hypoxia and the patient's response to therapy. **Patient-Centered Care** QSEN
- Apply oxygen to anyone who is hypoxemic. **Evidence-Based Practice** QSEN
- Ensure that oxygen therapy delivered to the patient is humidified. **Evidence-Based Practice** QSEN
- Assess lung sounds bilaterally each hour for patients who are receiving PEEP. **Patient-Centered Care** QSEN
- Check all ventilator settings against the prescription at least once per shift. **Safety** QSEN
- Administer drugs for pain to patients who have rib fractures, and encourage deep breaths. **Patient-Centered Care** QSEN
- Evaluate nutrition status, and collaborate with the dietitian to meet the patient's nutrition needs. **Teamwork and Collaboration** QSEN
- If a patient experiences respiratory distress during mechanical ventilation, remove him or her from the ventilator and provide ventilation by bag-valve-mask device. **Safety** QSEN

UNIT VIII

Problems of Cardiac Output and Tissue Perfusion: Management of Patients with Problems of the Cardiovascular System

OUTLINE

CHAPTER 33

Assessment of the Cardiovascular System

Donna Ignatavicius

PRIORITY CONCEPTS

- Perfusion
- Fluid and Electrolyte Balance

Learning Outcomes

Safe and Effective Care Environment

1. Prioritize care for patients having invasive cardiac diagnostic tests.

Health Promotion and Maintenance

2. Identify patients at risk for cardiovascular (CV) problems.
3. Differentiate modifiable and nonmodifiable risk factors for CV disease.
4. Teach patients about evidence-based ways to decrease their risk for CV health problems.
5. Explain nursing implications related to CV changes that affect perfusion in older adults.

Psychosocial Integrity

6. Describe common psychological responses to CV disease.

Physiological Integrity

7. Review the anatomy and physiology of the CV system.
8. Describe the unique characteristics of heart disease in women.
9. Perform focused physical assessment for patients with CV problems.
10. Interpret laboratory test findings for patients with suspected or actual

CV disease.

 http://evolve.elsevier.com/Iggy/

As the name implies, the cardiovascular (CV) system is made up of the heart and blood vessels (both arteries and veins). It is responsible for supplying oxygen to body organs and other tissues (perfusion). The heart muscle, called the **myocardium**, must receive sufficient oxygen to pump blood to other parts of the body. The arteries must be patent so that the pumped blood can reach the rest of the body. *Oxygen in the blood* is needed for cells to live and function properly. When diseases or other problems of the CV systems occur, oxygenation and perfusion decrease, often resulting in life-threatening events or a risk for these events.

The CV system works with the respiratory and hematologic systems to meet the human need for oxygenation and tissue perfusion (see Fig. 1 of the *Concept Overview*). Any problem in these systems requires the CV system to work harder to meet oxygenation and tissue perfusion needs.

Cardiovascular disease (CVD) continues to be the number-one cause of death in the United States. An average of one death in the United States occurs every 40 seconds from CVD (Go et al., 2013). The disease kills more people than the next four causes of death combined, including cancer, chronic lower respiratory diseases, accidents, and diabetes. *Of particular concern is that CVD is the leading cause of death for women*. In addition, the American Heart Association (AHA) estimates that more than one in three adults is living with some form of the disease. About 20% of people who experience a myocardial infarction will die within 1 year from the initial cardiac event (Go et al., 2013).

Anatomy and Physiology Review

Heart

Structure

The human heart is a fist-sized, muscular organ located in the mediastinum between the lungs (Fig. 33-1). Each beat of the heart pumps about 60 mL of blood, or 5 L/min. During strenuous physical activity, it can double the amount of blood pumped to meet the body's increased oxygenation needs. The heart is protected by a covering called the *pericardium*. A muscular wall (septum) separates the heart into two halves: right and left. Each half has an atrium and a ventricle (Fig. 33-2).

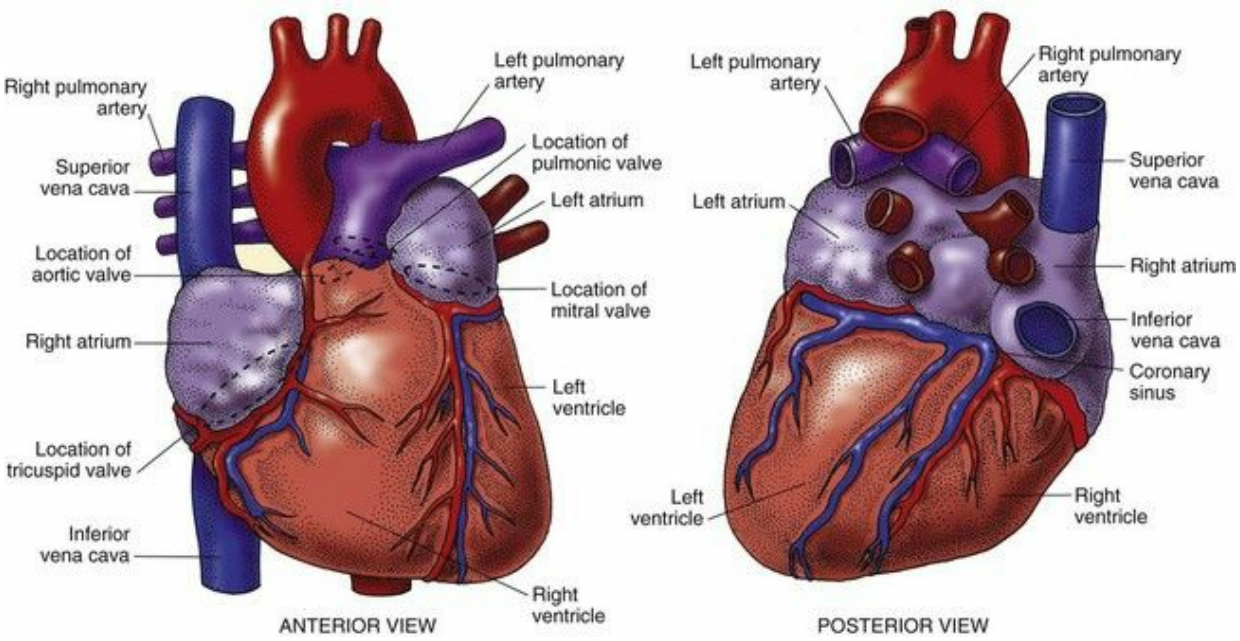

FIG. 33-1 Surface anatomy of the heart.

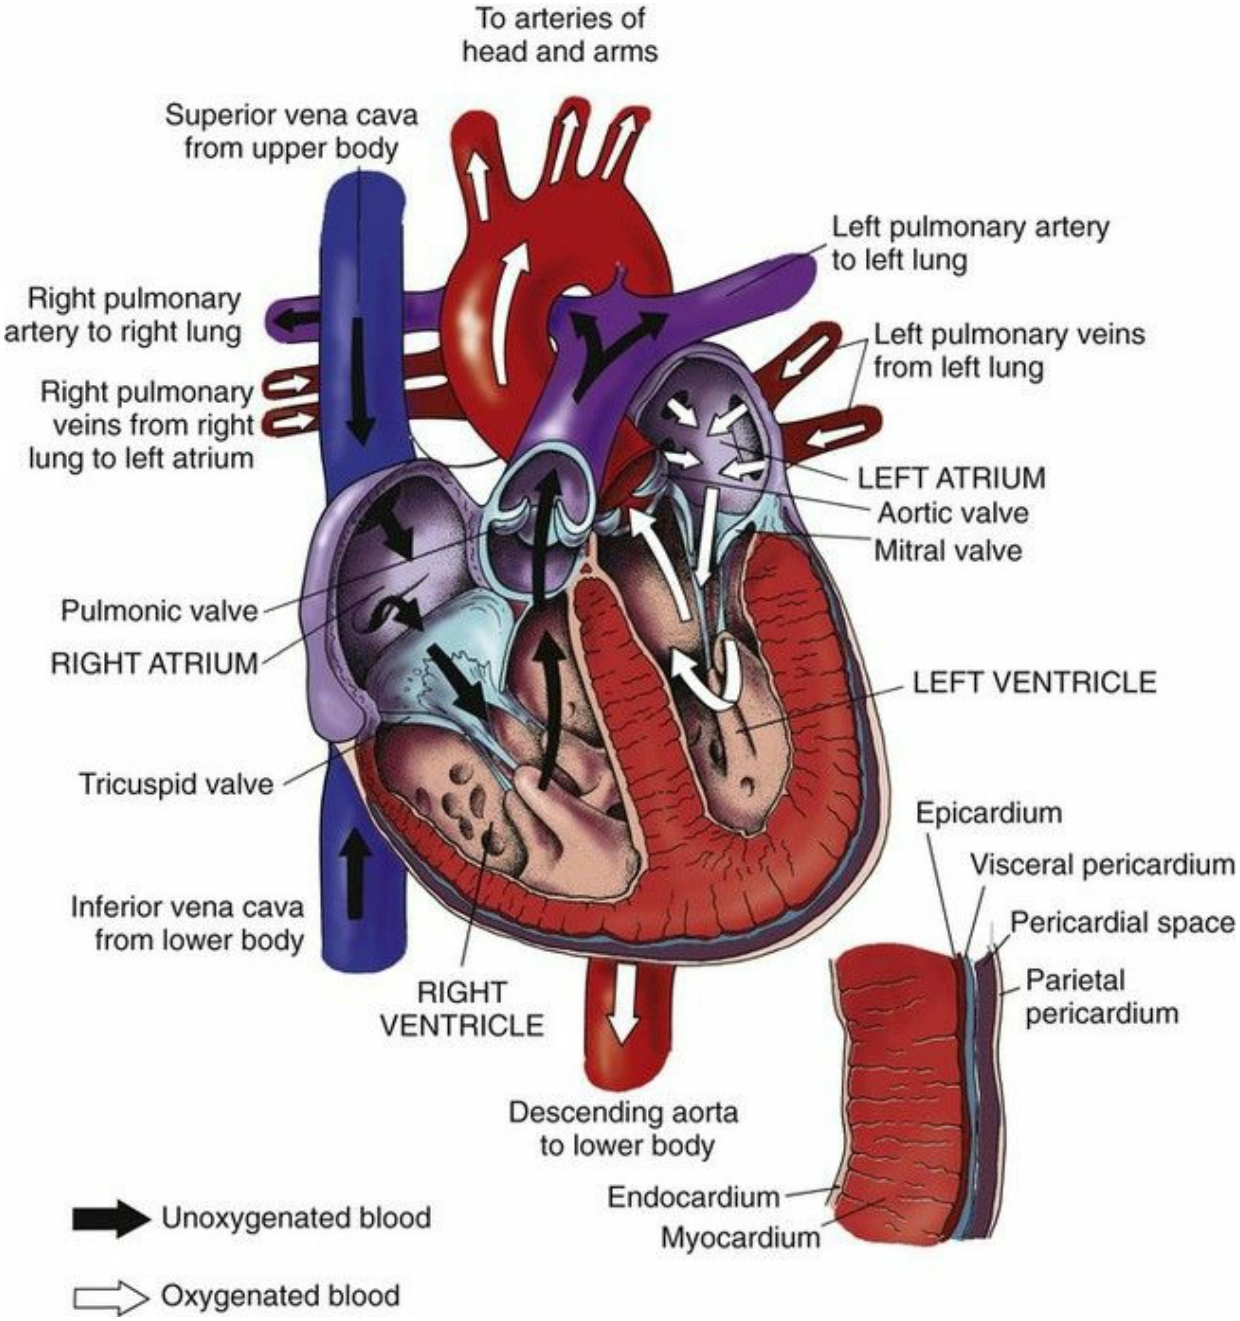

FIG. 33-2 Blood flow through the heart.

The *right atrium (RA)* receives *deoxygenated* venous blood, which is returned from the body through the superior and inferior venae cavae. It also receives blood from the heart muscle through the coronary sinus. Most of this venous return flows passively from the RA, through the opened tricuspid valve, and to the right ventricle during ventricular diastole, or filling. The remaining venous return is actively propelled by the RA into the right ventricle during atrial systole, or contraction.

The *right ventricle (RV)* is a muscular pump located behind the sternum. It generates enough pressure to close the tricuspid valve, open the pulmonic valve, and propel blood into the pulmonary artery and the lungs.

After blood is *reoxygenated* in the lungs, it flows freely from the four pulmonary veins into the left atrium. Blood then flows through an opened mitral valve into the left ventricle during ventricular diastole. When the left ventricle is almost full, the *left atrium (LA)* contracts, pumping the remaining blood volume into the left ventricle. With systolic contraction, the *left ventricle (LV)* generates enough pressure to close the mitral valve and open the aortic valve. Blood is propelled into the aorta and into the systemic arterial circulation. Blood flow through the heart is shown in Fig. 33-2.

Blood moves from the aorta throughout the systemic circulation to the various tissues of the body. The pressure of blood in the aorta of a young adult averages about 100 to 120 mm Hg, whereas the pressure of blood in the RA averages about 0 to 5 mm Hg. These differences in pressure produce a pressure gradient, with blood flowing from an area of higher pressure to an area of lower pressure. The heart and vascular structures are responsible for maintaining these pressures.

The four *cardiac valves* are responsible for maintaining the forward flow of blood through the chambers of the heart (see Fig. 33-2). These valves open and close when pressure and volume change within the heart's chambers. The cardiac valves are classified into two types: atrioventricular (AV) valves and semilunar valves.

The *AV valves* separate the atria from the ventricles. The *tricuspid valve* separates the RA from the RV. The *mitral (bicuspid) valve* separates the LA from the LV. During ventricular diastole, these valves act as funnels and help move the flow of blood from the atria to the ventricles. During systole, the valves close to prevent the backflow **(valvular regurgitation)** of blood into the atria.

The *semilunar valves* are the pulmonic valve and the aortic valve, which prevent blood from flowing back into the ventricles during diastole. The *pulmonic valve* separates the right ventricle from the pulmonary artery. The *aortic valve* separates the left ventricle from the aorta.

The heart muscle receives blood to meet its metabolic needs through the coronary arterial system (Fig. 33-3). The coronary arteries originate from an area on the aorta just beyond the aortic valve. All of the coronary arteries feeding the left heart originate from the left main coronary artery (LMCA). The right coronary artery (RCA) branches from the aorta to perfuse the right heart and inferior wall of the left heart.

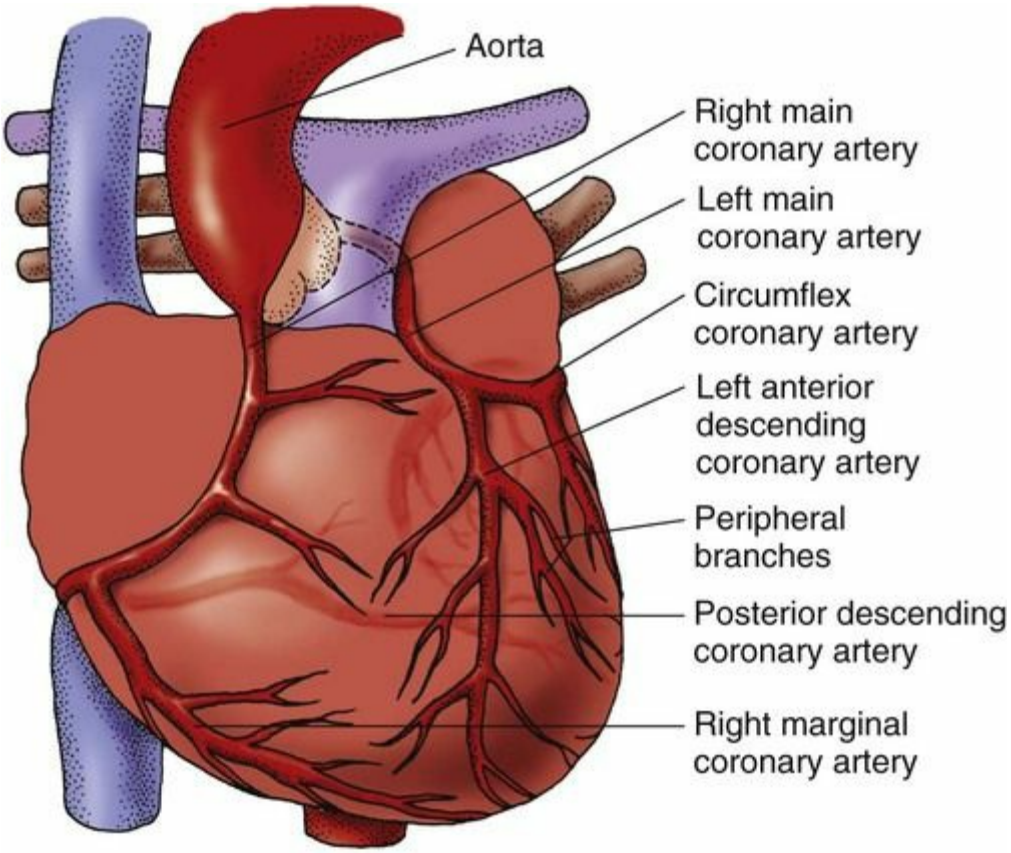

FIG. 33-3 Coronary arterial system.

Coronary artery blood flow to the myocardium occurs primarily during diastole, when coronary vascular resistance is minimized. *To maintain adequate blood flow through the coronary arteries,* **mean arterial pressure (MAP)** *must be at least 60 mm Hg. A MAP of between 60 and 70 mm Hg is necessary to maintain perfusion of major body organs, such as the kidneys and brain.*

The *left main artery* divides into two branches: the left anterior descending (LAD) branch and the left circumflex (LCX) branch. The LAD branch descends toward the anterior wall and the apex of the left ventricle. It supplies blood to portions of the left ventricle, ventricular septum, chordae tendineae, papillary muscle, and, to a lesser extent, the right ventricle.

The LCX branch descends toward the lateral wall of the left ventricle and apex. It supplies blood to the left atrium, the lateral and posterior surfaces of the left ventricle, and sometimes portions of the interventricular septum. In about half of people, the LCX branch supplies the sinoatrial (SA) node. In a very small number of people, it supplies the AV node. Peripheral branches arise from the LAD and LCX branches and form an abundant network of vessels throughout the entire myocardium.

The *right coronary artery (RCA)* originates from the right sinus of

Valsalva, encircles the heart, and descends toward the apex of the right ventricle. The RCA supplies the RA, RV, and inferior portion of the LV. In about half of people, the RCA supplies the SA node, and in almost everyone, it supplies the AV node.

Function

The *electrophysiologic properties* of heart muscle are responsible for regulating heart rate (HR) and rhythm. Cardiac muscle cells possess the characteristics of automaticity, excitability, conductivity, contractility, and refractoriness. Chapter 34 describes these properties and cardiac conduction in detail.

Sequence of Events During the Cardiac Cycle.

The phases of the cardiac cycle are generally described in relation to changes in pressure and volume in the left ventricle during filling (diastole) and ventricular contraction (systole) (Fig. 33-4). **Diastole,** normally about two thirds of the cardiac cycle, consists of relaxation and filling of the atria and ventricles. **Systole** consists of the contraction and emptying of the atria and ventricles.

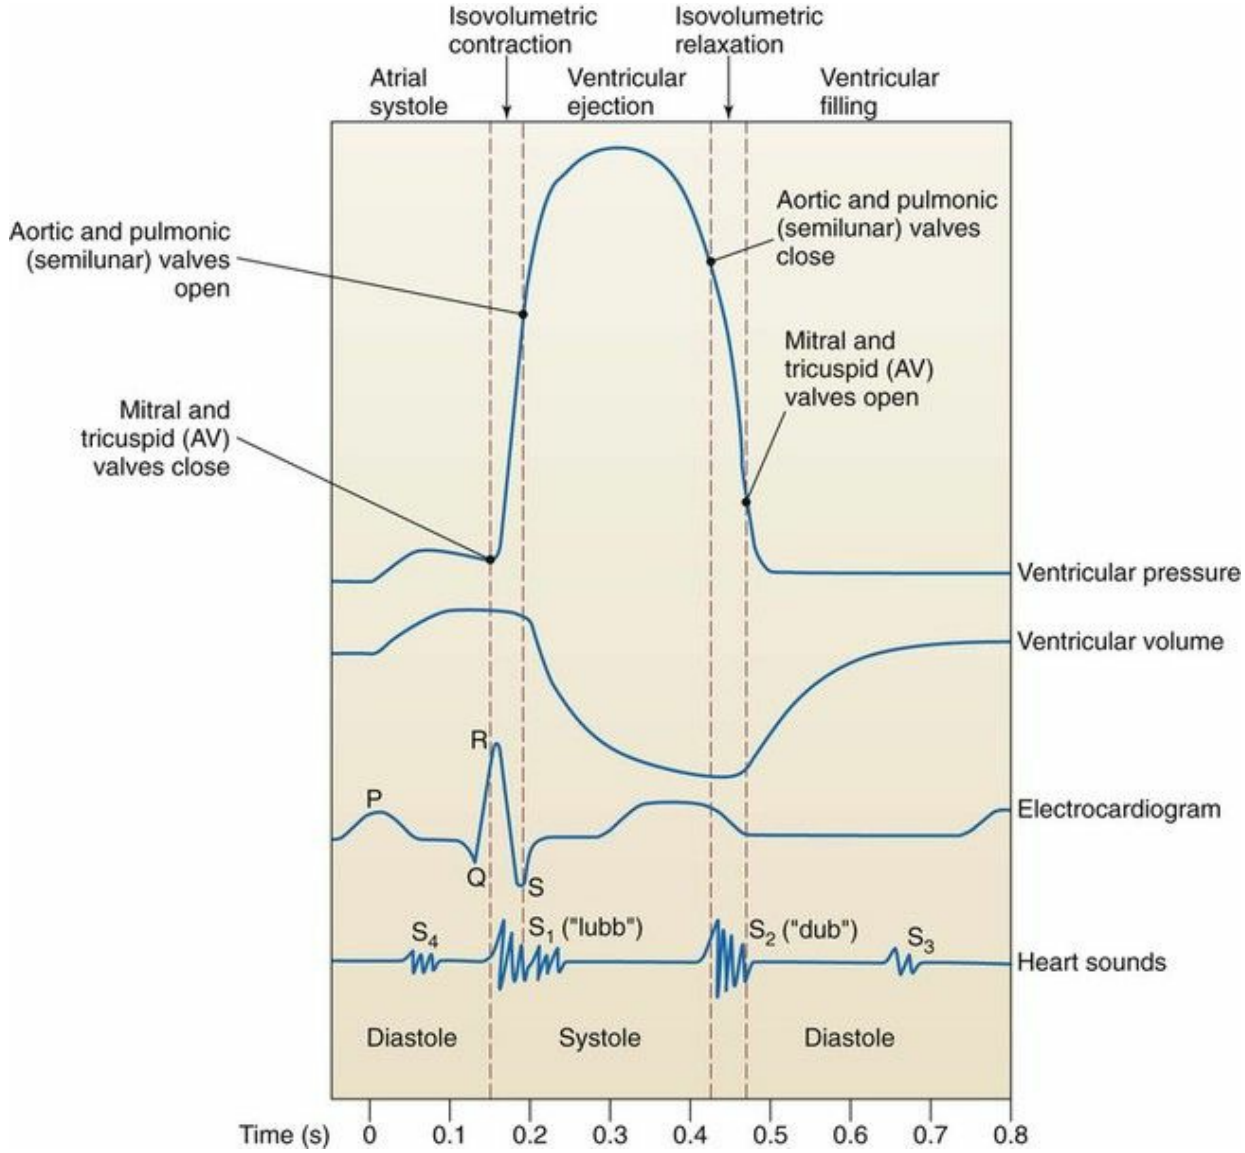

FIG. 33-4 Events of the cardiac cycle.

Myocardial contraction results from the release of large numbers of calcium ions from the sarcoplasmic reticulum and from the blood. These ions diffuse into the myofibril sarcomere (the basic contractile unit of the myocardial cell). Calcium ions promote the interaction of actin and myosin protein filaments, causing these filaments to link and overlap. Cross-bridges, or linkages, are formed as the protein filaments slide over or overlap each other. These cross-bridges act as force-generating sites. The sliding of these protein filaments shortens the sarcomeres, producing myocardial contraction.

Cardiac muscle relaxes when calcium ions are pumped back into the sarcoplasmic reticulum, causing a decrease in the number of calcium ions around the myofibrils. This reduced number of ions causes the protein filaments to disengage, the sarcomere to lengthen, and the muscle to relax.

Mechanical Properties of the Heart.

The electrical and mechanical properties of cardiac muscle determine the function of the cardiovascular system. The healthy heart can adapt to various pathophysiologic conditions (e.g., stress, infections, hemorrhage) to maintain PERFUSION to the various body tissues. Blood flow from the heart into the systemic arterial circulation is measured clinically as **cardiac output (CO),** the amount of blood pumped from the left ventricle each minute. *CO depends on the relationship between heart rate (HR) and stroke volume (SV);* it is the product of these two variables:

$$\text{Cardiac output} = \text{Heart rate} \times \text{Stroke volume}$$

In adults, the CO ranges from 4 to 7 L/min. Because CO requirements vary according to body size, the cardiac index is calculated to adjust for differences in body size. The **cardiac index** can be determined by dividing the CO by the body surface area. The normal range is 2.7 to 3.2 L/min/m^2 of body surface area.

Heart rate (HR) refers to the number of times the ventricles contract each minute. The normal resting HR for an adult is between 60 and 100 beats/min. Increases in rate increase myocardial oxygen demand. The HR is extrinsically controlled by the autonomic nervous system (ANS), which adjusts rapidly when necessary to regulate cardiac output. *The parasympathetic (vagus nerve) system slows the HR, whereas sympathetic stimulation increases the heart rate.* An increase in circulating catecholamines (e.g., epinephrine and norepinephrine) usually causes an increase in HR and contractility. Many cardiovascular drugs, particularly beta blockers, block this sympathetic (fight or flight) pattern by decreasing the HR.

Stroke volume (SV) is the amount of blood ejected by the left ventricle during each contraction. Several variables influence SV and, ultimately, CO. These variables include HR, preload, afterload, and contractility.

Preload refers to the degree of myocardial fiber stretch at the end of diastole and just before contraction. The stretch imposed on the muscle fibers results from the volume contained within the ventricle at the end of diastole. *Preload is determined by the amount of blood returning to the heart from both the venous system (right heart) and the pulmonary system (left heart) (left ventricular end-diastolic [LVED] volume).*

An increase in ventricular volume increases muscle-fiber length and

tension, thereby enhancing contraction and improving stroke volume. This statement is derived from Starling's law of the heart: The more the heart is filled during diastole (within limits), the more forcefully it contracts. Excessive filling of the ventricles results in excessive LVED volume and pressure, however, and may result in decreased cardiac output.

Another factor affecting stroke volume, **afterload,** is the pressure or resistance that the ventricles must overcome to eject blood through the semilunar valves and into the peripheral blood vessels. The amount of resistance is directly related to arterial blood pressure and the diameter of the blood vessels.

Impedance, the peripheral component of afterload, is the pressure that the heart must overcome to open the aortic valve. The amount of impedance depends on aortic compliance and total systemic vascular resistance, a combination of blood viscosity (thickness) and arteriolar constriction. A decrease in stroke volume can result from an increase in afterload without the benefit of compensatory mechanisms, thus leading to a decrease in cardiac output.

Myocardial contractility affects stroke volume and CO and is the force of cardiac contraction independent of preload. Contractility is increased by factors such as sympathetic stimulation, calcium release, and positive inotropic drugs. It is decreased by factors such as hypoxia and acidemia.

Vascular System

The vascular system serves several purposes:

- Provides a route for blood to travel from the heart to nourish the various tissues of the body
- Carries cellular wastes to the excretory organs
- Allows lymphatic flow to drain tissue fluid back into the circulation
- Returns blood to the heart for recirculation

The vascular system is divided into the arterial system and the venous system. In the arterial system, blood moves from the larger arteries to a network of smaller blood vessels, called *arterioles*, which meet the capillary bed. In the venous system, blood travels from the capillaries to the venules and to the larger system of veins, eventually returning in the vena cava to the heart for recirculation.

Arterial System

The primary function of the arterial system is to deliver oxygen and nutrients to various tissues in the body. Nutrients are carried through

arteries to arterioles, then branch into smaller terminal arterioles, and finally join with capillaries and venules to form a capillary network. Within this network, nutrients are exchanged across capillary membranes by three primary processes: osmosis, filtration, and diffusion. (See Chapter 11 for detailed discussions of these processes.)

The arterial system delivers blood to various tissues for oxygen and nourishment. At the tissue level, nutrients, chemicals, and body defense substances are distributed and exchanged for cellular waste products, depending on the needs of the particular tissue. The arteries transport the cellular wastes to the excretory organs (e.g., kidneys and lungs) to be reprocessed or removed. These vessels also contribute to temperature regulation in the tissues. Blood can be either directed toward the skin to promote heat loss or diverted away from the skin to conserve heat.

Blood pressure (BP) *is the force of blood exerted against the vessel walls.* Pressure in the larger arterial blood vessels is greater (about 80 to 100 mm Hg) and decreases as blood flow reaches the capillaries (about 25 mm Hg). By the time blood enters the right atrium, the BP is about 0 to 5 mm Hg. Volume, ventricular contraction, and vascular tone are necessary to maintain blood pressure.

BP is determined primarily by the quantity of blood flow or cardiac output (CO), as well as by the resistance in the arterioles:

$$\text{Blood pressure} = \text{Cardiac output} \times \text{Peripheral vascular resistance}$$

Any factor that increases CO or total peripheral vascular resistance increases the BP. In general, BP is maintained at a relatively constant level. Therefore an increase or decrease in total peripheral vascular resistance is associated with a decrease or an increase in CO, respectively. Three mechanisms mediate and regulate BP:

- The autonomic nervous system (ANS), which excites or inhibits sympathetic nervous system activity in response to impulses from chemoreceptors and baroreceptors
- The kidneys, which sense a change in blood flow and activate the renin-angiotensin-aldosterone mechanism
- The endocrine system, which releases various hormones (e.g., catecholamine, kinins, serotonin, histamine) to stimulate the sympathetic nervous system at the tissue level

Systolic BP is the amount of pressure/force generated by the left ventricle to distribute blood into the aorta with each contraction of the heart. It is a measure of how effectively the heart pumps and is an indicator of vascular tone. **Diastolic BP** is the amount of pressure/force against the arterial walls during the relaxation phase of the heart.

BP is regulated by balancing the sympathetic and parasympathetic nervous systems of the autonomic nervous system. Changes in autonomic activity are responses to messages sent by the sensory receptors in the various tissues of the body. These receptors, including the baroreceptors, chemoreceptors, and stretch receptors, respond differently to the biochemical and physiologic changes of the body.

Baroreceptors in the arch of the aorta and at the origin of the internal carotid arteries are stimulated when the arterial walls are stretched by an increased BP. Impulses from these baroreceptors inhibit the vasomotor center, which is located in the pons and the medulla. Inhibition of this center results in a drop in BP.

Several 1- to 2-mm collections of tissue have been identified in the carotid arteries and along the aortic arch known as **peripheral chemoreceptors.** These receptors are sensitive primarily to hypoxemia (a decrease in the partial pressure of arterial oxygen [Pa_{O_2}]). When stimulated, these chemoreceptors send impulses along the vagus nerves to activate a vasoconstrictor response and raise BP.

The central chemoreceptors in the respiratory center of the brain are also stimulated by **hypercapnia** (an increase in partial pressure of arterial carbon dioxide [Pa_{CO_2}]) and acidosis. The direct effect of carbon dioxide on the central nervous system (CNS), however, is 10 times stronger than the effect of hypoxia on the peripheral chemoreceptors.

Stretch receptors in the vena cavae and the right atrium are sensitive to pressure or volume changes. When a patient is hypovolemic, stretch receptors in the blood vessels sense a reduced volume or pressure and send fewer impulses to the CNS. This reaction stimulates the sympathetic nervous system to increase the heart rate (HR) and constrict the peripheral blood vessels.

The *kidneys* also help regulate cardiovascular activity. When renal blood flow or pressure decreases, the kidneys retain sodium and water. BP tends to rise because of fluid retention and activation of the renin-angiotensin-aldosterone mechanism (see Fig. 11-6 in Chapter 11). This mechanism results in vasoconstriction and sodium retention (and thus fluid retention). Vascular volume is also regulated by the release of antidiuretic hormone (vasopressin) from the posterior pituitary gland

(see Chapter 11).

Other factors can also influence the activity of the cardiovascular system. Emotional behaviors (e.g., excitement, pain, anger) stimulate the sympathetic nervous system to increase blood pressure (BP) and heart rate (HR). Increased physical activity such as exercise also increases BP and HR during the activity. Body temperature can affect the metabolic needs of the tissues, thereby influencing the delivery of blood. In hypothermia, tissues require fewer nutrients and blood pressure falls. In hyperthermia, the metabolic requirement of the tissues is greater and BP and pulse rate rise.

Venous System

The primary function of the venous system is to complete the circulation of blood by returning blood from the capillaries to the right side of the heart. It is composed of a series of veins that are located next to the arterial system. A second superficial venous circulation runs parallel to the subcutaneous tissue of the extremity. These two venous systems are connected by communicating veins that provide a means for blood to travel from the superficial veins to the deep veins. Blood flow is directed toward the deep venous circulation.

Veins have the ability to accommodate large shifts in volume with minimal changes in venous pressure. This flexibility allows the venous system to accommodate the administration of IV fluids and blood transfusions, as well as to maintain pressure during blood loss and dehydration. Veins in the superficial and deep venous systems (except the smallest and the largest veins) have valves that direct blood flow back to the heart and prevent backflow. Skeletal muscles in the extremities provide a force that helps push the venous blood forward. The superior vena cava and inferior vena cava are valveless and large enough to allow blood flow to return easily to the heart.

Gravity exerts an increase in **hydrostatic pressure** in the capillaries when the patient is in an upright position, delaying venous return. Hydrostatic pressure is decreased in dependent areas such as the legs when the patient is lying down, and thus there is less hindrance of venous return to the heart.

Cardiovascular Changes Associated with Aging

A number of physiologic changes in the cardiovascular system occur with advancing age (Chart 33-1). Many of these changes result in a loss of cardiac reserve. Thus these changes are usually not evident when the

older adult is resting. They become apparent only when the person is physically or emotionally stressed and the heart cannot meet the increased metabolic demands of the body.

Chart 33-1 Nursing Focus on the Older Adult

Changes in the Cardiovascular System Related to Aging

CHANGE	NURSING INTERVENTIONS	RATIONALES
Cardiac Valves		
Calcification and mucoid degeneration occur, especially in mitral and aortic valves.	Assess heart rate and rhythm and heart sounds for murmurs. Question patients about dyspnea.	Murmurs may be detected before other symptoms. Valvular abnormalities may result in rhythm changes.
Conduction System		
Pacemaker cells decrease in number. Fibrous tissue and fat in the sinoatrial node increase. Few muscle fibers remain in the atrial myocardium and bundle of His. Conduction time increases.	Assess the electrocardiogram (ECG) and heart rhythm for dysrhythmias or a heart rate less than 60 beats/min.	The sinoatrial (SA) node may lose its inherent rhythm. Atrial dysrhythmias occur in many older adults; 80% of older adults experience premature ventricular contractions (PVCs).
Left Ventricle		
The size of the left ventricle increases. The left ventricle becomes stiff and less distensible. Fibrotic changes in the left ventricle decrease the speed of early diastolic filling by about 50%.	Assess the ECG for a widening QRS complex and a longer QT interval.	Ventricular changes result in decreased stroke volume, ejection fraction, and cardiac output during exercise; the heart is less able to meet increased oxygen demands.
	Assess the heart rate at rest and with activity. Assess for activity intolerance.	Maximum heart rate with exercise is decreased. The heart is less able to meet increased oxygen demands.
Aorta and Other Large Arteries		
The aorta and other large arteries thicken and become stiffer and less distensible. Systolic blood pressure increases to compensate for the stiff arteries. Systemic vascular resistance increases as a result of less distensible arteries; therefore the left ventricle pumps against greater resistance, contributing to left ventricular hypertrophy.	Assess blood pressure. Note increases in systolic, diastolic, and pulse pressures. Assess for activity intolerance and shortness of breath. Assess the peripheral pulses.	Hypertension may occur and must be treated to avoid target organ damage.
Baroreceptors		
Baroreceptors become less sensitive.	Assess the patient's blood pressure with the patient lying and then sitting or standing. Assess for dizziness when the patient changes from a lying to a sitting or standing position. Teach the patient to change positions slowly.	Orthostatic (postural) and postprandial changes occur because of ineffective baroreceptors. Changes may include blood pressure decreases of 10 mm Hg or more, dizziness, and fainting.

Assessment Methods

Patient History

The focus of the patient history is on obtaining information about risk factors and symptoms of cardiovascular disease. Assess *nonmodifiable* (uncontrollable) risk factors including the patient's age, gender, ethnic origin, and family history of cardiovascular disease. Ask about any chronic disease or illness that the patient may have. The incidence of conditions such as coronary artery disease (CAD) and valvular disease increases with age. The incidence of CAD also varies with the patient's gender. Men have a higher risk for CAD than women of all ages except in the oldest age-group of 80 years and older (Go et al., 2013).

Gender Health Considerations

Patient-Centered Care QSEN

Postmenopausal women are 2 to 3 times more likely than premenopausal women to have CAD. The incidence for the disease in women is about 10 years later than in men and 20 years later for myocardial infarction (MI) and death to occur. After an acute MI, women tend to have a higher mortality rate and suffer more complications when compared with men (Go et al., 2013).

Women with waist and abdominal obesity (greater waist-hip ratio) are more likely to experience cardiovascular disease (CVD) than are women with excess fat in their buttocks, hips, and thighs.

Heart disease is the leading cause of diabetes-related death for both men and women. Adults with diabetes have heart disease death rates 2 to 4 times higher than those without diabetes. The risk for stroke is also 2 to 4 times higher among people with diabetes. The number of premature deaths (younger than 65 years) from heart disease is greatest among American Indians and Alaska Natives and lowest among Asians (Go et al., 2013).

Modifiable (controllable) risk factors should also be assessed. *Modifiable* risk factors are personal lifestyle habits, including cigarette use, physical inactivity, obesity, and psychological variables. Ask the patient about each of these common risk factors.

Cigarette smoking is a major risk factor for CVD, specifically coronary artery disease (CAD) and peripheral vascular disease (PVD). Three compounds in cigarette smoke have been implicated in the development of CAD: tar, nicotine, and carbon monoxide. The smoking history should

include the number of cigarettes smoked daily, the duration of the smoking habit, and the age of the patient when smoking started. Record the smoking history in **pack-years,** which is the number of packs per day multiplied by the number of years the patient has smoked.

Ask about the patient's desire to quit, past attempts to quit, and the methods used. Determine nicotine dependence by asking questions such as:

- How soon after you wake up in the morning do you smoke?
- Do you wake up in the middle of your sleep time to smoke?
- Do you find it difficult not to smoke in places where smoking is prohibited?
- Do you smoke when you are ill?

Three to four years after a patient has stopped smoking, his or her CVD risk appears to be similar to that of a person who has never smoked. Be sure to ask those who do not currently smoke whether they have ever smoked and when they quit. Passive smoke significantly reduces blood flow in healthy young adults' coronary arteries, and the risk for dying increases among those who are exposed to secondhand smoke (American Heart Association [AHA], 2013).

A *sedentary lifestyle* is also a major risk factor for heart disease. Regular physical activity promotes cardiovascular fitness and produces beneficial changes in blood pressure and levels of blood lipids and clotting factors. Unfortunately, few people in the United States follow the recommended exercise guidelines: 30 minutes daily of light to moderate exercise, which is equivalent to a 30-minute brisk walk. According to the AHA (2013), fewer than two thirds of people in the United States engage in this much exercise 5 times a week and fewer engage in more vigorous physical activity to promote cardiopulmonary fitness. Encourage increased physical exercise as part of a lifestyle change to reduce the risk for CAD. Ask patients about the type of exercise they perform, how long a period they have participated in the exercise, and the frequency and intensity of the exercise.

About two thirds of American adults are **overweight** when defined as a body mass index (BMI) of 25 to 30. **Obesity,** defined as a BMI greater than 30, is particularly a problem for African-American women, Mexican Americans, and native Hawaiians, but the exact cause of this cultural difference is unknown (AHA, 2013). Obesity is also associated with hypertension, hyperlipidemia, and diabetes; all are known contributors to CVD.

The American Heart Association provides guidelines to combat obesity and improve cardiac health, including ingesting more nutrient-

rich foods that have vitamins, minerals, fiber, and other nutrients but are low in calories. To get the necessary nutrients, teach patients to choose foods like vegetables, fruits, unrefined whole-grain products, and fat-free dairy products most often. Also teach patients to not eat more calories than they can burn every day (AHA, 2013).

A variety of *psychological factors* make people more vulnerable to the development of heart disease. Those who are highly competitive, overly concerned about meeting deadlines, and often hostile or angry are at higher risk for heart disease. Psychological stress, anger, depression, and hostility are all closely associated with risk for developing heart disease.

You might ask the patient "How do you respond when you have to wait for an appointment?" Chronic anger and hostility appear to be closely associated with CVD. The constant arousal of the sympathetic nervous system as a result of anger may influence blood pressure, serum fatty acids and lipids, and clotting mechanisms. Observe the patient, and assess his or her response to stressful situations.

Review the patient's medical history, noting any major illnesses such as diabetes mellitus, renal disease, anemia, high BP, stroke, bleeding disorders, connective tissue diseases, chronic pulmonary diseases, heart disease, and thrombophlebitis. These conditions can influence the patient's cardiovascular status.

Ask about previous treatment for CVD, identify previous diagnostic procedures (e.g., electrocardiography [ECG], cardiac catheterization), and request information about any medical or invasive treatment of CVD. Ask specifically about recurrent tonsillitis, streptococcal infections, and rheumatic fever, because these conditions may lead to valvular abnormalities of the heart. In addition, inquire about any known congenital heart defects. Many patients with congenital heart problems live into adulthood because of improved treatment and surgeries.

Ask patients about their drug history, beginning with any current or recent use of prescription or over-the-counter (OTC) medications or herbal/natural products. Inquire about known sensitivities to any drug and the nature of the reaction (e.g., nausea, rash). Patients should be asked whether they have recently used cocaine or any IV "street" drugs, because these substances are often associated with heart disease.

Gender Health Considerations

Patient-Centered Care QSEN

Ask young women whether they are taking oral contraceptives or an estrogen replacement. The incidence of myocardial infarction (MI) and

stroke in women older than 35 years who take oral contraceptives is increased if they smoke, have diabetes, or have hypertension. Ask menopausal women and transgender women if they are on hormone therapy, because these drugs can also cause an increased incidence of MIs and strokes.

The *social history* includes information about the patient's living situation, including having a domestic partner, other household members, environment, and occupation. Identification of support systems is especially important in exploring the possibility that the patient might have difficulty paying for medications or treatment. People who are from a low socioeconomic (SE) group have a greater chance of having MIs than those from a higher SE status (Wright et al., 2009).

Ask about occupation, including the type of work performed and the requirements of the specific job. For instance, does the job involve physical exertion such as lifting heavy objects? Is the job emotionally stressful? What does a day's work entail? Does the patient's job require him or her to be outside in extreme weather conditions?

Nutrition History

A nutrition history includes the patient's recall of food and fluid intake during a 24-hour period, self-imposed or medically prescribed dietary restrictions or supplementations, and the amount and type of alcohol consumption. If needed, the dietitian may review the type of foods selected by the patient for the amount of sodium, sugar, cholesterol, fiber, and fat. Cultural beliefs and economic status can influence the choice of food items and therefore are seriously considered. Family members or significant others who are responsible for shopping and cooking should be included in this screening.

NCLEX Examination Challenge

Health Promotion and Maintenance

The nurse is providing education to help reduce cardiovascular risks for a women's book club. Which statement made by a participant indicates a need for further teaching?

A "We are more likely to die from cardiovascular disease than men."
B "We need to walk or do other exercise every day for 30 minutes."
C "We need to stay away from people who smoke."
D "We should take hormones for menopause to decrease the risk for

heart attack."

Family History and Genetic Risk

Review the family history, and obtain information about the age, health status, and cause of death of immediate family members. A positive family history for CAD in a first-degree relative (parent, sibling, or child) is a major risk factor. It is *more* important than other factors such as hypertension, obesity, diabetes, or sudden cardiac death.

Genetic/Genomic Considerations

Patient-Centered Care QSEN

Cardiovascular disease has many contributory factors, including a genetic tendency. A significant association between familial cardiac history and cardiovascular disease is consistently demonstrated in the evidence of multiple large-scale prospective epidemiology studies (Go, et al., 2013). Although several genes have been reported to be associated with heart disease, stroke, and hypertension, the impact of each individual gene is not fully understood. Numerous genetic association studies are underway to determine more specific genetic variants that may underlie the family history (Go, et al., 2013). Additional discussions about genetic factors related to specific CV diseases are found in other chapters in this unit.

Current Health Problems

Ask the patient to describe his or her health concerns. Expand on the description of these concerns by obtaining information about their onset, duration, sequence, frequency, location, quality, intensity, associated symptoms, and precipitating, aggravating, and relieving factors. Major symptoms usually identified by patients with CVD include chest pain or discomfort, dyspnea, fatigue, palpitations, weight gain, syncope, and extremity pain.

Pain or discomfort, considered a traditional symptom of heart disease, can result from ischemic heart disease, pericarditis, and aortic dissection. Chest pain can also be due to noncardiac conditions such as pleurisy, pulmonary embolus, hiatal hernia, gastroesophageal reflux disease, neuromuscular abnormalities, and anxiety.

Nursing Safety Priority QSEN

Action Alert

Thoroughly evaluate the nature and characteristics of the chest pain. Because pain resulting from myocardial ischemia is life threatening and can lead to serious complications, its cause should be considered ischemic (reduced or obstructed blood flow to the myocardium) until proven otherwise. When assessing for symptoms, ask the patient if he or she has "discomfort," "heaviness," "pressure," and "indigestion."

Gender Health Considerations

Patient-Centered Care QSEN

Some patients, especially women, do not experience pain in the chest but, instead, feel discomfort or indigestion. Women often present with a "triad" of symptoms. In addition to indigestion or feeling of abdominal fullness, chronic fatigue despite adequate rest and feelings of an "inability to catch my breath" (dyspnea) are also common in heart disease. The patient may also describe the sensation as aching, choking, strangling, tingling, squeezing, constricting, or viselike. Others with severe neuropathy may experience few or no traditional symptoms except shortness of breath, despite major ischemia.

Ask the patient to identify when the symptoms were first noticed (onset):

- Did the symptoms begin suddenly or develop gradually (manner of onset)?
- How long did the symptoms last (duration)?

If he or she has repeated painful episodes, assess how often the symptoms occur (frequency). If pain is present, ask whether it is different from any other episodes of pain. Ask the patient to describe what activities he or she was doing when it first occurred, such as sleeping, arguing, or running (precipitating factors). If possible, the patient should point to the area where the chest pain occurred (location) and describe if and how the pain radiated (spread).

In addition, ask how the pain feels and whether it is sharp, dull, or crushing (quality of pain). To understand the severity of the pain, ask the patient to grade it from 0 to 10, with 10 indicating severe pain (intensity). He or she may also report other signs and symptoms that occur at the same time (associated symptoms), such as dyspnea, diaphoresis

(excessive sweating), nausea, and vomiting. Other factors that need to be addressed are those that may have made the chest pain worse (aggravating factors) or less intense (relieving factors). Chest pain can arise from a variety of sources (Table 33-1). By obtaining the appropriate information, you can help identify the source of the chest discomfort.

TABLE 33-1

Assessment of Chest Discomfort: How Various Types of Chest Pain Differ

ONSET	QUALITY AND SEVERITY	LOCATION AND RADIATION	DURATION AND RELIEVING FACTORS
Angina			
Sudden, usually in response to exertion, emotion, or extremes in temperature	Squeezing, viselike pain	Usually the left side of chest without radiation Substernal; may spread across the chest and the back and/or down the arms	Usually lasts less than 15 min; relieved with rest, nitrate administration, or oxygen therapy
Myocardial Infarction			
Sudden, without precipitating factors, often in early morning	Intense stabbing, viselike pain or pressure, severe	Substernal; may spread throughout the anterior chest and to the arms, jaw, back, or neck	Continuous or no chest discomfort; relieved with morphine, cardiac drugs, and oxygen therapy
Pericarditis			
Sudden	Sharp, stabbing, moderate to severe	Substernal; usually spreads to the left side or the back	Intermittent; relieved with sitting upright, analgesia, or administration of anti-inflammatory agents
Pleuropulmonary			
Variable	Moderate ache, worse on inspiration	Lung fields	Continuous until the underlying condition is treated or the patient has rested
Esophageal-Gastric			
Variable	Squeezing, heartburn, variable severity	Substernal; may spread to the shoulders or the abdomen	Variable; may be relieved with antacid administration, food intake, or taking a sitting position
Anxiety			
Variable, may be in response to stress or fatigue	Dull ache to sharp stabbing; may be associated with numbness in fingers	Not well located and usually does not radiate to other parts of the body as pain	Usually lasts a few minutes

Dyspnea (difficult or labored breathing) can occur as a result of both cardiac and pulmonary disease. It is experienced by the patient as uncomfortable breathing or shortness of breath. When obtaining the history, ask what factors precipitate and relieve dyspnea, what level of activity produces dyspnea, and what the patient's body position was when dyspnea occurred.

Dyspnea that is associated with activity, such as climbing stairs, is referred to as **dyspnea on exertion (DOE).** *This is usually an early symptom of heart failure and may be the only symptom experienced by women.*

The patient with advanced heart disease may experience **orthopnea** (dyspnea that appears when he or she lies flat). Several pillows may be needed to elevate the head and chest, or a recliner to prevent breathlessness may be used. *The severity of orthopnea is measured by the number of pillows or the amount of head elevation needed to provide restful sleep.* This symptom is usually relieved within a matter of minutes by

sitting up or standing.

Paroxysmal nocturnal dyspnea (PND) develops after the patient has been lying down for several hours. In this position, blood from the lower extremities is redistributed to the venous system, which increases venous return to the heart. A diseased heart cannot compensate for the increased volume and is ineffective in pumping the additional fluid into the circulatory system. Pulmonary congestion results. The patient awakens abruptly, often with a feeling of suffocation and panic. He or she sits upright and dangles the legs over the side of the bed to relieve the dyspnea. This sensation may last for 20 minutes.

Fatigue may be described as a feeling of tiredness or weariness resulting from activity. The patient may report that an activity takes longer to complete or that he or she tires easily after activity. Although fatigue in itself is not diagnostic of heart disease, many people with heart failure are limited by leg fatigue during exercise. Fatigue that occurs after mild activity and exertion usually indicates inadequate cardiac output (due to low stroke volume) and anaerobic metabolism in skeletal muscle. *It can also accompany other symptoms or may be an early indication of heart disease in women.*

Ask about the time of day the patient experiences fatigue and the activities that he or she can perform. Fatigue resulting from decreased cardiac output is often worse in the evening. Ask whether the patient can perform the same activities as he or she could perform a year ago or the same activities as others of the same age. Often he or she limits activities in response to fatigue and, unless questioned, is unaware how much less active he or she has become.

A feeling of fluttering or unpleasant feeling in the chest caused by an irregular heartbeat is referred to as **palpitations.** They may result from a change in heart rate or rhythm or from an increase in the force of heart contractions. Rhythm disturbances that may cause palpitations include paroxysmal supraventricular tachycardia, premature contractions, and sinus tachycardia. Those that occur during or after strenuous physical activity, such as running and swimming, may indicate overexertion or possibly heart disease. Noncardiac factors that may precipitate palpitations include anxiety, stress, fatigue, insomnia, hyperthyroidism, and the ingestion of caffeine, nicotine, or alcohol. Ask the patient about specific factors that cause his or her palpitations.

A sudden weight increase of 2.2 pounds (1 kg) can result from excess fluid (1 L) in the interstitial spaces. *The best indicator of fluid balance is weight.* Excess fluid accumulation is commonly known as **edema.** It is possible for weight gains of up to 10 to 15 pounds (4.5 to 6.8 kg, or 4 to 7 L

of fluid) to occur before edema is apparent. Ask whether the patient has noticed a tightness of shoes, indentations from socks, or tightness of rings.

Syncope refers to a brief loss of consciousness. The most common cause is decreased perfusion to the brain. Any condition that suddenly reduces cardiac output, resulting in decreased cerebral blood flow, can lead to a syncopal episode. Conditions such as cardiac rhythm disturbances, especially ventricular dysrhythmias, and valvular disorders, such as aortic stenosis, may trigger this symptom. **Near-syncope r**efers to dizziness with an inability to remain in an upright position. Explore the circumstances that lead to dizziness or syncope.

Considerations for Older Adults

Patient-Centered Care QSEN

Syncope in the aging person may result from hypersensitivity of the carotid sinus bodies in the carotid arteries. Pressure applied to these arteries while turning the head, shrugging the shoulders, or performing a Valsalva maneuver (bearing down during defecation) may stimulate a vagal response. A decrease in blood pressure and heart rate can result, which can produce syncope. This type of syncopal episode may also result from postural (orthostatic) or postprandial (after eating) hypotension.

Extremity pain may be caused by two conditions: ischemia from atherosclerosis and venous insufficiency of the peripheral blood vessels. Patients who report a moderate to severe cramping sensation in their legs or buttocks associated with an activity such as walking have **intermittent claudication** related to decreased arterial tissue perfusion. *Claudication pain is usually relieved by resting or lowering the affected extremity to decrease tissue demands or to enhance arterial blood flow.* Leg pain that results from prolonged standing or sitting is related to venous insufficiency from either incompetent valves or venous obstruction. This pain may be relieved by elevating the extremity.

Functional History

After the history of the patient's cardiovascular status is obtained, he or she may be classified according to the New York Heart Association Functional Classification (Table 33-2) or other system. The four classifications (I, II, III, and IV) depend on the degree to which ordinary

physical activities (routine ADLs) are affected by heart disease. The Killip Classification provides a more objective description of the hemodynamics of heart failure and is described in Chapter 38.

TABLE 33-2

New York Heart Association Functional Classification of Cardiovascular Disability

Class I
• Patients with cardiac disease but without resulting limitations of physical activity • Ordinary physical activity does not cause undue fatigue, palpitation, dyspnea, or anginal pain
Class II
• Patients with cardiac disease resulting in slight limitation of physical activity • They are comfortable at rest • Ordinary physical activity results in fatigue, palpitation, dyspnea, or anginal pain
Class III
• Patients with cardiac disease resulting in marked limitation of physical activity • They are comfortable at rest • Less than ordinary physical activity causes fatigue, palpitation, dyspnea, or anginal pain
Class IV
• Patients with cardiac disease resulting in inability to carry on any physical activity without discomfort • Symptoms of cardiac insufficiency or of the anginal syndrome may be present, even at rest • If any physical activity is undertaken, discomfort is increased

Excerpted from The New York Heart Association. (1964). *Diseases of the heart and blood vessels: Nomenclature and criteria for diagnosis* (6th ed.). Boston: Little, Brown.

Physical Assessment

A thorough physical assessment is the foundation for the nursing database and the patient's priority problems. Any changes noted during the course of illness can be compared with this initial database. Evaluate the patient's vital signs on admission to the hospital or during the initial visit to the clinic or primary care provider's office.

General Appearance

Physical assessment begins with the patient's general appearance. Assess general build and appearance, skin color, distress level, level of consciousness, shortness of breath, position, and verbal responses.

Patients can have left- or right-sided heart failure, or both. They can also be diagnosed with systolic and/or diastolic heart failure. *As a result, poor cardiac output and decreased cerebral perfusion may cause confusion, memory loss, and slowed verbal responses, especially in older adults.* Patients with chronic heart failure may also appear malnourished, thin, and cachectic. Late signs of severe right-sided heart failure are ascites, jaundice, and **anasarca** (generalized edema) as a result of prolonged congestion of the

liver. Heart failure may also cause fluid retention and may be manifested by obvious generalized dependent edema. Chapter 35 differentiates right and left failure and systolic from diastolic heart failure in detail.

Skin

Skin assessment includes color and temperature. The best areas in which to assess circulation include the nail beds, mucous membranes, and conjunctival mucosa, because small blood vessels are located near the surface of the skin in those areas.

If there is normal blood flow or adequate perfusion to a given area in *light-colored skin*, it appears pink, perhaps rosy, and is warm. *Decreased perfusion is manifested as cool, pale, and moist skin. Pallor is characteristic of anemia and can be seen in areas such as the nail beds, palms, and conjunctival mucous membranes in any patient.*

A bluish or darkened discoloration of the skin and mucous membranes in *light-skinned* people is referred to as **cyanosis.** This condition results from an increased amount of deoxygenated hemoglobin. It is not an early sign of decreased perfusion but occurs later with other symptoms. *Dark-skinned patients may experience cyanosis as a graying of the same tissues.*

Central cyanosis involves decreased oxygenation of the arterial blood in the lungs and appears as a bluish tinge of the conjunctivae and the mucous membranes of the mouth and tongue. Central cyanosis may indicate impaired lung function or a right-to-left shunt found in congenital heart conditions. Because of impaired circulation, there is marked desaturation of hemoglobin in the peripheral tissues, which produces a bluish or darkened discoloration of the nail beds, earlobes, lips, and toes.

Peripheral cyanosis occurs when blood flow to the peripheral vessels is decreased by peripheral vasoconstriction. Constriction results from a low cardiac output or an increased extraction of oxygen from the peripheral tissues. Peripheral cyanosis localized in an extremity is usually a result of arterial or venous insufficiency. **Rubor** (dusky redness) that replaces pallor in a dependent foot suggests arterial insufficiency.

Skin *temperature* can be assessed for symmetry by touching different areas of the body with the dorsal (back) surface of the hand or fingers. Decreased blood flow results in decreased skin temperature. It is lowered in several clinical conditions, including heart failure, peripheral vascular disease, and shock.

Extremities

Assess the patient's hands, arms, feet, and legs for skin changes, vascular changes, clubbing, and edema. Skin mobility and turgor are affected by fluid status. Dehydration and aging reduce skin turgor, and edema decreases skin elasticity. Vascular changes in an affected extremity may include paresthesia, muscle fatigue and discomfort, numbness, pain, coolness, and loss of hair distribution from a reduced blood supply.

Clubbing of the fingers and toes is caused by *chronic* oxygen deprivation in body tissues. It is common in patients with advanced chronic pulmonary disease, congenital heart defects, and cor pulmonale (right-sided heart failure). The angle of the normal nail bed is 160 degrees. With **clubbing,** the nail straightens out to an angle of 180 degrees and the base of the nail becomes spongy. Fig. 30-12 in Chapter 30 shows late clubbing.

Peripheral edema (fluid accumulation in the legs and feet) is a common finding in patients with cardiovascular problems. The location of edema helps determine its potential cause. Bilateral edema of the legs may be seen in those with heart failure or chronic venous insufficiency. Abdominal and leg edema can be seen in patients with heart disease and cirrhosis of the liver. Localized edema in one extremity may be the result of venous obstruction (thrombosis) or lymphatic blockage of the extremity (lymphedema). Edema may also be noted in dependent areas, such as the sacrum, when a patient is confined to bed. In other patients, edema results from third spacing when plasma proteins decrease. Dependent foot and ankle edema is also a common side effect of certain antihypertensive drugs, such as amlodipine (Norvasc).

Document the location of edema as precisely as possible (e.g., midtibial or sacral) and the number of centimeters from an anatomic landmark. The extent of edema can be assessed as mild, moderate, or severe (or 1+, 2+, 3+, or 4+). However, these values are not precise and are very unreliable. Determine whether the edema is **pitting** (the skin can be indented) (Fig. 33-5) or nonpitting.

FIG. 33-5 Peripheral pitting edema.

The finger is typically used for pulse oximetry as a noninvasive method for assessing oxygenation and perfusion of many medical-surgical nursing patients. Correct placement of the pulse oximetry sensor is essential for accurate readings. Oxygen saturation levels of above 90% are considered normal, depending on the patient's age. Detailed information about this assessment method can be found in Chapter 27.

Blood Pressure

Arterial blood pressure is measured *indirectly* by sphygmomanometry. This technique of measurement is described in detail in nursing skills textbooks.

The 8th National High Blood Pressure Education Program Joint National Committee (JNC) on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (2013) defines **hypertension** as a systolic pressure of 140 mm Hg or higher or a diastolic pressure of 90 mm Hg or higher, or taking drugs to control blood pressure. Specific treatment goals were outlined for patients based on age and co-morbidities. Chapter 36 describes hypertension in detail.

A BP less than 90/60 mm Hg (hypotension) may not be adequate for providing enough oxygen and sufficient nutrition to body cells. In certain circumstances, such as shock, the Korotkoff sounds are less audible or are absent. In these cases, palpate the BP, use an ultrasonic device (Doppler device), or obtain a direct measurement by arterial catheter in the critical care setting. When BP is palpated, only the systolic pressure can be determined. Patients may report dizziness or light-headedness when they move from a flat, supine position to a sitting or a standing position at the edge of the bed. Normally these symptoms are transient

and pass quickly; pronounced symptoms may be due to postural hypotension. **Postural (orthostatic) hypotension** *occurs when the BP is not adequately maintained while moving from a lying to a sitting or standing position. It is defined as a decrease of more than 20 mm Hg of the systolic pressure or more than 10 mm Hg of the diastolic pressure, as well as a 10% to 20% increase in heart rate.* The causes of postural hypotension include cardiovascular drugs, blood volume decrease, prolonged bedrest, age-related changes, or disorders of the ANS.

To detect orthostatic changes in BP, first measure the BP when the patient is supine. After remaining supine for at least 3 minutes, the patient changes position to sitting or standing. Normally systolic pressure drops slightly or remains unchanged as the patient rises, whereas diastolic pressure rises slightly. After the position change, wait for at least 1 minute before auscultating BP and counting the radial pulse. The cuff should remain in the proper position on the patient's arm. Observe and record any signs or symptoms of dizziness. If the patient cannot tolerate the position change, return him or her to the previous position of comfort.

Paradoxical blood pressure is an exaggerated decrease in systolic pressure by more than 10 mm Hg during the inspiratory phase of the respiratory cycle (normal is 3 to 10 mm Hg). Certain clinical conditions that potentially alter the filling pressures in the right and left ventricles may produce a paradoxical BP. Such conditions include pericardial tamponade, constrictive pericarditis, and pulmonary hypertension. During inspiration, the filling pressures normally decrease slightly. However, decreased fluid volume in the ventricles resulting from these pathologic conditions produces a marked reduction in cardiac output. The difference between the systolic and diastolic values is referred to as **pulse pressure.** This value can be used as an indirect measure of cardiac output. Narrowed pulse pressure is rarely normal and results from increased peripheral vascular resistance or decreased stroke volume in patients with heart failure, hypovolemia, or shock. It can also be seen in those with mitral stenosis or regurgitation. An increased pulse pressure may occur in patients with slow heart rates, aortic regurgitation, atherosclerosis, hypertension, and aging.

The **ankle-brachial index (ABI)** can be used to assess the vascular status of the lower extremities. A BP cuff is applied to the lower extremity just above the malleolus. The systolic pressure is measured by Doppler ultrasound at both the dorsalis pedis and posterior tibial pulses. The higher of these two pressures is then divided by the higher of the two brachial pulses to obtain the ABI.

Normal values for the ABI are 1.00 or higher because BP in the legs is usually higher than BP in the arms. ABI values less than 0.80 usually indicate moderate vascular disease, whereas values less than 0.50 indicate severe vascular compromise. Although used primarily to help identify peripheral vascular disease, the ABI may be effective as a risk factor in predicting other CV disease in women, especially coronary artery disease (Pearson, 2010).

A **toe brachial pressure index (TBPI)** may be performed instead of or in addition to the ABI to determine arterial perfusion in the feet and toes. TBPI is the toe systolic pressure divided by the brachial (arm) systolic pressure.

Venous and Arterial Pulses

Observe the *venous pulsations* in the neck to assess the adequacy of blood volume and central venous pressure (CVP). Specially educated or critical care nurses can assess jugular venous pressure (JVP) to estimate the filling volume and pressure on the right side of the heart. An increase in JVP causes **jugular venous distention (JVD).**

Normally the JVP is 3 to 10 cm H_2O. Increases are usually caused by right ventricular failure. Other causes include tricuspid regurgitation or stenosis, pulmonary hypertension, cardiac tamponade, constrictive pericarditis, hypervolemia, and superior vena cava obstruction.

Assessment of *arterial pulses* provides information about vascular integrity and circulation. For patients with suspected or actual vascular disease, all major peripheral pulses should be assessed for presence or absence, amplitude, contour, rhythm, rate, and equality. Palpate the peripheral arteries in a head-to-toe approach with a side-to-side comparison (Fig. 33-6).

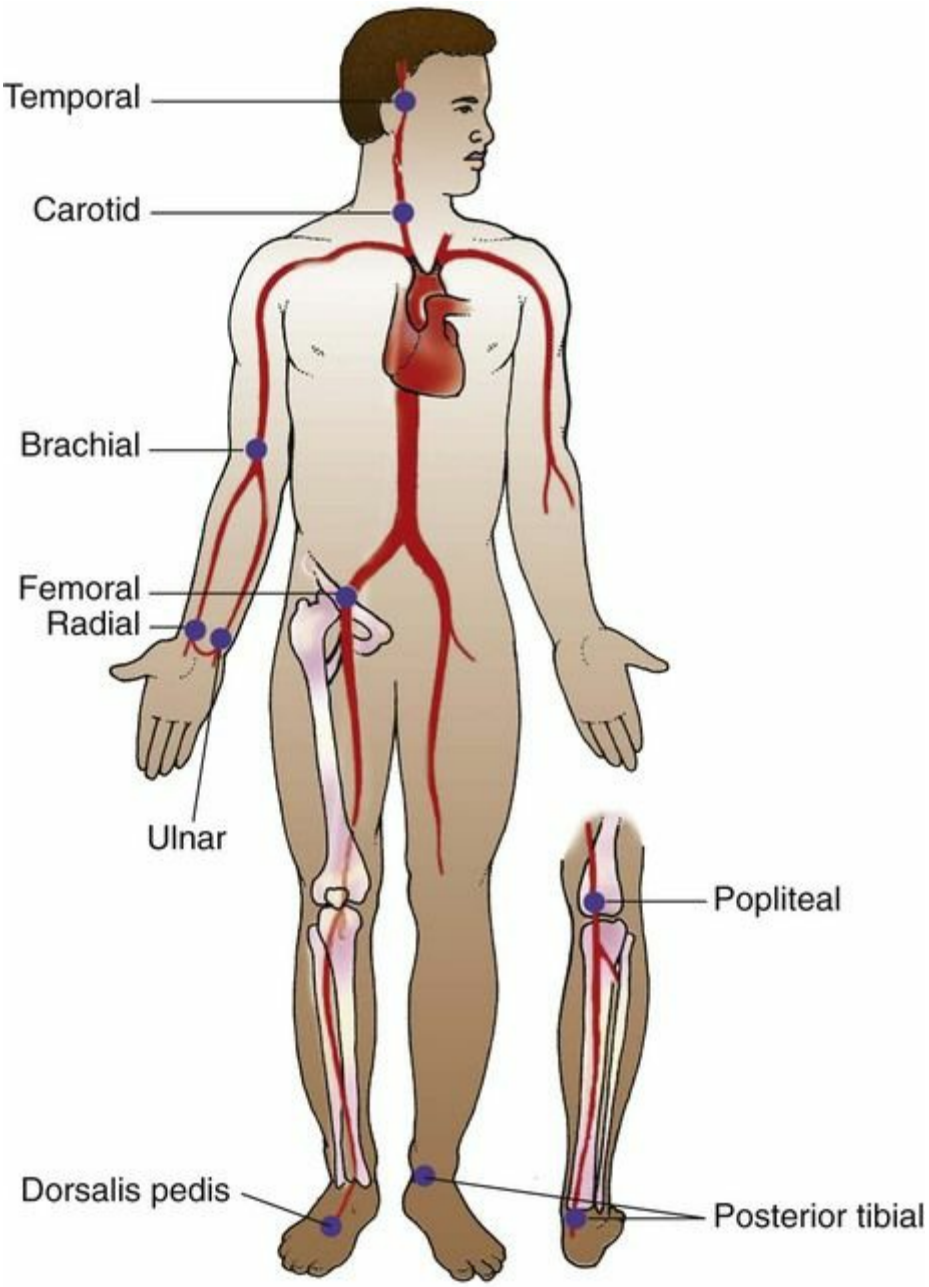

FIG. 33-6 Pulse points for assessment of arterial pulses.

A *hypokinetic* pulse is a weak pulse indicative of a narrow pulse pressure. It is seen in patients with hypovolemia, aortic stenosis, and decreased cardiac output. A *hyperkinetic* pulse is a large, "bounding" pulse caused by an increased ejection of blood. It occurs in patients with a high cardiac output (with exercise, sepsis, or thyrotoxicosis) and in those with increased sympathetic system activity (with pain, fever, or anxiety).

Auscultation of the major arteries (e.g., carotid and aorta) is necessary to assess for bruits. **Bruits** are swishing sounds that may occur from turbulent blood flow in narrowed or atherosclerotic arteries. Assess for the absence or presence of bruits by placing the bell of the stethoscope on the neck over the carotid artery while the patient holds his or her

breath. Normally there are no sounds if the artery has uninterrupted blood flow. A bruit may develop when the internal diameter of the vessel is narrowed by 50% or more, but this does not indicate the severity of disease in the arteries. Once the vessel is blocked 90% or greater, the bruit often cannot be heard.

Precordium

Assessment of the precordium (the area over the heart) involves inspection, palpation, percussion, and auscultation. *In most settings, the medical-surgical nurse seldom performs precordial palpation and percussion. Critical care nurses and advanced practice nurses are qualified to perform the complete assessment.* Therefore only inspection and auscultation are described here. Begin by placing the patient in a supine position, with the head of the bed slightly elevated for comfort. Some patients may require elevation of the head of the bed to 45 degrees for ease and comfort in breathing.

Inspection.

A cardiac examination is usually performed in a systematic order, beginning with inspection. Inspect the chest from the side, at a right angle, and downward over areas of the precordium where vibrations are visible. Cardiac motion is of low amplitude, and sometimes the inward movements are more easily detected by the naked eye.

Examine the entire precordium (Fig. 33-7), and note any prominent pulses. Movement over the aortic, pulmonic, and tricuspid areas is abnormal. Pulses in the mitral area (the apex of the heart) are considered normal and are referred to as the **apical impulse,** or the **point of maximal impulse (PMI).** The PMI should be located at the left fifth intercostal space (ICS) in the midclavicular line. If it appears in more than one ICS and has shifted lateral to the midclavicular line, the patient may have left ventricular hypertrophy.

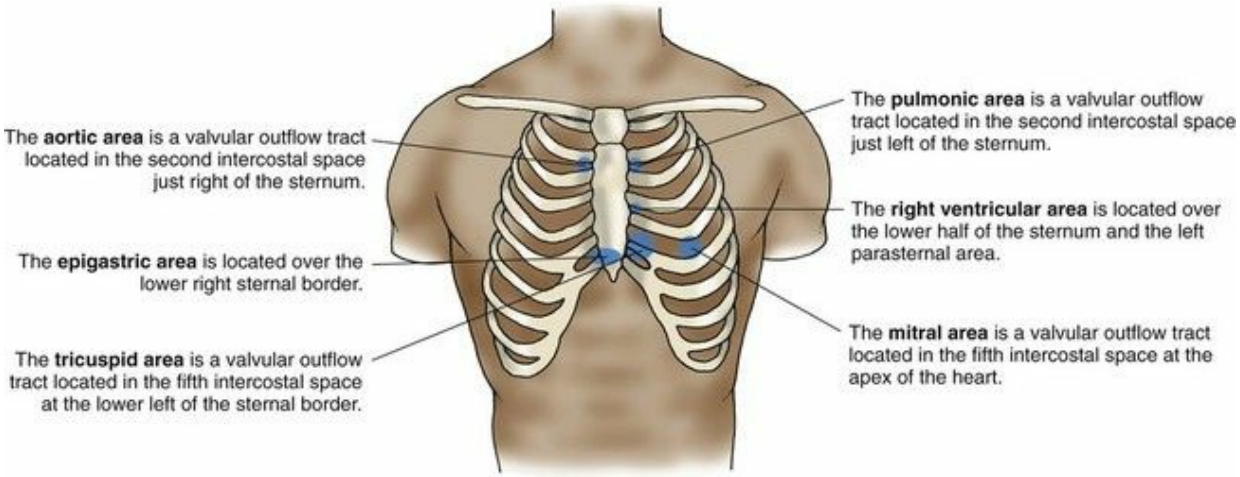

FIG. 33-7 Areas for myocardial inspection and auscultation.

Auscultation.

Auscultation evaluates heart rate and rhythm, cardiac cycle (systole and diastole), and valvular function. The technique of auscultation requires a good-quality stethoscope and extensive clinical practice. Identifying specific abnormal heart sounds is most important in critical care and telemetry.

Listen to heart sounds in a systematic order. Examination usually begins at the aortic area and progresses slowly to the apex of the heart. The diaphragm of the stethoscope is pressed tightly against the chest to listen for high-frequency sounds and is useful in listening to the first and second heart sounds and high-frequency murmurs. Repeat the progression from the base to the apex of the heart using the bell of the stethoscope, which is held lightly against the chest. The bell can screen out high-frequency sounds and is useful in listening for low-frequency gallops (diastolic filling sounds) and murmurs.

Normal Heart Sounds.

The **first heart sound (S1)** is created by the closure of the mitral and tricuspid valves (atrioventricular valves) (see Fig. 33-4). When auscultated, S_1 is softer and longer; it is of a low pitch and is best heard at the lower left sternal border or the apex of the heart. It may be identified by palpating the carotid pulse while listening. S_1 marks the beginning of ventricular systole and occurs right after the QRS complex on the ECG.

S_1 can be accentuated or intensified in conditions such as exercise, hyperthyroidism, and mitral stenosis. A decrease in sound intensity occurs in patients with mitral regurgitation and heart failure. If you have

difficulty hearing heart sounds, have the patient lean forward or roll to his or her left side.

The *second heart sound (S_2)* is caused mainly by the closing of the aortic and pulmonic valves (semilunar valves) (see Fig. 33-4). S_2 is characteristically shorter. It is higher pitched and is heard best at the base of the heart at the end of ventricular systole.

The splitting of heart sounds is often difficult to differentiate from diastolic filling sounds (gallops). A splitting of S_1 (closure of the mitral valve followed by closure of the tricuspid valve) occurs physiologically because left ventricular contraction occurs slightly before right ventricular contraction. Closure of the mitral valve is louder than closure of the tricuspid valve, however, so splitting is often not heard. Normal splitting of S_2 occurs because of the longer systolic phase of the right ventricle. Splitting of S_1 and S_2 can be accentuated by inspiration (due to increased venous return), and it narrows during expiration.

Abnormal Heart Sounds.

Abnormal splitting of S_2 is referred to as **paradoxical splitting** and has a wider split heard on expiration. Paradoxical splitting of S_2 is heard in patients with severe myocardial depression that causes early closure of the pulmonic valve or a delay in aortic valve closure. Such conditions include myocardial infarction (MI), left bundle-branch block, aortic stenosis, aortic regurgitation, and right ventricular pacing.

Gallops and murmurs are common abnormal heart sounds that may occur with heart disease, but they can occur in some healthy people. Diastolic filling sounds (S_3 and S_4) are produced when blood enters a noncompliant chamber during rapid ventricular filling. The third heart sound (S_3) is produced during the rapid passive filling phase of ventricular diastole when blood flows from the atrium to a noncompliant ventricle. The sound arises from vibrations of the valves and supporting structures. The fourth heart sound (S_4) occurs as blood enters the ventricles during the active filling phase at the end of ventricular diastole.

S_3 is called a **ventricular gallop,** and S_4 is referred to as **atrial gallop.** These sounds can be caused by decreased compliance of either or both ventricles. Left ventricular diastolic filling sounds are best heard with the patient on his or her left side. The bell of the stethoscope is placed at the apex and at the left lower sternal border during expiration.

An S_3 heart sound is most likely to be a normal finding in those

younger than 35 years. An S_3 gallop in patients older than 35 years is considered abnormal and represents a decrease in left ventricular compliance. It can be detected as an early sign of heart failure or as a ventricular septal defect.

An atrial gallop (S_4) may be heard in patients with hypertension, anemia, ventricular hypertrophy, MI, aortic or pulmonic stenosis, and pulmonary emboli. *It may be heard also with advancing age because of a stiffened ventricle.*

Murmurs reflect turbulent blood flow through normal or abnormal valves. They are classified according to their timing in the cardiac cycle: *systolic* murmurs (e.g., aortic stenosis and mitral regurgitation) occur between S_1 and S_2, whereas *diastolic* murmurs (e.g., mitral stenosis and aortic regurgitation) occur between S_2 and S_1. Murmurs can occur during presystole, midsystole, or late systole or diastole or can last throughout both phases of the cardiac cycle. They are also graded by the primary care provider according to their intensity, depending on their level of loudness (Table 33-3).

TABLE 33-3

Grading of Heart Murmurs

Grade I	Very faint
Grade II	Faint but recognizable
Grade III	Loud but moderate in intensity
Grade IV	Loud and accompanied by a palpable thrill
Grade V	Very loud, accompanied by a palpable thrill, and audible with the stethoscope partially off the patient's chest
Grade VI	Extremely loud, may be heard with the stethoscope slightly above the patient's chest, accompanied by a palpable thrill

Although you are not expected to grade murmurs as a medical-surgical nurse, describe their location based on where they are best heard. Some murmurs transmit or radiate from their loudest point to other areas, including the neck, the back, and the axilla. The configuration is described as *crescendo* (increases in intensity) or *decrescendo* (decreases in intensity). The quality of murmurs can be further characterized as harsh, blowing, whistling, rumbling, or squeaking. They are also described by pitch—usually *high* or *low*.

A **pericardial friction rub** originates from the pericardial sac and occurs

with the movements of the heart during the cardiac cycle. Rubs are usually transient and are a sign of inflammation, infection, or infiltration. They may be heard in patients with pericarditis resulting from MI, cardiac tamponade, or post-thoracotomy.

Psychosocial Assessment

To most people, the heart is a symbol of their ability to exist, survive, and love. A patient with a heart-related illness, whether acute or chronic, usually perceives it as a major life crisis. The patient and family confront not only the possibility of death but also fears about pain, disability, lack of self-esteem, physical dependence, and changes in family dynamics. Assess the meaning of the illness to the patient and family by asking "What do you understand about what happened to you (or the patient)?" and "What does that mean to you?" When they perceive the stressor as overwhelming, formerly adequate support systems may no longer be effective. In these circumstances, the patient and family members attempt to cope to regain a sense or feeling of control.

Coping behaviors vary among patients and their families. Those who feel helpless to meet the demands of the situation may exhibit behaviors such as disorganization, fear, and anxiety. Ask them "Have you ever encountered such a situation before?" "How did you manage that situation?" and "To whom can you turn for help?" The answers to these questions often reassure the patient and family that they have encountered difficult situations in the past and have the ability and resources to cope with them.

A common and normal response is denial, which is a defense mechanism that enables the patient to cope with threatening circumstances. He or she may deny the current cardiovascular condition, may state that it was present but is now absent, or may be excessively cheerful. Denial becomes maladaptive when the patient is noncompliant or does not adhere to the interdisciplinary plan of care.

Family members and significant others may be more anxious than the patient. Often they recall all events of the illness, are unprotected by denial, and are afraid of recurrence. Disagreements may occur between the patient and family members over adherence to appropriate follow-up care.

Clinical Judgment Challenge

Safety; Teamwork and Collaboration QSEN

A middle-aged man is admitted to the cardiac unit after reports of a severe headache and flushing of the face. He is diagnosed with severe hypertension. The patient is alert and oriented; BP = 192/104 and HR = 88. You are the RN assigned to his care. There is an unlicensed nursing technician working with you.

1. What assessment data will you perform upon his arrival to the unit? Why?
2. The cardiologist prescribes IV fluids, hourly blood pressure checks, blood pressure medication, and oxygen at 2 liters per nasal cannula. What part of the patient's care will you delegate to the unlicensed nursing technician? What information will you communicate upon delegation?
3. What interventions will you implement to ensure this patient's safety?
4. The patient's wife is very concerned about her husband returning to work as owner of a roofing company. What education will you provide the patient and his wife at this time? With what health care team members will you collaborate to ensure positive patient outcomes?

Diagnostic Assessment

Laboratory Assessment

Assessment of the patient with cardiovascular dysfunction includes examination of the blood for abnormalities. The examination is performed to help establish a diagnosis, detect concurrent disease, assess risk factors, and monitor response to treatment. Normal values for serum cardiac enzymes and serum lipids are listed in Chart 33-2.

Chart 33-2 Laboratory Profile

Cardiovascular Assessment

NORMAL RANGE	SIGNIFICANCE OF ABNORMAL FINDINGS
Serum Cardiac Enzymes	
Creatine kinase (CK) *Females:* 30-135 units/L *Males:* 55-170 units/L Values higher after exercise	Elevations indicate possible brain, myocardial, and skeletal muscle necrosis or injury.
CK-MB (CK_2) 0% of total CK	Elevations occur with myocardial injury or after percutaneous transluminal angioplasty and intracoronary streptokinase infusion.
Serum Lipids	
Total lipids 400-1000 mg/dL	Elevation indicates increased risk for coronary artery disease (CAD).
Cholesterol Less than 200 mg/dL	Elevation indicates increased risk for CAD.
Triglycerides *Females:* 35-135 mg/dL *Males:* 40-160 mg/dL	Elevation indicates increased risk for CAD.
Plasma high-density lipoproteins (HDLs) *Females:* >55 mg/dL *Males:* >45 mg/dL *Older adults:* range increases with age	Elevations protect against CAD.
Plasma low-density lipoproteins (LDLs) <130 mg/dL	Elevation indicates increased risk for CAD.
HDL : LDL ratio 3 : 1	Elevated ratios may protect against CAD.
VLDL 7-32 ng/dL	Elevated level indicates risk for CAD.
C-reactive protein (CRP) <1.0 mg/dL	Elevation may indicate tissue infarction or damage.
Serum Markers	
Troponins Cardiac troponin T <0.10 ng/mL Cardiac troponin I <0.03 ng/mL	Elevations indicate myocardial injury or infarction.
Myoglobin <90 mcg/L	Elevation indicates myocardial infarction.

VLDL, Very-low-density lipoproteins.

Serum Markers of Myocardial Damage.

Events leading to cellular injury cause a release of enzymes from intracellular storage, and circulating levels of these enzymes are dramatically elevated. Acute myocardial infarction (MI), also known as **acute coronary syndrome,** can be confirmed by abnormally high levels of certain proteins or isoenzymes. These serum studies are commonly referred to as **cardiac markers** and include troponin, creatine kinase–MB, and myoglobin.

Troponin is a myocardial muscle protein released into the bloodstream with injury to myocardial muscle. Troponins T and I are not found in healthy patients, so any rise in values indicates cardiac necrosis or acute MI. Specific markers of myocardial injury, troponins T and I, have a wide diagnostic time frame, making them useful for patients who present several hours after the onset of chest pain. Even low levels of troponin T are treated aggressively because of increased risk for death from cardiovascular disease (CVD). Obtaining cardiac markers at the bedside in the emergency department can be done as "point of care" (POC) testing for patients experiencing or at risk for acute MI, with results available within 15 to 20 minutes. These markers are evaluated in

addition to clinical signs and symptoms and ECG changes when identifying at-risk patients.

Creatine kinase (CK) is an enzyme specific to cells of the brain, myocardium, and skeletal muscle. The appearance of CK in the blood indicates tissue necrosis or injury, with levels following a predictable rise and fall during a specified period. Cardiac specificity must be determined by measuring isoenzyme activity. There are three isoenzymes of CK: CK-MM is the predominant isoenzyme of skeletal muscle; CK-MB is found in myocardial muscle; and CK-BB occurs in the brain. CK-MB activity is most specific for MI and shows a predictable rise and fall during 3 days; a peak level occurs about 24 hours after the onset of chest pain.

Treatment modalities for early intervention after acute MI and acute ischemia require more rapid diagnosis of MI. An assay using monoclonal anti–CK-MB antibodies (stat CK) can detect myocardial necrosis accurately 3 hours after emergency department admission when examined with an ECG. Two subforms of CK-MB ($CK\text{-}MB_1$ and $CK\text{-}MB_2$) have also been identified. Abnormal elevations of these CK subforms may occur as early as 2 hours after MI. They remain elevated for up to 12 hours after MI and appear to be very sensitive and specific early diagnostic markers of MI.

Another early marker of an MI is myoglobin. **Myoglobin,** a low–molecular-weight heme protein found in cardiac and skeletal muscle, is the earliest marker detected—as early as 2 hours after an MI with rapid decline after 7 hours. Because myoglobin is not cardiac specific and is found in skeletal and cardiac muscle, its clinical usefulness is more limited than troponin.

Serum Lipids.

Elevated lipid levels are considered a risk factor for coronary artery disease (CAD). **Cholesterol, triglycerides,** and the protein components of **high-density lipoproteins (HDLs)** and **low-density lipoproteins (LDLs)** are evaluated to assess the risk for CAD. The desired ranges for lipids are (Pagana & Pagana, 2014):

- Total cholesterol less than 200 mg/dL
- Triglycerides between 40 and 160 mg/dL for men and between 35 and 135 mg/dL for women
- HDL more than 45 mg/dL for men; more than 55 mg/dL for women ("good" cholesterol)
- LDL less than 130 mg/dL

Each of the lipoproteins contains varying proportions of cholesterol,

triglyceride, protein, and phospholipid. HDL contains mainly protein and 20% cholesterol, whereas LDL is mainly cholesterol. Elevated LDL levels are positively correlated with CAD, whereas elevated HDL levels are negatively correlated and appear to be protective for heart disease. LDL pattern size is of significant importance in determining risk for CVD. LDL pattern A is associated with non–insulin resistance; normal glucose, insulin, and HDL levels; and a normal blood pressure. LDL pattern B is associated with insulin resistance; increased glucose, insulin, and triglyceride levels; and hypertension.

A fasting blood sample for the measurement of serum cholesterol levels is preferable to a nonfasting sample. If triglycerides are to be evaluated with cholesterol, the health care provider requests the specimen after a 12-hour fast

Lipoprotein-a, or Lp(a), is a modified form of LDL, the most common familial lipoprotein disorder in patients with premature coronary artery disease. Lp(a) is atherogenic (increases atherosclerotic plaques) and prothrombotic (increases clots). Therefore the desired outcome is a value less than 30 mg/dL. The patient should be fasting and avoid smoking before the test (Pagana & Pagana, 2014).

Other Laboratory Tests.

Homocysteine is an amino acid that is produced when proteins break down. A certain amount of homocysteine is present in the blood, but elevated values may be an independent risk factor for the development of CVD. Although the relationship between homocysteine and CVD remains controversial, elevated levels of homocysteine may increase the risk for disease as much as smoking and hyperlipemia, especially in women. High-risk patients who have a personal or family history of premature heart disease should be screened. A level less than 14 mmol/dL is considered optimal, but this level increases as one ages (Pagana & Pagana, 2014).

Inflammation is a common and critical component to the development of atherothrombosis. **Highly sensitive C-reactive protein (hsCRP)** has been the most studied marker of inflammation. Any inflammatory process can produce CRP in the blood. Elevations are seen also with hypertension, infection, and smoking. A level less than 1 mg/dL is considered low risk; a level over 3 mg/dL places the patient at high risk for heart disease. The CRP is very helpful in determining treatment outcomes in patients at risk for coronary disease and in managing statin therapy after an acute myocardial infarction. The most useful time to measure CRP appears to be for risk assessment in middle-aged or older

persons.

Microalbuminuria, or small amounts of protein in the urine, has been shown to be a clear marker of widespread endothelial dysfunction in cardiovascular disease (along with elevated CRP). It should be screened annually in all patients with hypertension, metabolic syndrome, or diabetes mellitus. Microalbuminuria has also been used as a marker for renal disease, particularly in patients with hypertension and diabetes.

Blood coagulation studies evaluate the ability of the blood to clot. They are important in patients with a greater tendency to form thrombi (e.g., those with atrial fibrillation, prosthetic valves, or infective endocarditis). These tests are also essential for monitoring patients receiving anticoagulant therapy (e.g., during cardiac surgery, during treatment of an established thrombus).

Prothrombin time (PT) and *international normalized ratio (INR)* are used when initiating and maintaining therapy with oral anticoagulants, such as sodium warfarin (Coumadin, Warfilone). They measure the activity of prothrombin, fibrinogen, and factors V, VII, and X. INR is the most reliable way to monitor anticoagulant status in warfarin therapy. The therapeutic ranges vary significantly based on the reason for the anticoagulation and the patient's history. The normal INR is 1.

Partial thromboplastin time (PTT) is assessed in patients who are receiving heparin (Hepalean). It measures deficiencies in all coagulation factors except VII and XIII.

Arterial blood gas (ABG) determinations are often obtained in patients with CVD. Determination of tissue oxygenation, carbon dioxide removal, and acid-base status is essential to appropriate treatment. (See Chapter 12 for a complete discussion of ABGs.)

fluid and electrolyte balance is essential for normal cardiovascular performance. Cardiac manifestations often occur when there is an imbalance in either fluids or electrolytes in the body. For example, the cardiac effects of hypokalemia (low serum potassium level) include increased electrical instability, ventricular dysrhythmias, and an increased risk for digitalis toxicity. The effects of hyperkalemia on the myocardium include slowed ventricular conduction, peaked T waves on the ECG, and contraction followed by asystole (cardiac standstill).

Cardiac manifestations of hypocalcemia are ventricular dysrhythmias, a prolonged QT interval, and cardiac arrest. Hypercalcemia shortens the QT interval and causes AV block, digitalis hypersensitivity, and cardiac arrest. Serum sodium values reflect fluid balance and may be decreased, indicating a fluid excess in patients with heart failure (dilutional hyponatremia).

Because magnesium regulates some aspects of myocardial electrical activity, hypomagnesemia has been implicated in some forms of ventricular dysrhythmias known as *torsades de pointes*. Hypomagnesemia prolongs the QT interval, causing this specific type of ventricular tachycardia. Chapter 11 describes these electrolytes in more detail.

The *erythrocyte (red blood cell [RBC]) count* is usually decreased in rheumatic fever and infective endocarditis. It is increased in heart diseases as needed to compensate for decreased available oxygen.

Decreased *hematocrit and hemoglobin* levels (e.g., caused by hemorrhage or hemolysis from prosthetic valves) indicate anemia and can lead to angina or aggravate heart failure. Vascular volume depletion with hemoconcentration (e.g., hypovolemic shock and excessive diuresis) results in an elevated hematocrit.

The *leukocyte (white blood cell [WBC]) count* is typically elevated after an MI and in various infectious and inflammatory diseases of the heart (e.g., infective endocarditis and pericarditis). An increased WBC has been implicated as a strong independent risk factor for stroke and heart disease, particularly in postmenopausal women (Go et al., 2013).

Other Diagnostic Assessment

Posteroanterior (PA) and left lateral *x-ray* views of the chest are routinely obtained to determine the size, silhouette, and position of the heart. In acutely ill patients, a simple anteroposterior (AP) view may be obtained at the bedside. Cardiac enlargement, pulmonary congestion, cardiac calcifications, and placement of central venous catheters, endotracheal tubes, and hemodynamic monitoring devices are assessed by x-ray.

Angiography of the arterial vessels, or **arteriography,** is an invasive diagnostic procedure that involves fluoroscopy and the use of contrast media. This procedure is performed when an arterial obstruction, narrowing, or aneurysm is suspected. The interventional radiologist performs selective arteriography to evaluate specific areas of the arterial system. For example, a coronary arteriography, which is performed during left-sided cardiac catheterization, assesses arterial circulation within the heart. It can also be performed on arteries in the extremities, mesentery, and cerebrum. Angiography is discussed under the appropriate associated diseases elsewhere in this text.

Cardiac Catheterization.

The most definitive but most invasive test in the diagnosis of heart disease is cardiac catheterization. **Cardiac catheterization** may include

studies of the right or left side of the heart and the coronary arteries. Some of the most common indications for cardiac catheterization are listed in Table 33-4.

TABLE 33-4

Indications For Cardiac Catheterization

- To confirm suspected heart disorders, including congenital abnormities, coronary artery disease, myocardial disease, valvular disease, and valvular dysfunction
- To determine the location and extent of the disease process
- To assess:
  - Stable, severe angina unresponsive to medical management
  - Unstable angina pectoris
  - Uncontrolled heart failure, ventricular dysrhythmias, or cardiogenic shock associated with acute myocardial infarction, papillary muscle dysfunction, ventricular aneurysm, or septal perforation
- To determine best therapeutic option (percutaneous transluminal coronary angioplasty, stents, coronary artery bypass graft, valvulotomy versus valve replacement)
- To evaluate effects of medical or invasive treatment on cardiovascular function, percutaneous transluminal coronary angioplasty, or coronary artery bypass graft patency

Patient Preparation.

Assess the patient's physical and psychosocial readiness and knowledge level about the procedure because many patients have anxiety and fear about cardiac catheterization. Review the purpose of the procedure, inform the patient about the length of the procedure, state who will be present, and describe the appearance of the catheterization laboratory. Tell the patient about the sensations he or she may experience during the procedure, such as palpitations (as the catheter is passed up to the left ventricle), a feeling of heat or a hot flash (as the medium is injected into either side of the heart), and a desire to cough (as the medium is injected into the right side of the heart). Written, electronic, or illustrated materials or DVDs may be used to assist in understanding.

The risks of cardiac catheterization are usually explained by the cardiologist. The risks vary with the procedures to be performed and the patient's physical status (Table 33-5). Although not common, several serious complications may follow coronary arteriography, such as:

TABLE 33-5

Complications of Cardiac Catheterization

Right-Sided Heart Catheterization
• Thrombophlebitis • Pulmonary embolism • Vagal response
Left-Sided Heart Catheterization and Coronary Arteriography
• Myocardial infarction • Stroke • Arterial bleeding or thromboembolism • Dysrhythmias
Right-Sided or Left-Sided Heart Catheterization*
• Cardiac tamponade • Hypovolemia • Pulmonary edema • Hematoma or blood loss at insertion site • Reaction to contrast medium

*In addition to those cited for each procedure.

- Myocardial infarction (MI)
- Stroke
- Arterial bleeding
- Thromboembolism
- Lethal dysrhythmias
- Arterial dissection
- Death

The cardiologist or interventional radiologist obtains a written informed consent from the patient or responsible party before the procedure.

The patient is admitted to the hospital on the day of the catheterization procedure. He or she may be admitted earlier if there is renal dysfunction. Fluids may be given 12 to 24 hours before the procedure for renal protection. Contrast-induced renal dysfunction can result from vasoconstriction and the direct toxic effect of the contrast agent on the renal tubules. Hydration and the administration of acetylcysteine pre- and post-study help eliminate or minimize contrast-induced renal toxicity.

Standard preoperative tests are performed, which usually include a chest x-ray, complete blood count, coagulation studies, and 12-lead ECG. The patient receives nothing by mouth after midnight or has only a liquid breakfast if the catheterization is scheduled for the afternoon. The catheterization site is antiseptically prepared with hairs clipped according to agency policy.

Before the procedure, take the patient's vital signs, auscultate the heart

and the lungs, and assess the peripheral pulses. Question him or her about any history of allergy to iodine-based contrast agents. An antihistamine or steroid may be given to a patient with a positive history or to prevent a reaction. Be sure that the signed informed consent is completed, as required by The Joint Commission's National Patient Safety Goals (NPSGs). A mild sedative is usually administered before the procedure. If the patient normally takes a digitalis preparation or diuretic, it is usually withheld before the catheterization. Analysis of electrolytes, blood urea nitrogen (BUN), creatinine, coagulation profile, and complete blood count (CBC) is essential before and after the procedure, and abnormalities are discussed with the health care provider.

Procedure.

The patient is taken to the cardiac catheterization laboratory (sometimes referred to as the "cath lab"), placed in the supine position on the x-ray table, and securely strapped to the table. The physician injects a local anesthetic at the insertion site. During the procedure, the patient is instructed to report any chest pain, pressure, or other symptoms to the staff.

The *right side of the heart* is catheterized first and may be the only side examined. The cardiologist inserts a catheter through the femoral vein to the inferior vena cava or through the basilic vein to the superior vena cava. The catheter is advanced through either the inferior or the superior vena cava and, guided by fluoroscopy, is advanced through the right atrium, through the right ventricle, and, at times, into the pulmonary artery. Intracardiac pressures (right atrial, right ventricular, pulmonary artery, and pulmonary artery wedge pressures) and blood samples are obtained. A contrast medium is usually injected to detect any cardiac shunts or regurgitation from the pulmonic or tricuspid valves.

In a *left-sided heart catheterization*, the cardiologist advances the catheter against the blood flow from the femoral, brachial, or radial artery up the aorta, across the aortic valve, and into the left ventricle (Fig. 33-8). Alternatively, the catheter may be passed from the right side of the heart through the atrial septum, using a special needle to puncture the septum. Intracardiac pressures and blood samples are obtained. The pressures of the left atrium, left ventricle, and aorta, as well as mitral and aortic valve status, are evaluated. The cardiologist injects contrast dye into the ventricle; digital subtraction angiography evaluates left ventricular motion. Calculations are made regarding end-systolic volume, end-diastolic volume, stroke volume, and ejection fraction.

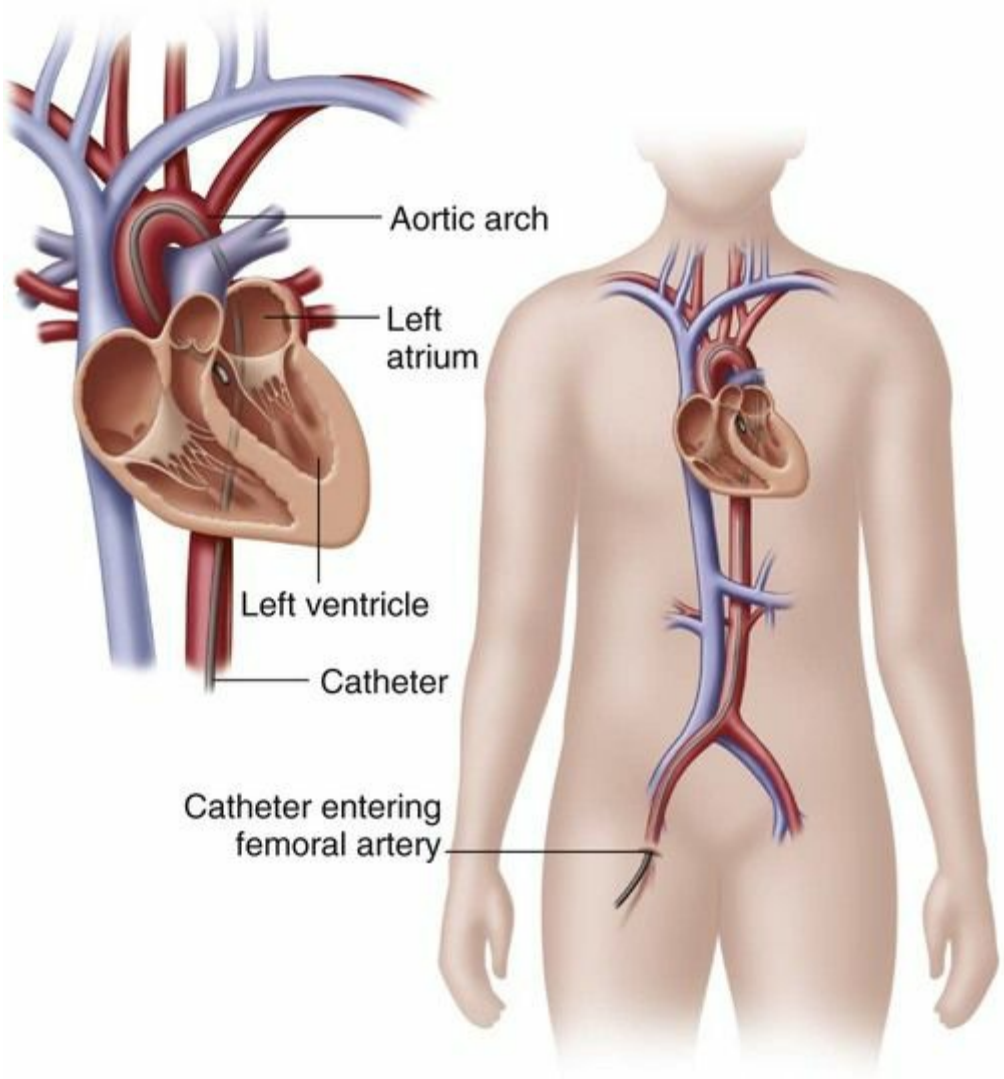

FIG. 33-8 Left-sided cardiac catheterization.

The technique for *coronary arteriography* is the same as for left-sided heart catheterization. The catheter is advanced into the aortic arch and positioned selectively in the right or left coronary artery. Injection of a contrast medium permits viewing the coronary arteries. By assessing the flow of the medium through the coronary arteries, information about the site and severity of coronary lesions is obtained.

An alternative to injecting a medium into the coronary arteries is **intravascular ultrasonography (IVUS),** which introduces a flexible catheter with a miniature transducer at the distal tip to view the coronary arteries. The transducer emits sound waves, which reflect off the plaque and the arterial wall to create an image of the blood vessel. IVUS is more reliable than angiography in indicating plaque distribution and composition, arterial dissection, and degree of stenosis of the occluded artery.

Follow-up Care.

The patient recovers in a specialty area equipped with monitored beds. After cardiac catheterization, restrict the patient to bedrest and keep the insertion site extremity straight. A soft knee brace can be applied to prevent bending of the affected extremity. Some cardiologists allow the head of the bed to be elevated up to 30 degrees during the period of bedrest, whereas other cardiologists prefer that the patient remain supine. Current practice is for patients to remain in bed for 2 to 6 hours depending on the type of vascular closure device used. Various types of vascular closure devices are used to eliminate the need for manual compression after the catheterization. Examples include arteriotomy sutures and collagen plugs to seal the insertion site.

Monitor the patient's vital signs every 15 minutes for 1 hour, then every 30 minutes for 2 hours or until vital signs are stable, and then every 4 hours or according to hospital policy. Assess the insertion site for bloody drainage or hematoma formation. Complications with vascular closure devices are not common but can be very serious. Assess peripheral pulses in the affected extremity, as well as skin temperature and color, with every vital sign check. Observe for complications of cardiac catheterization (see Table 33-5).

Nursing Safety Priority QSEN

Critical Rescue

If the patient experiences symptoms of cardiac ischemia such as chest pain, dysrhythmias, bleeding, hematoma formation, or a dramatic change in peripheral pulses in the affected extremity, contact the Rapid Response Team or physician immediately to provide prompt intervention! Neurologic changes indicating a possible stroke, such as visual disturbances, slurred speech, swallowing difficulties, and extremity weakness, should also be reported immediately.

Because the contrast medium acts as an osmotic diuretic, monitor urine output and ensure that the patient receives sufficient oral and IV fluids for adequate excretion of the medium. Pain medication for insertion site or back discomfort may be given as prescribed.

Review home instructions and risk factor modification with the patient before discharge. Remind the patient to:

- Limit activity for several days, including avoiding lifting and exercise.
- Leave the dressing in place for at least the first day at home.
- Observe the insertion site over the next few weeks for increased

swelling, redness, warmth, and pain. Bruising or a small hematoma is expected.

NCLEX Examination Challenge

Physiological Integrity

A client is admitted to the telemetry unit after a right-sided cardiac catheterization. What is the nurse's priority when caring for this client?
A Assess the intensity and quality of the client's pain.
B Position the client in a sitting position to improve breathing.
C Check the client's arterial insertion site.
D Apply oxygen at 2 L/min via nasal cannula.

Electrocardiography.

The electrocardiogram (ECG) is a routine part of every cardiovascular evaluation and is one of the most valuable diagnostic tests. Various forms are available: resting ECG, continuous ambulatory ECG (Holter monitoring), exercise ECG (stress test), signal-averaged ECG, and 30-day event monitoring. The resting ECG provides information about cardiac dysrhythmias, myocardial ischemia, the site and extent of MI, cardiac hypertrophy, electrolyte imbalances, and the effectiveness of cardiac drugs. The normal ECG pattern and a detailed discussion of the interpretation of abnormal patterns are discussed in Chapter 34.

Electrophysiologic Studies.

An **electrophysiologic study (EPS)** is an invasive procedure during which programmed electrical stimulation of the heart is used to cause and evaluate lethal dysrhythmias and conduction abnormalities. Patients who have survived cardiac arrest, have recurrent tachydysrhythmias, or experience unexplained syncopal episodes may be referred for EPS. Induction of the dysrhythmia during EPS helps find an accurate diagnosis and aids in effective treatment. These procedures have risks similar to those for cardiac catheterization and are performed in a special catheterization laboratory, where conditions are strictly controlled and immediate treatment is available for any adverse effects.

Exercise Electrocardiography (Stress Test).

The **exercise electrocardiography** test (also known as **exercise tolerance,** or **stress test**) assesses cardiovascular response to an increased workload. The stress test helps determine the functional capacity of the heart and

screens for asymptomatic coronary artery disease. Dysrhythmias that develop during exercise may be identified, and the effectiveness of antidysrhythmic drugs can be evaluated.

Patient Preparation.

Because risks are associated with exercising, the patient must be adequately informed about the purpose of the test, the procedure, and the risks involved. Written consent must be obtained. Anxiety and fear are common before stress testing. Therefore assure the patient that the procedure is performed in a controlled environment in which prompt nursing and medical attention are available.

Instruct the patient to get plenty of rest the night before the procedure. He or she may have a light meal 2 hours before the test but should avoid smoking or drinking alcohol or caffeine-containing beverages on the day of the test. The cardiologist decides whether the patient should stop taking any cardiac medications. Usually cardiovascular drugs such as beta blockers or calcium channel blockers are withheld on the day of the test to allow the heart rate to increase during the stress portion of the test. Patients are advised to wear comfortable, loose clothing and rubber-soled, supportive shoes. Remind them to tell the physician if symptoms such as chest pain, dizziness, shortness of breath, and an irregular heartbeat are experienced during the test.

Before the stress test, a resting 12-lead ECG, cardiovascular history, and physical examination are performed to check for any ECG abnormalities or medical factors that might interfere with the test. Check to see that all emergency supplies such as cardiac drugs, a defibrillator, and other necessary resuscitation equipment are available in the room in which the stress test is performed. It is important to be proficient in the use of resuscitation equipment when assisting the physician because chest pain, dysrhythmias, and other ECG changes may occur.

Procedure.

The technician places electrodes on the patient's chest and attaches them to a multilead monitoring system. Note baseline blood pressure (BP), heart rate (HR), and respiratory rate. The two major modes of exercise available for stress testing are pedaling a bicycle ergometer and walking on a treadmill. A bicycle ergometer has a wheel operated by pedals that can be adjusted to increase the resistance to pedaling. The treadmill is a motorized device with an adjustable conveyor belt. It can reach speeds of 1 to 10 miles/hr and can also be adjusted from a flat position to a 22-

degree incline.

After the patient is shown how to use the bicycle or to walk on the treadmill, he or she begins to exercise. During the test, the BP and ECG are closely monitored as the resistance to cycling or the speed and incline of the treadmill are increased (Fig. 33-9). The patient exercises until one of these findings occurs:

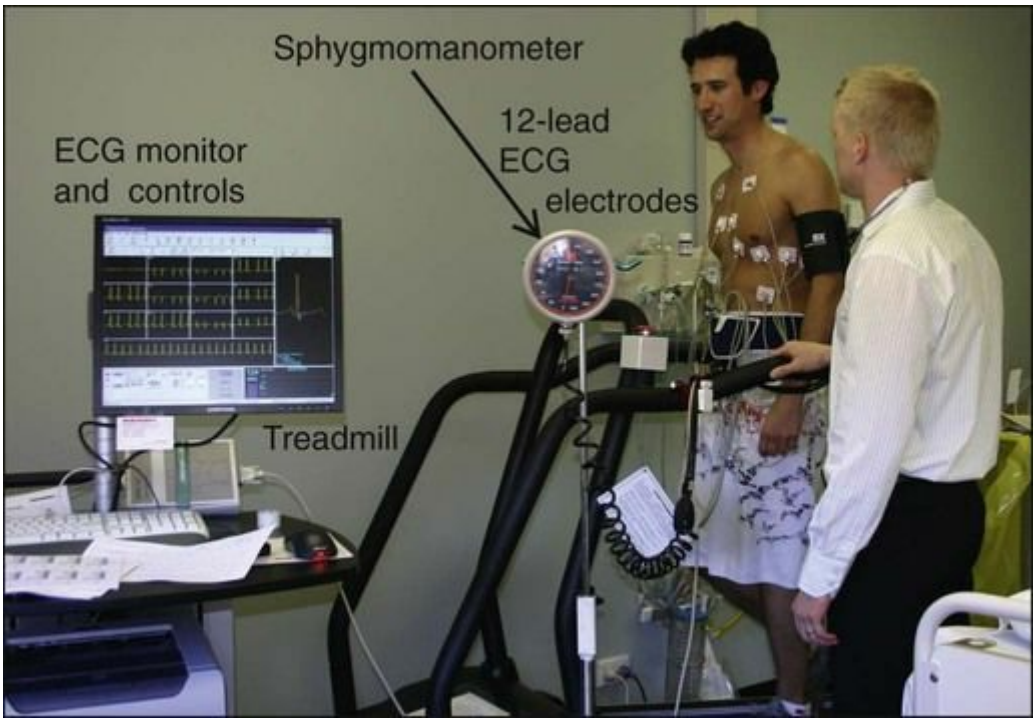

FIG. 33-9 Patient using a treadmill for a stress test.

- A predetermined HR is reached and maintained.
- Signs and symptoms such as chest pain, fatigue, extreme dyspnea, vertigo, hypotension, and ventricular dysrhythmias appear.
- Significant ST-segment depression or T-wave inversion occurs.
- The 20-minute protocol is completed.

Follow-up Care.

After the test, the nurse or other qualified health care team member monitors the ECG and BP until the patient has completely recovered. After recovery, he or she can return home if the test was performed on an ambulatory basis. Advise him or her to avoid a hot shower for 1 to 2 hours after the test because this may cause hypotension. If he or she does not recover but continues to have pain or ventricular dysrhythmias or appears medically unstable, admission to a telemetry unit for observation is needed.

For patients who cannot exercise because of conditions such as

peripheral vascular disease or arthritis, pharmacologic stress testing with agents such as dobutamine (Dobutrex) may be indicated. The nursing considerations are similar to those for the patient who has undergone an exercise ECG.

Echocardiography.

As a noninvasive, risk-free test, echocardiography is easily performed at the bedside or on an ambulatory care basis. **Echocardiography** uses ultrasound waves to assess cardiac structure and mobility, particularly of the valves. It helps assess and diagnose cardiomyopathy, valvular disorders, pericardial effusion, left ventricular function, ventricular aneurysms, and cardiac tumors.

There is no special *preparation* for echocardiography. Inform the patient that the test is painless and takes 30 to 60 minutes to complete. The patient is instructed to lie quietly during the test and on his or her left side with the head elevated 15 to 20 degrees.

During an echocardiogram, a small transducer lubricated with gel to facilitate movement and conduction is placed on the patient's chest at the level of the third or fourth intercostal space near the left sternal border. The transducer transmits high-frequency sound waves and receives them as they are reflected from different structures. These echoes are usually videotaped simultaneously with the echocardiogram and can be recorded on graph paper for a permanent record.

After the images are taped, cardiac measurements that require several images can be obtained. Routine measurements include chamber size, ejection fraction, and flow gradient across the valves. There is no specific *follow-up care* for a patient who has undergone an echocardiogram.

A slightly more aggressive form of echocardiogram is a **pharmacologic stress echocardiogram** using either dobutamine or dipyridamole. This test is usually used when patients cannot tolerate exercise. Dobutamine (Dobutrex) increases the heart's contractility; dipyridamole (Persantine, Apo-Dipyridamole) is a coronary artery dilator. Patients are required to be NPO status for 3 to 6 hours before the test except for sips of water with medications. The technician ensures that IV access is present before the procedure and monitors BP and pulse continuously throughout the procedure. After the procedure, vital signs are monitored until BP returns to baseline and the pulse rate slows to less than 100 beats/min.

Transesophageal Echocardiography.

Echocardiograms may also be performed transesophageally (through the esophagus). **Transesophageal echocardiography (TEE)** examines cardiac

structure and function with an ultrasound transducer placed immediately behind the heart in the esophagus or stomach. The transducer provides especially detailed views of posterior cardiac structures such as the left atrium, mitral valve, and aortic arch. Preparation and follow-up are similar to that for an upper GI endoscopic examination (see Chapter 52).

Myocardial Nuclear Perfusion Imaging.

The use of radionuclide techniques in cardiovascular assessment is called **myocardial nuclear perfusion imaging (MNPI).** Cardiovascular abnormalities can be viewed, recorded, and evaluated using radioactive tracer substances. These studies are useful for detecting myocardial infarction (MI) and decreased myocardial blood flow and for evaluating left ventricular ejection. Conducting myocardial nuclear imaging tests, in conjunction with exercise or the administration of vasodilating agents, allows clearer identification of how the heart responds to stress.

Inform the patient that these tests are noninvasive. Because the amount of radioisotope is small, radiation exposure risks are minimal. If a dilating agent is to be used, advise the patient to avoid cigarettes and caffeinated food or drinks for 4 hours before administration of the vasodilator.

Common tests in nuclear cardiology include technetium (^{99m}Tc) pyrophosphate scanning, thallium imaging, and multigated cardiac blood pool imaging. Each test requires the injection of different types of radioactive isotopes into the antecubital vein. After the cells and tissues have time to take up the radioactive substances, usually 10 minutes to 2 hours, nuclear imaging can detect the difference between healthy and unhealthy tissue.

During the *technetium scan*, radioisotopes (^{99m}Tc pyrophosphate) accumulate in damaged myocardial tissue, which appears as a "hot spot" during the scan. This test helps detect the location and size of acute myocardial infarctions.

Alternatively, during the *thallium imaging scan*, necrotic or ischemic tissue does not absorb the radioisotope (thallium-201) and appears as "cold spots" on the scan. Thallium imaging is used to assess myocardial scarring and perfusion, to detect the location and extent of an acute or chronic myocardial infarction, to evaluate graft patency after coronary bypass surgery, and to evaluate antianginal therapy, thrombolytic therapy, or balloon angioplasty.

Thallium imaging may be performed during an exercise test or with

the patient at rest. Thallium imaging performed during an exercise test may demonstrate perfusion deficits not apparent at rest. First, the stress test procedure is performed. After the patient reaches maximum activity level, a small dose of thallium-201 is injected IV. The patient continues to exercise for about 1 to 2 minutes, after which the scanning is performed. Nuclear cardiologists often compare the resting and stress images to differentiate between fixed and reversible defects in the myocardium.

If a patient cannot exercise on a bike or treadmill, dipyridamole (Persantine, Apo-Dipyridamole) or dobutamine hydrochloride (Dobutrex) is administered to simulate the effects of exercise. Tell the patient that these vasodilators may cause flushing, headache, dyspnea, and chest tightness for a few moments after injection.

Cardiac blood pool imaging is a noninvasive test for evaluating cardiac motion and calculating ejection fraction. It uses a computer to synchronize the patient's ECG with pictures taken by a special camera. The technician attaches the patient to an ECG and injects a small amount of ^{99m}Tc IV. The radioisotope is not taken up by tissue but remains "tagged" to red blood cells in the circulation. The camera may take pictures of the radioactive material as it makes its first pass through the heart.

During **multigated blood pool scanning,** the computer breaks the time between R waves on the ECG into fractions of a second, called "gates." The camera records blood flow through the heart during each of these gates. By analyzing the information from multiple gates, the computer can evaluate the ventricular wall motion and calculate ejection fraction (percentage of the left ventricular volume that is ejected with each contraction) and ejection velocity. Areas of decreased, absent, or paradoxical movement of the left ventricle may also be identified.

Positron emission tomography (PET) scans are used to compare cardiac perfusion and metabolic function and differentiate normal from diseased myocardium. The technician administers the first radioisotope (nitrogen-13-ammonia) and then begins a 20-minute scan to detect myocardial perfusion. Next, the technician administers a second radioisotope (fluoro-18-deoxyglucose). After a pause, a second scan is performed to detect the metabolically active myocardium, which is using glucose.

The two scans are compared. In a normal heart, performance and metabolic function will match. In an ischemic heart, there will be a mismatch—a reduction in perfusion and increased glucose uptake by the ischemic myocardium. The scanning procedure takes 2 to 3 hours, and the patient may be asked to use a treadmill or exercise bicycle in conjunction with the scan.

Depending on which test is performed, the patient may report fatigue or discomfort at the antecubital injection site. If a stress test was paired with the study, he or she will need follow-up care for the stress test.

Magnetic Resonance Imaging.

Magnetic resonance imaging (MRI) is a noninvasive diagnostic option. An image of the heart or great vessels is produced through the interaction of magnetic fields, radio waves, and atomic nuclei showing hydrogen density. Simply put, the radio waves "bounce off" the body tissue being examined. Because each tissue has its own density, the computer image clearly differentiates between various types of tissues. MRI permits determination of cardiac wall thickness, chamber dilation, valve and ventricular function, and blood movement in the great vessels. Improved MRI techniques allow coronary artery blood flow to be mapped with nearly the accuracy of a cardiac catheterization.

Before an MRI, ensure that the patient has removed all metallic objects, including watches, jewelry, clothing with metal fasteners, and hair clips. Patients with pacemakers or implanted defibrillators may not be able to have an MRI because the magnetic fields can deactivate them. However, some newer MRI machines have eliminated this complication. A few patients experience claustrophobia during the 15 to 60 minutes required to complete the scan.

Nursing Concepts and Clinical Judgment Review

What might you NOTICE in a patient with adequate oxygenation and perfusion related to the cardiovascular system?

Physical assessment:

- Vital signs within normal limits or baseline
- No abnormal heart sounds
- Strong and equal peripheral pulses
- Even and unlabored respirations
- Regular heartbeat
- No pallor, cyanosis, or clubbing
- No syncope, fatigue, or chest pain
- No edema
- Can perform ADLs without dyspnea

Diagnostic assessment:

- No serum markers of myocardial damage
- Serum lipids within normal ranges
- Normal C-reactive protein and homocysteine
- Normal electrocardiogram (ECG)

Get Ready for the NCLEX® Examination!

Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Assess patients for allergy to iodine-based contrast media before having invasive diagnostic tests requiring an iodine-based contrast agent. **Safety** QSEN
- After invasive cardiovascular diagnostic testing, such as angiography and cardiac catheterization, monitor the insertion site for bleeding and hematoma formation. **Safety** QSEN
- Assess vital signs carefully in patients having invasive cardiovascular testing; report and document any new dysrhythmias after testing. **Informatics** QSEN

Health Promotion and Maintenance

- Identify patients at risk for cardiovascular disease, especially those with hyperlipidemia, hypertension, excess weight, physical inactivity, smoking, psychological stress, a positive family history, and diabetes. **Evidence-Based Practice** QSEN
- Teach patients how to reduce the risk for heart disease through modifiable factors such as exercise, diet modification, smoking cessation, and medications, as needed. **Patient-Centered Care** QSEN
- Inform patients that genetics and other nonmodifiable risk factors, such as family history and gender, contribute to the development of CAD.
- Assess the older adult for cardiovascular changes associated with aging as described in Chart 33-1.

Psychosocial Integrity

- Discuss with the patient any feelings or concerns he or she might have about the stress of cardiac illness, diagnostic testing, or other issues, and use therapeutic measures to decrease anxiety. **Patient-Centered Care** QSEN
- Recognize that denial is a common and normal response to help patients cope with threatening circumstances.
- Be aware that coping behaviors of those who have cardiovascular problems vary from patient to patient. **Patient-Centered Care** QSEN

- Allow the patient to express feelings about an actual or perceived loss of health or social status related to cardiovascular disease.

Physiological Integrity

- Be aware of the importance of recalling the anatomy and physiology of the cardiovascular (CV) system to best understand how to care for patients with CV health problems.
- Assess the patient's report of pain to differentiate the pain of angina and myocardial infarction (MI) from other noncardiac causes; *discomfort, indigestion, squeezing, heaviness,* and *viselike* are common terms used to describe chest pain of cardiac origin.
- Recall that syncope is a transient loss of consciousness and is common in older adults.
- Be aware that women often present with different indicators of heart disease when compared with men; examples include dyspnea, chest discomfort, indigestion, and fatigue. **Evidence-Based Practice** QSEN
- Use jugular venous pressure to assess the filling volume and pressure on the right side of the heart.
- Assess for bruits, which are swishing sounds that develop in narrowed arteries.
- Auscultate the heart for normal first and second sounds, as well as for abnormalities such as an S_3, S_4, murmur, or gallop.
- Monitor serum markers of myocardial damage and other cardiac-related laboratory tests as listed in Chart 33-2.
- Prepare patients having a cardiac catheterization for expectations of the procedure and postprocedure care.
- Assess patients having cardiac catheterizations for potential complications as listed in Table 33-5. **Safety** QSEN

CHAPTER 34

Care of Patients with Dysrhythmias

Laura Dechant

PRIORITY CONCEPTS

- Perfusion

Learning Outcomes

Safe and Effective Care Environment

1. Provide a safe environment for patients and staff when using a cardiac defibrillator.

Health Promotion and Maintenance

2. Teach patients and their families about drug therapy used for common dysrhythmias.
3. Educate patients and families about procedures and other interventions for common dysrhythmias.

Physiological Integrity

4. Identify typical physical assessment findings associated with common dysrhythmias.
5. Explain how to perform an electrocardiogram (ECG) test.
6. Analyze an ECG rhythm strip to identify normal sinus rhythm and common or life-threatening dysrhythmias.
7. Plan collaborative care for patients experiencing common dysrhythmias.
8. Explain the purpose and types of pacing used as interventions for patients with dysrhythmias to promote perfusion.
9. Explain the need to perform evidence-based emergency care procedures, such as cardiopulmonary resuscitation (CPR) and

automated external defibrillation.

10. Teach patients with a pacemaker or implantable cardioverter/defibrillator about self-management when in the community.

http://evolve.elsevier.com/Iggy/

Cardiac dysrhythmias are abnormal rhythms of the heart's electrical system that can affect its ability to effectively pump *oxygenated* blood throughout the body. Some dysrhythmias are life threatening, and others are not. They are the result of disturbances of cardiac electrical impulse formation, conduction, or both. When the heart does not work effectively as a pump, perfusion to vital organs and peripheral tissues can be impaired, resulting in organ dysfunction or failure.

Many health problems, especially coronary artery disease (CAD), electrolyte imbalances, impaired oxygenation, and drug toxicity (both legal and illicit drugs), can cause abnormal heart rhythms. Dysrhythmias can occur in people of any age but occur most often in older adults. To provide collaborative patient-centered care using best practices, a *basic* understanding of cardiac electrophysiology, the conduction system of the heart, and the principles of electrocardiography is needed as a medical-surgical nurse. Specialty nurses and advanced practice nurses have a more in-depth knowledge as they manage patients with these cardiac problems in critical care and ambulatory care settings.

Review of Cardiac Conduction System

The cardiac conduction system consists of specialized myocardial cells (Fig. 34-1). The electrophysiologic properties of those cells regulate heart rate and rhythm and possess unique properties: automaticity, excitability, conductivity, and contractility.

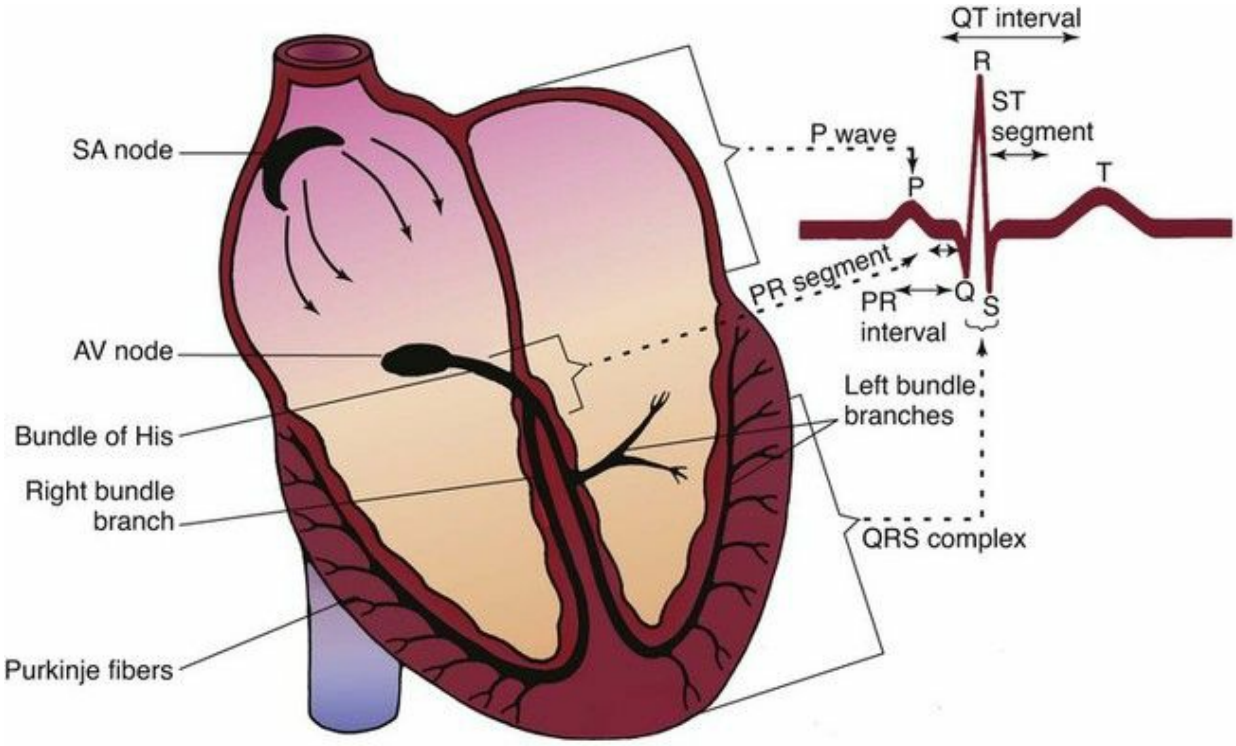

FIG. 34-1 The cardiac conduction system.

Automaticity (pacing function) is the ability of cardiac cells to generate an electrical impulse spontaneously and repetitively. Normally, only primary pacemaker cells (sinoatrial [SA] node) can generate an electrical impulse. Under certain conditions, such as myocardial ischemia (decreased blood flow), electrolyte imbalance, hypoxia, drug toxicity, and infarction (cell death), any cardiac cell may produce electrical impulses independently and create dysrhythmias. Disturbances in automaticity may involve either an increase or a decrease in pacing function.

Excitability is the ability of non-pacemaker heart cells to respond to an electrical impulse that begins in pacemaker cells and to depolarize. **Depolarization** occurs when the normally negatively charged cells within the heart muscle develop a positive charge.

Conductivity is the ability to send an electrical stimulus from cell membrane to cell membrane. As a result, excitable cells depolarize in rapid succession from cell to cell until all cells have depolarized. *The wave of depolarization causes the deflections of the electrocardiogram (ECG)*

waveforms that are recognized as the P wave and the QRS complex. Disturbances in conduction result when conduction is too rapid or too slow, when the pathway is totally blocked, or when the electrical impulse travels an abnormal pathway.

Contractility is the ability of atrial and ventricular muscle cells to shorten their fiber length in response to electrical stimulation, causing sufficient pressure to push blood forward through the heart. In other words, *contractility is the mechanical activity of the heart.*

Specialized cells of the myocardium are responsible for cardiac conduction. They consist of the sinoatrial node, atrioventricular junctional area, and bundle branch system.

Conduction begins with the **sinoatrial (SA) node** (also called the *sinus node*), located close to the surface of the right atrium near its junction with the superior vena cava. *The SA node is the heart's primary pacemaker.* It can spontaneously and rhythmically generate electrical impulses at a rate of 60 to 100 beats per minute and therefore has the greatest degree of automaticity.

The SA node is richly supplied by the sympathetic and parasympathetic nervous systems, which increase and decrease the rate of discharge of the sinus node, respectively. This process results in changes in the heart rate.

Impulses from the sinus node move directly through atrial muscle and lead to atrial depolarization, which is *reflected in a P wave on the ECG*. Atrial muscle contraction should follow. Within the atrial muscle are slow and fast conduction pathways leading to the atrioventricular (AV) node.

The **atrioventricular (AV) junctional** area consists of a transitional cell zone, the AV node itself, and the bundle of His. The AV node lies just beneath the right atrial endocardium, between the tricuspid valve and the ostium of the coronary sinus. Here T-cells (transitional cells) cause impulses to slow down or to be delayed in the AV node before proceeding to the ventricles. This delay is *reflected in the PR segment on the ECG*. This slow conduction provides a short delay, allowing the atria to contract and the ventricles to fill. The contraction is known as "atrial kick" and contributes additional blood volume for a greater cardiac output. The AV node is also controlled by both the sympathetic and the parasympathetic nervous systems. The bundle of His connects with the distal portion of the AV node and continues through the interventricular septum.

The *bundle of His* extends as a right bundle branch down the right side of the interventricular septum to the apex of the right ventricle. On the

left side, it extends as a left bundle branch, which further divides.

At the ends of both the right and the left bundle branch systems are the Purkinje fibers. These fibers are an interweaving network located on the endocardial surface of both ventricles, from apex to base. The fibers then partially penetrate into the myocardium. **Purkinje cells** make up the bundle of His, bundle branches, and terminal Purkinje fibers. These cells are responsible for the rapid conduction of electrical impulses throughout the ventricles, leading to ventricular depolarization and the subsequent ventricular muscle contraction. A few nodal cells in the ventricles also occasionally demonstrate automaticity, giving rise to ventricular beats or rhythms.

Electrocardiography

The **electrocardiogram (ECG)** provides a graphic representation, or picture, of cardiac electrical activity. The cardiac electrical currents are transmitted to the body surface. Electrodes, consisting of a conductive gel on an adhesive pad, are placed on specific sites on the body and attached to cables connected to an ECG machine or to a monitor. The cardiac electrical current is transmitted via the electrodes and through the lead wires to the machine or monitor, which displays the cardiac electrical activity.

A **lead** provides one view of the heart's electrical activity. Multiple leads, or views, can be obtained. Electrode placement is the same for male and female patients.

Lead systems are made up of a positive pole and a negative pole. An imaginary line joining these two poles is called the **lead axis.** The direction of electrical current flow in the heart is the **cardiac axis.** The relationship between the cardiac axis and the lead axis is responsible for the deflections seen on the ECG pattern:

- The baseline is the **isoelectric** line. It occurs when there is no current flow in the heart after complete depolarization and also after complete repolarization. Positive deflections occur above this line, and negative deflections occur below it. Deflections represent depolarization and repolarization of cells.
- If the direction of electrical current flow in the heart (cardiac axis) is toward the positive pole, a **positive deflection** (above the baseline) is viewed (Fig. 34-2, *A*).

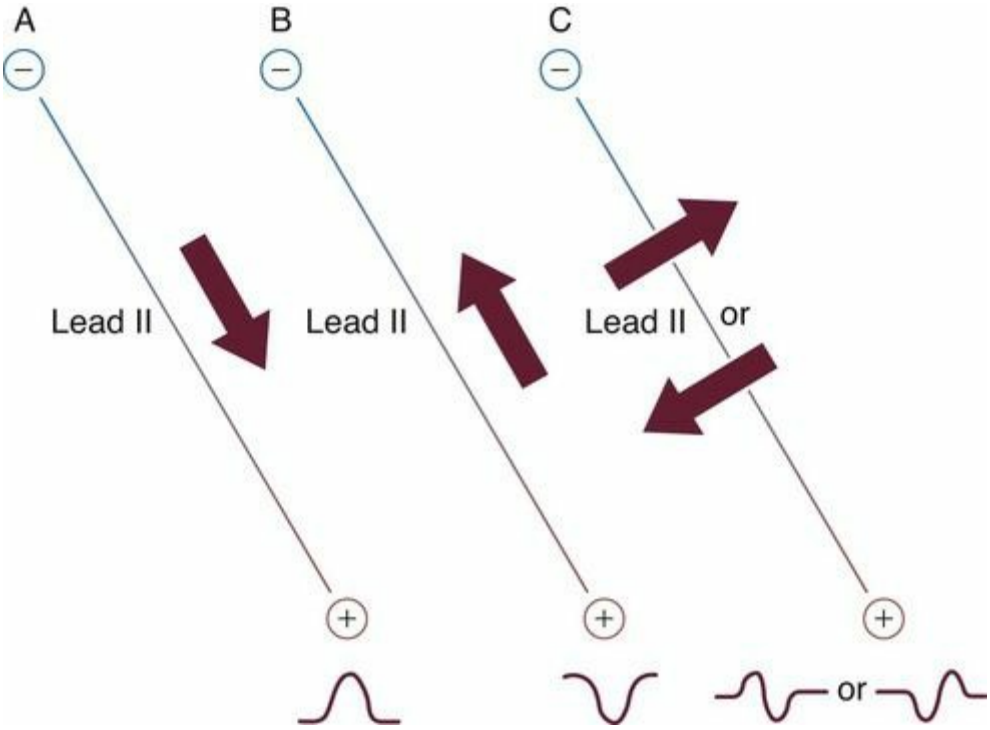

FIG. 34-2 **A,** The cardiac axis *(bold arrow)* is parallel to the lead axis *(the line between the negative and the positive electrodes)*, going toward the positive electrode; a positive deflection is inscribed. **B,** The cardiac axis is parallel to the lead axis, going toward the negative electrode; a negative deflection is inscribed. **C,** The cardiac axis is perpendicular to the lead axis, going neither toward the positive electrode nor toward the negative electrode; a biphasic deflection is inscribed.

- If the direction of electrical current flow in the heart (cardiac axis) is moving away from the positive pole toward the negative pole, a **negative deflection** (below the baseline) is viewed (Fig. 34-2, *B*).
- If the cardiac axis is moving neither toward nor away from the positive pole, a biphasic complex (both above and below baseline) will result (Fig. 34-2, *C*).

Lead Systems

The standard 12-lead ECG consists of 12 leads (or views) of the heart's electrical activity. Six of the leads are called *limb leads* because the electrodes are placed on the four extremities in the frontal plane. The remaining six leads are called *chest (precordial) leads* because the electrodes are placed on the chest in the horizontal plane.

Standard bipolar *limb leads* consist of three leads (I, II, and III) that each measures the electrical activity between two points and a fourth lead (right leg) that acts as a ground electrode. Of the three measuring

leads, the right arm is always negative, the left leg is always positive, and the left arm can be either positive or negative.

Other lead systems include the 18-lead ECG, which adds six leads placed on the horizontal plane on the right side of the chest to view the right side of the heart. This is sometimes referred to as a "right-sided ECG." The extra leads are sometimes placed on the back. The latest evidence indicates an 80-lead ECG, which looks at the heart from 80 views instead of only 12 and gives a 360-degree view of the heart. Evaluation of this 80-lead ECG revealed an increase in diagnosing myocardial infarctions (MIs), particularly in the posterior wall and right ventricular region, which was missed in the 12-lead ECG (Franks & Lawson, 2012). This device consists of a vest which contains 58 anterior leads, 12 lateral leads, and 10 posterior leads. One limitation is that vests are available in only four sizes and therefore may not be appropriate for some patients.

Unipolar limb leads consist of a positive electrode only. The unipolar limb leads are aVR, aVL, and aVF, with *a* meaning augmented. *V* is a designation for a unipolar lead. The third letter denotes the positive electrode placement: *R* for right arm, *L* for left arm, and *F* for foot (left leg). The positive electrode is at one end of the lead axis. The other end is the center of the electrical field, at about the center of the heart (Table 34-1).

TABLE 34-1

Electrode Placement for 12 Leads

LEAD	NEGATIVE ELECTRODE	POSITIVE ELECTRODE	GROUND ELECTRODE
I	Right arm or under the right clavicle	Left arm or under the left clavicle	Right leg or lowest rib, left midclavicular line
II	Right arm or under the right clavicle	Left leg or lowest rib, left midclavicular line	Right leg or under the left clavicle
III	Left arm or under the left clavicle	Left leg or lowest rib, left midclavicular line	Right leg or under the right clavicle
aVR	Average potential of left arm (or under the left clavicle) and left leg (or lowest rib, left midclavicular line)	Right arm or under the right clavicle	Right leg or lowest rib, right midclavicular line
aVL	Average potential of right arm (or under the right clavicle) and left leg (or lowest rib, left midclavicular line)	Left arm or under the left clavicle	Same as for aVR
aVF	Average potential of right arm (or under the right clavicle) and left arm (or under the left clavicle)	Left leg or lowest rib, left midclavicular line	Same as for aVR
V_1	Average potential of right arm, left arm, and left leg	Fourth intercostal space (ICS), right sternal border	Same as for aVR
V_2	Same as for V_1	Fourth ICS, left sternal border	Same as for aVR
V_3	Same as for V_1	Midway between V_2 and V_4	Same as for aVR
V_4	Same as for V_1	Fifth ICS, left midclavicular line	Same as for aVR
V_5	Same as for V_1	Horizontal to V_4, left anterior axillary line	Same as for aVR
V_6	Same as for V_1	Horizontal to V_4, left midaxillary line	Same as for aVR

There are six unipolar (or V) *chest leads*, determined by the placement of the chest electrode. The four limb electrodes are placed on the extremities, as designated on each electrode (right arm, left arm, right leg, and left leg). The fifth (chest) electrode on a monitor system is the positive, or exploring, electrode and is placed in one of six designated positions to obtain the desired chest lead. With a 12-lead ECG, four leads are placed on the limbs and six are placed on the chest, eliminating the need to move any electrodes about the chest.

Positioning of the electrodes is crucial in obtaining an accurate ECG. Comparisons of ECGs taken at different times will be valid only when electrode placement is accurate and identical at each test. Positioning is particularly important when working with patients with chest deformities or large breasts. Patients may be asked to move the breasts to ensure proper electrode placement.

While obtaining a 12-lead ECG, remind the patient to be as still as possible in a semi-reclined position, breathing normally. Any repetitive movement will cause artifact and could lead to inaccurate interpretation of the ECG.

Nurses are sometimes responsible for obtaining 12-lead ECGs, but more commonly, technicians are trained to perform this skill. Remind the technician to notify the nurse or physician of any suspected abnormality. A nurse may direct a technician to take a 12-lead ECG on a patient experiencing chest pain to observe for diagnostic changes, but it is ultimately the health care provider's responsibility to definitively interpret the ECG.

Continuous Electrocardiographic Monitoring

For continuous ECG monitoring, the electrodes are not placed on the limbs because movement of the extremities causes “noise,” or motion artifact, on the ECG signal. Place the electrodes on the trunk, a more stable area, to minimize such artifacts and to obtain a clearer signal. If the monitoring system provides five electrode cables, place the electrodes as follows:

- Right arm electrode just below the right clavicle
- Left arm electrode just below the left clavicle
- Right leg electrode on the lowest palpable rib, on the right midclavicular line
- Left leg electrode on the lowest palpable rib, on the left midclavicular line
- Fifth electrode placed to obtain one of the six chest leads

With this placement, the monitor lead select control may be changed to provide lead I, II, III, aVR, aVL, or aVF or one chest lead. The monitor automatically alters the polarity of the electrodes to provide the lead selected.

The clarity of continuous ECG monitor recordings is affected by skin preparation and electrode quality. To ensure the best signal transmission and to decrease skin impedance, clean the skin and clip hairs if needed. Make sure the area for electrode placement is dry. The gel on each electrode must be moist and fresh. Attach the electrode to the lead cable and then to the contact site. The contact site should be free of any lotion, tincture, or other substance that increases skin impedance. Electrodes cannot be placed on irritated skin or over scar tissue. The application of electrodes may be done by unlicensed assistive personnel (UAP), but the nurse determines which lead to select and checks for correct electrode placement. Assess the quality of the ECG rhythm transmission to the monitoring system.

The ECG cables can be attached directly to a wall-mounted monitor (a hard-wired system) if the patient's activity is restricted to bedrest and sitting in a chair, as in a critical care unit. For an ambulatory patient, the ECG cable is attached to a battery-operated transmitter (a **telemetry** system) held in a pouch. The ECG is transmitted to a remote monitor via antennae located in strategic places, usually in the ceiling. Telemetry allows freedom of movement within a certain area without losing transmission of the ECG.

Most acute care facilities have monitor technicians (monitor "techs") who are educated in ECG rhythm interpretation and are responsible for:

- Watching a bank of monitors on a unit
- Printing ECG rhythm strips routinely and as needed
- Interpreting rhythms
- Reporting the patient's rhythm and significant changes to the nurse

The technical support is particularly helpful on a telemetry unit that does not have monitors at the bedside. The nurse is responsible for accurate patient assessment and management.

Some units have full-disclosure monitors, which continuously store ECG rhythms in memory up to a certain amount of time. This system allows nurses and health care providers to access and print rhythm strips for more thorough patient assessment. Routine strips, as well as any changes in rhythm, are printed and documented in the patient's record.

The health care provider is responsible for determining when monitoring can be suspended, such as during showering. He or she also determines whether monitoring is needed during off-unit testing

procedures and for transportation to other facilities.

Prehospital personnel, such as paramedics and emergency medical technicians (EMTs) with advanced training, frequently monitor ECG rhythms at the scene and on the way to a health care facility. They function under medical direction and protocols but may also be communicating with a nurse in the emergency department.

The ECG strip is printed on graph paper (Fig. 34-3), with each small block measuring 1 mm in height and width. ECG recorders and monitors are standardized at a speed of 25 mm/sec. Time is measured on the horizontal axis. At this speed, each small block represents 0.04 second. Five small blocks make up one large block, defined by darker bold lines and representing 0.20 second. Five large blocks represent 1 second, and 30 large blocks represent 6 seconds. Vertical lines in the top margin of the graph paper are usually 15 large blocks apart, representing 3-second segments (Fig. 34-4).

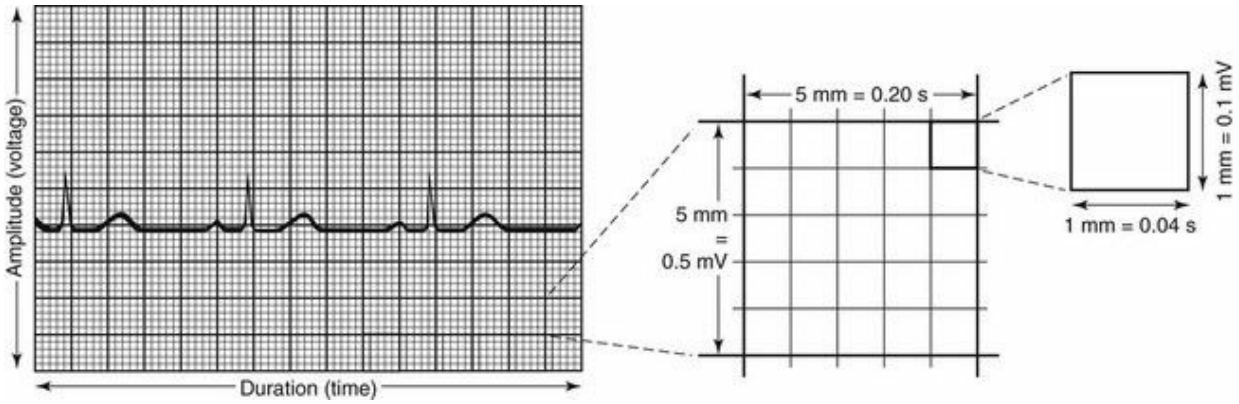

FIG. 34-3 Electrocardiographic waveforms are measured in amplitude (voltage) and duration (time).

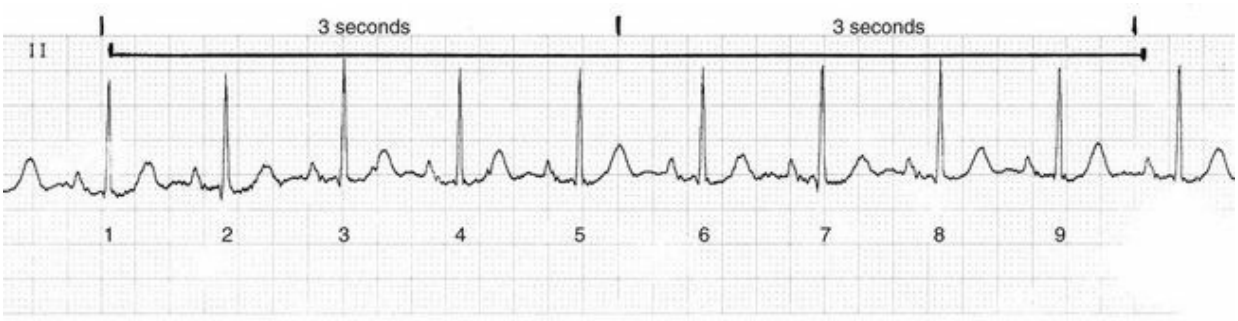

FIG. 34-4 Each segment between the dark lines *(above the monitor strip)* represents 3 seconds when the monitor is set at a speed of 25 mm per second. To estimate the ventricular rate, count the QRS complexes in a 6-second strip and then multiply that number by 10 to estimate the rate for 1 minute. In this example, there are 9 QRS complexes in 6 seconds. Therefore the heart rate can be estimated to be 90 beats per minute.

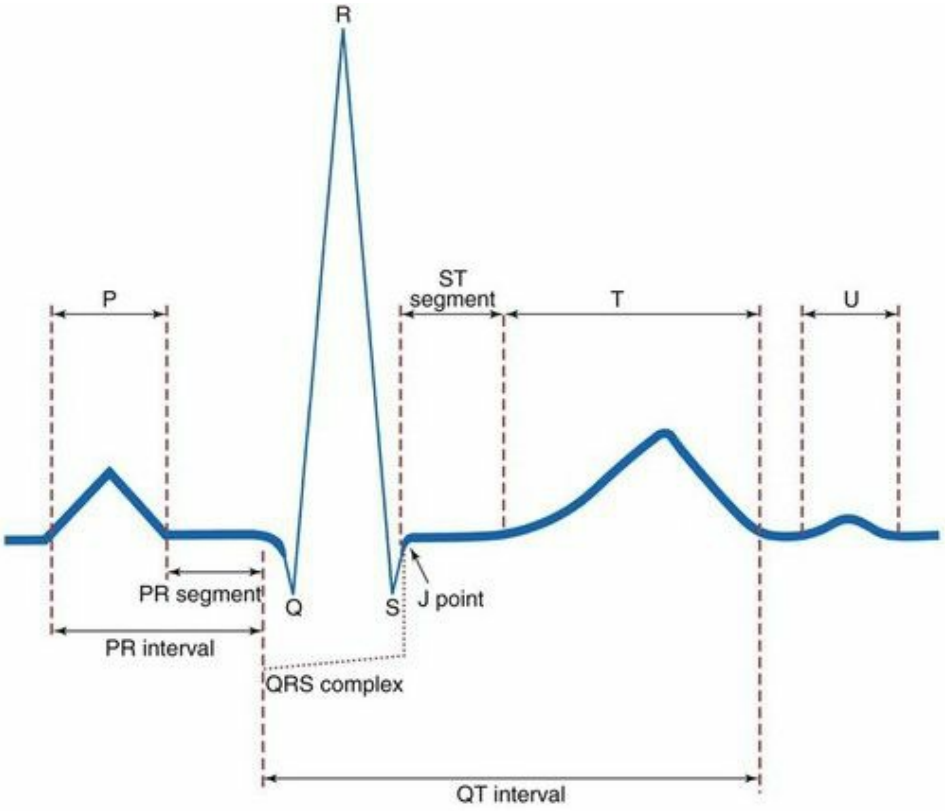
Electrocardiographic Complexes, Segments, and Intervals

Complexes that make up a normal ECG consist of a P wave, a QRS complex, a T wave, and possibly a U wave. Segments include the PR segment, the ST segment, and the TP segment. Intervals include the PR interval, the QRS duration, and the QT interval (Fig. 34-5).



P wave:	Represents atrial depolarization.
PR segment:	Represents the time required for the impulse to travel through the AV node, where it is delayed, and through the bundle of His, bundle branches, and Purkinje fiber network, just before ventricular depolarization.
PR interval:	Represents the time required for atrial depolarization as well as impulse travel through the conduction system and Purkinje fiber network, inclusive of the P wave and PR segment. It is measured from the beginning of the P wave to the end of the PR segment.
QRS complex:	Represents ventricular depolarization and is measured from the beginning of the Q (or R) wave to the end of the S wave.
J point:	Represents the junction where the QRS complex ends and the ST segment begins.
ST segment:	Represents early ventricular repolarization.
T wave:	Represents ventricular repolarization.
U wave:	Represents late ventricular repolarization.
QT interval:	Represents the total time required for ventricular depolarization and repolarization and is measured from the beginning of the QRS complex to the end of the T wave.

FIG. 34-5 The components of a normal electrocardiogram.

The **P wave** is a deflection representing atrial depolarization. The shape of the P wave may be a positive, negative, or biphasic (both positive and negative) deflection, depending on the lead selected. When the electrical impulse is consistently generated from the sinoatrial (SA) node, the P waves have a consistent shape in a given lead. If an impulse is then generated from a different (ectopic) focus, such as atrial tissue, the shape of the P wave changes in that lead, indicating that an ectopic focus has fired.

The **PR segment** is the isoelectric line from the end of the P wave to the beginning of the QRS complex, when the electrical impulse is traveling through the atrioventricular (AV) node, where it is delayed. It then travels through the ventricular conduction system to the Purkinje fibers.

The **PR interval** is measured from the beginning of the P wave to the

end of the PR segment. It represents the time required for atrial depolarization as well as the impulse delay in the AV node and the travel time to the Purkinje fibers. It normally measures from 0.12 to 0.20 second (five small blocks).

The **QRS complex** represents ventricular depolarization. The shape of the QRS complex depends on the lead selected. The Q wave is the first negative deflection and is not present in all leads. When present, it is small and represents initial ventricular septal depolarization. When the Q wave is abnormally present in a lead, it represents myocardial necrosis (cell death). The R wave is the first positive deflection. It may be small, large, or absent, depending on the lead. The S wave is a negative deflection following the R wave and is not present in all leads.

The **QRS duration** represents the time required for depolarization of both ventricles. It is measured from the beginning of the QRS complex to the J point (the junction where the QRS complex ends and the ST segment begins). It normally measures from 0.04 to 0.12 second (up to three small blocks).

The **ST segment** is normally an isoelectric line and represents early ventricular repolarization. It occurs from the J point to the beginning of the T wave. Its length varies with changes in the heart rate, the administration of medications, and electrolyte disturbances.

The **T wave** follows the ST segment and represents ventricular repolarization. It is usually positive, rounded, and slightly asymmetric. T waves may become tall and peaked, inverted (negative), or flat as a result of myocardial ischemia, potassium or calcium imbalances, medications, or autonomic nervous system effects.

The *TP segment* begins at the end of the T wave and ends at the beginning of the P wave. It is the true isoelectric interval in the ECG.

The **U wave,** when present, follows the T wave and may result from slow repolarization of ventricular Purkinje fibers. It is of the same polarity as the T wave, although generally it is smaller. It is not normally seen in all leads and is more common in lead V_3. An abnormal U wave may suggest an electrolyte abnormality (particularly hypokalemia) or other disturbance. Correct identification is important so that it is not mistaken for a P wave. If in doubt, notify the health care provider and request that a potassium level be obtained.

The **QT interval** represents the total time required for ventricular depolarization and repolarization. The QT interval is measured from the beginning of the Q wave to the end of the T wave. This interval varies with the patient's age and gender and changes with the heart rate, lengthening with slower heart rates and shortening with faster rates. It

may be prolonged by certain medications, electrolyte disturbances, or subarachnoid hemorrhage. A prolonged QT interval may lead to a unique type of ventricular tachycardia called *torsades de pointes*.

Artifact is interference seen on the monitor or rhythm strip, which may look like a wandering or fuzzy baseline. It can be caused by patient movement, loose or defective electrodes, improper grounding, or faulty ECG equipment, such as broken wires or cables. Some artifact can mimic lethal dysrhythmias like ventricular tachycardia (with tooth brushing) or ventricular fibrillation (with tapping on the electrode). *Assess the patient to differentiate artifact from actual lethal rhythms! Do not rely only on the ECG monitor.*

Determination of Heart Rate

The heart rate can be estimated by counting the number of QRS complexes in 6 seconds and multiplying that number by 10 to calculate the rate for a full minute. This is called the *6-second strip method* and is a quick method to determine the mean or average heart rate. This method is the least accurate; however, it is the method of choice for irregular rhythms.

For accuracy, the *big block method* is used if the QRS complexes are regular or evenly spaced. Count the number of big blocks between the same point in any two successive QRS complexes (usually R wave to R wave) and divide into 300. There are 300 big blocks in 1 minute. It is easiest to use a QRS that falls on a dark line. If little blocks are left over when counting big blocks, count each little block as 0.2, add this to the number of big blocks, and then divide that total into 300 (Fig. 34-6).

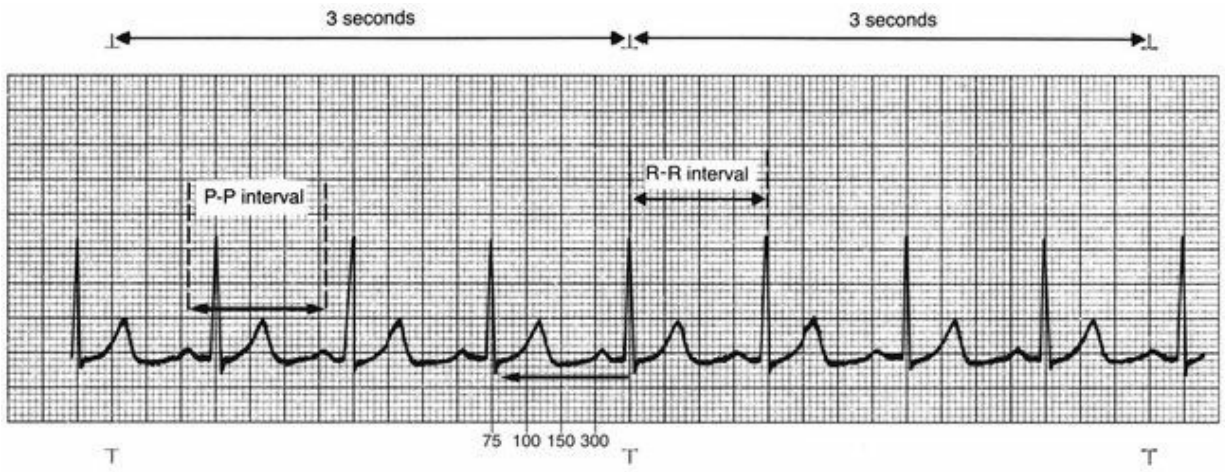


FIG. 34-6 In this example, the heart rate using the big block method is 300 ÷ 4 big blocks (between QRS complexes), or 75 beats per minute. The memory method is also demonstrated with a heart rate of 75 beats per minute.

Count the number of large blocks in an interval and divide into 300 (the number of large blocks in 1 minute). For example, three large blocks equals a heart rate of 100 beats per minute (300 ÷ 3 = 100).

Another method (called the *memory method*) relies on memorizing this sequence: 300, 150, 100, 75, 60, 50, 43, 37, 33, 30. This is the big block method with the math already done. Find a QRS complex that falls on the dark line representing 0.2 second or a big block, and count backwards to the next QRS complex. Each dark line is a memorized number. This is the method most widely used in hospitals for calculating heart rates for regular rhythms.

Commercially prepared ECG rate rulers are based on these calculations and may be used for regular rhythms. Current monitoring systems will display a continuous heart rate and print the heart rate on the ECG strip. *Use caution and confirm that the rate is correct by assessing the patient's heart rate directly.* Many factors can incorrectly alter the rate displayed by the monitor.

Electrocardiographic Rhythm Analysis

Analysis of an ECG rhythm strip requires a systematic approach using an eight-step method facilitated by use of a measurement tool called an **ECG caliper** (Palmer, 2011):

1. ***Determine the heart rate.*** If the atrial and ventricular rhythms are regular, use any of the methods previously described to calculate the heart rate. If the rhythms are irregular, use the 6-second strip method for accuracy. Normal heart rates fall between 60 and 100 beats/min. A rate less than 60 beats/min is called **bradycardia**. A rate greater than 100

beats/min is called **tachycardia**.

2. ***Determine the heart rhythm.*** Assess for atrial and/or ventricular regularity. Heart rhythms can be either regular or irregular. Irregular rhythms can be regularly irregular, occasionally irregular, or irregularly irregular. Check the regularity of the atrial rhythm by assessing the PP intervals, placing one caliper point on a P wave and placing the other point on the precise spot on the next P wave. Then move the caliper from P wave to P wave along the entire strip ("walking out" the P waves) to determine the regularity of the rhythm. P waves of a different shape (ectopic waves), if present, create an irregularity and do not walk out with the other P waves. A slight irregularity in the PP intervals, varying no more than three small blocks, is considered essentially regular if the P waves are all of the same shape. This alteration is caused by changes in intrathoracic pressure during the respiratory cycle.

Check the regularity of the ventricular rhythm by assessing the RR intervals, placing one caliper point on a portion of the QRS complex (usually the most prominent portion of the deflection) and the other point on the precise spot of the next QRS complex. Move the caliper from QRS complex to QRS complex along the entire strip (walking out the QRS complexes) to determine the regularity of the rhythm. QRS complexes of a different shape (ectopic QRS complexes), if present, create an irregularity and do not walk out with the other QRS complexes. A slight irregularity of no more than three small blocks between intervals is considered essentially regular if the QRS complexes are all of the same shape.

3. ***Analyze the P waves.*** Check that the P-wave shape is consistent throughout the strip, indicating that atrial depolarization is occurring from impulses originating from one focus, normally the SA node. Determine whether there is one P wave occurring before each QRS complex, establishing that a relationship exists between the P wave and the QRS complex. This relationship indicates that an impulse from one focus is responsible for both atrial and ventricular depolarization. The nurse may observe more than one P wave shape, more P waves than QRS complexes, absent P waves, or P waves coming after the QRS, each indicating that a dysrhythmia exists. Ask these five questions when analyzing P waves:

- Are P waves present?
- Are the P waves occurring regularly?
- Is there one P wave for each QRS complex?
- Are the P waves smooth, rounded, and upright in appearance, or are they inverted?

• Do all the P waves look similar?

4. ***Measure the PR interval.*** Place one caliper point at the beginning of the P wave and the other point at the end of the PR segment. The PR interval normally measures between 0.12 and 0.20 second. The measurement should be constant throughout the strip. The PR interval cannot be determined if there are no P waves or if P waves occur after the QRS complex. Ask these three questions about the PR interval:

• Are PR intervals greater than 0.20 second?
• Are PR intervals less than 0.12 second?
• Are PR intervals constant across the ECG strip?

5. ***Measure the QRS duration.*** Place one caliper point at the beginning of the QRS complex and the other at the J point, where the QRS complex ends and the ST segment begins. The QRS duration normally measures between 0.04 and 0.10 second. The measurement should be constant throughout the entire strip. Check that the QRS complexes are consistent throughout the strip. When the QRS is narrow (0.10 second or less), this indicates that the impulse was not formed in the ventricles and is referred to as *supraventricular* or *above the ventricles*. When the QRS complex is wide (greater than 0.10 second), this indicates that the impulse is either of ventricular origin or of supraventricular origin with aberrant conduction, meaning deviating from the normal course or pattern. More than one QRS complex pattern or occasionally missing QRS complexes may be observed, indicating a dysrhythmia.

Ask these questions to evaluate QRS intervals:

• Are QRS intervals less than or greater than 0.12 second?
• Are the QRS complexes similar in appearance across the ECG paper?

6. ***Examine the ST segment.*** The normal ST segment begins at the isoelectric line. ST elevation or depression is significant if displacement is 1 mm (one small box) or more above or below the line and is seen in two or more leads. ST *elevation* may indicate problems such as myocardial infarction, pericarditis, and hyperkalemia. ST *depression* is associated with hypokalemia, myocardial infarction, or ventricular hypertrophy.

7. ***Assess the T wave.*** Note the shape and height of the T wave for peaking or inversion. Abnormal T waves may indicate problems such as myocardial infarction and ventricular hypertrophy.

8. ***Measure the QT interval.*** A normal QT interval should be equal to or less than one-half the distance of the R-to-R interval.

Using steps 1 through 8, you can interpret the cardiac rhythm and differentiate normal and abnormal cardiac rhythms (dysrhythmias).

Overview of Normal Cardiac Rhythms

Normal sinus rhythm (NSR) is the rhythm originating from the sinoatrial (SA) node (dominant pacemaker) that meets these ECG criteria (Fig. 34-7):

FIG. 34-7 Normal sinus rhythm. Both atrial and ventricular rhythms are essentially regular (a slight variation in rhythm is normal). Atrial and ventricular rates are both 87 beats per minute. There is one P wave before each QRS complex, and all the P waves are of a consistent morphology, or shape. The PR interval measures 0.18 second and is constant; the QRS complex measures 0.06 second and is constant.

- *Rate:* Atrial and ventricular rates of 60 to 100 beats/min
- *Rhythm:* Atrial and ventricular rhythms regular
- *P waves:* Present, consistent configuration, one P wave before each QRS complex
- *PR interval:* 0.12 to 0.20 second and constant
- *QRS duration:* 0.04 to 0.10 second and constant

Sinus arrhythmia is a variant of NSR. It results from changes in intrathoracic pressure during breathing. In this context, the term *arrhythmia* does not mean an absence of rhythm, as the term suggests. Instead, the heart rate increases slightly during inspiration and decreases slightly during exhalation. This irregular rhythm is frequently observed in healthy adults.

Sinus arrhythmia has all the characteristics of NSR except for its irregularity. The PP and RR intervals vary, with the difference between the shortest and the longest intervals being greater than 0.12 second (three small blocks):

- *Rate:* Atrial and ventricular rates between 60 and 100 beats/min
- *Rhythm:* Atrial and ventricular rhythms irregular, with the shortest PP or RR interval varying at least 0.12 second from the longest PP or RR interval

- *P waves:* One P wave before each QRS complex; consistent configuration
- *PR interval:* Normal, constant
- *QRS duration:* Normal, constant

Sinus arrhythmias occasionally are due to nonrespiratory causes, such as digitalis or morphine. These drugs enhance vagal tone and cause decreased heart rate and irregularity unrelated to the respiratory cycle.

Common Dysrhythmias

Any disorder of the heartbeat is called a **dysrhythmia**. Historically, the term *arrhythmia* has been used in the literature. Although the terms are often used interchangeably, *dysrhythmia* is more accurate. Although many dysrhythmias have no clinical manifestations, many others have serious consequences if not treated.

❖ Pathophysiology

Dysrhythmias are classified in several ways. As broad categories, they include premature complexes, bradydysrhythmias (bradycardias), and tachydysrhythmias (tachycardias). **Premature complexes** are early rhythm complexes. They occur when a cardiac cell or cell group, other than the sinoatrial (SA) node, becomes irritable and fires an impulse before the next sinus impulse is produced. The abnormal focus is called an *ectopic focus* and may be generated by atrial, junctional, or ventricular tissue. After the premature complex, there is a pause before the next normal complex, creating an irregularity in the rhythm. The patient with premature complexes may be unaware of them or may feel **palpitations** or a "skipping" of the heartbeat. If premature complexes, especially those that are ventricular, become more frequent, the patient may experience symptoms of decreased cardiac output.

Premature complexes may occur *repetitively in a rhythmic fashion:*

- **Bigeminy** exists when normal complexes and premature complexes occur alternately in a repetitive two-beat pattern, with a pause occurring after each premature complex so that complexes occur in pairs.
- **Trigeminy** is a repeated three-beat pattern, usually occurring as two sequential normal complexes followed by a premature complex and a pause, with the same pattern repeating itself in triplets.
- **Quadrigeminy** is a repeated four-beat pattern, usually occurring as three sequential normal complexes followed by a premature complex and a pause, with the same pattern repeating itself in a four-beat pattern.

Bradydysrhythmias occur when the heart rate is less than 60 beats per minute. These rhythms can also be significant because:

- Myocardial oxygen demand is reduced from the slow heart rate, which can be beneficial.
- Coronary perfusion time may be adequate because of a prolonged diastole, which is desirable.
- Coronary perfusion pressure may decrease if the heart rate is too slow

to provide adequate cardiac output and blood pressure; this is a serious consequence.

Therefore the patient may tolerate the bradydysrhythmia well if the blood pressure is adequate. If the blood pressure is not adequate, symptomatic bradydysrhythmias may lead to myocardial ischemia or infarction, dysrhythmias, hypotension, and heart failure.

Tachydysrhythmias are heart rates greater than 100 beats per minute. They are a major concern in the adult patient with coronary artery disease (CAD). Coronary artery blood flow occurs mostly during diastole when the aortic valve is closed and is determined by diastolic time and blood pressure in the root of the aorta. Tachydysrhythmias are serious because they:

- Shorten the diastolic time and therefore the coronary perfusion time (the amount of time available for blood to flow through the coronary arteries to the myocardium).
- Initially increase cardiac output and blood pressure. However, a continued rise in heart rate decreases the ventricular filling time because of a shortened diastole, decreasing the stroke volume. Consequently, cardiac output and blood pressure will begin to decrease, reducing aortic pressure and therefore coronary perfusion pressure.
- Increase the work of the heart, increasing myocardial oxygen demand.

The patient with a tachydysrhythmia may have:

- Palpitations
- Chest discomfort (pressure or pain from myocardial ischemia or infarction)
- Restlessness and anxiety
- Pale, cool skin
- Syncope ("blackout") from hypotension

Tachydysrhythmias may also lead to heart failure. Presenting symptoms of heart failure may include dyspnea, lung crackles, distended neck veins, fatigue, and weakness (see Chapter 35). Chart 34-1 summarizes key features of sustained bradydysrhythmias and tachydysrhythmias.

Chart 34-1 Key Features

Sustained Tachydysrhythmias and Bradydysrhythmias

- Chest discomfort, pressure, or pain, which may radiate to the jaw, the back, or the arm

- Restlessness, anxiety, nervousness, confusion
- Dizziness, syncope
- Palpitations (in tachydysrhythmias)
- Change in pulse strength, rate, and rhythm
- Pulse deficit
- Shortness of breath, dyspnea
- Tachypnea
- Pulmonary crackles
- Orthopnea
- S_3 or S_4 heart sounds
- Jugular venous distention
- Weakness, fatigue
- Pale, cool, skin; diaphoresis
- Nausea, vomiting
- Decreased urine output
- Delayed capillary refill
- Hypotension

Etiology

Dysrhythmias occur for many reasons, including myocardial infarction (MI), electrolyte imbalances (especially potassium and magnesium), hypoxia, drug toxicity, and hypovolemia (decreased blood volume). People who use cocaine and illicit inhalants are particularly at risk for potentially fatal dysrhythmias. Stress, fear, anxiety, and caffeine can cause an increased heart rate (tachycardia or premature ventricular contractions). Nicotine and alcohol excess can lead to abnormal heart rates such as atrial fibrillation. Specific etiologies are described for each common dysrhythmia discussed in this chapter.

❖ Patient-Centered Collaborative Care

Dysrhythmias may also be classified by their site of origin in the heart. These include common sinus, atrial, and ventricular dysrhythmias. Although there are many specific dysrhythmias that can occur, general assessment and interventions for patient care may be similar (Chart 34-2). Assess the patient's apical and radial pulses for a full minute for any irregularity, which may occur with premature beats or atrial fibrillation. If the apical pulse differs from the radial pulse rate, a **pulse deficit** exists and indicates that the heart is not pumping adequately to achieve optimal perfusion to the body.

Chart 34-2 Best Practice for Patient Safety & Quality Care QSEN

Care of the Patient with Dysrhythmias

- Assess vital signs at least every 4 hours and as needed.
- Monitor patient for cardiac dysrhythmias.
- Evaluate and document the patient's response to dysrhythmias.
- Encourage the patient to notify the nurse when chest pain occurs.
- Assess chest pain (e.g., location, intensity, duration, radiation, and precipitating and alleviating factors).
- Assess peripheral circulation (e.g., palpate for presence of peripheral pulses, edema, capillary refill, color, and temperature of extremity).
- Provide antidysrhythmic therapy according to unit policy (e.g., antidysrhythmic medication, cardioversion, or defibrillation), as appropriate.
- Monitor and document patient's response to antidysrhythmic medications or interventions.
- Monitor appropriate laboratory values (e.g., cardiac enzymes, electrolyte levels).
- Monitor the patient's activity tolerance and schedule exercise/rest periods to avoid fatigue.
- Observe for respiratory difficulty (e.g., shortness of breath, rapid breathing, labored respirations).
- Promote stress reduction.
- Offer spiritual support to the patient and/or family (e.g., contact clergy), as appropriate.

Dysrhythmias are often managed with antidysrhythmic drug therapy. Specific drugs and other treatments are discussed for common dysrhythmias starting on p. 667.

Drug Classifications

When dysrhythmias are sustained and/or life threatening, drug therapy from one or more classes of antidysrhythmic agents is often used (Chart 34-3). The **Vaughn-Williams classification** is commonly used to categorize drugs according to their effects on the action potential of cardiac cells (classes I though IV). Other drugs also have antidysrhythmic effects but do not fit the Vaughn-Williams classification.

Chart 34-3 Common Examples of Drug Therapy

Common Dysrhythmias

DRUG	USUAL DOSAGE	NURSING INTERVENTIONS	RATIONALES
Class I Drugs			
Type IA			
Disopyramide phosphate (Norpace) Used for AF, WPW syndrome, PSVT, PVCs, VT	100-200 mg orally every 6 hr	Monitor BP.	Hypotension is a common side effect.
		Watch for shortness of breath and weight gain.	Disopyramide can cause heart failure in a patient with CAD.
		Monitor for widening QRS complex, prolonged QT or PR interval, or heart block.	Toxic side effects necessitate stopping disopyramide administration.
Type IB			
Lidocaine (Xylocaine) Used for PVCs, VT, VF	1-1.5 mg/kg IV bolus, then 0.5-0.75 mg/kg IV boluses every 5-10 min to a loading dose of 3 mg/kg, followed by 2-4 mg/min infusion For VF or pulseless VT: 1-1.5 mg/kg IV bolus every 3-5 min to a loading dose of 3 mg/kg, followed by 1-4 mg/min infusion	Watch for confusion, paresthesias, slurring of speech, drowsiness, or seizure activity.	CNS adverse effects predominate; they may require a decrease in dosage or discontinuation of the infusion.
Mexiletine hydrochloride (Mexitil) Used for PVCs, VT, VF	200-300 mg orally every 8 hr with food	Monitor BP and heart rate.	Hypotension and bradycardia may occur.
	125-250 mg IV bolus over 5-10 min 0.5-1.5 mg/min infusion	Assess for tremors, blurred vision, dizziness, ataxia, or confusion.	CNS adverse reactions predominate.
Tocainide hydrochloride (Tonocard) Used for PVCs, VT, VF	400 mg orally every 8 hr initially Increase to 800 mg orally every 8 hr if needed Maximum of 2.4 g daily Take with food	Watch for tremors.	Tremors indicate that the maximum dose is being approached.
		Monitor heart rate and BP.	Bradycardia and hypotension may occur.
		Teach patient to report shortness of breath, wheezing, chest pain, or cough, as well as dyspnea and distended neck veins or swelling of the extremities.	Pulmonary fibrosis is a serious side effect, which necessitates discontinuation of the drug; the drug may also cause CHF.
Type IC			
Flecainide acetate (Tambocor) Used for AF, PSVT, life-threatening ventricular dysrhythmias	100 mg orally twice daily Maximum dose of 400 mg daily	Monitor for an increase in frequency and severity of dysrhythmias.	Flecainide can induce dysrhythmias.
		Monitor heart rate and BP.	Bradycardia and hypotension may occur.
		Monitor for CHF, dizziness, visual disturbances, paresthesias, and tremors.	Side effects may require a decrease in dosage or discontinuation of the drug.
Propafenone hydrochloride (Rythmol) Used for PAF, WPW syndrome, life-threatening ventricular dysrhythmias	150-300 mg orally every 8 hr	Monitor for an increase in dysrhythmias.	Propafenone can induce dysrhythmias.
		Monitor heart rate and BP.	Bradycardia and hypotension may occur.
		Monitor for CNS effects, dizziness, anxiety, ataxia, insomnia, confusion, and seizures, as well as CHF and GI distress.	Side effects may require a decrease in dosage or discontinuation of the drug.
Class II Drugs			
Propranolol hydrochloride (Inderal, Apo-Propranolol 🍁) Used for AF, atrial flutter, PSVT, PVCs	10-80 mg orally four times daily before meals 0.1 mg/kg slow IV bolus divided into 3 equal doses given at intervals of 2-3 min at rate of 1 mg/min	Monitor heart rate and BP.	Bradycardia and decreased BP are expected effects.
		Assess for shortness of breath or wheezing.	Beta$_2$-blocking effects on the lungs can cause bronchospasm.
		Assess for insomnia, fatigue, and dizziness.	Side effects may require decrease in dosage or discontinuation of the drug.
Acebutolol hydrochloride (Sectral) Used for AF, atrial flutter, PSVT, PVCs	600-1200 mg orally daily	Monitor heart rate and BP.	Bradycardia and decreased BP are expected effects.
		Assess for shortness of breath or wheezing.	Beta$_2$-blocking effects on the lungs can cause bronchospasm.
		Assess for insomnia, fatigue, and dizziness.	Side effects may require a decrease in dosage or discontinuation of the drug.
Esmolol hydrochloride (Brevibloc) Used for AF, atrial flutter, PSVT, PVCs	Initially, 500 mcg/kg/min over 1 min, then 50 mcg/kg/min for 4 min IV Titrate up if necessary	Monitor heart rate and BP.	Bradycardia and decreased BP are expected effects.
		Assess for shortness of breath or wheezing.	Beta$_2$-blocking effects on the lungs can cause bronchospasm.
		Assess for insomnia, fatigue, and seizures.	Side effects may require a decrease in dosage or discontinuation of the drug.

DRUG	USUAL DOSAGE	NURSING INTERVENTIONS	RATIONALES
Sotalol hydrochloride (Betapace) Used for AF, PAF, PSVT, life-threatening ventricular dysrhythmias	Initial dose of 80 mg orally twice daily Dosage may be increased every 2-3 days, if necessary, to 240-320 mg daily in 2-3 divided doses	Assess ECG rhythm for torsades de pointes and other serious new ventricular dysrhythmias.	Sotalol may have proarrhythmic effects.
		Assess for fatigue, bradycardia, dyspnea, CHF, chest pain, hypotension, dizziness, hypoglycemia, nausea, and vomiting.	Adverse reactions may warrant drug discontinuation.
		Sotalol should not be administered to patients with hypokalemia or hypomagnesemia before correction of these imbalances.	Hypokalemia or hypomagnesemia may prolong the QT interval and cause torsades de pointes.
		Sotalol is contraindicated in patients with bronchial asthma, sinus bradycardia, or second- and third-degree AV block (unless a functioning pacemaker is present), prolonged QT syndrome, cardiogenic shock, or CHF.	Sotalol has beta-blocking (class II) effects and class III effects.
Class III Drugs			
Amiodarone hydrochloride (Cordarone) Used for AF, PAF, PSVT, life-threatening ventricular dysrhythmias	800-1600 mg orally daily in divided doses for 1-3 wk, then 600-800 mg daily for 1 mo, then 200-600 mg daily (average of 400 mg daily) Rapid loading dose: 150 mg IV over first 10 min (15 mg/min); slow loading dose: 360 mg IV over next 6 hr (1 mg/min); maintenance infusion: 540 mg IV over next 18 hr (0.5 mg/min), then 720 mg/24 hr (0.5 mg/min) For pulseless VT/Vfib: 300 mg IV/IO push; may repeat 150 mg IV/IO if necessary	Use volumetric infusion pump and polyvinyl chloride tubing with in-line filter, and infuse via central line.	Drug is irritating to peripheral vasculature; drug is more stable in glass bottle.
		Rapid-loading IV dose must not be administered faster than 10 min. Must stay with patient and monitor heart rate and BP.	Hypotension may occur. It should be treated by slowing the infusion or using other standard therapy. Cordarone should not be discontinued unless necessary.
		Continually monitor ECG rhythm during IV infusion; measure QT and QTc.	Bradycardia and AV block may occur and are treated by slowing the infusion rate and providing pacemaker therapy, if necessary. May cause a worsening of ventricular dysrhythmias.
		Assess the patient's knowledge of the treatment regimen and side effects.	Drug has major side effects, which make noncompliance a problem; patients may take the drug for 1½-3 mo before full clinical effects are apparent.
		Monitor heart rate, BP, and cardiac rhythm when initiating therapy.	Bradycardia, hypotension, and worsening dysrhythmia can occur.
		Teach patients to report any muscle weakness, tremors, or difficulty with ambulation.	Muscle-related side effects usually develop during the first week of treatment.
		Teach patients to report shortness of breath, cough, pleuritic pain, or fever.	Pulmonary side effects may indicate drug-induced pulmonary toxicity.
		Teach patients to report any visual disturbances and to wear sunglasses outdoors in the daytime if they have photophobia.	Corneal pigmentation occurs in most patients but generally does not interfere with vision; if it does, the dosage is decreased.
		Teach patients to use barrier sunscreens.	Photosensitivity reactions may occur.
		Teach patients to report any signs of thyroid problems or hepatotoxicity.	Thyroid problems or hepatotoxicity may occur, necessitating a decrease in dosage or discontinuation of the drug.
Dronedarone (Multaq) Used for AF, atrial flutter	400 mg twice daily with meals	Monitor heart rate, BP, and cardiac rhythm when initiating therapy.	Bradycardia and worsening dysrhythmia can occur.
		Monitor BUN, creatinine, and liver function panel.	May cause worsening renal function. Drug is contraindicated for patients with severe hepatic impairment.
		Teach patients to take with a meal. Do not take with grapefruit juice.	Better absorbed with food. Grapefruit juice alters drug effectiveness.
		Teach patients to notify the doctor if signs of worsening heart failure such as weight gain, dependent edema, or increasing shortness of breath.	Drug is contraindicated for patients with heart failure.
		Teach patients that if a dose is missed, take at next regularly scheduled dose. Do not double dose.	
		Advise patients to report all medications to doctor (prescription, OTC, and herbal products, especially St. John's wort).	May have serious drug interaction and cause potentially fatal dysrhythmias.
Ibutilide fumarate (Corvert) Used for AF, atrial flutter	1 mg IV over 10 min for patients >60 kg; 0.01 mg/kg over 10 min for patients <60 kg May repeat dose 10 min after completion of first infusion if necessary	Stop infusion as soon as dysrhythmia is terminated, or in event of sustained or nonsustained VT, or marked prolongation of QT or QTc.	Drug may cause potentially fatal dysrhythmias.
		Observe patients with continuous ECG monitoring and measure QT or QTc for at least 4 hr after infusion or until QTc has returned to baseline.	Acute ventricular dysrhythmias must be promptly identified and treated. Patient may develop heart blocks.
		Patients with atrial fibrillation of >2-3 days' duration must be adequately anticoagulated for at least 2 wk.	Atrial fibrillation is associated with formation of thrombi in atrial chambers.
		Hypokalemia and hypomagnesemia must be corrected before Corvert infusion.	This is important to reduce potential for proarrhythmic effects.

DRUG	USUAL DOSAGE	NURSING INTERVENTIONS	RATIONALES
Dofetilide (Tikosyn) Used for AF, atrial flutter	125-500 mcg orally twice daily	Teach patients to change positions slowly.	Orthostatic hypotension is a common side effect of the drug.
		Inform patients that dosages will be adjusted, depending on their creatinine clearance level.	The patient must have adequate creatinine clearance to prevent drug toxicity.
		Monitor patients on telemetry for several days; observe for and report bradycardia and hypotension.	Bradycardia and hypotension are common side effects.
Class IV Drugs			
Verapamil hydrochloride (Calan, Isoptin) Used for AF, atrial flutter, PSVT	2.5-5 mg IV over 1-2 min for narrow-complex SVT or PSVT; after 15-30 min may give 5-10 mg IV over 1-2 min, if necessary, and repeat to a maximum of 20 mg 80-120 mg orally every 6-8 hr	Monitor heart rate and BP.	Bradycardia and hypotension are common side effects.
		Teach patients to remain recumbent for at least 1 hr after IV administration.	Hypotension may occur; may be reversed with calcium chloride ($CaCl_2$), 0.5-1 g slow IV.
		Teach patients to change positions slowly when receiving oral therapy.	Dizziness and orthostatic hypotension often occur until tolerance develops.
		Teach patients to report dyspnea, orthopnea, distended neck veins, or swelling of the extremities.	Heart failure may occur, necessitating a decrease in dosage or discontinuation of the drug.
Diltiazem hydrochloride (Cardizem) Used for AF, atrial flutter, PSVT	0.25 mg/kg IV over 2 min After 15 min, give 0.35 mg/kg IV over 2 min 5-15 mg/hr IV infusion	Monitor heart rate and BP.	Bradycardia and hypotension are common side effects.
		Teach patients to remain recumbent for at least 1 hr after IV administration.	Hypotension may occur.
		Teach patients to report dyspnea, orthopnea, distended neck veins, or swelling of the extremities.	Heart failure may occur, necessitating a decrease in dosage or discontinuation of the drug.
Other Drugs			
Digoxin (Lanoxin, Novo-Digoxin) Used for CHF, AF, atrial flutter, PSVT	Rapid digitalization: 0.5-1 mg orally or IV initially; 0.125-0.5 mg orally every 6 hr or IV until a total of 1-1.5 mg is reached Maintenance: 0.125-0.25 mg orally or IV daily or every other day (may be less for older adults)	Assess apical heart rate for 1 min before each dose.	Decreased heart rate is an expected response, but bradycardia may indicate toxicity.
		Assess for sudden increase in heart rate and change of rhythm from regular to irregular, or irregular to regular.	Changes in heart rate or rhythm may indicate toxicity.
		Teach patients to report anorexia, nausea, vomiting, diarrhea, paresthesias, confusion, or visual disturbances.	Side effect can indicate toxicity.
		Monitor serum potassium levels.	Hypokalemia increases the risk for toxicity and ventricular dysrhythmias.
		Monitor serum creatinine levels.	Impaired renal function can cause toxicity; the dosage is altered if this occurs.
Atropine sulfate Used for bradycardia	0.5 mg IV bolus may be repeated every 3-5 min, if necessary, to a maximum of 0.04 mg/kg (total 3 mg)	Monitor heart rate and rhythm after administration.	Increased heart rate is expected.
		Assess for chest pain after administration.	Increased heart rate may cause ischemia in patients with CAD.
		Assess for urinary retention and dry mouth after administration.	Atropine is an anticholinergic agent.
		Avoid using in patients with acute angle-closure glaucoma.	Atropine increases intraocular pressure.
Adenosine (Adenocard) Used for PSVT, WPW syndrome	6 mg rapid IV over 1-3 sec followed by 20-mL saline flush; repeat in 1-2 min at 12 mg IV over 1-3 sec with 20-mL flush	Monitor heart rate and rhythm after administration.	A short period of asystole is common after administration; bradycardia and hypotension may occur.
		Assess patients for facial flushing, shortness of breath, dyspnea, and chest pain.	These side effects commonly occur.
		Assess patients for recurrence of PSVT or ventricular ectopy.	Recurrence of PSVT is common; PVCs may occur.
Magnesium sulfate Used for torsades de pointes	1-2 g diluted in 100 mL of D_5W administered IV over 1-2 min for VF or VT 1-2 g in 50-100 mL of D_5W for 5-60 min for loading dose; 0.5-1 g/hr over 24 hr for supplementation	Assess ECG rhythm for conversion to sinus rhythm.	Hypomagnesemia may precipitate refractory VF.
		Assess patients for facial flushing, hypotension, and respiratory and CNS depression.	Magnesium sulfate causes vasodilation and respiratory and CNS depression.

AF, Atrial fibrillation; *AV,* atrioventricular; *BP,* blood pressure; *BUN,* blood urea nitrogen; *CAD,* coronary artery disease; *CHF,* congestive heart failure; *CNS,* central nervous system; *D_5W,* 5% dextrose in water; *ECG,* electrocardiogram; *EMD,* electromechanical dissociation; *IO,* intraosseous; *OTC*, over-the-counter; *PAF,* paroxysmal atrial fibrillation/flutter; *PSVT,* paroxysmal supraventricular tachycardia; *PVC,* premature ventricular complex; *SVT,* supraventricular tachycardia; *V fib,* ventricular fibrillation; *VF,* ventricular fibrillation; *VT,* ventricular tachycardia; *WPW syndrome,* Wolff-Parkinson-White syndrome.

Class I antidysrhythmics are membrane-stabilizing agents used to

decrease automaticity. The three subclassifications in this group include type IA drugs, which moderately slow conduction and prolong repolarization, prolonging the QT interval. These drugs are used to treat or to prevent supraventricular and ventricular premature beats and tachydysrhythmias, but they are not as commonly used as other drugs. An example is procainamide hydrochloride (Pronestyl). Type IB drugs shorten repolarization. These drugs are used to treat or prevent ventricular premature beats, ventricular tachycardia (VT), and ventricular fibrillation (VF). Examples include lidocaine and mexiletine hydrochloride (Mexitil). Type IC drugs markedly slow conduction and widen the QRS complex. These agents are used primarily to treat or to prevent recurrent, life-threatening ventricular premature beats, VT, and VF. Examples include flecainide acetate (Tambocor) and propafenone hydrochloride (Rythmol).

Class II antidysrhythmics control dysrhythmias associated with excessive beta-adrenergic stimulation by competing for receptor sites and thereby decreasing heart rate and conduction velocity. Beta-adrenergic blocking agents, such as propranolol (Inderal) and esmolol hydrochloride (Brevibloc), are class II drugs. They are used to treat or to prevent supraventricular and ventricular premature beats and tachydysrhythmias. Sotalol hydrochloride (Betapace, Sotacor) is an antidysrhythmic agent with both non-cardioselective beta-adrenergic blocking effects (class II) and action potential duration prolongation properties (class III). It is an oral agent that may be used for the treatment of documented ventricular dysrhythmias, such as VT, that are life threatening.

Class III antidysrhythmics lengthen the absolute refractory period and prolong repolarization and the action potential duration of ischemic cells. Class III drugs include amiodarone (Cordarone) and ibutilide (Corvert) and are used to treat or prevent ventricular premature beats, VT, and VF.

Class IV antidysrhythmics slow the flow of calcium into the cell during depolarization, thereby depressing the automaticity of the sinoatrial (SA) and atrioventricular (AV) nodes, decreasing the heart rate, and prolonging the AV nodal refractory period and conduction. Calcium channel blockers, such as verapamil hydrochloride (Calan, Isoptin) and diltiazem hydrochloride (Cardizem), are class IV drugs. They are used to treat supraventricular tachycardia (SVT) and atrial fibrillation (AF) to slow the ventricular response.

Other drugs, such as digoxin, atropine, adenosine, and magnesium sulfate, may be used to treat dysrhythmias. Digoxin (Lanoxin, Novo-

Digoxin) increases vagal tone, slowing AV nodal conduction. It is useful in treating chronic AF by controlling the rate of ventricular response. However, digoxin does not convert AF to sinus rhythm. Atropine is a parasympatholytic or vagolytic agent used to treat vagally induced symptomatic bradydysrhythmias. Adenosine is an endogenous nucleoside that slows AV nodal conduction to interrupt re-entry pathways. Magnesium sulfate is an electrolyte administered to treat refractory VT or VF because these patients may be hypomagnesemic, with increased ventricular irritability. The drug is also used for a life-threatening VT called **torsades de pointes** that can result from certain antidysrhythmics, such as amiodarone.

Sinus Dysrhythmias

The sinoatrial (SA) node in the right atrium is the pacemaker in all sinus dysrhythmias. Innervation from sympathetic and parasympathetic nerves is normally in balance to ensure a normal sinus rhythm (NSR). An imbalance increases or decreases the rate of SA node discharge either as a normal response to activity or physiologic changes or as a pathologic response to disease. Sinus tachycardia and sinus bradycardia are the two most common types of sinus dysrhythmias.

Sinus Tachycardia.

Sympathetic nervous system stimulation or vagal (parasympathetic) inhibition results in an increased rate of SA node discharge, which increases the heart rate. When the rate of SA node discharge is more than 100 beats per minute, the rhythm is called **sinus tachycardia** (Fig. 34-8, *A*). From age 10 years to adulthood, the heart rate normally does not exceed 100 beats per minute except in response to activity and then usually does not exceed 160 beats per minute. Rarely does the heart rate reach 180 beats per minute.

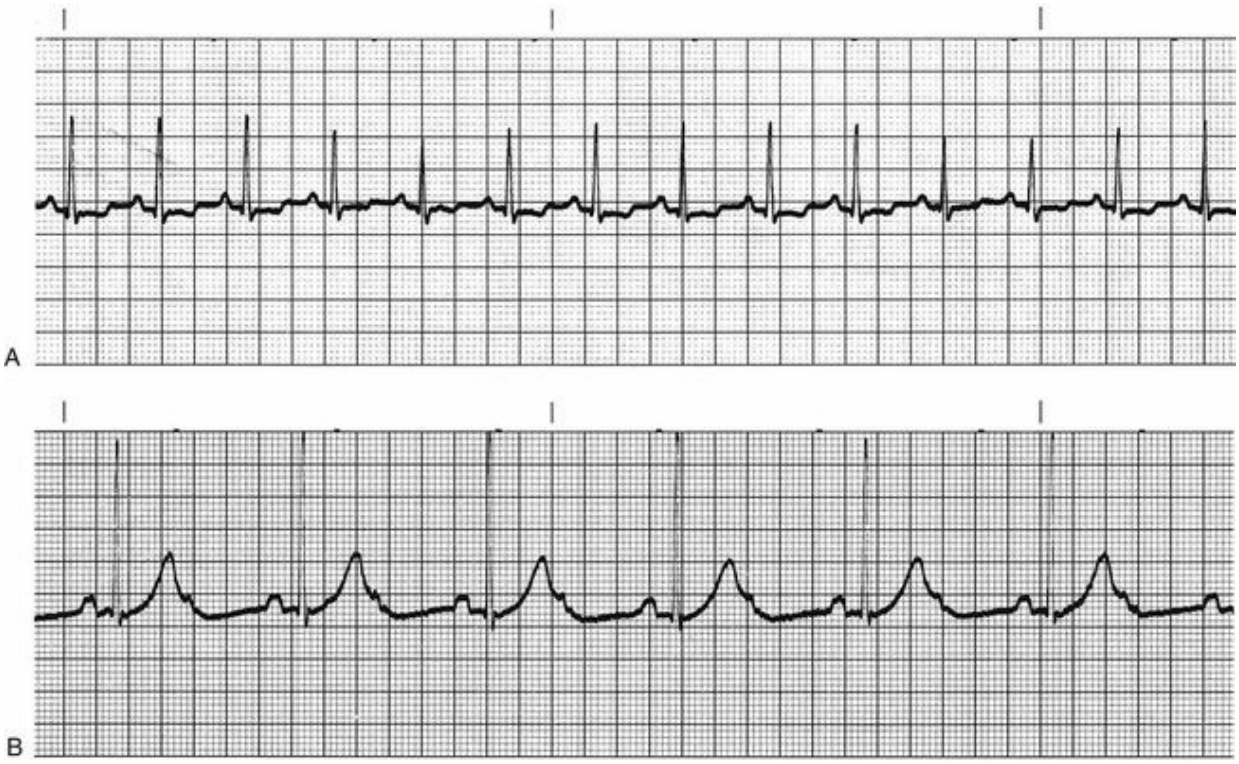

FIG. 34-8 Sinus rhythms. **A,** Sinus tachycardia (heart rate, 115 beats per minute; PR interval, 0.12 second; QRS complex, 0.08 second). **B,** Sinus bradycardia (heart rate, 52 beats per minute; PR interval, 0.18 second; QRS complex, 0.08 second).

Sinus tachycardia initially increases cardiac output and blood pressure. However, continued increases in heart rate decrease coronary perfusion time, diastolic filling time, and coronary perfusion pressure while increasing myocardial oxygen demand.

Increased sympathetic stimulation is a normal response to physical activity but may also be caused by anxiety, pain, stress, fever, anemia, hypoxemia, and hyperthyroidism. Drugs such as epinephrine, atropine, caffeine, alcohol, nicotine, cocaine, aminophylline, and thyroid medications may also increase the heart rate. In some cases, sinus tachycardia is a compensatory response to decreased cardiac output or blood pressure, as occurs in dehydration, hypovolemic shock, myocardial infarction (MI), infection, and heart failure. Assess patients for clinical manifestations of hypovolemia and dehydration, including increased pulse rate, decreased urinary output, decreased blood pressure, and dry skin and mucous membranes.

The patient may be asymptomatic except for an increased pulse rate. However, if the rhythm is not well tolerated, he or she may have symptoms.

Nursing Safety Priority QSEN

Action Alert

For patients with sinus tachycardia, assess for fatigue, weakness, shortness of breath, orthopnea, decreased oxygen saturation, increased pulse rate, and decreased blood pressure. Also assess for restlessness and anxiety from decreased cerebral perfusion and for decreased urine output from impaired renal perfusion. The patient may also have anginal pain and palpitations. The ECG pattern may show T-wave inversion or ST-segment elevation or depression in response to myocardial ischemia.

The desired outcome is to decrease the heart rate to normal levels by treating the underlying cause. Remind the patient to remain on bedrest if the tachycardia is causing hypotension or weakness. Teach the patient to avoid substances that increase cardiac rate, including caffeine, alcohol, and nicotine. Help patients develop stress management strategies, or refer the patient to a mental health professional.

NCLEX Examination Challenge

Physiological Integrity

A client who had open abdominal surgery 4 hours ago reports feeling weak and dizzy. The client's current blood pressure has decreased to 98/50, and pulse rate is 108. What is the nurse's best action at this time?
A Document the vital signs, and continue to monitor the client.
B Remind the client to stay in bed if feeling weak and dizzy.
C Call the health care provider immediately.
D Increase the client's IV rate to restore fluid volume.

Sinus Bradycardia.

Excessive vagal (parasympathetic) stimulation to the heart causes a decreased rate of sinus node discharge. It may result from carotid sinus massage, vomiting, suctioning, Valsalva maneuvers (e.g., bearing down for a bowel movement or gagging), ocular pressure, or pain. Increased parasympathetic stimuli may also result from hypoxia, inferior wall MI, and the administration of drugs such as beta-adrenergic blocking agents, calcium channel blockers, and digitalis. Bradycardia may also be caused by Lyme disease and hypothyroidism.

The stimuli slow the heart rate and decrease the speed of conduction through the heart. When the sinus node discharge rate is less than 60 beats per minute, the rhythm is called **sinus bradycardia** (Fig. 34-8, *B*). Sinus bradycardia increases coronary perfusion time, but it may decrease

coronary perfusion pressure. However, myocardial oxygen demand is *decreased*. Well-conditioned athletes who are bradycardic have a hypereffective heart in which the strong heart muscle provides an adequate stroke volume and a low heart rate to achieve a normal cardiac output.

Assessment.

The patient with sinus bradycardia may be asymptomatic except for the decreased pulse rate. In many cases, the cause of sinus bradycardia is unknown. Assess the medication administration record (MAR) to determine if the patient is receiving medications that slow the conduction through the SA or AV node. Assess the patient for:

- Syncope ("blackouts" or fainting)
- Dizziness and weakness
- Confusion
- Hypotension
- Diaphoresis (excessive sweating)
- Shortness of breath
- Chest pain

Interventions.

If the patient has any of these symptoms and the underlying cause cannot be determined, the treatment is to administer drug therapy with atropine 0.5 mg IV, increase intravascular volume via IV fluids, and apply oxygen. Drugs suspected of causing the bradycardia are discontinued. If the heart rate does not increase sufficiently, prepare for transcutaneous or transvenous pacing to increase the heart rate. If treatment of the underlying cause does not restore normal sinus rhythm, the patient will require permanent pacemaker implantation.

Temporary Pacing.

Temporary pacing is a nonsurgical intervention that provides a timed electrical stimulus to the heart when either the impulse initiation or the conduction system of the heart is defective. The electrical stimulus then spreads throughout the heart to depolarize the cells, which should be followed by contraction and cardiac output. Electrical stimuli may be delivered to the right atrium or right ventricle (single-chamber pacemakers) or to both (dual-chamber pacemakers).

Temporary pacing is used for patients with symptomatic, atropine-refractory bradydysrhythmias or for patients with asystole (discussed on p. 671 in this chapter). The two basic types of *temporary* pacing are

transcutaneous and transvenous pacing. ***Transcutaneous pacing*** is accomplished through the application of two large external electrodes. The electrodes are attached to an external pulse generator. The generator emits electrical pulses, which are transmitted through the electrodes and then transcutaneously to stimulate ventricular depolarization when the patient's heart rate is slower than the rate set on the pacemaker. A transvenous system consists of an external battery-operated pulse generator and pacing electrodes, or lead wires. These wires attach to the generator on one end and are threaded to the right atrium via the subclavian or femoral vein (Fig. 34-9). Electrical pulses, or stimuli, are emitted from the negative terminal of the generator, flow through a lead wire, and stimulate the cardiac cells to depolarize. The current seeks ground by returning through the other lead wire to the positive terminal of the generator, thus completing a circuit. The intensity of electrical current is set by selecting the appropriate current output, measured in milliamperes.

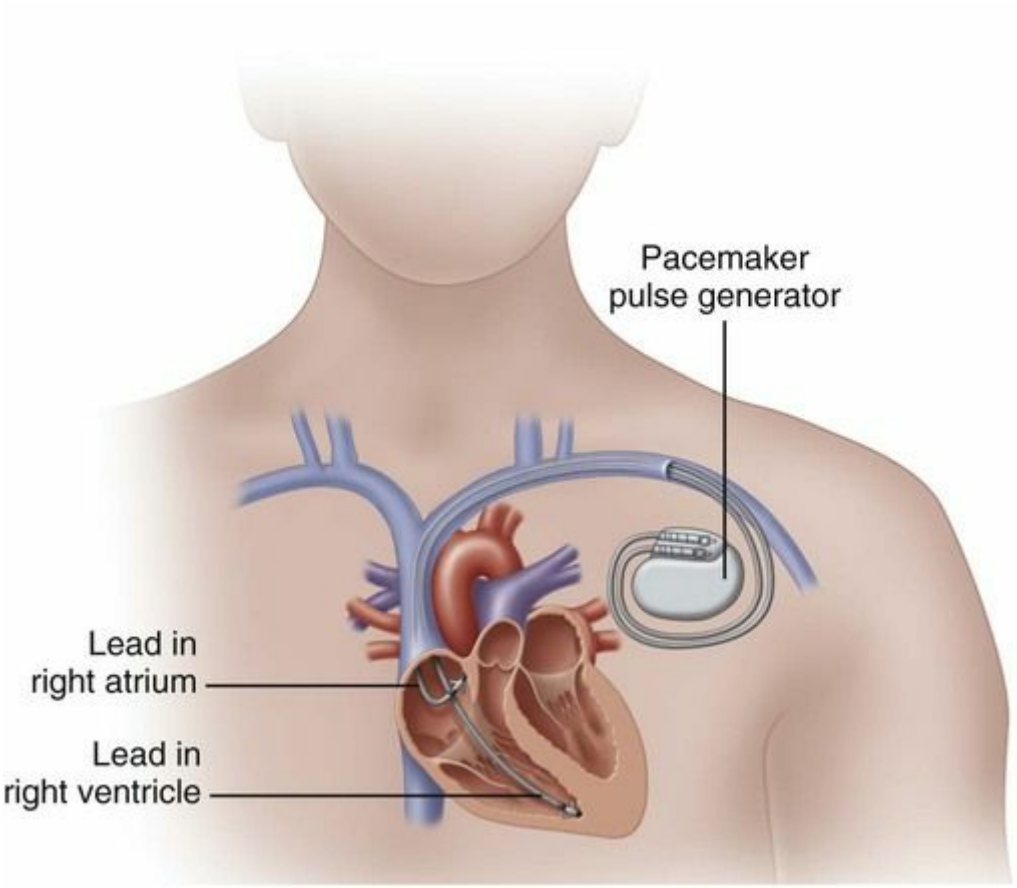

FIG. 34-9 Placement of pacemaker in chest and heart leads.

The two major modes of pacing are synchronous (demand) pacing and asynchronous (fixed-rate) pacing. Temporary pacing is *usually* done in

the synchronous (demand) pacing mode. The pacemaker's sensitivity is set to sense the patient's own beats. When the patient's heart rate is above the rate set on the pulse generator, the pacemaker does not fire (inhibits itself). When the patient's heart rate is less than the generator setting, the pacemaker provides electrical impulses (paces).

Transcutaneous pacing is used as an *emergency* measure to provide demand ventricular pacing in a profoundly bradycardic or asystolic patient until invasive pacing can be used or the patient's heart rate returns to normal. It may be used prophylactically when performing procedures or transporting patients at risk for bradydysrhythmias. However, it is used only as a temporary measure to maintain heart rate and perfusion until a more permanent method of pacing is used.

When a pacing stimulus is delivered to the heart, a spike (or pacemaker artifact) is seen on the monitor or ECG strip. The spike should be followed by evidence of depolarization (i.e., a P wave, indicating atrial depolarization, or a QRS complex, indicating ventricular depolarization). This pattern is referred to as *capture*, indicating that the pacemaker has successfully depolarized, or captured, the chamber.

Permanent Pacemaker.

Pacemaker insertion is performed to treat conduction disorders that are not temporary, including complete heart block. These pacemakers are usually powered by a lithium battery and have an average life span of 10 years. After the battery power is depleted, the generator must be replaced by a procedure done with the patient under local anesthesia. Some pacemakers are nuclear-powered and have a life span of 20 years or longer. Other pacemakers can be recharged externally. Combination pacemaker/defibrillator devices are also available.

A biventricular pacemaker may be utilized to coordinate contractions between the right and left ventricles. In addition to pacing used in the right side of the heart, an additional lead is placed in the left lateral wall of the left ventricle through the coronary sinus. This procedure allows synchronized depolarization of the ventricles and is used in patients with moderate to severe heart failure to improve functional ability.

The electrophysiologist implants the pulse generator in a surgically made subcutaneous pocket at the shoulder in the right or left subclavicular area, which may create a visible bulge. The leads are introduced transvenously via the cephalic or the subclavian vein to the endocardium on the right side of the heart. After the procedure, monitor the ECG rhythm to check that the pacemaker is working correctly. Assess the implantation site for bleeding, swelling, redness, tenderness, and

infection. The dressing over the site should remain clean and dry. The patient should be afebrile and have stable vital signs. The physician prescribes initial activity restrictions, which are then gradually changed. Complications of permanent pacemakers are similar to those of temporary invasive pacing.

Pacemaker checks are done on an ambulatory care basis at regular intervals. Reprogramming may be needed if pacemaker problems develop. The pulse generator is interrogated using an electronic device to determine the pacemaker settings and battery life (Fig. 34-10). In addition, most pacemaker manufacturers offer wireless home transmitter devices. Data are then sent via landline telephone to a database, which is then accessed by the device clinic or health care provider. Stress the need to keep follow-up appointments for more detailed pacemaker checks and reprogramming, if necessary, as well as for assessment.

FIG. 34-10 Permanent pacemaker, programmer, and rhythm strip.

Atrial Dysrhythmias

In patients with atrial dysrhythmias, the focus of impulse generation shifts away from the sinus node to the atrial tissues. The shift changes

the axis (direction) of atrial depolarization, resulting in a P-wave shape that differs from normal P waves. The most common atrial dysrhythmias are:

- Premature atrial complexes
- Supraventricular tachycardia
- Atrial fibrillation

Premature Atrial Complexes.

A **premature atrial complex (contraction) (PAC)** occurs when atrial tissue becomes irritable. This ectopic focus fires an impulse before the next sinus impulse is due. The premature P wave may not always be clearly visible because it can be hidden in the preceding T wave. Examine the T wave closely for any change in shape, and compare with other T waves. A PAC is usually followed by a pause.

The causes of atrial irritability include:

- Stress
- Fatigue
- Anxiety
- Inflammation
- Infection
- Caffeine, nicotine, or alcohol
- Drugs such as epinephrine, sympathomimetics, amphetamines, digitalis, or anesthetic agents

PACs may also result from myocardial ischemia, hypermetabolic states, electrolyte imbalance, or atrial stretch. Atrial stretch can result from congestive heart failure, valvular disease, and pulmonary hypertension with cor pulmonale.

The patient usually has no symptoms except for possible heart palpitations. No intervention is needed except to treat causes such as heart failure. If PACs occur frequently, they may lead to more serious atrial tachydysrhythmias and therefore may need treatment. Administration of prescribed antidysrhythmic drugs may be necessary (see Chart 34-3). Teach the patient measures to manage stress and substances to avoid, such as caffeine and alcohol, that are known to increase atrial irritability.

Supraventricular Tachycardia.

Supraventricular tachycardia (SVT) involves the rapid stimulation of atrial tissue at a rate of 100 to 280 beats per minute in adults. During SVT, P waves may not be visible, especially if there is a 1 : 1 conduction with rapid rates, because the P waves are embedded in the preceding T wave.

SVT may occur in healthy young people, especially women.

SVT is usually due to a re-entry mechanism in which one impulse circulates repeatedly throughout the atrial pathway, re-stimulating the atrial tissue at a rapid rate. The term **paroxysmal supraventricular tachycardia (PSVT)** is used when the rhythm is intermittent. It is initiated suddenly by a premature complex such as a PAC and terminated suddenly with or without intervention.

Assessment.

The clinical manifestations depend on the duration of the SVT and the rate of the ventricular response. In patients with a *sustained* rapid ventricular response, assess for palpitations, chest pain, weakness, fatigue, shortness of breath, nervousness, anxiety, hypotension, and syncope. Cardiovascular deterioration may occur if the rate does not sustain adequate blood pressure. In that case, SVT can result in angina, heart failure, and cardiogenic shock. With a *nonsustained* or slower ventricular response, the patient may be asymptomatic except for occasional palpitations.

Interventions.

If SVT occurs in a healthy person and stops on its own, no intervention may be needed other than eliminating identified causes. If it continues, the patient should be studied in the electrophysiology study (EPS) laboratory. The preferred treatment for recurrent SVT is radiofrequency catheter ablation, described later in this chapter on p. 668. In sustained SVT with a rapid ventricular response, the desired outcomes of treatment are to decrease the ventricular response, convert the dysrhythmia to a sinus rhythm, and treat the cause.

Vagal maneuvers induce vagal stimulation of the cardiac conduction system, specifically the SA and AV nodes. Although not as common today, vagal maneuvers may be attempted to treat supraventricular tachydysrhythmias and include carotid sinus massage and Valsalva maneuvers. The results of these interventions, however, are often temporary and may cause "rebound" tachycardia or severe bradycardia. Further therapy must be initiated.

In *carotid sinus massage*, the physician massages over one carotid artery for a few seconds, observing for a change in cardiac rhythm. This intervention causes vagal stimulation, slowing SA and AV nodal conduction. Prepare the patient for the procedure. Instruct him or her to turn the head slightly away from the side to be massaged, and observe the cardiac monitor for a change in rhythm. An ECG rhythm strip is

recorded before, during, and after the procedure. After the procedure, assess vital signs and the level of consciousness. Complications include bradydysrhythmias, asystole, ventricular fibrillation (VF), and cerebral damage. Because of these risks, carotid massage is not commonly performed. *A defibrillator and resuscitative equipment must be immediately available during the procedure.*

To stimulate a *vagal reflex*, the health care provider instructs the patient to bear down as if straining to have a bowel movement. Assess the patient's heart rate, heart rhythm, and blood pressure. Observe the cardiac monitor; and record an ECG rhythm strip before, during, and after the procedure to determine the effect of therapy.

Drug therapy is prescribed for some patients to convert SVT to a normal sinus rhythm (NSR). Adenosine (Adenocard) is used to terminate the acute episode and given rapidly (over several seconds) followed by a normal saline bolus.

Nursing Safety Priority QSEN

Drug Alert

Side effects of adenosine include significant bradycardia with pauses, nausea, and vomiting. When administering adenosine, be sure to have emergency equipment readily available!

AV nodal blocking agents, such as beta and calcium channel blockers, are also given to treat SVT. Chart 34-3 lists medications that may be used for SVT.

If symptoms of poor perfusion are severe and persistent, the patient may require synchronized cardioversion to immediately terminate the SVT. For long-term treatment, patients are referred to an electrophysiologist for radiofrequency catheter ablation. Synchronized cardioversion and catheter ablation are discussed in detail on p. 668 of this chapter.

Atrial Fibrillation.

Atrial fibrillation (AF) is the most common dysrhythmia seen in clinical practice. It can impair quality of life, cause considerable morbidity and mortality, and impose a large economic burden on health care systems (Dagres & Anastasiou-Nana, 2010).

AF is associated with atrial fibrosis and loss of muscle mass. A mutation in the *lamin AC* (LMAC) gene has been linked to atrial fibrosis and dilation (Hardin & Steele, 2008). These structural changes are

common in heart diseases such as hypertension, heart failure, and coronary artery disease. As AF progresses, cardiac output decreases by as much as 20 to 30 percent.

Currently, about 2.3 million people in the United States are diagnosed with AF; it is estimated that more than 12 million people will have AF by the year 2050 (Tedrow et al., 2010). The incidence of AF increases with age; AF causes serious problems in older people, leading to stroke and/or heart failure. Risk factors include hypertension (HTN), previous ischemic stroke, transient ischemic attack (TIA) or other thromboembolic event, coronary heart disease, diabetes mellitus, heart failure, and mitral valve disease.

In addition to advanced age, obesity, Caucasian race, and excessive alcohol have been identified as risk factors for AF (see the Evidence-Based Practice box). About half of obese adults may develop AF (Chilukuri et al., 2010). Caucasians are more at risk for AF than African Americans and other ethnic groups, perhaps because of the larger left atrial diameter in Caucasians (Marcus et al., 2010). AF that is temporary and reversible is associated with excessive alcohol consumption (sometimes called *"holiday heart syndrome"*).

Evidence-Based Practice QSEN

Is There a Relationship Between Obesity and Atrial Fibrillation?

Tedrow, U.B., Conen, D., Ridker, P.M., Cook, N.R., Koplan, B.A., Manson, J.E., et al. (2010). The long- and short-term impact of elevated body mass index on the risk of new atrial fibrillation: The WHS (Women's Health Study). *Journal of the American College of Cardiology, 55*(21), 2319-2327.

There has been an increase in atrial fibrillation (AF) in recent years that is not explained by aging alone. Modifiable risk factors must be identified. Recent evidence estimates that 32.2% of adults are obese (body mass index [BMI] >30) and 6.9% of women are extremely obese (BMI >40). This study used data from the Women's Health Study (WHS) and included 34,309 women who were followed for about 12.9 years. Participants reported their weight on questionnaires at 24-, 36-, 60-, 72-, and 108-month intervals. During this time, 834 AF events were confirmed. BMI was linearly associated with AF risk, and being overweight and/or obese was associated with short-term increases in AF risk. Participants who became obese had a 41% risk for developing AF.

Study limitations include the heterogeneous population with self-reported height/weight and lack of electrocardiograph (ECG) screening. The researchers concluded that weight-control strategies may reduce AF incidence.

Level of Evidence: 1

The evidence was obtained from a randomized trial of a very large longitudinal national study using multiple methods of data collection.

Commentary: Implications for Practice and Research

Obesity is a major health concern in the United States. Cases of AF are increasing. Both affect the economy of health care because of complications and hospital admissions. Nurses need to recognize AF risk factors and provide proactive education to patients at risk for obesity, cardiovascular disease, and atrial fibrillation. Further research is needed to replicate the study on different populations, to determine the economic impact on health care, and to determine if weight loss reduces the incidence of AF.

Assessment.

In patients with AF, multiple rapid impulses from many atrial foci depolarize the atria in a totally disorganized manner at a rate of 350 to 600 times per minute; ventricular response is usually 120 to 200 beats per minute. The result is a chaotic rhythm with no clear P waves, no atrial contractions, loss of atrial kick, and an irregular ventricular response (Fig. 34-11). The atria merely quiver in fibrillation (commonly called "A fib"). Often the ventricles beat with a rapid rate in response to the numerous atrial impulses. The rapid and irregular ventricular rate decreases ventricular filling and reduces cardiac output, further impairing the heart's perfusion ability.

FIG. 34-11 Atrial fibrillation. Note wavy baseline with atrial electrical activity and irregular ventricular rhythm.

Nursing Safety Priority QSEN

Action Alert

The loss of coordinated atrial contractions in AF can lead to pooling of blood resulting in thrombus formation. *The patient is at high risk for pulmonary embolism!* Thrombi may form within the right atrium and then move through the right ventricle to the lungs. In addition, the patient is at risk for systemic emboli, particularly an embolic stroke, which may cause severe neurologic impairment or death. Patients with AF who have valvular disease are particularly at risk for venous thromboembolism (VTE). Monitor patients carefully for these complications discussed elsewhere in this text.

Interventions.

Interventions for AF depend on the severity of the problem and the patient's response. Drug therapy is often effective for treating AF.

Drug Therapy.

Traditional interventions for AF include antidysrhythmic drugs to slow the ventricular conduction or to convert the AF to normal sinus rhythm (NSR). Examples of these drugs are calcium channel blockers like diltiazem (Cardizem) or, for more difficult-to-control AF, amiodarone (Cordarone). Dronedarone (Multaq) is a new drug similar to amiodarone, yet better tolerated by patients, for maintenance of sinus rhythm after cardioversion (Cheng, 2010). However, dronedarone should not be used in patients with a history or current congestive heart failure because it can cause an exacerbation of cardiac symptoms.

Beta blockers, such as metoprolol (Toprol, Dutoprol) and esmolol

(Brevibloc), may also be used to slow ventricular response. Digoxin (Lanoxin, Novo-Digoxin) is given for patients with heart failure and AF. These drugs are described in Chart 34-3. Carefully monitor the pulse rate of patients taking these drugs.

Health care providers use the **$CHADS_2$ scoring system** (Congestive heart failure, Hypertension, Age ≥75, Diabetes mellitus, Stroke) to determine if the patient with atrial fibrillation needs preventive anticoagulant therapy (Table 34-2). If the patient scores a 0 or 1 on the scale, aspirin is utilized as the anticoagulant of choice. Patients with a score of 2 or more are considered high risk for clot development and are placed on anticoagulants, such as heparin, enoxaparin (Lovenox), and warfarin (Coumadin). Because of the unpredictable drug response and many food-drug interactions, laboratory test monitoring (e.g., international normalized ratio [INR]) is required when a patient is taking warfarin. Teach patients the importance of avoiding high vitamin K foods and avoiding herbs, such as ginger, ginseng, goldenseal, *Ginkgo biloba*, and St. John's wort, which could interfere with the drug's action. Chapter 36 describes care of patients receiving anticoagulant therapy in detail on p. 731.

TABLE 34-2

$CHADS_2$ Scoring System for Risk of Stroke in Patients Who Have Atrial Fibrillation

RISK FACTOR	PRESENT	SCORE
History of congestive heart failure	Yes	1
	No	0
History of hypertension	Yes	1
	No	0
Age ≥75 years	Yes	1
	No	0
History of diabetes	Yes	1
	No	0
History of stroke or TIA	Yes	2
	No	0
Score of 0: Low risk—recommended 325 mg of aspirin Score of 1: Moderate risk—recommended aspirin or warfarin Score of 2: High risk—warfarin with INR goal of 2.0-3.0 or other anticoagulant (see Chart 34-3)		

INR, International normalized ratio; *TIA,* transient ischemic attack.

Source: Gage, B.F., Waterman, A.D., Shannon, W., Boechler, M., Rich, M.W., & Radford, M.J. (2001). Validation of clinical classification schemes for predicting stroke: Results from the National Registry of Atrial Fibrillation. *Journal of the American Medical Association, 285*(22), 2864-2870; MDCalc.com. (2013). *$CHADS_2$ score for atrial fibrillation stroke risk.* Retrieved July 2014, from www.mdcalc.com/chads2-score-for-atrial-fibrillation-stroke-risk/; QxMD.com.(2013). *$HADS_2$.* Retrieved July 2014, from www.qxmd.com/calculate-online/cardiology/chads2-stroke-risk-in-atrial-fibrillation.

Because of the problems associated with warfarin, alternative anticoagulant agents such as dabigatran (Pradaxa), rivaroxaban (Xarelto), or apixaban (Eliquis) may be given on a long-term basis to prevent strokes associated with nonvalvular AF (Chart 34-4). Because these drugs achieve a steady state, there is no need for laboratory test monitoring. However, if the patient does experience severe bleeding, reversal agents are not available and prothrombin time (PT) and INR are not accurate predictors of bleeding time. These drugs should be used cautiously in patients older than 75 years because of their risk for falls (Sellers & Newby, 2011).

Chart 34-4 Common Examples of Drug Therapy

Nonvalvular Atrial Fibrillation

DRUG	USUAL DOSAGE	NURSING INTERVENTIONS	RATIONALES	REVERSAL AGENT
Rivaroxaban (Xarelto) (factor Xa inhibitor)	20 mg orally daily with evening meal 15 mg orally daily if CrCl <15-50 mL	Monitor for signs and symptoms of bleeding. Teach patient the importance of taking as directed.	Abrupt discontinuation may put patient at high risk for stroke.	None
Dabigatran (Pradaxa) (thrombin inhibitor)	150 mg orally twice daily	Monitor for signs and symptoms of bleeding. Teach patient the importance of taking as directed.	Abrupt discontinuation may put patient at high risk for stroke.	None Hemodialysis may remove dabigatran—limited data available.
Apixaban (Eliquis) (factor Xa inhibitor)	5 mg orally twice daily 2.5 mg orally twice daily used in patients with at least 2 of these characteristics: age ≥80 years, body weight ≤60 kg, or serum creatinine ≥1.5mg/dL	Monitor for signs and symptoms of bleeding. Teach patient the importance of taking as directed.	Abrupt discontinuation may put patient at high risk for stroke.	None

CrCl, Creatinine clearance.

Nursing Safety Priority QSEN

Drug Alert

Teach patients taking any type of anticoagulant drug to report bruising, bleeding nose or gums, and other signs of bleeding to their health care provider immediately. Also remind them to take aspirin with food to prevent GI distress.

NCLEX Examination Challenge

Physiological Integrity

The health care provider prescribes warfarin (Coumadin) for a client with atrial fibrillation. Which foods will the nurse teach the client taking this drug to avoid? **Select all that apply.**

A Spinach
B Corn
C Tomatoes
D Brussels sprouts
E Potatoes

Cardioversion.

Cardioversion is a *synchronized* countershock that may be performed (1) in emergencies for unstable ventricular or supraventricular tachydysrhythmias or (2) electively for stable tachydysrhythmias that are resistant to medical therapies. If the patient has been taking digoxin, the drug is withheld for up to 48 hours before an elective cardioversion. Digoxin increases ventricular irritability and puts the patient at risk for

VF after the countershock. For elective cardioversion for atrial fibrillation, the patient must take anticoagulants for 4 to 6 weeks before the procedure to prevent clots from moving from the heart to the brain or lungs. If unsure of onset of AF, a transesophageal echocardiogram (TEE) may be performed to assess for clot formation in the left atrium.

The shock depolarizes a large amount of myocardium during the cardiac depolarization. It is intended to stop the re-entry circuit and allow the sinus node to regain control of the heart. Emergency equipment must be available during the procedure. The physician, advanced practice nurse, or other qualified nurse explains the procedure to the patient and family. Assist the patient in signing a consent form unless the procedure is an emergency for a life-threatening dysrhythmia. Because he or she is usually conscious, a short-acting anesthetic agent is administered for sedation.

One electrode is placed to the left of the precordium, and the other is placed on the right next to the sternum and below the clavicle. The defibrillator should be set in the synchronized mode. This avoids discharging the shock during the T wave, which may increase ventricular irritability, causing ventricular fibrillation (VF). Charge the defibrillator to the energy level requested, usually starting at a low rate of 120 to 200 joules for biphasic machines.

Nursing Safety Priority QSEN

Critical Rescue

For safety before cardioversion, turn oxygen off and away from patient; fire could result. Shout "CLEAR" before shock delivery for electrical safety!

After cardioversion, assess the patient's response and heart rhythm. Therapy is repeated, if necessary, until the desired result is obtained or alternative therapies are considered. If the patient's condition deteriorates into VF after cardioversion, check to see that the synchronizer is turned off so that immediate defibrillation can be administered.

Nursing care after cardioversion includes:

- Maintaining a patent airway
- Administering oxygen
- Assessing vital signs and the level of consciousness
- Administering antidysrhythmic drug therapy, as prescribed

- Monitoring for dysrhythmias
- Assessing for chest burns from electrodes
- Providing emotional support
- Documenting the results of cardioversion

Radiofrequency Catheter Ablation.

Radiofrequency catheter ablation is an invasive procedure that may be used to destroy an irritable focus causing a supraventricular or ventricular tachydysrhythmia. The patient must first undergo electrophysiologic studies and mapping procedures to locate the focus. Then radiofrequency waves are delivered to abolish the irritable focus. When ablation is performed in the AV nodal or His bundle area, damage may also occur to the normal conduction system, causing heart blocks and requiring implantation of a permanent pacemaker. In AF, pulmonary vein isolation and ablation creates scar tissue that blocks impulses and disconnects the pathway of the abnormal rhythm. Patients with AF with a rapid ventricular rate not responsive to drug therapy may have AV nodal ablation performed to totally disconnect the conduction from the atria to the ventricles, which requires implantation of a permanent pacemaker

Other Nonsurgical Management.

Bi-ventricular pacing may be another alternative for patients with heart failure and conduction disorders. Bi-atrial pacing, anti-tachycardia pacing, and implantable atrial defibrillators are other methods used to suppress or resolve AF.

Patients in AF with heart failure (discussed in Chapter 35) may benefit from the *surgical* **maze procedure**, an open-chest surgical technique often performed with coronary artery bypass grafting (CABG). Before this procedure, electrophysiologic mapping studies are done to confirm the diagnosis of AF. The surgeon places a maze of sutures in strategic places in the atrial myocardium, pulmonary artery, and possibly the superior vena cava to prevent electrical circuits from developing and continuing AF. Sinus impulses can then depolarize the atria before reaching the AV node and preserve the atrial kick. Postoperative care is similar to that after other open-heart surgical procedures (see Chapter 38).

The *catheter* maze procedure is done by inserting a catheter through a leg vein into the atria and dragging a heated ablating catheter along the atria to create lines (scars) of conduction block. Patients having this minimally invasive form of the procedure have fewer complications, less pain, and a quicker recovery than those with the open, surgical maze procedure.

NCLEX Examination Challenge

Physiological Integrity

A client is prescribed to take rivaroxaban (Xarelto) 20 mg orally every day. What is the nurse's priority when teaching the client about this drug?

A "Be sure to keep laboratory appointments to check your clotting times."
B "Take the medication every morning before breakfast."
C "Report any signs of bleeding to your health care provider."
D "Have vitamin K available in case you need it."

Ventricular Dysrhythmias

Ventricular dysrhythmias are potentially more life threatening than atrial dysrhythmias because the left ventricle pumps oxygenated blood throughout the body to perfuse vital organs and other tissues. The most common or life-threatening ventricular dysrhythmias include:

- Premature ventricular complexes
- Ventricular tachycardia
- Ventricular fibrillation
- Ventricular asystole

Premature Ventricular Complexes.

Premature ventricular complexes (PVCs), also called *premature ventricular contractions*, result from increased irritability of ventricular cells and are seen as early ventricular complexes followed by a pause. When multiple PVCs are present, the QRS complexes may be unifocal or uniform, meaning that they are of the same shape (Fig. 34-12, *A*), or multifocal or multiform, meaning that they are of different shapes (Fig. 34-12, *B*). PVCs frequently occur in repetitive rhythms, such as bigeminy (two), trigeminy (three), and quadrigeminy (four). Two sequential PVCs are a pair, or couplet. Three or more successive PVCs are usually called **nonsustained ventricular tachycardia (NSVT)**.

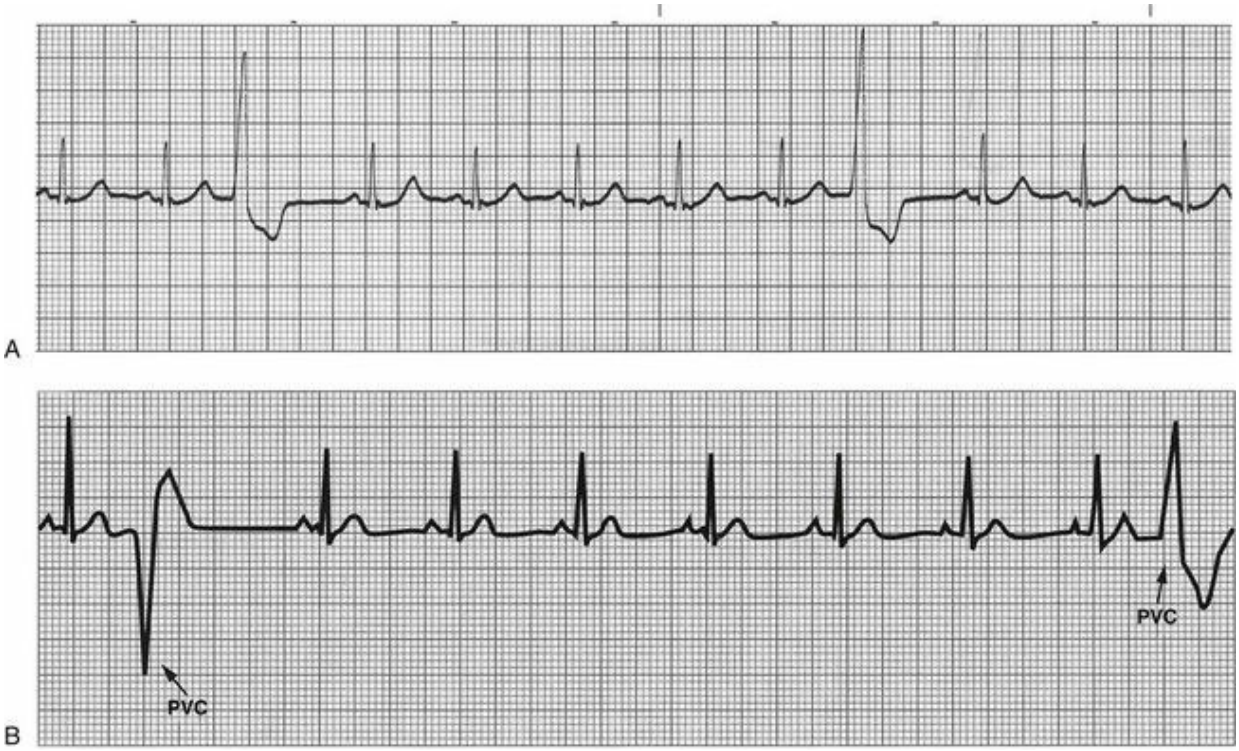

FIG. 34-12 Premature ventricular contractions. **A,** Normal sinus rhythm with unifocal premature ventricular complexes (PVCs). **B,** Normal sinus rhythm with multifocal PVCs (one negative and the other positive).

Premature ventricular contractions are common, and their frequency increases with age. They may be insignificant or may occur with problems such as myocardial infarction, chronic heart failure, chronic obstructive pulmonary disease (COPD), and anemia. PVCs may also be present in patients with hypokalemia or hypomagnesemia. Sympathomimetic agents, anesthesia drugs, stress, nicotine, caffeine, alcohol, infection, or surgery can also cause PVCs, especially in older adults. Postmenopausal women often find that caffeine causes palpitations and PVCs.

Assessment.

The patient may be asymptomatic or experience palpitations or chest discomfort caused by increased stroke volume of the normal beat after the pause. Peripheral pulses may be diminished or absent with the PVCs themselves because the decreased stroke volume of the premature beats may *decrease peripheral* perfusion.

Nursing Safety Priority QSEN

Action Alert

Because other dysrhythmias can cause widened QRS complexes,

assess whether the premature complexes perfuse to the extremities. Palpate the carotid, brachial, or femoral arteries while observing the monitor for widened complexes or auscultating apical heart sounds. With acute MI, PVCs may be considered as a warning, possibly triggering life-threatening ventricular tachycardia (VT) or ventricular fibrillation (VF).

Interventions.

If there is no underlying heart disease, PVCs are not usually treated other than by eliminating or managing any contributing cause (e.g., caffeine, stress). Potassium or magnesium is given for replacement therapy if hypokalemia or hypomagnesemia is the cause. People with more than 5000 PVCs in a 24-hour period are usually placed on beta-adrenergic blocking agents (beta blockers) (see Chart 34-3).

Ventricular Tachycardia.

Ventricular tachycardia (VT), sometimes referred to as "V tach," occurs with repetitive firing of an irritable ventricular ectopic focus, usually at a rate of 140 to 180 beats/min or more (Fig. 34-13). VT may result from increased automaticity or a re-entry mechanism. It may be intermittent (nonsustained VT) or sustained, lasting longer than 15 to 30 seconds. The sinus node may continue to discharge independently, depolarizing the atria but not the ventricles, although P waves are seldom seen in sustained VT.

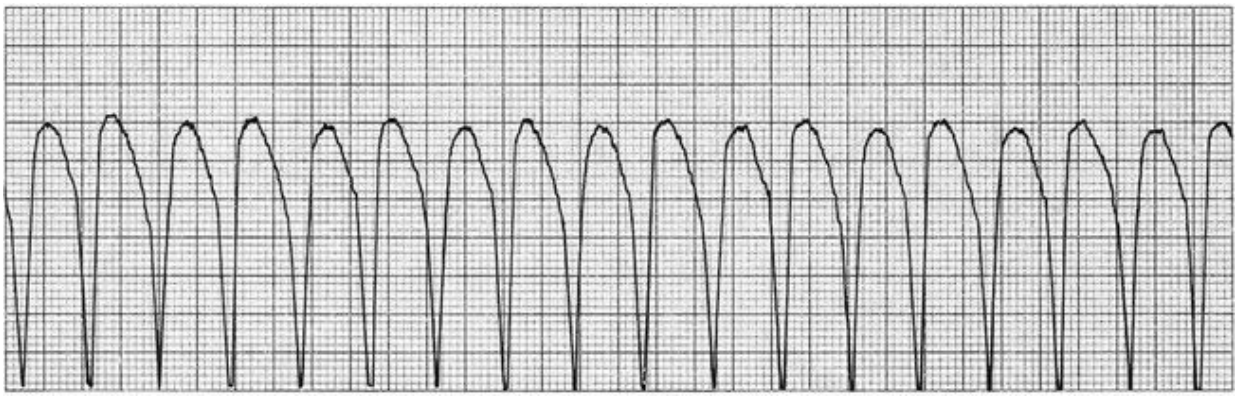

FIG. 34-13 Sustained ventricular tachycardia at a rate of 166 beats per minute.

Ventricular tachycardia may occur in patients with ischemic heart disease, MI, cardiomyopathy, hypokalemia, hypomagnesemia, valvular heart disease, heart failure, drug toxicity (e.g., steroids), or hypotension. Patients who use cocaine or illicit inhalants are at a high risk for VT. *In*

patients who go into cardiac arrest, VT is commonly the initial rhythm before deterioration into ventricular fibrillation (VF) as the terminal rhythm!

Clinical manifestations of sustained VT partially depend on the ventricular rate. Slower rates are better tolerated.

Nursing Safety Priority QSEN

Critical Rescue

In some patients, VT causes cardiac arrest. Assess the patient's airway, breathing, circulation, level of consciousness, and oxygenation level. For the *stable* patient with sustained VT, administer oxygen and confirm the rhythm via a 12-lead ECG. Amiodarone (Cordarone), lidocaine, or magnesium sulfate may be given.

Current Advanced Cardiac Life Support (ACLS) guidelines state that elective cardioversion is highly recommended for stable VT. The physician may prescribe an oral antidysrhythmic agent, such as mexiletine (Mexitil) or sotalol (Betapace, Sotacor), to prevent further occurrences. Patients who persist with episodes of stable VT may require radiofrequency catheter ablation (see p. 668 of this chapter). *Unstable* VT without a pulse is treated the same way as ventricular fibrillation as described below.

Ventricular Fibrillation.

Ventricular fibrillation (VF), sometimes called "V fib," is the result of electrical chaos in the ventricles and is *life threatening*! Impulses from many irritable foci fire in a totally disorganized manner so that ventricular contraction cannot occur. There are no recognizable ECG deflections (Fig. 34-14, *A*). The ventricles merely quiver, consuming a tremendous amount of oxygen. *There is no cardiac output or pulse and therefore no cerebral, myocardial, or systemic perfusion. This rhythm is rapidly fatal if not successfully ended within 3 to 5 minutes.*

FIG. 34-14 Ventricular dysrhythmias. **A,** Coarse ventricular fibrillation. **B,** Ventricular asystole with one idioventricular complex.

VF may be the first manifestation of coronary artery disease (CAD). Patients with myocardial infarction (MI) are at great risk for VF. It may also occur in those with hypokalemia, hypomagnesemia, hemorrhage, drug therapy, rapid supraventricular tachycardia (SVT), or shock. Surgery or trauma may also cause VF.

Emergency Care: Ventricular Fibrillation.

When VF begins, the patient becomes faint, immediately loses consciousness, and becomes pulseless and apneic (no breathing). There is no blood pressure, and heart sounds are absent. Respiratory and metabolic acidosis develop. Seizures may occur. Within minutes, the pupils become fixed and dilated and the skin becomes cold and mottled. *Death results without prompt intervention.*

The desired outcomes of collaborative care are to resolve VF promptly and convert it to an organized rhythm. *Therefore the priority is to defibrillate the patient immediately according to ACLS protocol.* If a defibrillator is not readily available, high quality CPR must be initiated and continued until the defibrillator arrives. An automated external defibrillator (AED) is frequently used because it is simple for both medical and lay personnel. Defibrillation is discussed on p. 672.

Ventricular Asystole.

Ventricular asystole, sometimes called *ventricular standstill*, is the complete absence of any ventricular rhythm (Fig. 34-14, *B*). There are no electrical impulses in the ventricles and therefore *no* ventricular depolarization, no QRS complex, no contraction, no cardiac output, and no perfusion to the rest of the body.

Assessment.

The patient in ventricular asystole has no pulse, respirations, or blood pressure. *The patient is in full cardiac arrest.* The sinoatrial (SA) node, in some cases, may continue to fire and depolarize the atria, with only P waves seen on the ECG. The sinus impulses, however, do not conduct to the ventricles, and QRS complexes remain absent. In most cases, the entire conduction system is electrically silent, with no P waves seen on the ECG.

Ventricular asystole usually results from myocardial hypoxia, which may be a consequence of advanced heart failure. It may also be caused by severe hyperkalemia and acidosis. If P waves are seen, asystole is likely because of severe ventricular conduction blocks.

Interventions.

When cardiac arrest occurs, cardiac output stops. The underlying rhythm is usually ventricular tachycardia (VT), ventricular fibrillation (VF), or asystole. Without cardiac output, the patient is pulseless and becomes unconscious because of inadequate cerebral perfusion and oxygenation. Shortly after cardiac arrest, respiratory arrest occurs. Therefore cardiopulmonary resuscitation is essential to prevent brain damage and death.

Cardiopulmonary Resuscitation and Defibrillation.

Cardiopulmonary resuscitation (CPR), also known as **Basic Cardiac Life Support (BCLS)**, must be initiated immediately when asystole occurs. When finding an unresponsive patient, confirm unresponsiveness and call 911 (in community or long-term care setting) or the emergency response team (in the hospital). Gather the AED or defibrillator *before initiating CPR*. Guidelines for CPR have changed from an ABC (airway-breathing-compressions) approach to the initial priorities of CAB (compressions-airway-breathing) (American Heart Association [AHA], 2010).

- Check for a carotid pulse for 5 to 10 seconds
- *If carotid pulse is absent*, start chest **c**ompressions of at least 100 compressions per minute and a compression depth of at least 2 inches.

Push hard and fast!

- Maintain a patent **a**irway.
- Ventilate (**b**reathing) with a mouth-to-mask device. Give rescue breaths at a rate of 10 to 12 breaths/min. If an advanced airway is in place, one breath should be given every 6 to 8 seconds (8 to 10 breaths/min).
- Ventilation to compression ratio should be maintained at 30 compressions to 2 breaths if advanced airway is not in place

Be sure to use Standard Precautions when administering CPR. Be aware that complications of CPR include:

- Rib fractures
- Fracture of the sternum
- Costochondral separation
- Lacerations of the liver and spleen
- Pneumothorax
- Hemothorax
- Cardiac tamponade
- Lung contusions
- Fat emboli

As soon as help arrives, place a board under the patient who is not on a firm surface. To make room for the resuscitation team and the crash cart, ask that the area be cleared of movable items and unnecessary personnel. When the AED or defibrillator arrives, *do not stop chest compressions while the defibrillator is being set up*. If trained to use the AED or defibrillator, apply hands-off defibrillator pads to the patient's chest and turn on the monitor. If the patient is in VF or pulseless VT, the immediate priority is to defibrillate! **Defibrillation**, an *asynchronous* countershock, depolarizes a critical mass of myocardium simultaneously to stop the re-entry circuit, allowing the sinus node to regain control of the heart. After defibrillation, CPR is resumed. CPR must continue at all times except during defibrillation.

Nursing Safety Priority QSEN

Critical Rescue

Early defibrillation is critical in resolving pulseless ventricular tachycardia (VT) or ventricular fibrillation (VF). It must not be delayed for any reason after the equipment and skilled personnel are present. The earlier defibrillation is performed, the greater the chance of survival! *Do not defibrillate ventricular asystole.*

Before defibrillation, loudly and clearly command all personnel to

clear contact with the patient and the bed and check to see they are clear before the shock is delivered. Deliver shock and immediately resume CPR for 5 cycles or about 2 minutes. Reassess the rhythm every 2 minutes and if indicated. Charge the defibrillator to deliver an additional shock at the same energy level previously used. During the 2-minute intervals while high-quality CPR is being delivered, the Advanced Cardiac Life Support (ACLS) team administers medications and performs interventions to try and restore an organized cardiac rhythm. *Discussion of ACLS protocol is beyond the scope of this text.*

After the ACLS team initiates interventions, the role of the medical-surgical nurse is to provide information about the patient. Specific nursing responsibilities include providing a brief summary of the patient's medical condition and the events that occurred up until the time of cardiac arrest. Report the patient's initial cardiac rhythm. Remain in the room to answer questions, document the event, and assist with compressions. If family is present, provide emotional support and explanation of events in the room.

An emerging clinical practice is allowing or encouraging family presence at resuscitation attempts. This can be a positive experience for family members and significant others because it promotes closure after the death of a loved one. Although there may be staff resistance and some limits to family presence, overall it is a beneficial practice that should be considered in all resuscitation attempts.

When spontaneous circulation resumes, the patient is transported to the intensive care unit. Be ready to give hand-off report to the ICU nurse using SBAR communication or other agency system, and assist with patient transport

Clinical Judgment Challenge

Teamwork and Collaboration; Evidence-Based Practice; Safety QSEN

A 72-year-old woman is transported to the ED with a diagnosis of chest pain to rule out myocardial infarction (MI). During the initial assessment, the nurse notes the cardiac rhythm changes from sinus tachycardia to ventricular tachycardia (VT) with a pulse. Her vital signs are: blood pressure, 84/40 mm Hg; pulse, 154/min; and respirations, 30/min.

1. What is the initial treatment for this patient at this time?

2. What drugs should you anticipate administering to this patient? Why are they indicated?
3. What evidence-based precautions must be taken to promote safety for both the patient and the ACLS team?
4. If this rhythm deteriorates to ventricular fibrillation or VT without a pulse, what steps should you take? Why?

Automated External Defibrillation.

The American Heart Association promotes the use of automated external defibrillators (AEDs) for use by laypersons and health care professionals responding to cardiac arrest emergencies (Fig. 34-15). These devices are found in many public places such as malls, airports, and commercial jets. The patient in cardiac arrest must be on a firm, dry surface. The rescuer places two large adhesive-patch electrodes on the patient's chest in the same positions as for defibrillator electrodes. The rescuer stops CPR and commands anyone present to move away, ensuring that no one is touching the patient. This measure eliminates motion artifact when the machine analyzes the rhythm. The rescuer presses the "analyze" button on the machine. After rhythm analysis, which may take up to 30 seconds, the machine either advises that a shock is necessary or advises that a shock is not indicated. *Shocks are recommended for VF or pulseless VT only.*

FIG. 34-15 Automated external defibrillator.

If a shock is indicated, issue a command to clear all contact with the patient and press the charge button. Once the AED is charged, press the

shock button and the shock will be delivered. The shock is delivered through the patches, so it is hands-off defibrillation, which is safer for the rescuer. The rescuer then resumes CPR until the AED instructs to "stop CPR" to analyze the rhythm. If the rhythm is VF or VT and another shock is indicated, the AED will instruct the rescuer to charge and deliver another shock. Newer AEDs perform rhythm analysis and defibrillation without the need for a rescuer to press a button to analyze or to shock the victim. It is essential that Advanced Cardiac Life Support (ACLS) be provided as soon as possible. Use of AEDs allows for earlier defibrillation. Therefore there is a greater chance of successful rhythm conversion and patient survival.

Implantable Cardioverter/Defibrillator.

The implantable cardioverter/defibrillator (ICD) is indicated for patients who have experienced one or more episodes of spontaneous sustained ventricular tachycardia (VT) or ventricular fibrillation (VF) not caused by an MI. Collaborate with the physician and the electrophysiology nurse to prepare the patient for this procedure. A psychological profile is done to determine whether the patient can cope with the discomfort and fear associated with internal defibrillation from the ICD. Many patients report anxiety, depression, and decreased quality of life, which improves for the majority of patients after 12 months (Hallas et al., 2010).

The leads of the device are introduced through the skin, and the generator is implanted in the left pectoral area, similar to a permanent pacemaker insertion procedure. This procedure is performed in the electrophysiology laboratory. If the patient experiences a VT or VF episode after ICD placement and the ICD therapies are not successful, the qualified nurse or health care provider promptly externally defibrillates and initiates high-quality CPR.

The generator may be activated or deactivated by the physician placing a magnet over the implantation site for a few moments. The patient requires close monitoring in the postoperative period for dysrhythmias and complications such as bleeding and cardiac tamponade. The nurse must know whether the ICD is activated or deactivated. Care of the patient is similar to that after implantation of a permanent pacemaker, discussed on p. 664 of this chapter.

Some patients use a lightweight, automated wearable cardioverter/defibrillator (WCD). This external vest-like device is worn 24 hours a day except when the patient showers or bathes. A family member must be present to call 911 and initiate CPR if the patient experiences pulseless VT or VF while in the shower. One popular brand is the Zoll

Lifecore LifeVest, which is programmed to monitor for VT and VF. If the patient is conscious while experiencing VT, he or she can press a button to prevent a shock. This precaution is an advantage over implantable devices because ICDs are programmed to always deliver a shock when VT or VF occurs.

NCLEX Examination Challenge

Safe and Effective Care Environment

A client in the telemetry unit is on a cardiac monitor. The monitor technician notices there are no ECG complexes and the alarm sounds. What is the first action by the nurse?
A Begin CPR immediately.
B Call the emergency response team.
C Press the record button to get an ECG strip.
D Assess the client and check lead placement.

Community-Based Care

For many patients, dysrhythmias are a disorder resulting from chronic cardiac and pulmonary diseases. Patients may be cared for in a variety of settings, including the acute care hospital, subacute unit, traditional nursing home, or their own home. They are admitted to the hospital when they experience life-threatening or potentially life-threatening dysrhythmias, often associated with an acute disorder.

Home Care Management.

Patients discharged from the hospital may have considerable needs, often more related to their underlying chronic diseases than to their dysrhythmias. A case manager or care coordinator can assess the need for health care resources and coordinate access to services.

The focus of the home care nurse's interventions is assessment and health teaching. Patients and families often fear recurrence of a life-threatening dysrhythmia. Patients with an ICD may dread or fear the activation of the device. The community-based nurse provides the patient and family members with an opportunity to verbalize their concerns and fears. Provide emotional support as well as information about support groups and referrals in the community. Assess the patient for possible side effects of antidysrhythmic agents or complications from a pacemaker or ICD.

Self-Management Education.

Teach the patient who has had a dysrhythmia caused by an acute problem, such as electrolyte imbalance or MI, about prevention, early recognition, and management of that disorder. Instruct the patient and family about lifestyle modifications designed to prevent, decrease, or control the occurrence of dysrhythmias, as outlined in Chart 34-5. This teaching may be provided in the acute care setting, primary care provider's office, health care clinic, or home setting.

Chart 34-5 Patient and Family Education: Preparing for Self-Management

How to Prevent or Decrease Dysrhythmias

For Patients at Risk for Vasovagal Attacks Causing Bradydysrhythmias

- Avoid doing things that stimulate the vagus nerve, such as raising your arms above your head, applying pressure over your carotid artery, applying pressure on your eyes, bearing down or straining during a bowel movement, and stimulating a gag reflex when brushing your teeth or putting objects in your mouth.

For Patients with Premature Beats and Ectopic Rhythms

- Take the medications that have been prescribed for you, and report any adverse effects to your physician.
- Stop smoking, avoid caffeinated beverages and energy drinks as much as possible, and drink alcohol only in moderation.
- Learn ways to manage stress and avoid getting too tired.

For Patients with Ischemic Heart Disease

- If you have an angina attack, treat it promptly with rest and nitroglycerin administration as prescribed by your physician. This decreases your chances of experiencing a dysrhythmia.
- If chest pain is not relieved after taking the amount of nitroglycerin that has been prescribed for you, seek medical attention promptly. Also, seek prompt medical attention if the pain becomes more severe or you experience other symptoms, such as sweating, nausea, weakness, and palpitations.

For Patients at Risk for Potassium Imbalance

- Know the symptoms of decreased potassium levels, such as muscle

weakness and cardiac irregularity.
- Eat foods high in potassium, such as tomatoes, beans, prunes, avocados, bananas, strawberries, and lettuce.
- Take the potassium supplements that have been prescribed for you.

Considerations for Older Adults

Patient-Centered Care QSEN

Older adults are at increased risk for dysrhythmias because of normal physiologic changes in their cardiac conduction system. The sinoatrial node has fewer pacemaker cells. There is a loss of fibers in the bundle branch system. Therefore older adults are at risk for sinus node dysfunction and may require pacemaker therapy. The most common dysrhythmias are premature atrial contractions, premature ventricular contractions, and atrial fibrillation. Dysrhythmias tend to be more serious in older patients because of underlying heart disease, causing cardiac decompensation. Consequently, blood flow to organs that may already be decreased because of the aging process may be further compromised, leading to multisystem organ dysfunction. Chart 34-6 highlights special considerations for older adults receiving antidysrhythmic therapy.

Chart 34-6 Nursing Focus on the Older Adult

Dysrhythmias

Special nursing considerations for the older patient with dysrhythmias are:
- Evaluate the patient with dysrhythmias immediately for the presence of a life-threatening dysrhythmia or hemodynamic deterioration.
- Assess the patient with a dysrhythmia for angina, hypotension, heart failure, and decreased cerebral and renal perfusion.
- Consider these causes of dysrhythmias when taking the patient's history: hypoxia, drug toxicity, electrolyte imbalances, heart failure, and myocardial ischemia or infarction.
- Assess the patient's level of education, hearing, learning style, and ability to understand and recall instructions to determine the best approaches for teaching.
- Assess the patient's ability to read written instructions.
- Teach the patient the generic and trade names of prescribed antidysrhythmic drugs, as well as their purposes, dosage, side effects,

and special instructions for their use.
- Provide clear written instructions in basic language and easy-to-read print.
- Provide a written drug dosage schedule for the patient, considering all the drugs the patient is taking and possible drug interactions.
- Assess the patient for possible side effects or adverse reactions to drugs considering age and health status.
- Teach the patient to take his or her pulse and to report significant changes in heart rate or rhythm to the health care provider.
- Inform the patient of available resources for blood pressure and pulse checks, such as blood pressure clinics, home health agencies, and cardiac rehabilitation programs.
- Instruct the patient on the importance of keeping follow-up appointments with the health care provider and reporting symptoms promptly.
- Include the patient's family members or significant other in all teaching whenever possible.
- Teach the patient to avoid drinking caffeinated beverages, to stop smoking, to drink alcohol only in moderation, and to follow his or her prescribed diet.

Patients and their families must have a thorough understanding of the prescribed *drug therapy*, including antidysrhythmic agents. Pharmacies provide written instructions with filled prescriptions. Teach patients and families the generic and trade names of their drugs, as well as the drugs' purposes, using basic terms that are easily understood. Clear instructions regarding dosage schedules and common side effects are important (see Chart 34-3). Emphasize the importance of reporting these side effects and any dizziness, nausea, vomiting, chest discomfort, or shortness of breath to the primary care provider.

Teach all patients and their family members how to take a pulse and blood pressure. Some patients may want to use technology to calculate and record their pulse rate. Several applications (apps) for handheld mobile devices (such as the iPhone) are available, but their accuracy varies. “Instant Health Rate” and “Quick Heart Rate” are examples of apps used to calculate pulse rate.

Remind patients to report any signs of a change in heart rhythm, such as a significant decrease in pulse rate, a rate more than 100 beats/min, or increased rhythm irregularity. Smart Blood Pressure (SmartBP) is a blood pressure and pulse management system that records, tracks, and analyzes data to share via an iPhone or iPad. The patient can send these

readings to their health care provider as needed to maintain frequent vital sign monitoring.

Give written and verbal information to patients who have a *permanent pacemaker* about the type and settings of their pacemaker. Teach the patient to report any pulse rate lower than that set on the pacemaker. Review the proper care of the pacemaker insertion site and the importance of reporting any fever or any redness, swelling, or drainage at the pacemaker insertion site. If the surgical incision is near either shoulder, teach and demonstrate range-of-motion exercises to perform to prevent shoulder stiffness.

Nursing Safety Priority QSEN

Action Alert

Teach patients who have permanent pacemakers to:

- Keep handheld cellular phones at least 6 inches away from the generator, with the handset on the ear opposite the side of the generator.
- Avoid sources of strong electromagnetic fields, such as magnets and telecommunications transmitters. These may cause interference and could change the pacemaker settings, causing a malfunction. Magnetic resonance imaging (MRI) is usually contraindicated, depending on the machine's technology.
- Carry a pacemaker identification card provided by the manufacturer and wear a medical alert bracelet at all times.

Chart 34-7 outlines the major points for patient and family teaching after the insertion of a permanent pacemaker.

Chart 34-7 Patient and Family Education: Preparing for Self-Management

Permanent Pacemakers

- Follow the instructions for pacemaker site skin care that have been specifically prepared for you. Report any fever or redness, swelling, or drainage from the incision site to your physician.
- Do not manipulate the pacemaker generator site.
- Keep your pacemaker identification card in your wallet, and wear a medical alert bracelet.
- Take your pulse for 1 full minute at the same time each day, and record

the rate in your pacemaker diary. Take your pulse any time you feel symptoms of a possible pacemaker failure, and report your heart rate and symptoms to your physician.

- Know the rate at which your pacemaker is set and the basic functioning of your pacemaker. Know what rate changes to report to your physician.
- Do not apply pressure over your generator. Avoid tight clothing or belts.
- You may take baths or showers without concern for your pacemaker.
- Inform all health care providers that you have a pacemaker. Certain tests they may wish to perform (e.g., magnetic resonance imaging) could affect or damage your pacemaker.
- Know the indications of battery failure for your pacemaker as you were instructed, and report these findings to your health care provider if they occur.
- Do not operate electrical appliances directly over your pacemaker site because this may cause your pacemaker to malfunction.
- Do not lean over electrical or gasoline engines or motors. Be sure that electrical appliances or motors are properly grounded.
- Avoid all transmitter towers for radio, television, and radar. Radio, television, other home appliances, and antennas do not pose a hazard.
- Be aware that antitheft devices in stores may cause temporary pacemaker malfunction. If symptoms develop, move away from the device.
- Inform airport personnel of your pacemaker before passing through a metal detector, and show them your pacemaker identification card. The metal in your pacemaker will trigger the alarm in the metal detector device.
- Stay away from any arc welding equipment.
- Be aware that it is safe to operate a microwave oven unless it does not have proper shielding (old microwave ovens) or is defective.
- Report any of these symptoms to your physician if you experience them: difficulty breathing, dizziness, fainting, chest pain, weight gain, and prolonged hiccupping. If you have any of these symptoms, check your pulse rate and call your health care provider.
- If you feel symptoms when near any device, move 5 to 10 feet away from it and then check your pulse. Your pulse rate should return to normal.
- Keep all of your health care provider and pacemaker clinic appointments.
- Take all medications prescribed for you as instructed.

- Follow your prescribed diet.
- Follow instructions on restrictions on physical activity, such as no sudden, jerky movement, for 8 weeks to allow the pacemaker to settle in place.

Patients with an *implantable cardioverter/defibrillator (ICD)* usually continue to receive antidysrhythmic drugs after discharge from the hospital. Provide health teaching about the purposes of drug therapy, dosage schedules, special instructions, and side effects that need to be reported. If patients experience an internal defibrillator shock, remind them to sit or lie down immediately and notify the primary care provider. Some patients describe the experience of a shock as a quick thud or kick in the chest, whereas others relate severe discomfort similar to that of external defibrillation. Usually the shock is not as severe because the heart is situated between the defibrillation pads, thus requiring less electrical current to convert the dysrhythmia. Inform family members that they may feel an electrical shock if they are touching the patient during delivery of the shock but that it is not harmful. Provide information about how to access the emergency medical services (EMS) system in the community. Recommend resources for the family to learn how to perform CPR.

Remind patients with an ICD to avoid sources of strong electromagnetic fields, such as large electrical generators and radio and television transmitters. Tell the patient that these items may inhibit tachydysrhythmia detection and therapy or may cause pacing or shocks. MRI should not be used for patients with ICDs unless the patient has an MRI-conditional ICD. Handheld cellular phones must be at least 6 inches away from the generator, with the handset held to the ear opposite the side of the ICD. If the pulse generator emits a beeping sound or provides some other indicator, the patient must move away from the area as quickly as possible to prevent deactivation of the device. Teach the patient with an ICD to carry an ICD identification card and wear a medical alert bracelet. Chart 34-8 highlights the important points for health teaching.

Chart 34-8 Patient and Family Education: Preparing for Self-Management

Implantable Cardioverter/Defibrillator

- Follow the instructions for implantable cardioverter/defibrillator (ICD)

site skin care that have been specifically prepared for you.
- Report to your health care provider any fever or redness, swelling, soreness, or drainage from your incision site.
- Do not wear tight clothing or belts that could cause irritation over the ICD generator.
- Do not manipulate your generator site
- Avoid activities that involve rough contact with the ICD implantation site.
- Keep your ICD identification card in your wallet, and consider wearing a medical alert bracelet.
- Know the basic functioning of your ICD device and its rate cutoff, as well as the number of consecutive shocks it can deliver.
- Avoid magnets directly over your ICD because they can inactivate the device. If beeping tones are coming from the ICD, move away from the electromagnetic field immediately (within 30 seconds) before the inactivation sequence is completed, and notify your health care provider.
- Inform all health care providers caring for you that you have an ICD implanted, because certain diagnostic tests and procedures must be avoided to prevent ICD malfunction. These include diathermy, electrocautery, and nuclear magnetic resonance tests.
- Avoid other sources of electromagnetic interference, such as devices emitting microwaves (not microwave ovens); transformers; radio, television, and radar transmitters; large electrical generators; metal detectors, including handheld security devices at airports; antitheft devices; arc welding equipment; and sources of 60-cycle (Hz) interference. Also avoid leaning directly over the alternator of a running motor of a car or boat.
- Report to your health care provider symptoms such as fainting, nausea, weakness, blackout, and rapid pulse rates.
- Take all medications prescribed for you as instructed.
- Follow instructions on restrictions on physical activity, such as not swimming, driving motor vehicles, or operating dangerous equipment.
- Follow your prescribed diet.
- Keep all health care provider and ICD clinic appointments.
- Sit or lie down immediately if you feel dizzy or faint to avoid falling if the ICD discharges.
- Post emergency telephone numbers.
- Know how to contact the local emergency medical services (EMS) systems in your community. Inform them in advance that you have an ICD so that they can be prepared if they need to respond to an

emergency call for you.
- Encourage family members to learn how to perform CPR. Family members should know that if they are touching you when the device discharges, they may feel a slight shock but that this is not harmful to them.
- Follow instructions on what to do if the ICD successfully discharges, after which you feel well. This may include maintaining a diary of the date, the time, activity preceding the shock, symptoms, the number of shocks delivered, and how you feel after the shock. The physician may wish to be notified each time the device discharges.
- Avoid strenuous activities that may cause your heart rate to meet or exceed the rate cutoff of your ICD because this causes the device to discharge inappropriately.
- Notify your health care provider for information regarding access to health care if you are leaving town or are relocating.

Health Care Resources.

The cardiac rehabilitation nurse typically provides written and oral information about dysrhythmias, antidysrhythmic drugs, pacemakers, and ICDs, as well as information about cardiac exercise programs, educational programs, and support groups. The office or ambulatory care nurse may also provide information about resources. Teach the patient how to contact the local chapter of the American Heart Association (www.americanheart.org) or the provincial chapter of the Heart and Stroke Foundation in Canada (www.heartandstroke.ca) for information about dysrhythmias, pacemakers, and CPR training.

Manufacturers of pacemakers and ICDs provide helpful booklets and CDs to give patients and their families a better understanding of these therapies. Teach patients how to use telephonic systems for transmission of their rhythms to the ambulatory care setting or health care provider's office. Stress the importance of keeping scheduled appointments for visits with the cardiologist and pacemaker or ICD clinic. Instruct patients to contact the local ambulance or paramedic services and emergency facilities to let them know that they have these devices implanted. Encourage the patient and family to attend pacemaker or ICD support groups.

Nursing Concepts and Clinical Judgment Review

What might you NOTICE if the patient is experiencing inadequate

oxygenation and tissue perfusion as a result of dysrhythmias?

- Report of chest discomfort or pain
- Report of dizziness or syncope
- Shortness of breath
- Weakness and fatigue
- Decreased urine output
- Pale, cool skin
- Diaphoresis
- Anxiety or restlessness

What should you INTERPRET and how should you RESPOND to a patient experiencing inadequate oxygenation and perfusion as a result of dysrhythmias?

Perform and interpret physical assessment, including:

- Taking vital signs (may have hypotension and weak pulse)
- Checking for pulse deficit
- Asking if patient has palpitations
- Checking capillary refill (decreased)
- Listening to lung and heart sounds
- Assessing cognition
- Taking an ECG
- Checking oxygen saturation

Respond by:

- Applying oxygen
- Keeping the head of the bed elevated unless patient is very hypotensive
- Maintaining or starting an IV line
- Notifying the health care provider or Rapid Response Team
- Giving drug therapy as prescribed
- Initiating CPR for asystole
- Defibrillating the patient in VF
- Assisting with other procedures as needed, for example, defibrillation

On what should you REFLECT?

- Evaluate patient's response to drug therapy.
- Observe for evidence of increased oxygenation and perfusion.
- Think about what else you could have done to assist the patient with this problem.

Get Ready for the NCLEX® Examination!

Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Be very careful to protect patients and staff to prevent electrical injury when assisting with invasive pacemakers, cardioversion, and defibrillation. **Safety** QSEN
- For safety during cardioversion, turn oxygen off and away from the patient to prevent a fire. Shout "CLEAR" before shock delivery for electrical safety. **Safety** QSEN
- Teach patients who have permanent pacemakers to keep cell phones at least 6 inches away from the generator, avoid electromagnetic fields such as telecommunication transmitters, wear a medical alert bracelet at all times, and carry a pacemaker identification card. **Safety** QSEN

Health Promotion and Maintenance

- Teach patients with dysrhythmias the correct drug, dose, route, time, and side effects of prescribed drugs, and teach them to notify their primary care provider if adverse effects occur (see Chart 34-3).
- Teach patients taking anticoagulant therapy to report any signs of bruising or unusual bleeding immediately to their health care provider.
- Teach family members where to learn cardiopulmonary resuscitation (CPR) to decrease their anxiety while living with a patient with dysrhythmias or ICD/pacemaker. **Patient-Centered Care** QSEN
- Teach patients the importance of adhering to their prescribed cardiac regimen, such as checking their pulse to ascertain pacemaker function.

Physiological Integrity

- Assess patients with dysrhythmias for a decrease in cardiac output resulting in inadequate oxygenation and perfusion to vital organs (see Chart 34-2); typical assessment findings include shortness of breath, dizziness or syncope, weakness and fatigue, and irregular pulse.
- Monitor patients with dysrhythmias, including conducting a physical assessment and health history, as well as interpreting ECG rhythm strips. Report significant changes to the health care provider.
- Interpret common dysrhythmias, especially bradycardia, tachycardia, atrial fibrillation (AF) and ventricular fibrillation (VF), premature

ventricular contractions (PVCs), and asystole, using the steps of ECG analysis.
- Use special considerations when caring for older adults with dysrhythmias, as described in Chart 34-6. **Patient-Centered Care** QSEN
- Recognize that noninvasive pacing is an emergency measure to provide demand ventricular pacing in patients with profound bradycardia or asystole. Teach patients to expect possible discomfort.
- Identify and intervene in life-threatening situations by providing cardiopulmonary resuscitation, electrical therapy, or drug administration. **Evidence-Based Practice** QSEN
- Be aware that automated external defibrillators (AEDs) are used by medical and lay personnel as an essential intervention for VF.
- Do not perform CPR while the patient is being defibrillated. **Safety** QSEN
- Educate patients who have permanent pacemakers or ICDs about self-management (see Charts 34-7 and 34-8).

CHAPTER 35

Care of Patients with Cardiac Problems

Laura M. Dechant

PRIORITY CONCEPTS

- Perfusion
- Gas Exchange
- Pain
- Infection

Learning Outcomes

Safe and Effective Care Environment

1. Evaluate the status of patients with end-stage heart disease regarding advance directives.
2. Provide the patient with heart failure (HF) and the family information on discharge to home, hospice, or other community-based setting.
3. Collaborate with the interdisciplinary team when providing care to patients with cardiac problems.

Health Promotion and Maintenance

4. Identify community resources for patients with cardiac problems and their families.
5. Provide special care needs of older adults with heart failure.
6. Teach patients about actions to maintain health and prevent worsening HF.
7. Engage patients and family members in active partnerships that promote health, safety, and self-management.

Psychosocial Integrity

8. Assess the patient and family response to living with chronic HF and possible transplantation.

Physiological Integrity

9. Explain the pathophysiology of HF.
10. Compare and contrast left-sided and right-sided HF.
11. Identify priority problems for patients with HF, including impaired gas exchange.
12. Perform a comprehensive assessment of patients experiencing cardiac problems.
13. Explain how common drug therapies improve cardiac output, enhance peripheral perfusion, and prevent worsening of HF.
14. Assess patients for adverse effects of drug therapy for cardiac problems.
15. Monitor the laboratory values for patients with cardiac problems.
16. Base the plan of care on patient values, clinical expertise, and current evidence to promote safety and quality of cardiovascular care.
17. Provide emergency care for patients experiencing life-threatening complications, such as cardiac tamponade and pulmonary edema.
18. Identify the four Heart Failure Core Measures required by The Joint Commission.
19. Describe essential focused assessments used by the home care nurse for patients with heart failure.
20. Compare and contrast common valvular disorders.
21. Describe surgical management for patients with valvular disease.
22. Develop a teaching/learning plan for patients with valvular disease.
23. Differentiate between common cardiac inflammations and infections—endocarditis, pericarditis, and rheumatic carditis.
24. Identify clinical assessment findings for patients with cardiomyopathy.
25. Plan postoperative care for patients having a heart transplant.

 http://evolve.elsevier.com/Iggy/

This chapter focuses on heart failure and its common causes in the adult population; coronary artery disease is discussed in Chapter 38. Heart failure is the most common reason for hospital stays in patients older than 65 years in the United States. When the heart is diseased, it

cannot effectively pump an adequate amount of arterial blood to the rest of the body. Arterial blood carries *oxygen* and nutrients to vital organs, such as the kidneys and brain, and to peripheral tissues. When these organs and other body tissues are not adequately *perfused,* they may not function properly.

Heart Failure

Heart failure, sometimes referred to as ***pump failure,*** is a general term for the inability of the heart to work effectively as a pump. It results from a number of acute and chronic cardiovascular problems that are discussed later in this chapter and elsewhere in the cardiovascular unit.

❖ Pathophysiology

Heart failure (HF) is a common *chronic* health problem, with acute episodes often causing hospitalization. Acute coronary disease and other structural or functional problems of the heart can lead to *acute* heart failure. Both acute and chronic HF can be life threatening if they are not adequately treated or if the patient does not respond to treatment.

Types of Heart Failure

The major types of heart failure are:

- Left-sided heart failure
- Right-sided heart failure
- High-output failure

Because the two ventricles of the heart represent two separate pumping systems, it is possible for one to fail by itself for a short period. *Most heart failure begins with failure of the left ventricle and progresses to failure of both ventricles.* Typical causes of **left-sided heart (ventricular) failure** include hypertension, coronary artery disease, and valvular disease involving the mitral or aortic valve. Decreased tissue perfusion from poor cardiac output and pulmonary congestion from increased pressure in the pulmonary vessels indicate left ventricular failure (LVF).

Left-sided heart failure was formerly referred to as **congestive heart failure (CHF);** however, not all cases of LVF involve fluid accumulation. In the clinical setting, though, the term *CHF* is still commonly used. Left-sided failure may be acute or chronic and mild to severe. It can be further divided into two subtypes: systolic heart failure and diastolic heart failure.

Systolic heart failure (systolic ventricular dysfunction) results when the heart cannot contract forcefully enough during systole to eject adequate amounts of blood into the circulation. Preload increases with decreased contractility, and afterload increases as a result of increased peripheral resistance (e.g., hypertension) (McCance et al., 2014). The **ejection fraction** (the percentage of blood ejected from the heart during systole) drops from a normal of 50% to 70% to below 40% with ventricular dilation. As it decreases, tissue perfusion diminishes and

blood accumulates in the pulmonary vessels. Manifestations of systolic dysfunction may include symptoms of inadequate tissue perfusion or pulmonary and systemic congestion. Systolic heart failure is often called "forward failure" because cardiac output is decreased and fluid backs up into the pulmonary system. Because these patients are at high risk for sudden cardiac death, patients with an ejection fraction of less than 30% are considered candidates for an implantable cardioverter/defibrillator (ICD; also known as an *internal cardioverter/defibrillator*) (see Chapter 34).

In contrast, **diastolic heart failure** (heart failure with preserved left ventricular function) occurs when the left ventricle cannot relax adequately during diastole. Inadequate relaxation or "stiffening" prevents the ventricle from filling with sufficient blood to ensure an adequate cardiac output. Although ejection fraction is more than 40%, the ventricle becomes less compliant over time because more pressure is needed to move the same amount of volume as compared with a healthy heart. Diastolic failure represents about 20% to 40% of all heart failure, primarily in older adults and in women who have chronic hypertension and undetected coronary artery disease. Clinical manifestations and management of diastolic failure are similar to those of systolic dysfunction (McCance et al., 2014).

Right-sided heart (ventricular) failure may be caused by left ventricular failure, right ventricular myocardial infarction (MI), or pulmonary hypertension. In this type of heart failure (HF), the right ventricle cannot empty completely. Increased volume and pressure develop in the venous system, and peripheral edema results.

High-output heart failure can occur when cardiac output remains normal or above normal, unlike left- and right-sided heart failure, which are typically low-output states. High-output failure is caused by increased metabolic needs or hyperkinetic conditions, such as septicemia, high fever, anemia, and hyperthyroidism. This type of heart failure is not as common as other types.

Classification and Staging of Heart Failure

The American College of Cardiology (ACC) and American Heart Association (AHA) have developed evidence-based guidelines for staging and managing heart failure as a chronic, progressive disease. These guidelines do not replace the New York Heart Association (NYHA) functional classification system, which is used to describe symptoms a patient may exhibit (see Table 33-2 in Chapter 33).

The ACC/AHA staging system when compared with the NYHA system categorizes patients as:

A Patients at high risk for developing heart failure (class I NYHA)
B Patients with cardiac structural abnormalities or remodeling who have not developed HF symptoms (class I NYHA)
C Patients with current or prior symptoms of heart failure (class II or III NYHA)
D Patients with refractory end-stage heart failure (class IV NYHA)

Another method for staging HF is the Killip classification system, which is based on the heart's hemodynamic ability. Table 38-3 in Chapter 38 outlines this system.

Compensatory Mechanisms

When cardiac output is insufficient to meet the demands of the body, compensatory mechanisms work to improve cardiac output (Fig. 35-1). Although these mechanisms may initially increase cardiac output, they eventually have a damaging effect on pump function. Major compensatory mechanisms include:

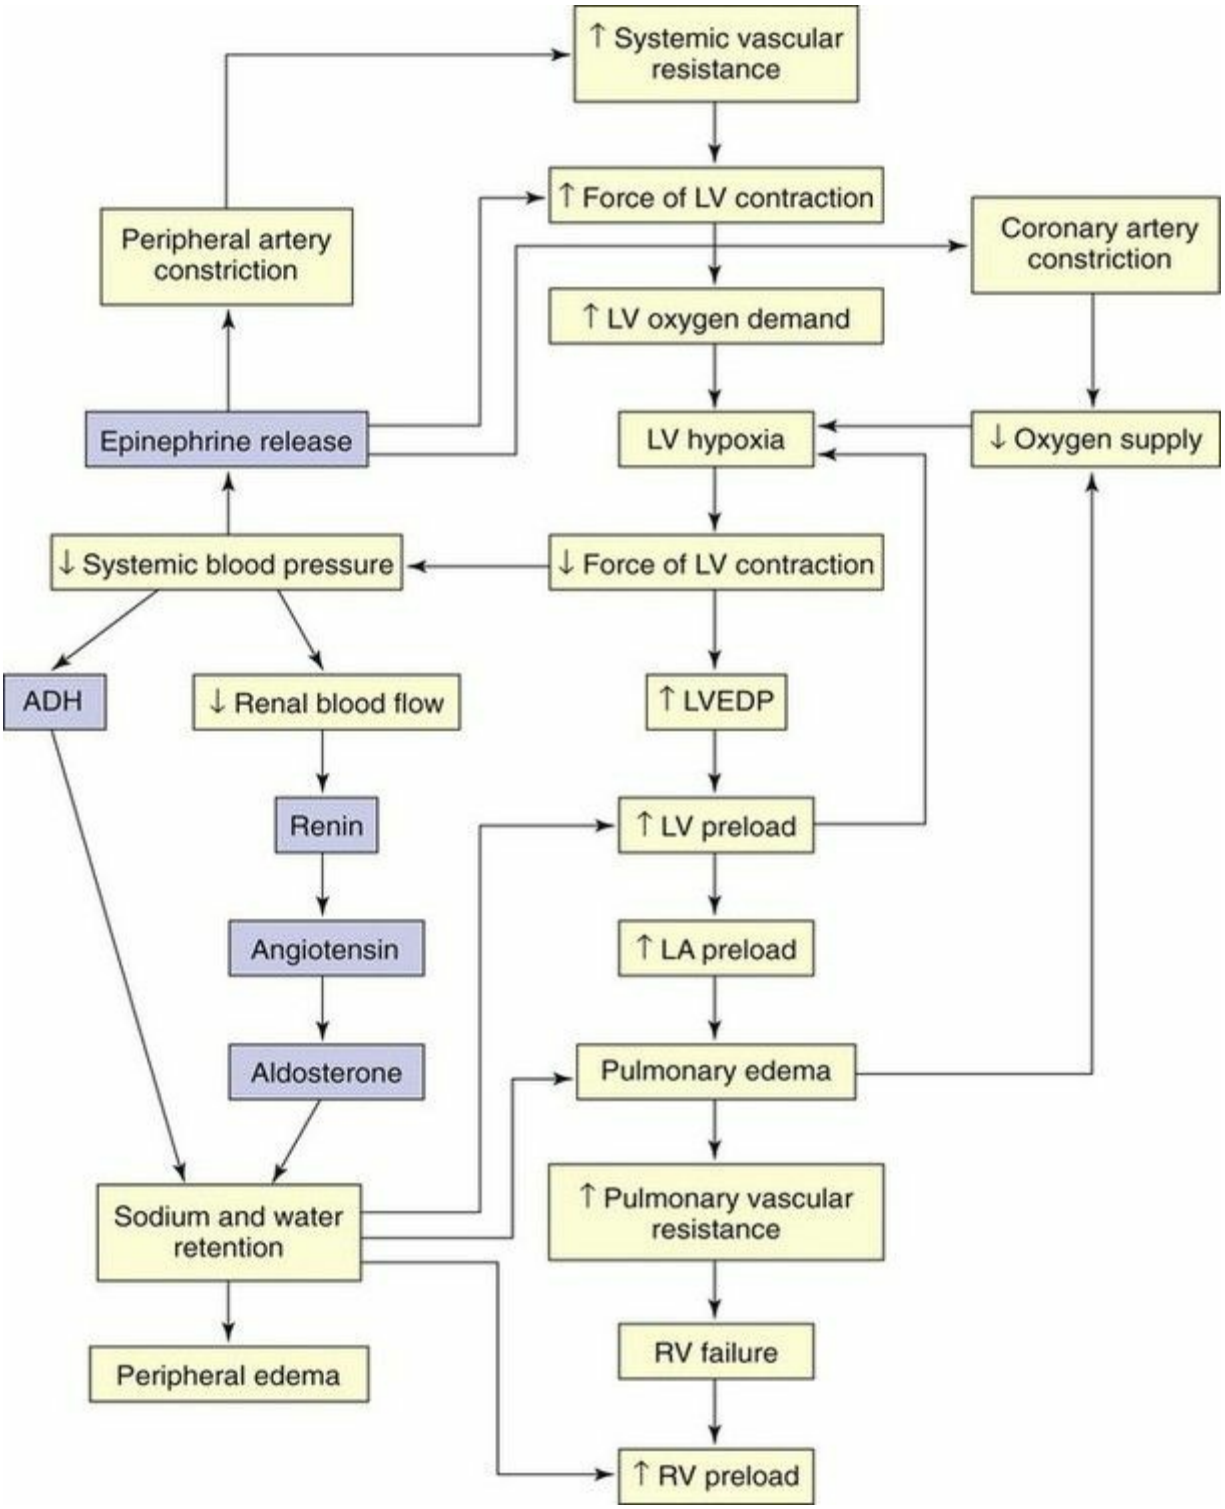

FIG. 35-1 Left-sided heart failure from elevated systemic vascular resistance. Left heart failure leads to right heart failure. Systemic vascular resistance and preload are exacerbated by renal and adrenal mechanisms. *ADH,* Antidiuretic hormone; *LA,* left atrial; *LV,* left ventricular; *LVEDP,* left ventricular end-diastolic pressure; *RV,* right ventricular.

- Sympathetic nervous system stimulation
- Renin-angiotensin system (RAS) activation (also called renin-angiotensin-aldosterone [RAAS] activation)

• Other chemical responses
• Myocardial hypertrophy

In heart failure (HF), *stimulation of the sympathetic nervous system* (i.e., increasing catecholamines) as a result of tissue hypoxia represents the most immediate compensatory mechanism. Stimulation of the adrenergic receptors causes an increase in heart rate (beta adrenergic) and blood pressure from vasoconstriction (alpha adrenergic).

Because cardiac output (CO) is the product of heart rate (HR) and stroke volume (SV), an increase in HR results in an immediate *increase in cardiac output.* The HR is limited, though, in its ability to compensate for decreased CO. If it becomes too rapid, diastolic filling time is limited and CO may start to decline. An increase in HR also significantly increases oxygen demand by the myocardium. If the heart is poorly perfused because of arteriosclerosis, HF may worsen.

Stroke volume (SV) is also *improved* by sympathetic stimulation. Sympathetic stimulation increases venous return to the heart, which further stretches the myocardial fibers causing dilation. According to Starling's law, increased myocardial stretch results in more forceful contraction. More forceful contractions increase SV and CO. After a critical point is reached within the cardiac muscle, further volume and stretch reduce the force of contraction and cardiac output.

Sympathetic stimulation also results in *arterial vasoconstriction.* Vasoconstriction has the benefit of maintaining blood pressure and improving tissue perfusion in low-output states. However, constriction of the arteries increases **afterload,** the resistance against which the heart must pump. Afterload is the major determinant of myocardial oxygen requirements. As it increases, the left ventricle requires more energy to eject its contents and SV may decline.

Reduced blood flow to the kidneys, a common occurrence in low-output states, results in *activation of the renin-angiotensin system (RAS).* Vasoconstriction becomes more pronounced in response to angiotensin II, and aldosterone secretion causes sodium and water retention. Preload and afterload increase. Angiotensin II contributes to *ventricular remodeling* resulting in progressive myocyte (myocardial cell) contractile dysfunction over time (McCance et al., 2014).

In addition to the sympathetic nervous system and RAS responses, other mechanisms are activated when a patient experiences heart failure (HF). Most of these actions contribute to worsening of the condition.

For example, in those who have had an MI, heart muscle cell injury causes an *immune response.* Pro-inflammatory cytokines, such as tumor necrosis factor (TNF) and interleukins (IL-1 and IL-6), are released,

especially with left-sided HF. These substances contribute to ventricular remodeling.

Natriuretic peptides are neurohormones that work to promote vasodilation and diuresis through sodium loss in the renal tubules. The **B-type natriuretic peptide (BNP)** is produced and released by the ventricles when the patient has fluid overload as a result of HF. It increases with age and has a greater concentration in women (Jessup et al., 2009). People who are obese have lower BNP levels compared with those who are not (Clerico et al., 2012).

Low cardiac output (CO) causes decreased cerebral perfusion. As a result, the posterior pituitary gland secretes *vasopressin* (antidiuretic hormone [ADH]). The hormone causes vasoconstriction and fluid retention, which worsen HF.

Endothelin is secreted by endothelial cells when they are stretched. As the myocardial fibers are stretched in patients with HF, this potent vasoconstrictor is released, which increases peripheral resistance and hypertension. HF worsens as a result of these actions.

Myocardial hypertrophy (enlargement of the myocardium), with or without chamber dilation, is another compensatory mechanism. The walls of the heart thicken to provide more muscle mass, which results in more forceful contractions, further increasing cardiac output. Cardiac muscle, however, may hypertrophy more rapidly than collateral circulation can provide adequate blood supply to the muscle. Often a hypertrophied heart is slightly oxygen deprived.

All the compensatory mechanisms contribute to an increase in the consumption of myocardial oxygen. When the demand for oxygen increases and the myocardial reserve has been exhausted, clinical manifestations of HF develop.

Etiology

Heart failure (HF) is caused by systemic hypertension in most cases. Some patients experiencing myocardial infarction (MI, "heart attack") also develop HF. The next most common cause is structural heart changes, such as valvular dysfunction, particularly pulmonic or aortic stenosis, which leads to pressure or volume overload on the heart. Common direct causes and risk factors for HF are listed in Table 35-1.

TABLE 35-1

Common Causes and Risk Factors For Heart Failure

- Hypertension
- Coronary artery disease
- Cardiomyopathy
- Substance abuse (alcohol and illicit/prescribed drugs)
- Valvular disease
- Congenital defects
- Cardiac infections and inflammations

- Dysrhythmias
- Diabetes mellitus
- Smoking/tobacco use
- Family history
- Obesity
- Severe lung disease
- Sleep apnea
- Hyperkinetic conditions (e.g., hyperthyroidism)

Considerations for Older Adults

Patient-Centered Care QSEN

Heart failure is a common problem among older adults. The use of certain drugs can contribute to the development or exacerbation of the problem in this population. For example, long-term use of NSAIDs for arthritis and other chronic pain can cause fluid and sodium retention. NSAIDs may cause peripheral vasoconstriction and increase the toxicity of diuretics and angiotensin-converting enzyme inhibitors (ACEIs). Thiazolidinediones (TZDs) (e.g., pioglitazone [Actos]) used for diabetics also cause fluid and sodium retention. Rosiglitazone (Avandia), another TZD drug, has recently been found to cause acute myocardial infarction (AMI) in patients with type 2 diabetes. These drugs should be used with caution and restrictions in the older adult population.

Right-sided HF in the absence of left-sided HF is usually the result of pulmonary problems such as chronic obstructive pulmonary disease (COPD) or pulmonary hypertension. Acute respiratory distress syndrome (ARDS) may also cause right-sided HF. These problems are discussed elsewhere in this text.

Incidence and Prevalence

Over five million people in the United States have HF, causing about 875,000 hospitalizations each year. HF is the most common reason for hospital admission for people older than 65 years. African Americans are affected more often than Euro-Americans, probably because they have more risk factors that can lead to HF (Go et al., 2013). The disease is a

major cause of disability and death after MI, often due to nonadherence to the treatment plan and recommended lifestyle changes.

Considerations for Older Adults

Patient-Centered Care QSEN

Heart failure has been referred to as a U.S. epidemic, although it is a major problem worldwide. One of the U.S. *Healthy People 2020* objectives is to reduce the number of hospitalizations of older adults with HF as the principal diagnosis. Patient and family education can help meet this objective (Table 35-2). As the "baby boomer" population reaches 65 years of age, the numbers of hospital stays and deaths from HF are likely to increase dramatically.

TABLE 35-2
Meeting *Healthy People 2020* Objectives

Cardiac Disease
To reduce hospitalizations of older adults with heart failure as the principal diagnosis.
• For patients hospitalized for heart failure, collaborate with the case manager for discharge planning, including adequate support in the community. • Provide a continuing plan of care for patients and their families or other caregivers when the patient is discharged from the hospital. • If the patient is discharged to home, call to check that he or she has no impending signs and symptoms of heart failure (the case manager may make calls). • Teach the patient and family or other caregiver about when to call the health care provider for health changes so the patient can be treated at home. • Ensure that the interdisciplinary team provides the patient with follow-up care in the home or nursing home.

Patient-Centered Collaborative Care

Assessment

History.

When obtaining a history, keep in mind the many conditions that can lead to HF. Carefully question the patient about his or her medical history, including hypertension, angina (cardiac pain), MI, rheumatic heart disease, valvular disorders, endocarditis, and pericarditis. Ask about the patient's perception of his or her activity tolerance, breathing pattern, sleeping pattern, urinary pattern, and fluid volume status, as well as his or her knowledge about HF.

Left-Sided Heart Failure.

With left ventricular systolic dysfunction, cardiac output (CO) is diminished, leading to impaired tissue perfusion, anaerobic metabolism, and unusual fatigue. Assess activity tolerance by asking whether the

patient can perform normal ADLs or climb flights of stairs without *fatigue* or dyspnea. Many patients with heart failure (HF) experience weakness or fatigue with activity or have a feeling of heaviness in their arms or legs. Ask about their ability to perform simultaneous arm and leg work (e.g., walking while carrying a bag of groceries). Such activity may place an unacceptable demand on the failing heart. Ask the patient to identify his or her most strenuous activity in the past week. Many people unconsciously limit their activities in response to fatigue or dyspnea and may not realize how limited they have become.

perfusion to the myocardium is often impaired as a result of left ventricular failure, especially with cardiac hypertrophy. The patient may report *chest discomfort* or may describe palpitations, skipped beats, or a fast heartbeat.

As the amount of blood ejected from the left ventricle diminishes, hydrostatic pressure builds in the pulmonary venous system and results in fluid-filled alveoli and pulmonary congestion, which results in a *cough.* The patient in early HF describes the cough as irritating, nocturnal (at night), and usually nonproductive. *As HF becomes very severe, he or she may begin expectorating frothy, pink-tinged sputum—a sign of life-threatening pulmonary edema.*

Dyspnea also results from increasing pulmonary venous pressure and pulmonary congestion. Carefully question about the presence of dyspnea and when and how it developed. The patient may refer to dyspnea as "trouble in catching my breath," "breathlessness," or "difficulty in breathing."

As **exertional dyspnea** develops (also called *dyspnea upon* or *on exertion [DUE/DOE]*), the patient often stops previously tolerated levels of activity because of shortness of breath. Dyspnea at rest in the recumbent (lying flat) position is known as **orthopnea.** Ask how many pillows are used to sleep or whether the patient sleeps in an upright position in a bed, recliner, or other type of chair.

Patients who describe sudden awakening with a feeling of breathlessness 2 to 5 hours after falling asleep have **paroxysmal nocturnal dyspnea (PND).** Sitting upright, dangling the feet, or walking usually relieves this condition.

Right-Sided Heart Failure.

Signs of systemic congestion occur as the right ventricle fails, fluid is retained, and pressure builds in the venous system. Edema develops in the lower legs and may progress to the thighs and abdominal wall. Patients may notice that their shoes fit more tightly, or their shoes or

socks may leave indentations on their swollen feet. They may have removed their rings because of swelling in their fingers and hands. Ask about weight gain. An adult may retain 4 to 7 liters of fluid (10 to 15 lb [4.5 to 6.8 kg]) before pitting edema occurs.

Reports of *nausea and anorexia* may be a direct consequence of liver engorgement (congestion) resulting from fluid retention. In *advanced* heart failure (HF), *ascites* and an increased abdominal girth may develop from severe liver congestion. Another common finding related to fluid retention is *diuresis at rest.* At rest, fluid in the peripheral tissue is mobilized and excreted and the patient describes frequent awakening at night to urinate.

Obtain a careful nutritional history, questioning about the use of salt and the types of food consumed. Ask about daily fluid intake. Patients with HF may experience increased thirst and drink excessive fluid (4000 to 5000 mL/day) because of sodium retention.

Physical Assessment/Clinical Manifestations.

Manifestations of HF depend on the type of failure, the ventricle involved, and the underlying cause. Impaired tissue perfusion, pulmonary congestion, and edema are associated with *left* ventricular failure (Chart 35-1). Conversely, systemic venous congestion and peripheral edema are associated with *right* ventricular failure (Chart 35-2).

Chart 35-1 Key Features

Left-Sided Heart Failure

DECREASED CARDIAC OUTPUT	PULMONARY CONGESTION
• Fatigue • Weakness • Oliguria during the day (nocturia at night) • Angina • Confusion, restlessness • Dizziness • Tachycardia, palpitations • Pallor • Weak peripheral pulses • Cool extremities	• Hacking cough, worse at night • Dyspnea/breathlessness • Crackles or wheezes in lungs • Frothy, pink-tinged sputum • Tachypnea • S_3/S_4 summation gallop

Chart 35-2 Key Features

Right-Sided Heart Failure

Systemic Congestion	
• Jugular (neck vein) distention • Enlarged liver and spleen • Anorexia and nausea • Dependent edema (legs and sacrum) • Distended abdomen	• Swollen hands and fingers • Polyuria at night • Weight gain • Increased blood pressure (from excess volume) or decreased blood pressure (from failure)

Left-Sided Heart Failure.

Left ventricular failure is associated with decreased cardiac output and elevated pulmonary venous pressure. It may appear clinically as:

- Weakness
- Fatigue
- Dizziness
- Acute confusion
- Pulmonary congestion
- Breathlessness
- Oliguria (scant urine output)

Decreased blood flow to the major body organs can cause dysfunction, especially renal failure. Nocturia may occur when the patient is at rest.

The pulse may be tachycardic, or it may alternate in strength **(pulsus alternans).** Take the apical pulse for a full minute, noting any irregularity in heart rhythm. *An irregular heart rhythm resulting from premature atrial contractions (PACs), premature ventricular contractions (PVCs), or atrial fibrillation (AF) is common in HF* (see Chapter 34). The sudden development of an irregular rhythm may further compromise CO. Carefully monitor the patient's respiratory rate, rhythm, and character, as well as oxygen saturation. The respiratory rate typically exceeds 20 breaths/min.

Assess whether the patient is oriented to person, place, and time. A short mental status examination may be used if there are concerns about orientation. Objective data are important because in daily conversation many people are skillful at covering up memory losses. Older adults are frequently disoriented or confused when the heart fails due to brain hypoxia (decreased oxygen).

Increased heart size is common with a displacement of the apical impulse to the left. A third heart sound, **S_3 gallop,** is an early diastolic filling sound indicating an increase in left ventricular pressure. This sound is often the first sign of HF. A fourth heart sound (S_4) also can occur; it is not a sign of failure but is a reflection of decreased ventricular compliance.

Auscultate for crackles and wheezes of the lungs. Late inspiratory

crackles and fine profuse crackles that repeat themselves from breath to breath and do not diminish with coughing indicate HF. *Crackles are produced by intra-alveolar fluid and are often noted first in the bases of the lungs and spread upward as the condition worsens.* Wheezes indicate a narrowing of the bronchial lumen caused by engorged pulmonary vessels. Identify the precise location of crackles and wheezes and whether the wheezes are heard on inspiration, expiration, or both.

Right-Sided Heart Failure.

Right ventricular failure is associated with increased systemic venous pressures and congestion. On inspection, assess the neck veins for distention and measure abdominal girth. Hepatomegaly (liver engorgement), hepatojugular reflux, and ascites may also be assessed. Abdominal fluid can reach volumes of more than 10 liters.

Assess for dependent edema. In ambulatory patients, edema commonly presents in the ankles and legs. When patients are restricted to bedrest, the sacrum is dependent and fluid accumulates there.

Nursing Safety Priority QSEN

Action Alert

Edema is an extremely unreliable sign of HF. Be sure that accurate daily weights are taken every morning to document fluid retention. *Weight is the most reliable indicator of fluid gain and loss!*

NCLEX Examination Challenge

Physiological Integrity

A client is diagnosed with left-sided heart failure. Which assessment findings will the nurse expect the client to have? **Select all that apply.**

A Peripheral edema
B Crackles in both lungs
C Breathlessness
D Ascites
E Tachypnea

Psychosocial Assessment.

Chronic heart failure (HF) is typically a slow, debilitating disease. Anxiety and frustration are common. Symptoms such as dyspnea increase the

patient's anxiety level.

Patients with HF, especially those with advanced disease, are at high risk for depression. It is not certain whether the functional impairments contribute to the depression or depression affects functional ability. Older hospitalized patients may be depressed, particularly those who have been re-admitted for an acute episode of HF. Lifestyle changes and quality-of-life issues can also cause depression many months after the initial diagnosis of HF.

Assess patients and their families for anxiety and depression. Ask them about their usual methods of coping, as well as any history of depression. If anxiety or depression is present, notify the health care provider for further assessment. Social workers, certified clinical chaplains, or psychologists may administer specific assessment tools to determine the extent of the problem. Some patients need drug therapy and nonpharmacologic modalities, such as cognitive behavior therapy, biofeedback, or relaxation training.

Hope is a major indicator of well-being for patients with HF. Those who are hopeful tend to feel better and are more socially involved. Ask patients about their daily activities and how often they interact with the significant people in their life to help determine patient and family coping strategies.

Laboratory Assessment.

Electrolyte imbalance may occur from complications of HF or as side effects of drug therapy, especially diuretic therapy. Regular evaluations of a patient's *serum electrolytes,* including sodium, potassium, magnesium, calcium, and chloride, are essential. Any impairment of renal function resulting from inadequate perfusion causes elevated blood urea nitrogen and serum creatinine and decreased creatinine clearance levels. *Hemoglobin* and *hematocrit* tests should be performed to identify HF resulting from anemia. If the patient has fluid volume excess, the hematocrit levels may be low as a result of hemodilution.

B-type natriuretic peptide (BNP) is used for diagnosing HF (in particular, diastolic HF) in patients with acute dyspnea. As discussed earlier, it is part of the body's response to decreased cardiac output from either left or right ventricular dysfunction. An increase in BNP, in conjunction with history and physical, best differentiates between the dyspnea of HF and that associated with lung dysfunction (Fard et al., 2012). However, patients with renal disease may also have elevated BNP levels (Chen et al., 2010). In the ambulatory care arena, BNP is trended over time to guide ambulatory care treatment of heart failure (DeBeradinis & Januzzi,

2012); as therapy is optimized, levels decrease. If levels increase, alternate causes such as ischemia are looked at prior to intensifying treatment.

Urinalysis may reveal proteinuria and high specific gravity. *Microalbuminuria* is an early indicator of decreased compliance of the heart and occurs before the BNP rises. It serves as an "early warning detector" that lets the health care provider know that the heart is experiencing early signs of decreased compliance, long before symptoms occur.

Considerations for Older Adults

Patient-Centered Care QSEN

Thyroxine (T_4) and thyroid-stimulating hormone (TSH) levels should be assessed in patients who are older than 65 years, have atrial fibrillation, or have evidence of thyroid disease. Heart failure (HF) may be caused or aggravated by hypothyroidism or hyperthyroidism.

Arterial blood gas (ABG) values often reveal hypoxemia (low blood oxygen level) because oxygen does not diffuse easily through fluid-filled alveoli. Respiratory alkalosis may occur because of hyperventilation; respiratory acidosis may occur because of carbon dioxide retention. Metabolic acidosis may indicate an accumulation of lactic acid.

Imaging Assessment.

Chest x-rays can be helpful in diagnosing left ventricular failure. Typically the heart is enlarged (cardiomegaly), representing hypertrophy or dilation. Pleural effusions develop less often and generally reflect biventricular failure. *Echocardiography is considered the best tool in diagnosing heart failure.* Cardiac valvular changes, pericardial effusion, chamber enlargement, and ventricular hypertrophy can be diagnosed using this noninvasive technique. The test can also be used to determine ejection fraction.

Radionuclide studies (thallium imaging or technetium pyrophosphate scanning) can also indicate the presence and cause of HF. Multigated acquisition (MUGA) scans, also called multigated blood pool scans, provide information about left ventricular ejection fraction and velocity, which are typically low in patients with HF. These tests are discussed in Chapter 33.

Other Diagnostic Assessment.

An *electrocardiogram* (ECG) is also performed. It may show ventricular hypertrophy, dysrhythmias, and any degree of myocardial ischemia, injury, or infarction. However, it is *not* helpful in determining the presence or extent of HF.

Invasive hemodynamic monitoring allows the direct assessment of cardiac function and volume status in acutely ill patients. Although medical-surgical nurses do not manage these systems on general hospital units, they should be familiar with the interpretation of some of the major hemodynamic pressures as they relate to patient assessment. These measurements can confirm the diagnosis and guide the management of HF. For example, right atrial pressure is either normal or elevated in left ventricular failure and elevated in right ventricular failure. Pulmonary artery pressure (PAP) and pulmonary artery wedge pressure (PAWP) are elevated in left-sided HF because volumes and pressures are increased in the left ventricle. Hemodynamic monitoring is described in detail in Chapter 38.

Analysis

The priority NANDA-I nursing diagnoses and collaborative problems for patients with heart failure (HF) include:
1. Impaired Gas Exchange related to ventilation/perfusion imbalance (NANDA-I)
2. Decreased Cardiac Output related to altered contractility, preload, and afterload (NANDA-I)
3. Fatigue related to hypoxemia (NANDA-I)
4. Potential for pulmonary edema related to left-sided HF

Planning and Implementation

The patient-centered collaborative care that patients with HF need depends on their disease stage and severity of signs and symptoms. Be sure to individualize care based on the patient's values and preferences, your clinical expertise, and best current evidence.

Improving Gas Exchange

Planning: Expected Outcomes.

The expected outcome is that the patient will have an optimal spontaneous breathing pattern that increases gas exchange and oxygenation and maintains a serum carbon dioxide level that is within normal limits.

Interventions.

The purpose of collaborative care is to help promote gas exchange and oxygenation. *Ventilation assistance* may be needed because the oxygen content of the blood is often decreased in patients who have pulmonary congestion. Monitor or have assistive personnel monitor the patient's respiratory rate, rhythm, and quality every 1 to 4 hours. Auscultate breath sounds every 4 to 8 hours.

Nursing Safety Priority QSEN

Action Alert

Provide the necessary amount of supplemental oxygen within a range prescribed by the health care provider *to maintain oxygen saturation at 90% or greater.* If the patient has dyspnea, place him or her in a high-Fowler's position with pillows under each arm to maximize chest expansion and improve oxygenation. Repositioning and performing coughing and deep-breathing exercises every 2 hours help improve oxygenation and prevent atelectasis. Collaborate with the respiratory therapist, if available, to plan the most effective methods for assisting with ventilation.

Improving Cardiac Output

Planning: Expected Outcomes.

The expected outcome is that the patient will have increased cardiac output by improving stroke volume (SV) (determined by preload, afterload, and contractility) and heart rate (HR).

Interventions.

Collaborative care begins with nonsurgical interventions, but the patient may need surgery if these are not successful in meeting optimal outcomes.

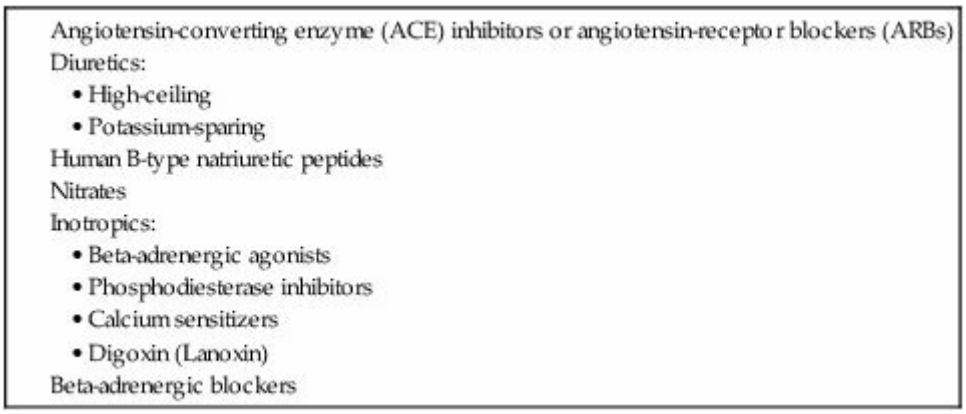
Nonsurgical Management.

Nonsurgical management relies primarily on a variety of drugs (Table 35-3). If drug therapy is ineffective, other nonsurgical options are available. Drugs to improve stroke volume include those that reduce afterload, reduce preload, and improve cardiac muscle contractility. A major role of the nurse is to give medications as prescribed, monitor for their therapeutic and adverse effects, and teach the patient and family about drug therapy. A variety of classes of drugs that reduce afterload and

preload are used to manage heart failure (see Table 35-3).

TABLE 35-3

Commonly Used Drug Classifications for Patients with Systolic Heart Failure



Drugs That Reduce Afterload.

By relaxing the arterioles, arterial vasodilators can reduce the resistance to left ventricular ejection (afterload) and improve CO. These drugs do not cause excessive vasodilation but reverse some of the inappropriate or excessive vasoconstriction common in HF.

Angiotensin-Converting Enzyme Inhibitors (ACEIs) and Angiotensin-Receptor Blockers (ARBs).

Patients with even mild heart failure (HF) resulting from left ventricular dysfunction are given a trial of ACE inhibitors or ARBs. Both ACE inhibitors (e.g., enalapril [Vasotec] and fosinopril [Monopril]) and ARBs (e.g., valsartan [Diovan], irbesartan [Avapro], and losartan [Cozaar]) improve function and quality of life for patients with HF. ACE inhibitors are the first-line drug of choice, but some health care providers prefer to start the patient on an ARB because ACE inhibitors can cause a nagging, dry cough. For patients with *acute* HF, the health care provider may prescribe an IV-push ACE inhibitor such as Vasotec IV.

The ACE inhibitors and ARBs suppress the renin-angiotensin system (RAS), which is activated in response to decreased renal blood flow. ACE inhibitors prevent conversion of angiotensin I to angiotensin II, resulting in arterial dilation and increased stroke volume. ARBs block the effect of angiotensin II receptors and thus decrease arterial resistance and arterial dilation. In addition, these drugs block aldosterone, which prevents sodium and water retention, thus decreasing fluid overload. *Both ACEIs and ARBs work more effectively for Euro-Americans than for African-American*

populations. Volume-depleted patients should receive a low starting dose, or the fluid volume should be restored before beginning the prescribed drug. Monitor for hyperkalemia, a potential adverse drug effect in patients who have renal dysfunction.

Nursing Safety Priority QSEN

Drug Alert

ACEIs and ARBs are started slowly and cautiously. The first dose may be associated with a rapid drop in blood pressure (BP). Patients at risk for hypotension usually have an initial systolic BP less than 100 mm Hg, are older than 75 years, have a serum sodium level less than 135 mEq/L, or are volume depleted. Monitor BP every hour for several hours after the initial dose and each time the dose is increased. Immediately report to the health care provider and document a systolic blood pressure of less than 90 mm Hg (or designated protocol level). If this problem occurs, place the patient flat and elevate legs to increase cerebral perfusion and promote venous return.

Assess for orthostatic hypotension, acute confusion, poor peripheral perfusion, and reduced urine output in patients with low systolic blood pressure. Monitor serum potassium and creatinine levels to determine renal dysfunction. Additional nursing implications for selected ACE inhibitor/ARB drugs are described in Chapter 38 on p. 766 in the Drug Therapy section.

Human B-type Natriuretic Peptides.

Human B-type natriuretic peptides (hBNPs) such as nesiritide (Natrecor) are often used to treat *acute* HF. Endogenous BNP is released in response to decreased CO and causes *natriuresis,* or loss of sodium in the renal tubules, as well as vasodilation. Natrecor lowers pulmonary capillary wedge pressure (PCWP) and improves renal glomerular filtration. It is given as an IV bolus over 60 seconds followed with a continuous infusion for up to 48 hours.

Nursing Safety Priority QSEN

Drug Alert

When giving Natrecor, monitor BP and pulse carefully because significant decreases in BP may occur. Although the patient's systolic BP

may be between 90 and 100 mm Hg, he or she is usually asymptomatic. *Give Natrecor through a separate infusion line because it is incompatible with heparin and most other parenteral medications.* Expect an increase in the serum BNP after drug administration.

Interventions That Reduce Preload.

Ventricular fibers contract less forcefully when they are overstretched, such as in a failing heart. Interventions aimed at reducing preload attempt to decrease volume and pressure in the left ventricle, increasing ventricular muscle stretch and contraction. Preload reduction is appropriate for HF accompanied by congestion with total body sodium and water overload.

Nutrition Therapy.

In HF, nutrition therapy is aimed at reducing sodium and water retention to decrease the workload of the heart. The primary care provider may restrict sodium intake in an attempt to decrease fluid retention. Many patients need to omit table salt (no added salt) from their diet, thus reducing sodium intake to about 3 g daily.

If salt intake must be reduced further, the patient may need to eliminate all salt in cooking and high-sodium foods (e.g., ham, bacon, pickles), thus reducing sodium intake to 2 g daily. If needed, collaborate with the dietitian to help the patient select foods that meet such a restricted therapeutic diet.

Few patients are placed on severe fluid restrictions. However, patients with excessive aldosterone secretion may experience thirst and drink 3 to 5 liters of fluid each day. As a result, their fluid intake may be limited to a more normal 2 liters daily. *Supervise unlicensed assistive personnel (UAP) to ensure that they limit the prescribed intake and accurately record intake and output.*

Weigh the patient daily, or delegate this activity to UAP and supervise that it is done. Keep in mind that *1 kg of weight gain or loss equals 1 liter of retained or lost fluid*. The same scale should be used every morning before breakfast for the most accurate assessment of weight. Monitor for an expected *decrease* in weight because excess fluid is excreted from the body.

Drug Therapy.

Common drugs prescribed to reduce preload are diuretics and venous vasodilators. *Morphine sulfate* is also given for patients in *acute* heart

failure to reduce anxiety, decrease preload and afterload, slow respirations, and reduce the pain associated with a myocardial infarction (MI).

The health care provider adds *diuretics* to the regimen when diet and fluid restrictions have not been effective in managing the symptoms of HF. Diuretics are the first-line drug of choice in older adults with HF and fluid overload. These drugs enhance the renal excretion of sodium and water by reducing circulating blood volume, decreasing preload, and reducing systemic and pulmonary congestion.

The type and dosage of diuretic prescribed depend on the severity of HF and renal function. High-ceiling (loop) diuretics, such as furosemide (Lasix, Furoside, Novosemide), torsemide (Demadex), and bumetanide (Bumex), are most effective for treating fluid volume overload.

Considerations for Older Adults

Patient-Centered Care QSEN

Loop diuretics continue to work even after excess fluid is removed. As a result, some patients, especially older adults, can become dehydrated. Observe for manifestations of dehydration in the older adult, especially acute confusion, decreased urinary output, and dizziness. Provide evidence-based interventions to reduce the risk for falls, as discussed in Chapter 2.

For those patients with *acute* HF, Lasix or Bumex can be administered by IV push (IVP). Lasix can be given in doses of 20 to 40 mg IVP and increased by 20 mg every 2 hours until the desired diuresis is obtained. The usual IVP initial dose for Bumex is 1 to 2 mg once or twice daily, but it is more often given in a continuous infusion of 10 mg over 24 hours.

The practitioner may initially use a thiazide diuretic, such as hydrochlorothiazide (HCTZ) (HydroDIURIL, Urozide) and metolazone (Zaroxolyn), for *older adults* with *mild* volume overload. Zaroxolyn is a long-acting agent and is therefore often given every second, third, or fourth day, depending on patient need and tolerance.

Unlike loop diuretics, the action of thiazides is self-limiting (i.e., diuresis decreases after edema fluid is lost). Therefore the dehydration that may occur with loop diuretics is not common with these drugs. Patients also prefer thiazides because of the gradual onset of diuresis.

As HF progresses, many patients develop diuretic resistance with refractory edema. The health care provider may choose to manage this

problem by prescribing both types of diuretics. Other strategies include IV continuous infusion of furosemide or bumetanide or rotating loop diuretics.

Monitor for and prevent potassium deficiency (hypokalemia) from diuretic therapy. The primary signs of hypokalemia are nonspecific neurologic and muscular symptoms, such as generalized weakness, depressed reflexes, and irregular heart rate. A potassium supplement may be prescribed for some patients. Other practitioners prescribe a potassium-sparing diuretic, such as spironolactone (Aldactone), for patients at risk for dysrhythmias from hypokalemia. Although not as effective as other diuretics, Aldactone helps retain potassium and thus decrease the risk for ventricular dysrhythmias and is usually used in stage III/IV heart failure. Monitor for hyperkalemia and renal failure if Aldactone inhibitors are utilized, and anticipate stopping the medication if potassium or creatinine levels rise.

Patients being managed with ACE inhibitors or ARBs and diuretics at the same time may not experience hypokalemia. However, if their kidneys are not functioning well, they may develop hyperkalemia (elevated serum potassium level). Review the patient's serum creatinine level. *If the creatinine is greater than 1.8 mg/dL, notify the health care provider before administering supplemental potassium.*

The health care provider may prescribe *venous vasodilators* (e.g., nitrates) for the patient with HF who has persistent dyspnea. Significant constriction of venous and arterial blood vessels occurs to compensate for reduced CO. Constriction reduces the volume of fluid that the vascular bed can hold and increases preload. Venous vasodilators may benefit by:

- Returning venous vasculature to a more normal capacity
- Decreasing the volume of blood returning to the heart
- Improving left ventricular function

Nitrates may be administered IV, orally, or topically. IV nitrates are used most often for *acute* HF. These drugs cause primarily venous vasodilation but also a significant amount of arteriolar vasodilation. Monitor the patient's blood pressure when starting nitrate therapy or increasing the dosage. Patients may initially report headache, but assure them that they will develop a tolerance to this effect and that the headache will cease or diminish. Acetaminophen (Tylenol, Exdol) can be given to help relieve discomfort.

Unfortunately, tolerance to the vasodilating effects develops when nitrates are given around-the-clock. To prevent this tolerance, the health care provider may prescribe at least one 12-hour nitrate-free period out of

every 24 hours (usually overnight). Nitrates such as isosorbide (Imdur, ISMO) are prescribed to provide nitrate-free periods and reduce the problem of tolerance. Chapter 38 discusses nitrates in more detail.

NCLEX Examination Challenge

Physiological Integrity

A client has been taking furosemide (Lasix) and valsartan (Diovan) for the past year. The hospital laboratory notifies the nurse that the client's serum potassium level is 6.2 mEq/L. What is the nurse's best action at this time?

A Assess the client's oxygen saturation level.
B Ask the laboratory to retest the potassium level.
C Give potassium as an IV infusion.
D Check the client's serum creatinine.

Drugs That Enhance Contractility.

Contractility of the heart can also be enhanced with drug therapy. Positive inotropic drugs are most commonly used, but vasodilators and beta-adrenergic blockers may also be administered. For *chronic* HF, low-dose beta blockers are most commonly used. Digoxin (Lanoxin) may be prescribed to improve symptoms, thereby decreasing dyspnea and improving functional activity. This older and long-used drug is not expensive. In some settings, nesiritide (Natrecor) may be administered for end-stage HF, although this drug is very expensive (see discussion of Natrecor for acute HF on p. 685).

Digoxin.

Although not as commonly used today, digoxin (Lanoxin, Novodigoxin), a cardiac glycoside, has been demonstrated to provide symptomatic benefits for patients in *chronic* heart failure (HF) with sinus rhythm and atrial fibrillation. Digoxin (sometimes called "dig") therapy reduces exacerbations of HF and hospitalizations when added to a regimen of ACE inhibitors or ARBs, beta blockers, and diuretics. However, it may increase mortality due to drug toxicity, especially in older adults.

The potential benefits of digoxin include:

- Increased contractility
- Reduced heart rate (HR)
- Slowing of conduction through the atrioventricular node
- Inhibition of sympathetic activity while enhancing parasympathetic

activity

Digoxin is erratically absorbed from the GI tract. Many drugs, especially antacids, interfere with its absorption. It is eliminated primarily by renal excretion. Older patients should be maintained on lower doses of the drug than younger patients.

Nursing Safety Priority QSEN

Drug Alert

Increased cardiac automaticity occurs with toxic digoxin levels or in the presence of hypokalemia, resulting in ectopic beats (e.g., premature ventricular contractions [PVCs]). Changes in potassium level, especially a decrease, cause patients to be more sensitive to the drug and cause toxicity.

The clinical manifestations of **digoxin toxicity** are often vague and nonspecific and include anorexia, fatigue, blurred vision, and changes in mental status, especially in older adults. Toxicity may cause nearly any dysrhythmia, but PVCs are most commonly noted. Assess for early signs of toxicity such as bradycardia and loss of the P wave on the ECG. Carefully monitor the apical pulse rate and heart rhythm of patients receiving digoxin.

The health care provider determines the desirable heart rate (HR) to achieve. Some health care providers prefer a rate between 50 and 60 beats per minute. Report the development of either an irregular rhythm in a patient with a previously regular rhythm or a regular rhythm in a patient with a previously irregular one. Monitor serum digoxin and potassium levels (hypokalemia potentiates digoxin toxicity) to identify toxicity. Older adults are more likely than other patients to become toxic because of decreased renal excretion.

Any drug that increases the workload of the failing heart also increases its oxygen requirement. Be alert for the possibility that the patient may experience angina (chest pain) in response to digoxin.

Other Inotropic Drugs.

Patients experiencing *acute* heart failure are candidates for IV drugs that increase contractility. For example, *beta-adrenergic agonists,* such as dobutamine (Dobutrex), are used for short-term treatment of *acute* episodes of HF. Dobutamine improves cardiac contractility and thus cardiac output and myocardial-systemic perfusion.

A more potent drug used for *acute* HF, milrinone (Primacor), functions

as a vasodilator/inotropic medication with phosphodiesterase activity. Also known as a *phosphodiesterase inhibitor,* this drug increases cyclic adenosine monophosphate (cAMP), which enhances the entry of calcium into myocardial cells to increase contractile function. Like the beta-adrenergic agonists, Primacor is given IV.

Levosimendan (Simdax) is a calcium-sensitizing medication and a positive inotropic drug. It appears to bind to troponin C in the heart muscle and therefore increases the contraction of the heart. Simdax is used most often in patients who have had or are at high risk for myocardial infarction. Chapter 38 discusses inotropic drugs in more detail.

NCLEX Examination Challenge

Physiological Integrity

An older adult taking digoxin and hydrochlorothiazide (HCTZ) for chronic heart failure is admitted to the emergency department (ED) with an apical pulse of 48. A family member states that the client has reported blurred vision and loss of appetite for 2 weeks. What is the nurse's first action?

A Call the ED physician immediately.
B Draw a serum digoxin level.
C Assess for signs of hypokalemia.
D Establish the client's airway.

Beta-Adrenergic Blockers.

Beta-adrenergic blockers (commonly referred to as "beta blockers") improve the condition of some patients in HF. Prolonged exposure to increased levels of sympathetic stimulation and catecholamines worsens cardiac function. Beta-adrenergic blockade reverses this effect, improving morbidity, mortality, and quality of life for patients in HF.

Beta blockers must be started slowly for HF. *Patients in acute HF should not be started on these drugs.* Carvedilol (Coreg), metoprolol succinate (Toprol XL), and bisoprolol (Zebeta) are approved for treatment of *chronic* HF. ***Do not confuse metoprolol tartrate with metoprolol succinate.*** Current guidelines only recommend the sustained-release formulation of metoprolol for chronic HF treatment. The first dose is extremely low. Monitor the patient either in the hospital or in the health care provider's office to assess for bradycardia or hypotension after the first dose is given.

Instruct the patient to weigh daily and to report any signs of worsening HF immediately. The health care provider gradually increases the drug dose if HF worsens. The patient is evaluated at least weekly for changes in BP, pulse, activity tolerance, and orthopnea. A modest drop in BP is acceptable if he or she remains asymptomatic and can stand without experiencing dizziness or a further drop in BP. The resting heart rate (HR) should remain between 55 and 60 and increase slightly with exercise. Activity tolerance improves, and less orthopnea is experienced. Most patients with mild and moderate HF demonstrate improved ejection fraction, decreased hospital admissions, and improvement in symptoms when beta blockers are added to their treatment regimens. The benefits of this therapy are seen over a long period rather than immediately.

For patients with *diastolic* HF, drug therapy has not been as effective. Calcium channel blockers, ACE inhibitors, and beta blockers have been used with various degrees of success.

Other Nonsurgical Options.

In addition to drug therapy, other nonsurgical options, both noninvasive and invasive, may be used and include:

- Continuous positive airway pressure (CPAP)
- Cardiac resynchronization therapy (CRT)
- Investigative gene therapy

Continuous positive airway pressure (CPAP) is a respiratory treatment that improves obstructive sleep apnea in patients with HF. It also improves cardiac output (CO) and ejection fraction (EF) by decreasing afterload and preload, blood pressure (BP), and dysrhythmias. Sleep apnea is directly correlated with coronary artery disease as a result of diminished oxygen supply to the heart during apneic episodes. This respiratory problem is discussed in detail in Chapter 29.

Cardiac resynchronization therapy (CRT), also called *biventricular pacing,* uses a permanent pacemaker alone or is combined with an implantable cardioverter/defibrillator. Electrical stimulation causes more synchronous ventricular contractions to improve EF, CO, and mean arterial pressure. This modality is indicated for patients with class III or IV HF and an EF of less than 35%. CRT improves the patient's ability to perform ADLs. Chapter 34 discusses pacing in more detail.

Gene therapy may be indicated for patients in end-stage HF who are not candidates for heart transplantation. This therapy replaces damaged genes with normal or modified genes by a series of injections of growth factor into the left ventricle. Although still investigative, this therapy

may result in improved exercise tolerance and regrowth of cardiac cells.

Surgical Management.

Heart transplantation is still the ultimate choice for end-stage HF (see discussion on p. 702). Several surgical procedures are available to improve CO in patients who are *not* candidates for a transplant or are awaiting transplant.

Ventricular Assist Devices.

Patients with debilitating end-stage heart failure are often sent home on drug therapy and referred to hospice. However, ventricular assist devices (VADs) can dramatically improve the lives of many patients. In this procedure, a mechanical pump is implanted to work with the patient's own heart (Fig. 35-2). Both left and right VADs are available, depending on the type of heart failure the patient has. Those with end-stage kidney disease, severe chronic lung disease, clotting disorders, and infections that do not respond to antibiotics are not candidates for this surgery. Postoperative complications include bleeding, infective endocarditis, ventricular dysrhythmias, and stroke. Nursing care is similar to that described for cardiac surgery in Chapter 38.

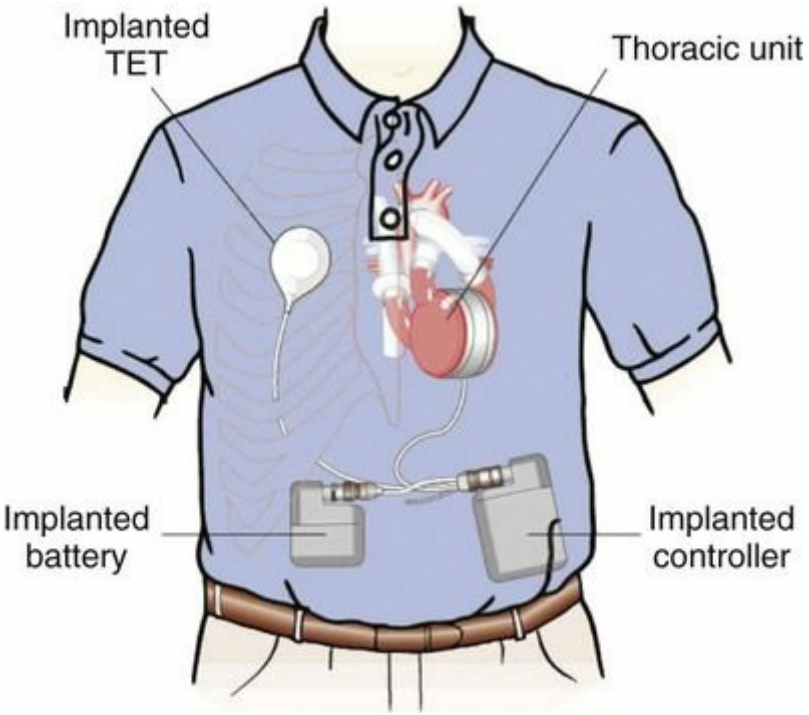


FIG. 35-2 The AbioCor Implantable Replacement Heart has four main parts that are placed inside the body. *TET,* Transtelephonic electrocardiographic transmission device.

Ventricular assist devices can be used short-term while awaiting heart transplantation (a "bridge-to-transplant" procedure) or long-term (destination therapy). Most patients survive with a VAD until a transplant is available. The evidence shows that patients who have long-term devices live longer and have an improved quality of life (Rogers et al., 2010).

Other Surgical Therapies.

Heart failure causes ventricular remodeling, or dilation, which worsens as the disease progresses. Several new therapies are used to reshape the left ventricle in patients with HF. Perioperative care is similar to that for the patient having a coronary artery bypass graft (CABG) (see Chapter 38). The most common ventricular reconstructive procedures include:

- **Partial left ventriculectomy (PLV)**
- Endoventricular circular patch cardioplasty
- Acorn cardiac support device
- Myosplint

Also known as *heart reduction surgery,* PLV (sometimes referred to as the *Batista procedure*) involves removing a triangle-shaped section of the weakened heart in the left lateral ventricle to reduce the ventricle's diameter and decrease wall tension. In *endoventricular circular patch cardioplasty,* the surgeon removes portions of the cardiac septum and left ventricular wall and grafts a circular patch (synthetic or autologous) into the opening. This procedure provides a more normal shape to the left ventricle to improve the heart's ejection fraction (EF) and cardiac output (CO).

The **Acorn cardiac support device** is a polyester mesh jacket that is placed over the ventricles to provide support and to avoid overstretching the myocardial muscle. The material for the jacket has been used for other procedures, such as vascular grafts. The jacket appears to reduce hypertrophy of the heart muscle and assists with improvement of the EF.

The **Myosplint** has recently been approved for use in the United States. Electrical stimulation of several tension pads (splints) on the outside of the ventricle changes it to a more normal shape to improve function.

Decreasing Fatigue

Planning: Expected Outcomes.

The expected outcome is that the patient will have decreased fatigue and will gain energy as heart failure improves.

Interventions.

The patient in severe heart failure initially requires physical and emotional rest for *energy management.* On the first day of hospitalization, he or she may sit up in a chair for meals and perform basic leg exercises while out of bed. Organize nursing care to allow periods of rest. Collaborate with the interdisciplinary team to observe and document the patient's physiologic response to activity.

As the patient's condition improves, the physical therapist (PT) starts ambulation, usually on hospital day 2. The PT or nurse checks the BP, pulse, and oxygen saturation before and after the activity. A BP change of more than 20 mm Hg or a pulse increase of more than 20 beats per minute may indicate that the activity is too stressful. Other indications of activity intolerance include dyspnea, fatigue, and chest pain. Ask a patient having any of these symptoms to rate how hard he or she has been working on a scale of 1 to 20, with 20 being the maximum perceived exertion. If the patient rates the exertion more than 12, remind him or her to slow down. If activity is tolerated, the PT steadily increases the activity level until the patient is ambulating 200 to 400 feet several times per day.

If the patient is able, the PT (or assistive nursing or PT personnel) might time him or her for 6 minutes while walking at a comfortable pace. The distance the patient can walk can be used to determine his or her functional level and activity plan.

Preventing or Managing Pulmonary Edema

Planning: Expected Outcomes.

The most desirable outcome is that the patient will not develop pulmonary edema as a result of heart failure (HF). However, if the patient progresses to pulmonary edema, the expected outcome is that he or she will recover from this complication without other problems.

Interventions.

Monitor for manifestations of acute pulmonary edema, a life-threatening event that can result from severe HF (with fluid overload), acute myocardial infarction (MI), mitral valve disease, and possibly dysrhythmias. In pulmonary edema, the left ventricle fails to eject sufficient blood and pressure increases in the lungs as a result. The increased pressure causes fluid to leak across the pulmonary capillaries and into the lung airways and tissues.

Nursing Safety Priority QSEN

Critical Rescue

Assess for and report early manifestations, such as crackles in the lung bases, dyspnea at rest, disorientation, and confusion, especially in older patients. Document the precise location of the crackles because the level of the fluid progresses from the bases to higher levels in the lungs when the condition worsens. The patient in acute pulmonary edema is also typically extremely anxious, tachycardic, and struggling for air. As pulmonary edema becomes more severe, he or she may have a moist cough productive of frothy, blood-tinged sputum and his or her skin may be cold, clammy, or cyanotic. Chart 35-3 lists the major clinical manifestations of this complication.

Chart 35-3 Key Features

Pulmonary Edema

- Crackles
- Dyspnea at rest
- Disorientation or acute confusion (especially in older adults as early symptom)
- Tachycardia
- Hypertension or hypotension
- Reduced urinary output
- Cough with frothy, pink-tinged sputum
- Premature ventricular contractions and other dysrhythmias
- Anxiety
- Restlessness
- Lethargy

The patient diagnosed with pulmonary edema is admitted to the acute care hospital, often in a critical care unit. Reassure the patient and family that his or her distress will decrease with proper management.

Nursing Safety Priority QSEN

Critical Rescue

If the patient is not hypotensive, place him or her in a sitting (high-Fowler's) position with his or her legs down to decrease venous return to

the heart. The *priority nursing action* is to administer high-flow oxygen therapy at 5 to 6 L/min by facemask or at 10 to 15 L/min by non-rebreather mask with reservoir (which may deliver up to 100% oxygen) to promote gas exchange and perfusion. Apply a pulse oximeter, and titrate the oxygen flow to keep the patient's oxygen saturation above 90%. If supplemental oxygen does not resolve the patient's respiratory distress, collaborate with the respiratory therapist, physician, advanced practice nurse, or physician assistant for more aggressive therapy, such as continuous positive airway pressure (CPAP) or bi-level positive airway pressure (BiPAP) ventilation. Intubation and mechanical ventilation may be needed for some patients.

If the patient's systolic blood pressure is above 100, give sublingual nitroglycerin (NTG) to decrease afterload and preload every 5 minutes for three doses while establishing IV access for additional drug therapy. The health care provider prescribes rapid-acting diuretics, such as Lasix or Bumex. Give Lasix IV push (IVP) over 1 to 2 minutes, usually at a starting dose of 20 to 40 mg for diuretic-naive patients, and another 40 mg if needed in 30 minutes. Patients already on oral diuretic therapy should be given an amount that is the same or doubled in milligrams as initial IV diuretic therapy. Administer each increment of 40 mg of Lasix over 1 to 2 minutes to avoid ototoxicity. Bumex may be administered 1 to 2 mg IVP or as a continuous infusion to provide consistent fluid removal over 24 hours. Monitor vital signs frequently, at least every 30 to 60 minutes.

If the patient's blood pressure is adequate, IV morphine sulfate may be prescribed, 1 to 2 mg at a time, to reduce venous return (preload), decrease anxiety, and reduce the work of breathing. Monitor respiratory rate and BP closely. Other drugs, such as IV NTG and drugs to treat HF, may be administered. Monitor the patient's vital signs closely (especially BP) while these drugs are being given.

In severe cases of fluid overload and renal dysfunction or diuretic resistance, ultrafiltration may be used. The benefits of ultrafiltration include:

- Decrease in cardiac filling pressures
- Decrease in pulmonary arterial pressure
- Increase in cardiac index
- Reduction in norepinephrine, rennin, and aldosterone

Ultrafiltration can remove up to 500 mL/hr and uses a blood flow rate of 10 to 40 mL/hr. Peripheral lines are used for IV access. See Chapter 68 for discussion of this procedure and nursing implications.

Clinical Judgment Challenge

Safety; Patient-Centered Care; Evidence-Based Practice; Informatics QSEN

A 71-year-old man is admitted to the telemetry unit with right-sided heart failure, type 2 diabetes mellitus, hypertension, and COPD. He is married but has no children. During your assessment, you observe that his color is pale, he is dyspneic, and he reports new onset of chest discomfort. Even though he has oxygen via nasal cannula at 2 L/min., you note that he seems a little confused and is oriented only to person. His oxygen saturation has decreased from 95% to 88%.

1. What lung sounds do you expect to hear and why?
2. What evidence-based actions will you plan to implement at this time based on your observations? What is the source of the evidence?
3. The patient's physician prescribes an initial dose of furosemide (Lasix) 40 mg IVP. What assessments will you perform to determine if the drug was effective?
4. What will you tell the patient's wife about his condition at this time? Should the patient's wife be present during his emergency treatment? Why or why not?
5. After two doses of Lasix, the patient's condition improves. What data will you document in the electronic medical record (EMR)?

Community-Based Care

Patients who are not adequately prepared for discharge or do not have adequate community support and follow-up for self-management are at high risk for repeated hospital admissions for heart failure. Collaborate with the case manager or care coordinator to assess the patient's needs for health care resources.

The Heart Failure Core Measure Set must be determined for hospitals accredited by The Joint Commission. These measures include that the patient with heart failure has:

- Discharge instructions (including information on diet, activity, medications, weight monitor, and plan for worsening symptoms)
- Evaluation of left ventricular systolic function
- An ACEI or ARB for left ventricular systolic dysfunction
- Adult smoking-cessation advice/counseling (if appropriate)

An inability to obtain help in activities such as food shopping and obtaining medications is a major contributor to hospital readmission. If home support is available, the patient may be discharged home in the

care of a family member or other caregiver. Home care nurses may direct the care and assess for adherence to the discharge plan; home health aides may provide assistance with ADLs for a short time. If the patient has multiple health problems or has been severely compromised by heart disease, he or she may require admission to a skilled unit for either transitional or long-term care.

Home Care Management.

The focus of the home care nurse's interventions is assessment and health teaching, which are reimbursable by Medicare and other third-party payers. Chart 35-4 lists the major areas of home health assessment.

Chart 35-4 Home Care Assessment

The Patient with Heart Failure

Assess for signs of heart failure, including:

- Changes in vital signs (heart rate >100 beats/min at rest, new atrial fibrillation, blood pressure <90 or >150 systolic)
- Indications of poor tissue perfusion:
  - Fatigue
  - Angina
  - Activity intolerance
  - Changes in mental status
  - Pallor or cyanosis
  - Cool extremities
- Indications of congestion:
  - Presence of cough or dyspnea
  - Weight gain
  - Jugular venous distention and peripheral edema

Assess functional ability, including:

- Performance of ADLs
- Mobility and ambulation (review frequency and duration of walking, development of symptoms, and pulse rate)
- Cognitive ability

Assess nutritional status, including:

- Food and fluid intake
- Intake of sodium-rich foods
- Alcohol consumption
- Skin turgor

Assess home environment, including:

• Safety hazards, especially related to oxygen therapy
• Structural barriers affecting functional ability
• Social support (family, home health services)

Assess the patient's adherence and understanding of illness and its treatment, including:

• Signs and symptoms to report to health care provider
• Dosages, effects, and side or toxic effects of medications
• When to report for laboratory and health care provider visits
• Ability to accurately weigh self on scale
• Presence of advance directive
• Use of home oxygen, if appropriate

Assess patient and caregiver coping skills

Patients with chronic HF need to make many adjustments in their lifestyles. They must adhere to the collaborative plan of care that includes dietary restrictions, activity, prescriptions, and drug therapy. They need careful, concise explanations of the self-management plan. The community-based nurse in any setting encourages the patient to verbalize fears and concerns about his or her illness and assists in exploring coping skills. Patient participation in self-management can help alleviate and control symptoms.

Self-Management Education.

Health teaching is essential for promoting self-management (also called *self-care*). Many patients are re-admitted to hospitals because they do not maintain their prescribed treatment plan, including lifestyle changes. Because of the need for extensive discharge instructions, most hospitals are using teaching packets with videos, CDs, and easy-to-read information about the importance of adhering to specific self-management strategies at home. One standardized and commonly used self-management plan called *MAWDS* is outlined in Table 35-4. Medication reconciliation is also important to be sure that similar drugs are not being prescribed and that patients meet the Core Measure requirements for HF. It is important to perform a learning needs assessment and tailor education to the patient's particular need to see changes in behavior and improved outcomes (see the Evidence-Based Practice box).

TABLE 35-4

Heart Failure Self-Management Health Teaching (MAWDS)

Medications:
- Take medications as prescribed, and do not run out.
- Know the purpose and side effects of each drug.
- Avoid NSAIDs to prevent sodium and fluid retention.

Activity:
- Stay as active as possible, but don't overdo it.
- Know your limits.
- Be able to carry on a conversation while exercising.

Weight:
- Weigh each day at the same time on the same scale to monitor for fluid retention.

Diet:
- Limit daily sodium intake to 2 to 3 grams as prescribed.
- Limit daily fluid intake to 2 liters.

Symptoms:
- Note any new or worsening symptoms, and notify the health care provider immediately.

Evidence-Based Practice QSEN

What is the Most Effective Education Method to Provide Heart Failure Education to Heart Failure Patients?

Boyde, M., Turner, C., Thompson, D., & Stewart, S. (2011). Educational interventions for patients with heart failure: A systematic review of randomized controlled trials. *Journal of Cardiovascular Nursing, 26*(4), E27-E35.

The purpose of this meta-analysis research was to determine the most effective educational interventions provided by nurses to improve outcomes of the heart failure population. Randomized control trials from CINAHL, MEDLINE, PsycINFO, EMBASE, and Cochrane between the years 1998 and 2008 were identified. A total of 1515 abstracts were reviewed by two independent reviewers, and a total of 19 met inclusion criteria. To be included, studies needed to have evaluation of a specific education intervention or learning activity. Interventions studied included one-on-one didactic education, video, interactive CDs, TV programs, and mailings. Although it is acknowledged that patients have different learning styles, only four studies provided learning needs assessment. The ultimate goal was not only to improve the knowledge base but also to change patient behavior and improve outcomes. Of the 19 studies, 8 evaluated self-care in which 7 showed significant improvements in self-care after intervention. Re-admission rates were evaluated in 13 studies; 4 showed decreased rates of admission, and 3 showed decreased death rates. Various outcomes were measured, and 15

studies were able to demonstrate statistically significant changes in outcomes related to the education initiative.

Level of Evidence: 1

The researchers used a systematic review of randomized controlled trials.

Commentary: Implications for Practice and Research

Gaining knowledge does not equate to a change in behavior and, therefore, improved outcomes. To impart knowledge, a learning needs assessment must be performed before tailoring an education program for the patient. It is not enough to measure the amount of knowledge transmitted; changes in behavior and outcomes need to be the endpoint of studies related to nursing education.

Ambulatory care clinics for heart failure patients are also becoming increasingly common. Their purpose is to offer assessments, drug therapy, and health teaching. Some nurses specialize in caring for patients with health failure.

Activity Schedule.

Encourage patients with heart failure to stay as active as possible and to develop a regular exercise regimen (e.g., home walking program). However, teach the patient not to overdo it. Medicare and third-party payers typically do not reimburse for cardiac rehabilitation for HF. Paying for a cardiac rehabilitation program out of pocket is expensive.

Remind patients with persistent crackles and uncontrolled edema to begin exercise after their condition stabilizes. When exercise is indicated, teach the patient to begin walking 200 to 400 feet per day. At home the patient should try to walk at least 3 times a week and should slowly increase the amount of time walked over several months. If chest pain or severe dyspnea occurs while exercising or the patient has fatigue the next day, he or she is probably advancing the activity too quickly and should slow down. Encourage him or her to keep a diary that documents the time and duration of each exercise session, as well as HR and any symptoms that occur with exercise.

Indications of Worsening or Recurrent Heart Failure.

Many patients who are re-admitted to hospitals for treatment of HF fail to seek medical attention promptly when symptoms recur.

Nursing Safety Priority QSEN

Action Alert

Per the HF Core Measure for discharge instructions, teach the patient and caregiver to immediately report to the health care provider the occurrence of *any* of these symptoms, which could indicate worsening or recurrent heart failure:

- Rapid weight gain (3 lb in a week or 1 to 2 lb overnight)
- Decrease in exercise tolerance lasting 2 to 3 days
- Cold symptoms (cough) lasting more than 3 to 5 days
- Excessive awakening at night to urinate
- Development of dyspnea or angina at rest or worsening angina
- Increased swelling in the feet, ankles, or hands

Drug Therapy.

Provide oral, written, and video instructions about the drug regimen. Teach the caregiver and patient how to count a pulse rate, especially if the patient is on digoxin or beta blockers. Chart 35-5 lists instructions for the patient taking either of these drugs at home.

Chart 35-5 Patient and Family Education: Preparing for Self-Management

Beta Blocker/Digoxin Therapy

- Establish same time of day to take this medication every day.
- Continue taking this medication unless your health care provider tells you to stop.
- Do not take digoxin at the same time as antacids or cathartics (laxatives).
- Take your pulse rate before taking each dose of digoxin. Notify your health care provider of a change in pulse rate (60 to 100 beats/min is typically normal, depending on your baseline pulse rate) or rhythm, as well as increasing fatigue, muscle weakness, confusion, or loss of appetite (signs of digoxin toxicity).
- If you forget to take a dose, it may be delayed a few hours. However, if you do not remember it until the next day, you should take only your usual daily dose.
- Report for scheduled laboratory tests (e.g., potassium and digoxin levels).

- If potassium supplements are prescribed, continue the dose until told to stop by your health care provider.

Advise the patient taking diuretics to take them in the morning to avoid waking during the night for voiding. After determining whether he or she has a weight scale and can use it, emphasize the importance of weighing each morning at the same time. Daily weights indicate whether the patient is losing or retaining fluid. Some patients are taught to use a sliding scale to adjust their daily diuretic dose depending on their daily weight, similar to the way a diabetic patient adjusts an insulin dose based on the capillary glucose level.

Teach patients taking ACEIs or ARBs to move slowly when changing positions, especially from a lying to a sitting position. Remind them to report dizziness, light-headedness, and cough to the health care provider.

Serum potassium level and renal function are monitored at least every few months for patients taking diuretics and ACE inhibitors or ARBs. Diuretics, especially loop diuretics such as Lasix and Bumex, deplete potassium and often cause hypokalemia. Conversely, ACE inhibitors, ARBs, or potassium-sparing diuretics may result in potassium retention. If serum potassium levels drop below 4.0 mEq/L, the health care provider may prescribe potassium supplements or add a potassium-sparing diuretic such as spironolactone (Aldactone) or eplerenone (Inspra). Provide information about potassium-rich foods to include in the diet for patients at risk for hypokalemia (see Chapter 11).

Nutrition Therapy.

Remind patients with chronic HF to restrict their dietary sodium. In collaboration with the home care nurse or dietitian, provide written instructions on low- or restricted-sodium diets. A 3-g sodium diet is recommended for *mild to moderate* disease. Remind the patient to avoid salty foods and table salt. Patients usually find this diet acceptable and fairly easy to follow.

A 2-g sodium diet may be needed for patients with *severe* HF. They should not add salt during or after meal preparation, avoid milk and milk products, use few canned or prepared foods, and read food labels to determine sodium content. This diet is not easily tolerated for many patients, and the cost of low-sodium foods can be a financial burden.

Commercial salt substitutes typically contain potassium. Teach patients that their renal status and serum potassium level must be evaluated while using these products. Suggest that patients try lemon, spices, and herbs to enhance the flavor of low-salt foods.

Advance Directives.

About 50% of deaths from HF are sudden—many without any warning or worsening of symptoms. Assess whether the patient has written advance directives. If not, provide information about them during his or her hospital stay. Because most of these deaths occur at home, it is important for the health care provider or home care nurse to discuss advance directives with the patient and family. The family should be prepared to act in agreement with the patient's wishes in the event of cardiac arrest. If resuscitation is desired, be sure that the family knows how to activate the emergency medical system (EMS) and how to provide cardiopulmonary resuscitation (CPR) until an ambulance arrives. If CPR is not desired, the patient, family, and nurse plan how the family will respond. For some patients with end-stage disease, hospice care is an option. Chapter 7 discusses hospice and end-of-life care in detail.

Health Care Resources.

A home care nurse, ambulatory care clinic, or nurse-led follow-up program may be needed to assess the patient's adherence to drug and nutrition therapy and to monitor for worsening or recurrent HF. Many large hospitals use follow-up telephone calls or teleconferencing/videoconferencing devices to monitor patients at home. Teleconferencing can also assess the patient's heart and lung sounds. These follow-up processes have been very successful in decreasing repeated hospital stays for chronic HF patients.

In addition to home care support, other resources are available for patient education and family support. The American Heart Association is an excellent community resource for print and electronic pamphlets, books, newsletters, and videotapes or DVDs related to HF and heart disease. The organization also provides referrals to various local support groups for patients and their caregivers.

For equipment needs (e.g., home oxygen therapy, hospital bed), medical supply companies provide setup and maintenance services. Chapter 30 provides a detailed description of home oxygen therapy.

Clinical Judgment Challenge

Quality Improvement; Informatics QSEN

At a recent staff meeting, the medical-surgical nurse manager reports that the rate of repeated hospitalizations for patients with chronic heart failure has increased 50% in the past 3 months. As a staff nurse, you

agree to be part of the unit quality improvement (QI) team to examine the cause(s) of the increase and make evidence-based recommendations for improving the outcomes for this patient population. Specific patient data and summaries are available for the team to review as needed.

1. Where will your team begin with this process during the first meeting of the team?
2. Formulate a PICOT clinical question using the format described in Chapter 5.
3. What Internet sites will your team use to determine best practices for decreasing repeated hospital stays and why?
4. How will your team interpret and use the evidence that you obtain? (See Chapter 5 for assistance.)
5. After your team assembles and analyzes the evidence to determine best practices, what will be done with the information?
6. How will you know if the plan of action to improve care was effective?

Evaluation: Outcomes

Evaluate the care of the patient with HF on the basis of the identified patient problems. The expected outcomes include that the patient will:

- Have adequate pulmonary tissue perfusion
- Have increased cardiac pump effectiveness
- Take actions to manage energy
- Be free of pulmonary edema

Valvular Heart Disease

Pathophysiology

Acquired valvular dysfunctions include mitral stenosis, mitral regurgitation, mitral valve prolapse, aortic stenosis, and aortic regurgitation (Chart 35-6). The tricuspid valve is not affected often and may occur following endocarditis in IV drug abusers.

Chart 35-6 Key Features

Valvular Heart Disease

MITRAL STENOSIS	MITRAL REGURGITATION	MITRAL VALVE PROLAPSE	AORTIC STENOSIS	AORTIC REGURGITATION
Fatigue Dyspnea on exertion Orthopnea Paroxysmal nocturnal dyspnea Hemoptysis Hepatomegaly Neck vein distention Pitting edema Atrial fibrillation Rumbling, apical diastolic murmur	Fatigue Dyspnea on exertion Orthopnea Palpitations Atrial fibrillation Neck vein distention Pitting edema High-pitched holosystolic murmur	Atypical chest pain Dizziness, syncope Palpitations Atrial tachycardia Ventricular tachycardia Systolic click	Dyspnea on exertion Angina Syncope on exertion Fatigue Orthopnea Paroxysmal nocturnal dyspnea Harsh, systolic crescendo-decrescendo murmur	Palpitations Dyspnea Orthopnea Paroxysmal nocturnal dyspnea Fatigue Angina Sinus tachycardia Blowing, decrescendo diastolic murmur
				

Mitral Stenosis

Mitral stenosis usually results from rheumatic carditis, which can cause valve thickening by fibrosis and calcification. Rheumatic fever is the most common cause of the problem. In more developed nations, congenital anomalies affect the majority of patients with mitral stenosis (Ray, 2010).

In mitral stenosis, the valve leaflets fuse and become stiff and the chordae tendineae contract and shorten. The valve opening narrows, preventing normal blood flow from the left atrium to the left ventricle. As a result of these changes, left atrial pressure rises, the left atrium dilates, pulmonary artery pressures increase, and the right ventricle hypertrophies.

Pulmonary congestion and right-sided heart failure occur first. Later, when the left ventricle receives insufficient blood volume, preload is decreased and cardiac output (CO) falls.

People with mild mitral stenosis are usually asymptomatic. As the valvular orifice narrows and pressure in the lungs increases, the patient experiences dyspnea on exertion, orthopnea, paroxysmal nocturnal dyspnea (sudden dyspnea at night), palpitations, and dry cough.

Hemoptysis (coughing up blood) and pulmonary edema occur as pulmonary hypertension and congestion progress. Right-sided HF can cause hepatomegaly (enlarged liver), neck vein distention, and pitting dependent edema late in the disorder.

On palpation, the pulse may be normal, rapid, or irregularly irregular (as in atrial fibrillation). Because the development of atrial fibrillation indicates that the patient may decompensate, the physician should be notified immediately of the development of an irregularly irregular rhythm. A rumbling, apical diastolic murmur is noted on auscultation.

Mitral Regurgitation (Insufficiency)

The fibrotic and calcific changes occurring in **mitral regurgitation** (insufficiency) prevent the mitral valve from closing completely during *systole*. Incomplete closure of the valve allows the backflow of blood into the left atrium when the left ventricle contracts (Ray, 2010). During *diastole*, regurgitant output again flows from the left atrium to the left ventricle along with the normal blood flow. The increased volume must be ejected during the next systole. To compensate for the increased volume and pressure, the left atrium and ventricle dilate and hypertrophy.

The primary causes of mitral regurgitation are "degenerative" due to aging and infective endocarditis (Ray, 2010). Other causes include papillary muscle dysfunction or rupture resulting from ischemic heart disease or congenital anomalies. Rheumatic heart disease is the number-one cause in developing nations. When it results from rheumatic heart disease, it usually coexists with some degree of mitral stenosis; it affects women more often than men.

Mitral regurgitation usually progresses slowly; patients may remain symptom-free for decades. Symptoms begin to occur when the left ventricle fails in response to chronic blood volume overload. They include fatigue and chronic weakness as a result of reduced cardiac output (CO). Dyspnea on exertion and orthopnea develop later. A significant number of patients report anxiety, atypical chest pains, and palpitations. Assessment may reveal normal BP, atrial fibrillation, or changes in respirations characteristic of left ventricular failure.

When right-sided HF develops, the neck veins become distended, the liver enlarges (hepatomegaly), and pitting edema develops. A high-pitched systolic murmur at the apex, with radiation to the left axilla, is heard on auscultation. Severe regurgitation often exhibits a third heart sound (S_3).

Mitral Valve Prolapse

Mitral valve prolapse (MVP) occurs because the valvular leaflets enlarge and prolapse into the left atrium during systole. This abnormality is usually benign but may progress to pronounced mitral regurgitation in some patients.

The etiology of MVP is variable and has been associated with conditions such as Marfan syndrome and other congenital cardiac defects. MVP also has a familial tendency. Usually, however, no other cardiac abnormality is found.

Most patients with MVP are asymptomatic. However, some may report chest pain, palpitations, or exercise intolerance. Chest pain is usually atypical with patients describing a sharp pain localized to the left side of the chest. Dizziness, **syncope** ("blackouts"), and palpitations may be associated with atrial or ventricular dysrhythmias.

A normal heart rate and BP are usually found on physical examination. A midsystolic click and a late systolic murmur may be heard at the apex of the heart. The intensity of the murmur is not related to the severity of the prolapse.

Aortic Stenosis

Aortic stenosis is the most common cardiac valve dysfunction in the United States and is often considered a disease of "wear and tear." In **aortic stenosis,** the aortic valve orifice narrows and obstructs left ventricular outflow during systole. This increased resistance to ejection or afterload results in ventricular hypertrophy. As stenosis worsens, cardiac output becomes fixed and cannot increase to meet the demands of the body during exertion. Symptoms then develop. Eventually the left ventricle fails, blood backs up in the left atrium, and the pulmonary system becomes congested. Right-sided HF can occur late in the disease. *When the surface area of the valve becomes 1 cm or less, surgery is indicated on an urgent basis!*

Congenital bicuspid or unicuspid aortic valves are the primary causes for aortic stenosis in many patients. Rheumatic aortic stenosis occurs with rheumatic disease of the mitral valve and develops in young and middle-aged adults. Atherosclerosis and degenerative calcification of the aortic valve are the major causative factors in older adults. *Aortic stenosis has become the most common valvular disorder in all countries with aging populations.*

The classic symptoms of aortic stenosis result from fixed cardiac output: dyspnea, angina, and syncope occurring on exertion. When cardiac output falls in the late stages of the disease, the patient

experiences marked fatigue, debilitation, and peripheral cyanosis. A narrow pulse pressure is noted when the BP is measured. A diamond-shaped, systolic crescendo-decrescendo murmur is usually noted on auscultation.

Aortic Regurgitation (Insufficiency)

In patients with **aortic regurgitation,** the aortic valve leaflets do not close properly during diastole and the *annulus* (the valve ring that attaches to the leaflets) may be dilated, loose, or deformed. This allows flow of blood from the aorta back into the left ventricle during diastole. The left ventricle, in compensation, dilates to accommodate the greater blood volume and eventually hypertrophies.

Aortic insufficiency usually results from nonrheumatic conditions such as infective endocarditis, congenital anatomic aortic valvular abnormalities, hypertension, and Marfan syndrome (a rare, generalized, systemic disease of connective tissue).

Patients with aortic regurgitation remain asymptomatic for many years because of the compensatory mechanisms of the left ventricle. As the disease progresses and left ventricular failure occurs, the major symptoms are exertional dyspnea, orthopnea, and paroxysmal nocturnal dyspnea. Palpitations may be noted with severe disease, especially when the patient lies on the left side. Nocturnal angina with diaphoresis often occurs.

On palpation, the nurse notes a "bounding" arterial pulse. The pulse pressure is usually widened, with an elevated systolic pressure and diminished diastolic pressure. The classic auscultatory finding is a high-pitched, blowing, decrescendo diastolic murmur.

Patient-Centered Collaborative Care

Assessment

A patient with valvular disease may suddenly become ill or slowly develop symptoms over many years. Collect information about the patient's family health history, including valvular or other forms of heart disease to which he or she may be genetically predisposed. Question about attacks of rheumatic fever and infective endocarditis, the specific dates when these occurred, and the use of antibiotics to prevent recurrence of these diseases. Also question the patient about a history of IV drug abuse, a common cause of infective endocarditis. Discuss the patient's fatigue level and tolerated activity level, the presence of angina or dyspnea, and the occurrence of palpitations, if present.

As part of the physical assessment, obtain vital signs, inspect for signs of edema, palpate and auscultate the heart and lungs, and palpate the peripheral pulses. Assessment findings are summarized in Chart 35-6.

Echocardiography is the noninvasive diagnostic procedure of choice to visualize the structure and movement of the heart. The more invasive transesophageal echocardiography (TEE) or transthoracic echocardiography (TTE) is also performed to assess most valve problems. Exercise tolerance testing (ETT) and stress echocardiography are sometimes done to evaluate symptomatic response and assess functional capacity. With either mitral or aortic stenosis, cardiac catheterization may be indicated to assess the severity of the stenosis and its other effects on the heart.

In patients with mitral stenosis, the chest x-ray shows left atrial enlargement, prominent pulmonary arteries, and an enlarged right ventricle. In those with mitral regurgitation (insufficiency), the chest x-ray reveals an increased cardiac shadow, indicating left ventricular and left atrial enlargement.

In the later stages of aortic stenosis, the chest x-ray may show left ventricular enlargement and pulmonary congestion. Left atrial and left ventricular dilation appear on the chest x-ray of patients with aortic regurgitation (insufficiency). If HF is present, pulmonary venous congestion is also evident.

The health care provider also requests an ECG to assess abnormalities such as left ventricular hypertrophy, as seen with mitral regurgitation and aortic regurgitation, or right ventricular hypertrophy, as seen in severe mitral stenosis. Atrial fibrillation is a common finding in both mitral stenosis and mitral regurgitation and may develop in aortic stenosis because of left atrial dilation.

Interventions

Management of valvular heart disease depends on which valve is affected and the degree of valve impairment. Some patients can be managed with yearly monitoring and drug therapy, whereas others require invasive procedures or heart surgery.

Nonsurgical Management.

Nonsurgical management focuses on drug therapy and rest. During the course of valvular disease, left ventricular failure with pulmonary or systemic congestion may develop.

Drug Therapy.

Diuretics, beta blockers, digoxin, and oxygen are often administered to improve the symptoms of heart failure. Nitrates are administered cautiously to patients with aortic stenosis because of the potential for syncope associated with a reduction in left ventricular volume (preload). Vasodilators such as calcium channel blockers may be used to reduce the regurgitant flow for patients with aortic or mitral stenosis.

Nursing Safety Priority QSEN

Drug Alert

Teach patients with valve disease the importance of prophylactic antibiotic therapy before any invasive dental or respiratory procedure. Prophylactic antibiotics are *not* recommended prior to gastrointestinal procedures such as upper GI endoscopy, colonoscopy, or procedures requiring genitourinary instrumentation.

A major concern in valvular heart disease is maintaining cardiac output if atrial fibrillation develops. With mitral valvular disease, left ventricular filling is especially dependent on atrial contraction. When atrial fibrillation develops, there is no longer a single coordinated atrial contraction. Cardiac output can decrease, and HF may occur. Ineffective atrial contraction may also lead to the stasis of blood and thrombi in the left atrium. Monitor the patient for the development of an irregular rhythm, and notify the primary care provider if it develops. (See Chapter 34 for a detailed explanation of atrial fibrillation.)

The primary care provider usually starts drug therapy first to control the heart rate and maintain cardiac output (<100 for heart rate is considered a controlled ventricular response). After those outcomes are met, drugs are used in an attempt to restore normal sinus rhythm (NSR). In some cases, the provider elects to convert a patient from atrial fibrillation to sinus rhythm using IV diltiazem (Cardizem, Apo-Diltiaz) or amiodarone (Cordarone, Pacerone). Monitor the patient on a unit where both cardiac rhythm and BP can be closely watched. Synchronized countershock (cardioversion) may be attempted if atrial fibrillation is rapid, the patient's condition worsens, and the rhythm is unresponsive to medical treatment (see Chapter 34).

If the patient remains in atrial fibrillation, low-dose amiodarone (Cordarone) is often prescribed to slow ventricular rate. Procainamide hydrochloride (Pronestyl hydrochloride, Procanbid) may be added to the regimen. A beta-blocking agent (e.g., metoprolol) may also be considered

to slow the ventricular response.

For valvular heart disease and chronic atrial fibrillation, anticoagulation with sodium warfarin (Coumadin, Warfilone) is usually a part of the plan of care to prevent thrombus formation. Thrombi (clots) may form in the atria or on defective valve segments, resulting in systemic emboli. If a portion breaks off and travels to the brain, one or more strokes may occur. Assess the patient's baseline neurologic status, and monitor for changes. A transesophageal echocardiography (TEE) is often done before synchronized cardioversion to ensure that thrombi are not present that could embolize when this therapy is administered. The newer direct thrombin inhibitors *rivaroxaban* (Xarelto) and *dabigatran* (Pradaxa) are *not recommended* to anticoagulate patients with atrial fibrillation related to valvular disease.

Rest is often an important part of treatment. Activity may be limited because cardiac output (CO) cannot meet increased metabolic demands and angina or HF can result. A balance of rest and exercise is needed to prevent skeletal muscle atrophy and fatigue.

Noninvasive Heart Valve Reparative Procedures.

Reparative procedures are becoming more popular because of continuing problems with thrombi, endocarditis, and left ventricular dysfunction after valve replacement. Reparative procedures do not result in a normal valve, but they usually "turn back the clock," resulting in a more functional valve and an improvement in cardiac output. Turbulent blood flow through the valve may persist, and degeneration of the repaired valve is possible.

Balloon valvuloplasty, an invasive nonsurgical procedure, is possible for stenotic mitral and aortic valves; however, careful selection of patients is needed. It may be the initial treatment of choice for people with noncalcified, mobile mitral valves. Patients selected for *aortic* valvuloplasty are usually older and are at high risk for surgical complications or have refused operative treatment. The benefits of this procedure for aortic stenosis tend to be short lived, rarely lasting longer than 6 months.

When performing *mitral* valvuloplasty, the physician passes a balloon catheter from the femoral vein, through the atrial septum, and to the mitral valve. The balloon is inflated to enlarge the mitral orifice. For *aortic* valvuloplasty, the physician inserts the catheter through the femoral artery and advances it to the aortic valve, where it is inflated to enlarge the orifice. The procedure usually offers immediate relief of symptoms because the balloon has dilated the orifice and improved leaflet mobility.

The results are comparable with those of surgical commissurotomy for appropriately selected patients.

Minimally invasive techniques have expanded. For patients who are not surgical candidates, *transcatheter aortic valve replacement (TAVR)* is an alternative option for treatment of aortic stenosis (Fig. 35-3). A bioprosthetic valve is placed percutaneously via either the transfemoral or transapical route under general anesthesia in a hybrid operating room (a combination of a catheterization laboratory and cardiovascular operating room). After initial balloon aortic valvuloplasty, the new valve, which is wrapped around a balloon on a large catheter, is inserted via the femoral artery. The patient is transvenously paced at a rate of about 200 beats per minute to mimic ventricular standstill. The balloon is then inflated and the valve deployed. In the transapical approach, a small incision is made at the apex of the heart. The catheter is then threaded through the incision and the left ventricle to gain access to the aortic valve. As in the transvenous approach, the balloon and catheter is deployed during rapid transvenous pacing. This procedure is performed by a health care team consisting of interventional cardiologists and cardiovascular surgeons. The team must be prepared to convert to an open or traditional aortic valve replacement (AVR) if necessary. Care of the patient is similar to the care of the patient undergoing CABG (see Chapter 38); however, this patient population only needs anticoagulation with aspirin and clopidogrel postprocedure.

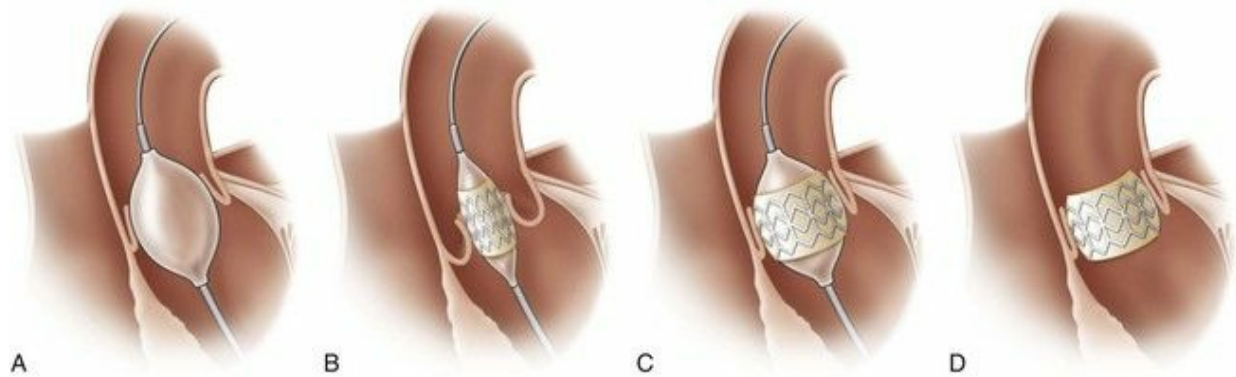

FIG. 35-3 Transcatheter aortic valve replacement (TAVR) procedure.

The pulmonary valve can also be replaced percutaneously by a device from Medtronic using a similar procedure to the TAVR. The Mitraclip, approved for use in Europe and under investigation for use in the United States, is used to repair the mitral valve in patients with mitral regurgitation. Under general anesthesia, access is gained percutaneously

via the femoral vein, and the catheter and Mitraclip is advanced in the left atria and then the left ventricle. The Mitraclip is then retracted and deployed to hold the leaflets of the valve together. Care is similar to the care of the patient undergoing CABG (see Chapter 38).

Nursing Safety Priority QSEN

Action Alert

After valvuloplasty, observe the patient closely for bleeding from the catheter insertion site and institute post-angiogram precautions. Bleeding is likely because of the large size of the catheter. Assess for signs of a regurgitant valve by closely monitoring heart sounds, CO, and heart rhythm. Because vegetations (thrombi) may have been dislodged from the valve, observe for any indication of systemic emboli (see the Infective Endocarditis section, p. 697).

Surgical Management.

Surgeries for patients with valvular heart disease include invasive reparative procedures and replacement. These procedures are performed after symptoms of left ventricular failure have developed but before irreversible dysfunction occurs. Surgical therapy is the *only* definitive treatment of *aortic stenosis* and is recommended when angina, syncope, or dyspnea on exertion develops.

Invasive Heart Valve Reparative Procedures.

Direct (open) commissurotomy is accomplished with cardiopulmonary bypass during open heart surgery. The surgeon visualizes the valve, removes thrombi from the atria, incises the fused commissures (leaflets), and débrides calcium from the leaflets, widening the orifice.

Mitral valve annuloplasty (reconstruction) is the reparative procedure of choice for most patients with acquired mitral insufficiency. To make the annulus (the valve ring that attaches to and supports the leaflets) smaller, the surgeon may suture the leaflets to an annuloplasty ring or take tucks in the patient's annulus. Leaflet repair is often performed at the same time. Elongated leaflets may be shortened, and shortened leaflets may be repaired by lengthening the chordae that bind them in place. Perforated leaflets may be patched with synthetic grafts.

Annuloplasty and leaflet repair result in an annulus of the appropriate size and in leaflets that can close completely. Thus regurgitation is eliminated or markedly reduced.

Heart Valve Replacement Procedures.

The development of a wide variety of *prosthetic* (synthetic) and *biologic* (tissue) valves has improved the surgical therapy and prognosis of valvular heart disease. Each type has advantages and disadvantages. An aortic valve can be replaced only with a prosthetic valve for symptomatic adults with aortic stenosis and aortic insufficiency. A biologic valve cannot be used because of the high pressure within the aorta.

Biologic valve replacements may be **xenograft** (from other species), such as a porcine valve (from a pig) (Fig. 35-4) or a bovine valve (from a cow). Because tissue valves are associated with little risk for clot formation, long-term anticoagulation is *not* indicated. Xenografts are not as durable as prosthetic valves and usually must be replaced every 7 to 10 years. The durability of the graft is related to the age of the recipient. Calcium in the blood, which is present in larger quantities in younger patients, breaks down the valves. The older the patient, the longer the xenograft will last. Valves donated from human cadavers and **pulmonary autographs** (relocation of the patient's own pulmonary valve to the aortic position [Ross procedure]) are also being used for valve replacement.

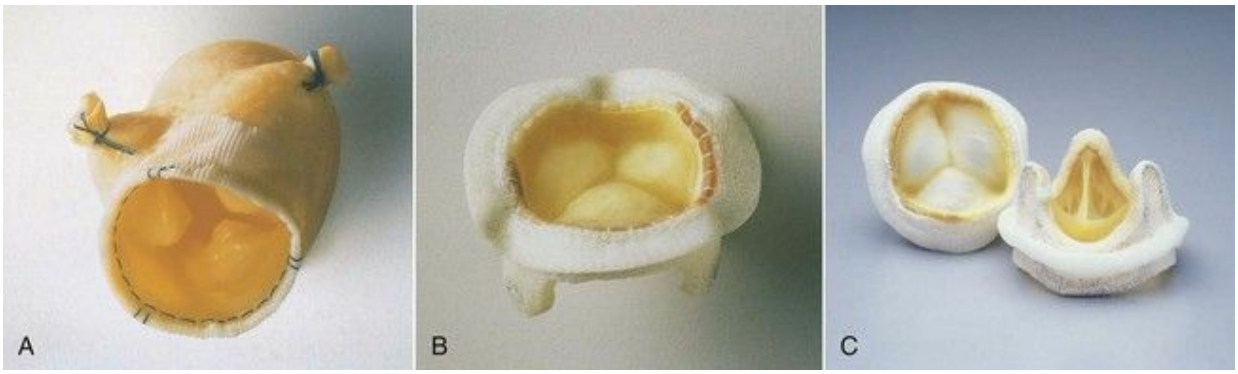

FIG. 35-4 Examples of biologic (tissue) heart valves. **A,** Freestyle, a stentless pig valve with no frame. **B,** Hancock II, a stented pig valve. **C,** Carpentier-Edwards pericardial bioprosthesis.

Patients having a valve replacement have open heart surgery similar to the procedure for a coronary artery bypass graft (CABG) (see Chapter 38). Ideally, surgery is an elective and planned procedure. Inform the patient and family about the management of postoperative pain, incision care, and strategies to prevent respiratory complications (see Chapters 14 and 16). Teach patients receiving oral anticoagulants to stop taking them before surgery, usually at least 72 hours before the procedure. Patients also need to have a preoperative dental examination. If dental caries or periodontal disease is present, these problems must be resolved before

valve replacement.

Postoperative nursing interventions for patients with valve replacement are similar to those for a CABG (see Chapter 38).

Nursing Safety Priority QSEN

Critical Rescue

Patients with mitral stenosis often have pulmonary hypertension and stiff lungs. Therefore monitor respiratory status closely during weaning from the ventilator. Be especially alert for bleeding in those with aortic valve replacements because of a higher risk for postoperative hemorrhage. If heart rate or blood pressure decreases, call the Rapid Response Team or other health care provider immediately!

Patients with valve replacements are also more likely to have significant reductions in cardiac output (CO) after surgery, especially those with aortic stenosis or left ventricular failure from mitral valve disease. Carefully monitor CO, and assess for indications of heart failure. Report any manifestations of HF to the surgeon immediately, and prepare for collaborative management (see earlier discussion on heart failure in this chapter).

Community-Based Care

The patient with valvular heart disease may be discharged home on medical therapy or postoperatively after valve repair or replacement. Because fatigue is a common problem, ensure that the home environment can provide rest while moving the patient toward increased activity levels. Some older adults with aortic stenosis live in long-term care settings.

Home Care Management.

A home care nurse may be needed to help the patient adhere to drug therapy and activity schedules and to detect any problems, particularly with anticoagulant therapy. Patients who have undergone surgery may require a nurse for assistance with incision care. A home care aide may assist with ADLs if the patient lives alone or is older.

Self-Management Education.

The teaching plan for the patient with valvular heart disease includes:

- The disease process and the possibility of heart failure

- Drug therapy, including diuretics, vasodilators, beta blockers, calcium channel blockers, antibiotics, and anticoagulants
- The prophylactic use of antibiotics
- A plan of activity and rest to conserve energy

Because patients with defective or repaired valves are at risk for infective endocarditis, teach them to adhere to the precautions described for endocarditis. *Remind them to inform all health care providers of the valvular heart disease history. Tell providers that they require antibiotic administration before all invasive procedures and tests.* Health teaching for the patient is summarized in Chart 35-7.

Chart 35-7 Patient and Family Education: Preparing for Self-Management

Valvular Heart Disease

- Notify all your health care providers that you have a defective heart valve.
- Remind the health care provider of your valvular problem when you have any invasive dental work (e.g., extraction) or respiratory procedure.
- Request antibiotic prophylaxis before and after these procedures if the health care provider does not offer it.
- Clean all wounds and apply antibiotic ointment to prevent infection.
- Notify your health care provider immediately if you experience fever, petechiae (pinpoint red dots on your skin), or shortness of breath.

Patients who have had valve replacements with prosthetic valves require lifetime prophylactic anticoagulation therapy to prevent thrombus formation. Teach patients taking anticoagulants how to manage their drug therapy successfully, including nutritional considerations (if taking warfarin) and the prevention of bleeding. For example, the patient should be taught to avoid foods high in vitamin K, especially dark green leafy vegetables, and to use an electric razor to avoid skin cuts. In addition, teach him or her to report any bleeding or excessive bruising to the health care provider.

For patients who have surgery, reinforce how to care for the sternal incision and instruct them to watch for and report any fever, drainage, or redness at the site. Most patients can usually return to normal activity after 6 weeks but should avoid heavy physical activity involving their upper extremities for 3 to 6 months to allow the incision to heal. Those

who have had valvular surgery should also avoid invasive dental procedures for 6 months because of the potential for endocarditis. Those with prosthetic valves need to avoid any procedure using magnetic resonance unless the newest technology is available. Remind patients to obtain a medical alert bracelet, card, or necklace to indicate they have a valve replacement and are taking anticoagulants.

Patients with valvular heart disease may have complicated medication schedules that can potentially lead to inadequate self-management. Provide clear, concise instructions about drug therapy, and discuss the risks associated with nonadherence. Patients with a failed valve or those who do not follow the treatment plan are at high risk for heart failure. Teach them to report any changes in cardiovascular status, such as dyspnea, syncope, dizziness, edema, and palpitations.

The psychological response to valve surgery is similar to that after coronary artery bypass surgery. Patients may experience an altered self-image as a result of the required lifestyle changes or the visible medial sternotomy incision. In addition, those with prosthetic valves may need to adjust to a soft but audible clicking sound of the prosthetic valve. Encourage patients to verbalize their feelings about the prosthetic heart valve. Patients may display a variety of emotions postoperatively, especially after hospital discharge.

NCLEX Examination Challenge

Physiological Integrity

A client who recently had a heart valve replacement is taking warfarin (Coumadin) as prescribed. What statement by the client indicates that the nurse will need to do additional health teaching?

A "I will take my pulse every day, and call my doctor if it is below 60."
B "I will eat foods that are high in vitamin K, such as kale and spinach."
C "I will weigh myself every day in the morning using the same scale."
D "I will take my blood pressure every day and call if it is too high or low."

Health Care Resources.

The American Heart Association's *Mended Hearts, Inc.* (www.mendedhearts.org) is a community resource that provides information about valvular heart disease. A wallet-size card can be obtained to identify the patient as needing prophylactic antibiotics. An identification bracelet or necklace that states the name of the drugs the

patient is taking should also be worn.

Inflammations and Infections

Infective Endocarditis

Pathophysiology

Infective endocarditis (previously called *bacterial endocarditis*) is a microbial infection (e.g., viruses, bacteria, fungi) of the endocardium. The most common infective organism is *Streptococcus viridans* or *Staphylococcus aureus.*

Infective endocarditis occurs primarily in patients who abuse IV drugs, have had valve replacements, have experienced systemic infection, or have structural cardiac defects. With a cardiac defect, blood may flow rapidly from a high-pressure area to a low-pressure zone, eroding a section of endocardium. Platelets and fibrin adhere to the denuded endocardium, forming a vegetative lesion. During bacteremia, bacteria become trapped in the low-pressure "sinkhole" and are deposited in the vegetation. Additional platelets and fibrin are deposited, which causes the vegetative lesion to grow. The endocardium and valve are destroyed. Valvular insufficiency may result when the lesion interferes with normal alignment of the valve. If vegetations become so large that blood flow through the valve is obstructed, the valve appears stenotic and then is very likely to *embolize* (i.e., cause emboli to be released into the systemic circulation) (McCance et al., 2010).

Possible ports of entry for infecting organisms include:

- The oral cavity (especially if dental procedures have been performed)
- Skin rashes, lesions, or abscesses
- Infections (cutaneous, genitourinary, GI, systemic)
- Surgery or invasive procedures, including IV line placement

Patient-Centered Collaborative Care

Assessment

Because the mortality rate remains high, early detection of infective endocarditis is essential. Unfortunately, many patients (especially older adults) are misdiagnosed. Clinical manifestations typically occur within 2 weeks of a bacteremia (Chart 35-8).

Chart 35-8 Key Features

Infective Endocarditis

- Fever associated with chills, night sweats, malaise, and fatigue

- Anorexia and weight loss
- Cardiac murmur (newly developed or change in existing)
- Development of heart failure
- Evidence of systemic embolization
- Petechiae
- Splinter hemorrhages
- Osler's nodes (on palms of hands and soles of feet)
- Janeway's lesions (flat, reddened maculae on hands and feet)
- Positive blood cultures

Most patients have recurrent fevers from 99° to 103° F (37.2° to 39.4° C). As a result of physiologic changes associated with aging, however, older adults may be afebrile. The severity of symptoms may depend on the virulence of the infecting organism.

Physical Assessment/Clinical Manifestations.

Assess the patient's *cardiovascular status.* Almost all patients with infective endocarditis develop murmurs. Carefully auscultate the precordium, noting and documenting any new murmurs (usually regurgitant in nature) or any changes in the intensity or quality of an old murmur. An S_3 or S_4 heart sound also may be heard.

Heart failure is the most common complication of infective endocarditis. Assess for right-sided HF (as evidenced by peripheral edema, weight gain, and anorexia) and left-sided HF (as evidenced by fatigue, shortness of breath, and crackles on auscultation of breath sounds). See discussion of HF earlier in this chapter.

Arterial embolization is a major complication in up to half of patients with infective endocarditis. Fragments of vegetation (clots) break loose and travel randomly through the circulation. When the left side of the heart is involved, vegetation fragments are carried to the spleen, kidneys, GI tract, brain, and extremities. When the right side of the heart is involved, emboli enter the pulmonary circulation.

Splenic infarction with sudden abdominal pain and radiation to the left shoulder can also occur. When performing an *abdominal assessment,* note rebound tenderness on palpation. The classic pain described with renal infarction is flank pain that radiates to the groin and is accompanied by hematuria (red blood cells in the urine) or pyuria (white blood cells in the urine). Mesenteric emboli cause diffuse abdominal pain, often after eating, and abdominal distention.

About a third of patients have *neurologic changes;* others have signs and symptoms of pulmonary problems. Emboli to the central nervous system

cause either transient ischemic attacks (TIAs) or a stroke. Confusion, reduced concentration, and aphasia or dysphagia may occur. Pleuritic chest pain, dyspnea, and cough are symptoms of pulmonary infarction related to embolization.

Petechiae (pinpoint red spots) occur in many patients with endocarditis. Examine the mucous membranes, the palate, the conjunctivae, and the skin above the clavicles for small, red, flat lesions. Assess the distal third of the nail bed for **splinter hemorrhages,** which appear as black longitudinal lines or small red streaks.

Diagnostic Assessment.

The most reliable criteria for diagnosing endocarditis include positive blood cultures, a new regurgitant murmur, and evidence of endocardial involvement by echocardiography.

A positive *blood culture* is a prime diagnostic test. Both aerobic and anaerobic specimens are obtained for culture. Some slow-growing organisms may take 3 weeks and require a specialized medium to isolate. Low hemoglobin and hematocrit levels may also be present.

Echocardiography has improved the ability to diagnose infective endocarditis accurately. Transesophageal echocardiography (TEE) allows visualization of cardiac structures that are difficult to see with transthoracic echocardiography (TTE) (see Chapter 33).

Interventions

Care of the patient with endocarditis usually includes antimicrobials, rest balanced with activity, and supportive therapy for HF. If these interventions are successful, surgery is usually not required.

Nonsurgical Management.

The major component of treatment for endocarditis is drug therapy. Other interventions help prevent the life-threatening complications of the disease.

Antimicrobials are the main treatment, with the choice of drug depending on the specific organism involved. Because vegetations surround and protect the offending microorganism, an appropriate drug must be given in a sufficiently high dose to ensure its destruction. Antimicrobials are usually given IV, with the course of treatment lasting 4 to 6 weeks. For most bacterial cases, the ideal antibiotic is one of the penicillins or cephalosporins.

Patients may be hospitalized for several days to institute IV therapy and then are discharged for continued IV therapy at home. After

hospitalization, most patients who respond to therapy may continue it at home when they become afebrile, have negative blood cultures, and have no signs of HF or embolization.

Anticoagulants do not prevent embolization from vegetations. Because they may result in bleeding, these drugs are avoided unless they are required to prevent thrombus formation (clotting) on a prosthetic valve.

The patient's activities are balanced with *adequate rest.* Consistently use appropriate aseptic technique to protect the patient from contact with potentially infective organisms. Continue to assess for signs of HF (e.g., rapid pulse, fatigue, cough, dyspnea) throughout the antimicrobial regimen, and report significant changes.

Surgical Management.

The cardiac surgeon may be consulted if antibiotic therapy is ineffective in sterilizing a valve, if refractory HF develops secondary to a defective valve, if large valvular vegetations are present, or if multiple embolic events occur. Current surgical interventions for infective endocarditis include:

- Removing the infected valve (either biologic or prosthetic)
- Repairing or removing congenital shunts
- Repairing injured valves and chordae tendineae
- Draining abscesses in the heart

Preoperative and postoperative care of patients having surgery involving the valves is similar to that described earlier for valve replacement (pp. 695-696).

Community-Based Care

Community-based care for patients with infective endocarditis is essential to resolve the problem, prevent relapse, and avoid complications. Patients and families need to be willing and have the knowledge, physical ability, and resources to administer IV antibiotics at home. Collaborate with the home care nurse to complete health teaching started in the hospital and to monitor patient adherence and health status as directed by The Joint Commission's National Patient Safety Goals.

In collaboration with the case manager, the home care nurse and pharmacist arrange for appropriate supplies to be available to the patient at home. Supplies include the prepared antibiotic, IV pump with tubing, alcohol wipes, IV access device, normal saline solution, and a saline flush solution drawn up in syringes. A saline lock, peripherally inserted central catheter (PICC) line, or central catheter is positioned at a venous site that

is easily accessible to the patient or a family member.

Teach the patient and family how to administer the antibiotic and care for the infusion site while maintaining aseptic technique. The patient or family member should demonstrate this technique before the patient is discharged from the hospital. Emphasize the importance of maintaining a blood level of the antibiotic by administering the antibiotics as scheduled. After stabilization at home, the case manager or other nurse contacts the patient every week to determine whether he or she is adhering to the antibiotic therapy and whether any problems have been encountered.

Encourage proper oral hygiene. Advise patients to use a soft toothbrush, to brush their teeth at least twice per day, and to rinse the mouth with water after brushing. They should not use irrigation devices or floss the teeth because bacteremia may result. Teach them to clean any open skin areas well and apply an antibiotic ointment.

Nursing Safety Priority QSEN

Action Alert

Patients must remind health care providers (including their dentists) of their endocarditis. Guidelines for antibiotic prophylaxis have been revised and are recommended only if the patient with a prosthetic valve, a history of infective endocarditis, or an unrepaired cyanotic congenital heart disease undergoes invasive dental, oral, or upper respiratory procedure.

Instruct patients to note any indications of recurring endocarditis such as fever. Remind them to monitor and record their temperature daily for up to 6 weeks. Teach them to report fever, chills, malaise, weight loss, increased fatigue, sudden weight gain, or dyspnea to their primary care provider.

Pericarditis

Pathophysiology

Acute pericarditis is an inflammation or alteration of the pericardium (the membranous sac that encloses the heart). The problem may be fibrous, serous, hemorrhagic, purulent, or neoplastic. Acute pericarditis is most commonly associated with:

- Infective organisms (bacteria, viruses, or fungi) (usually respiratory)
- Post–myocardial infarction (MI) syndrome (Dressler's syndrome)

- Post-pericardiotomy syndrome
- Acute exacerbations of systemic connective tissue disease

Chronic constrictive pericarditis occurs when chronic pericardial inflammation causes a fibrous thickening of the pericardium. It is caused by tuberculosis, radiation therapy, trauma, renal failure, or metastatic cancer. In chronic constrictive pericarditis, the pericardium becomes rigid, preventing adequate filling of the ventricles and eventually resulting in cardiac failure.

Patient-Centered Collaborative Care

Assessment

Assessment findings for patients with *acute pericarditis* include substernal precordial pain that radiates to the left side of the neck, the shoulder, or the back. pain is classically grating and oppressive and is aggravated by breathing (mainly on inspiration), coughing, and swallowing. The pain is worse when the patient is in the supine position and may be relieved by sitting up and leaning forward. Ask specific questions to evaluate chest discomfort to differentiate it from the pain associated with an acute MI (see Chapter 38).

A pericardial friction rub may be heard with the diaphragm of the stethoscope positioned at the left lower sternal border. This scratchy, high-pitched sound is produced when the inflamed, roughened pericardial layers create friction as their surfaces rub together.

Patients with acute pericarditis may have an elevated white blood cell count and usually have a fever. Therefore blood culture and sensitivity may be analyzed in the laboratory. The ECG usually shows ST-T spiking in almost all leads simultaneously, and aVR with ST depression with the onset of inflammation, which returns to baseline with treatment. Atrial fibrillation is also common. Echocardiograms may be used to determine a pericardial effusion.

Patients with *chronic constrictive pericarditis* have signs of right-sided HF, elevated systemic venous pressure with jugular distention, hepatic engorgement, and dependent edema. Exertional fatigue and dyspnea are common complications. Thickening of the pericardium is seen on echocardiography or a computed tomography (CT) scan.

Interventions

The focus of collaborative management is to relieve pain and treat the cause of pericarditis before severe complications occur.

Pain Management.

The health care provider usually prescribes NSAIDs for pain associated with pericarditis. Patients who do not obtain pain relief and who do not have bacterial pericarditis may receive corticosteroid therapy. Assist the patient to assume positions of comfort—usually sitting upright and leaning slightly forward. If the pain is not relieved within 24 to 48 hours, notify the health care provider. Colchicine 1 to 2 mg orally on Day 1 followed by 0.5 to 1 mg orally daily for 6 months has been shown to prevent pericarditis reoccurrence.

The various causes of pericarditis require specific therapies. For example, bacterial pericarditis (acute) usually requires antibiotics and pericardial drainage. The usual clinical course of acute pericarditis is short term (2 to 6 weeks), but episodes may recur. Chronic pericarditis caused by malignant disease may be treated with radiation or chemotherapy, whereas uremic pericarditis is treated by hemodialysis. The definitive treatment for chronic constrictive pericarditis is surgical excision of the pericardium **(pericardiectomy).**

Monitor all patients for **pericardial effusion,** which occurs when the space between the parietal and visceral layers of the pericardium fills with fluid. This complication puts the patient at risk for **cardiac tamponade,** or excessive fluid within the pericardial cavity.

Emergency Care: Acute Cardiac Tamponade.

Acute cardiac tamponade may occur when small volumes (20 to 50 mL) of fluid accumulate rapidly in the pericardium and cause a sudden decrease in cardiac output (CO). If the fluid accumulates slowly, the pericardium may stretch to accommodate several hundred milliliters of fluid. Report any suspicion of this complication to the physician immediately. Findings of cardiac tamponade include:

- Jugular venous distention
- **Paradoxical pulse,** also known as *pulsus paradoxus* (systolic blood pressure 10 mm Hg or more higher on expiration than on inspiration) (Chart 35-9)

Chart 35-9 Best Practice for Patient Safety & Quality Care QSEN

Care of the Patient with Pericarditis

- Assess the nature of the patient's chest discomfort. (Pericardial pain is typically substernal. It is worse on inspiration and decreases when the

patient leans forward.)
- Auscultate for a pericardial friction rub.
- Assist the patient to a position of comfort.
- Provide anti-inflammatory agents as prescribed.
- Explain that anti-inflammatory agents usually decrease the pain within 48 hours.
- Avoid the administration of aspirin and anticoagulants because these may increase the possibility of tamponade.
- Auscultate the blood pressure carefully to detect paradoxical blood pressure (pulsus paradoxus), a sign of tamponade:
  - Palpate the blood pressure, and inflate the cuff above the systolic pressure.
  - Deflate the cuff gradually, and note when sounds are first audible on expiration.
  - Identify when sounds are also audible on inspiration.
  - Subtract the inspiratory pressure from the expiratory pressure to determine the amount of pulsus paradoxus (>10 mm Hg is an indication of tamponade).
- Inspect for other indications of tamponade, including jugular venous distention with clear lungs, muffled heart sounds, and decreased cardiac output.
- Notify the physician if tamponade is suspected.

- Decreased heart rate, dyspnea, and fatigue
- Muffled heart sounds
- Hypotension

Cardiac tamponade is an emergency! The physician may initially manage the decreased cardiac output (CO) with increased fluid volume administration while awaiting an echocardiogram or x-ray to confirm the diagnosis. Unfortunately, these tests are not always helpful because the fluid volume around the heart may be too small to visualize. Hemodynamic monitoring in a specialized critical care unit usually demonstrates compression of the heart, with all pressures (right atrial, pulmonary artery, and wedge) being similar and elevated (plateau pressures).

The physician may elect to perform a **pericardiocentesis** to remove fluid and relieve the pressure on the heart. Under echocardiographic or fluoroscopic and hemodynamic monitoring, the cardiologist inserts an 8-inch (20.3-cm), 16- or 18-gauge pericardial needle into the pericardial space. When the needle is properly positioned, a catheter is inserted and all available pericardial fluid is withdrawn. A pericardial drain may be

temporarily placed. Monitor the pulmonary artery, wedge, and right atrial pressures during the procedure. The pressures should return to normal as the fluid compressing the heart is removed, and the clinical manifestations of tamponade should resolve. In situations in which the cause of the tamponade is unknown, pericardial fluid specimens may be sent to the laboratory for culture and sensitivity tests and cytology.

Nursing Safety Priority QSEN

Action Alert

After the pericardiocentesis, closely monitor the patient for the recurrence of tamponade. Pericardiocentesis alone often does not resolve acute tamponade. Be prepared to provide adequate fluid volumes to increase CO and to prepare the patient for emergency sternotomy if tamponade recurs.

If the patient has a recurrence of tamponade or recurrent effusions or adhesions from chronic pericarditis, a portion or all of the pericardium may need to be removed to allow adequate ventricular filling and contraction. The surgeon may create a pericardial window, which involves removing a portion of the pericardium to permit excessive pericardial fluid to drain into the pleural space. In more severe cases, removal of the toughened encasing pericardium (pericardiectomy) may be necessary.

Rheumatic Carditis

Pathophysiology

Rheumatic carditis, also called *rheumatic endocarditis,* is a sensitivity response that develops after an upper respiratory tract infection with group A beta-hemolytic *Streptococci*. It occurs in almost half of patients with rheumatic fever. The precise mechanism by which the infection causes inflammatory lesions in the heart is not established; however, inflammation is evident in all layers of the heart. The inflammation results in impaired contractile function of the myocardium, thickening of the pericardium, and valvular damage.

Rheumatic carditis is characterized by the formation of Aschoff bodies (small nodules in the myocardium that are replaced by scar tissue). A diffuse cellular infiltrate also develops and may be responsible for the resulting heart failure (HF). The pericardium becomes thickened and covered with exudate, and a serosanguineous pleural effusion may

develop. The most serious damage occurs to the endocardium, with inflammation of the valve leaflets developing. Hemorrhagic and fibrous lesions form along the inflamed surfaces of the valves, resulting in stenosis or regurgitation of the mitral and aortic valves (McCance et al., 2010).

Patient-Centered Collaborative Care

Rheumatic carditis is one of the major indicators of rheumatic fever. The common manifestations are:

- Tachycardia
- **Cardiomegaly** (enlarged heart)
- Development of a new murmur or a change in an existing murmur
- Pericardial friction rub
- Precordial pain
- Electrocardiogram (ECG) changes (prolonged PR interval)
- Indications of heart failure (HF)
- Evidence of an existing streptococcal infection

Primary prevention is extremely important. Teach all patients to remind their health care providers to provide appropriate antibiotic therapy if they develop the indications of streptococcal pharyngitis:

- Moderate to high fever
- Abrupt onset of a sore throat
- Reddened throat with exudate
- Enlarged and tender lymph nodes

Penicillin is the antibiotic of choice for treatment. Erythromycin (Eryc, Erythromid) is the alternative for penicillin-sensitive patients.

Once a diagnosis of rheumatic fever is made, antibiotic therapy is started immediately. Teach the patient to continue the antibiotic administration for the full 10 days to prevent re-infection. Suggest ways to manage fever, such as maintaining hydration and taking antipyretics. Encourage the patient to get adequate rest.

Explain to the patient and family that a recurrence of rheumatic carditis is most likely the result of reinfection by *Streptococcus.* Antibiotic prophylaxis is necessary for the rest of the patient's life to prevent infective endocarditis (see Infective Endocarditis, p. 697).

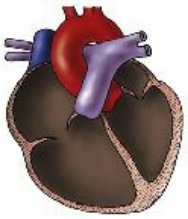
Cardiomyopathy

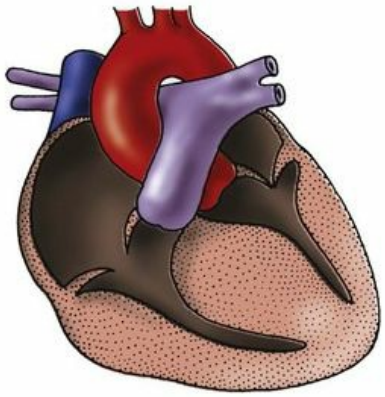
Pathophysiology

Cardiomyopathy is a subacute or chronic disease of cardiac muscle, and the cause may be unknown. Cardiomyopathies are classified into four categories on the basis of abnormalities in structure and function: dilated cardiomyopathy, hypertrophic cardiomyopathy, restrictive cardiomyopathy, and arrhythmogenic right ventricular cardiomyopathy (Table 35-5). Mortality at 1 year is 20% and 70% to 80% at year 8 for patients who develop heart failure (Go et al., 2013).

TABLE 35-5

Pathophysiology, Signs and Symptoms, and Treatment of Common Cardiomyopathies

	HYPERTROPHIC CARDIOMYOPATHY	
DILATED CARDIOMYOPATHY	NONOBSTRUCTED	OBSTRUCTED
Pathophysiology		
Fibrosis of myocardium and endocardium Dilated chambers Mural wall thrombi prevalent	Hypertrophy of all walls Hypertrophied septum Relatively small chamber size	Same as for nonobstructed except for obstruction of left ventricular outflow tract associated with the hypertrophied septum and mitral valve incompetence
		




Signs and Symptoms		
Fatigue and weakness Heart failure (left side) Dysrhythmias or heart block Systemic or pulmonary emboli S_3 and S_4 gallops Moderate to severe cardiomegaly	Dyspnea Angina Fatigue, syncope, palpitations Mild cardiomegaly S_4 gallop Ventricular dysrhythmias Sudden death common Heart failure	Same as for nonobstructed except with mitral regurgitation murmur Atrial fibrillation
Treatment		
Symptomatic treatment of heart failure Vasodilators Control of dysrhythmias Surgery: heart transplant	For both: Symptomatic treatment Beta blockers Conversion of atrial fibrillation Surgery: ventriculomyotomy or muscle resection with mitral valve replacement Nitrates and other vasodilators *contraindicated* with the obstructed form	

Dilated cardiomyopathy (DCM) is the structural abnormality most commonly seen. DCM involves extensive damage to the myofibrils and interference with myocardial metabolism. Ventricular wall thickness is normal, but both ventricles are dilated (left ventricle is usually worse) and systolic function is impaired. Causes may include alcohol abuse, chemotherapy, infection, inflammation, and poor nutrition. Decreased CO from inadequate pumping of the heart causes the patient to experience dyspnea on exertion (DOE), decreased exercise capacity, fatigue, and palpitations.

The cardinal features of **hypertrophic cardiomyopathy (HCM)** are asymmetric ventricular hypertrophy and disarray of the myocardial fibers. Left ventricular hypertrophy leads to a stiff left ventricle, which results in diastolic filling abnormalities. Obstruction in the left ventricular outflow tract is seen in most patients with HCM. In about half of patients, HCM is transmitted as a single-gene autosomal dominant trait (McCance et al., 2010). Some patients die without any symptoms, whereas others have dyspnea on exertion (DOE), syncope, dizziness, and palpitations. Many athletes who die suddenly probably had hypertrophic cardiomyopathy.

Restrictive cardiomyopathy, the rarest of the cardiomyopathies, is characterized by stiff ventricles that restrict filling during diastole. Symptoms are similar to left or right heart failure (HF) or both. The disease can be primary or caused by endocardial or myocardial disease such as sarcoidosis or amyloidosis. The prognosis for this type of cardiomyopathy is poor.

Arrhythmogenic right ventricular cardiomyopathy (dysplasia) results from replacement of myocardial tissue with fibrous and fatty tissue. Although the name implies right ventricle disease, about a third of patients also have left ventricle (LV) involvement. This disease has a familial association and most often affects young adults. Some patients have symptoms, and others do not.

Patient-Centered Collaborative Care

Assessment

Findings in cardiomyopathy depend on the structural and functional abnormalities. For example, left ventricular or biventricular failure is characteristic of *dilated* cardiomyopathy (DCM). Some patients with DCM are asymptomatic for months to years and have left and/or right ventricular dilation confirmed on x-ray examination or echocardiography. Others experience sudden, pronounced symptoms of left ventricular failure, such as progressive dyspnea on exertion, orthopnea, palpitations, and activity intolerance. Right-sided HF develops late in the disease and is associated with a poor prognosis. Atrial fibrillation occurs in some patients and is associated with embolism.

The clinical picture of *hypertrophic* cardiomyopathy (HCM) results from the hypertrophied septum causing a reduced stroke volume (SV) and cardiac output (CO). Most patients are asymptomatic until late adolescence or early adulthood. The primary symptoms of HCM are exertional dyspnea, angina, and syncope. The chest pain is atypical in

that it usually occurs at rest, is prolonged, has no relation to exertion, and is not relieved by the administration of nitrates. A high incidence of ventricular dysrhythmias is associated with HCM. Sudden death occurs and may be the first manifestation of the disease.

Echocardiography, radionuclide imaging, and angiocardiography during cardiac catheterization are performed to diagnose and differentiate cardiomyopathies.

Interventions

The treatment of choice for the patient with cardiomyopathy varies with the type of cardiomyopathy and may include both medical and surgical interventions.

Nonsurgical Management.

The care of patients with dilated or restrictive cardiomyopathy is initially the same as for HF. Drug therapy includes the use of diuretics, vasodilating agents, and cardiac glycosides to increase cardiac output (CO). Because patients are at risk for sudden death, teach them to report any palpitations, dizziness, or fainting, which might indicate a dysrhythmia. Antidysrhythmic drugs or implantable cardiac defibrillators may be used to control life-threatening dysrhythmias. To block inappropriate sympathetic stimulation and tachycardia, beta blockers (e.g., metoprolol) are used. If cardiomyopathy has developed in response to a toxin (such as alcohol), further exposure to that toxin must be avoided.

Management of obstructive HCM includes administering negative inotropic agents such as beta-adrenergic blocking agents (carvedilol) and calcium antagonists (diltiazem). These drugs decrease the outflow obstruction that accompanies exercise. They also decrease heart rate (HR), resulting in less angina, dyspnea, and syncope. Vasodilators, diuretics, nitrates, and cardiac glycosides are contraindicated in patients with obstructive HCM because vasodilating and positive inotropic effects may worsen the obstruction (Sherrid & Arabadjian, 2012). Strenuous exercise is also prohibited because it can increase the risk for sudden death.

Surgical Management

Myomectomy and Ablation.

The type of surgery performed depends on the type of cardiomyopathy. The most commonly used surgical treatment for obstructive HCM

involves excising a portion of the hypertrophied ventricular septum to create a wider outflow tract (**ventriculomyomectomy;** also called *ventricular septal myectomy*). This procedure results in long-term improvement in activity tolerance for most patients.

Percutaneous alcohol septal ablation is another option for patients with HCM. Absolute alcohol is injected into a target septal branch of the left anterior descending coronary artery to produce a small septal infarction.

The patient with arrhythmogenic right ventricular cardiomyopathy who does not respond to drug therapy may have a radiofrequency catheter ablation or placement of an implantable defibrillator (see Chapter 34 for discussion of these procedures).

Heart Transplantation.

Heart transplantation (surgical replacement with a donor heart) is the treatment of choice for patients with severe DCM and may be considered for patients with restrictive cardiomyopathy. The procedure may be done also for end-stage heart disease due to coronary artery disease, valvular disease, or congenital heart disease.

Preoperative Care.

Criteria for candidate selection for heart transplantation include:

- Life expectancy less than 1 year
- Age generally less than 65 years
- New York Heart Association (NYHA) class III or IV
- Normal or only slightly increased pulmonary vascular resistance
- Absence of active infection
- Stable psychosocial status
- No evidence of current drug or alcohol abuse

Once the candidate is eligible and a heart is available, provide preoperative care as described in Chapter 14.

Operative Procedures.

The surgeon transplants a heart from a donor with a comparable body weight and ABO compatibility into a recipient less than 6 hours after procurement. In the most common procedure **(bicaval technique),** the intact right atrium of the donor heart is preserved by anastomoses at the patient's (recipient's) superior and inferior venae cavae. In the more traditional **orthotopic** technique, cuffs of the patient's right and left atria are attached to the donor's atria. Anastomoses are made between the recipient and donor atria, aorta, and pulmonary arteries (Fig. 35-5).

Because the remaining remnant of the recipient's atria contains the sinoatrial (SA) node, two unrelated P waves are visible on the ECG.

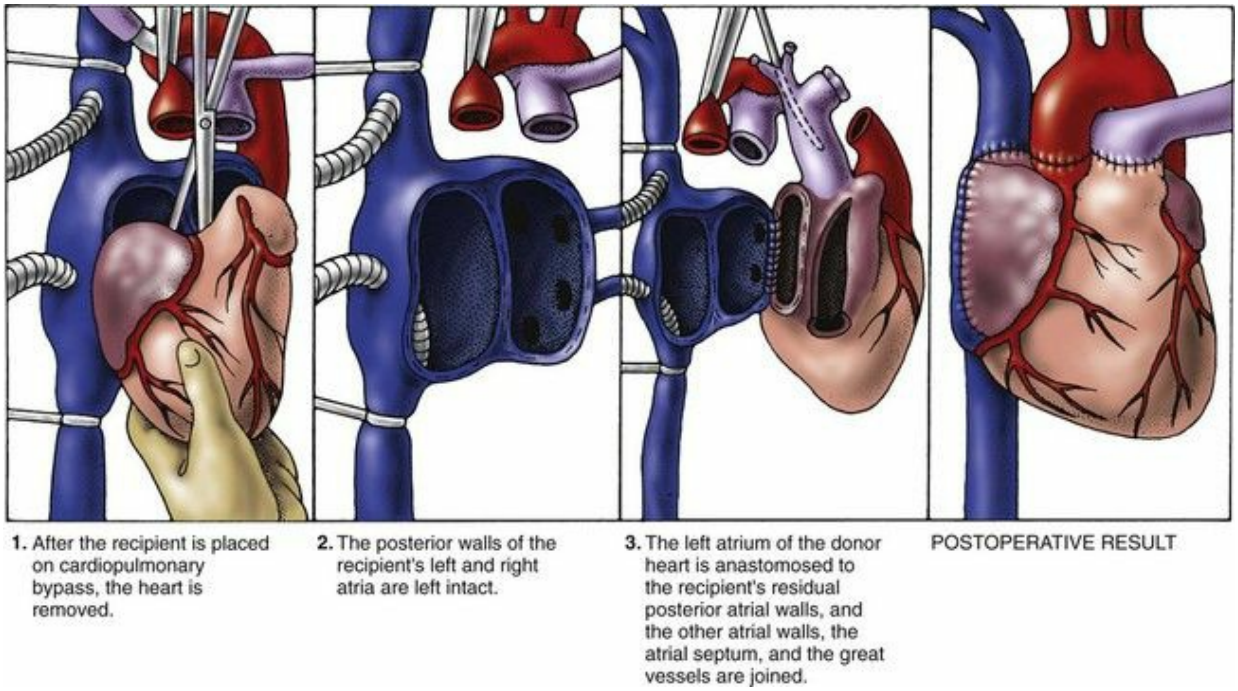


FIG. 35-5 One technique for heart transplantation.

Postoperative Care.

The postoperative care of the heart transplant recipient is similar to that for conventional cardiac surgery (see Chapter 38). However, the nurse must be especially observant to identify occult bleeding into the pericardial sac with the potential for tamponade (see earlier discussion of this complication on p. 699). The patient's pericardium has usually stretched considerably to accommodate the diseased, hypertrophied heart, predisposing him or her to have concealed postoperative bleeding.

The transplanted heart is denervated (disconnected from the body's autonomic nervous system) and is unresponsive to vagal stimulation. In the early postoperative phase, isoproterenol (Isuprel) may be titrated to support the HR and maintain cardiac output. Atropine, digoxin, and carotid sinus pressure are not used because they do not have their usual effects on the new heart. Denervation of the heart may cause pronounced orthostatic hypotension in the immediate postoperative phase. Caution the patient to change position slowly to help prevent this complication. Some patients also require a permanent pacemaker that is rate responsive to his or her activity level. The purpose is to increase CO and improve activity tolerance.

To suppress natural defense mechanisms (especially T- and B-cell

function) and prevent transplant rejection, patients require a combination of immunosuppressants for the rest of their lives. Chapter 17 describes transplant rejection and prevention in detail.

Nursing Safety Priority QSEN

Critical Rescue

After surgery, perform comprehensive cardiovascular and respiratory assessments frequently according to agency or heart transplant surgical protocol. Chart 35-10 lists the signs and symptoms of rejection that are specific to heart transplant. Report any of these manifestations to the surgeon immediately! To detect rejection, the surgeon performs right endomyocardial biopsies at regularly scheduled intervals and whenever symptoms occur.

Chart 35-10 Best Practice for Patient Safety & Quality Care QSEN

Assessing for Clinical Manifestations of Heart Transplant Rejection

- Shortness of breath
- Fatigue
- Fluid gain (edema, increased weight)
- Abdominal bloating
- New bradycardia
- Hypotension
- Atrial fibrillation or flutter
- Decreased activity tolerance
- Decreased ejection fraction (late sign)

Be very careful about handwashing and aseptic technique because patients are immunosuppressed from drug therapy. *Infection is the major cause of death* and usually develops in the immediate post-transplant period or during treatment for acute rejection.

About 50% of patients survive 10 years after transplantation (Eisen, 2014). Many of the surviving patients have a form of coronary artery disease (CAD) called **coronary artery vasculopathy (CAV),** which presents as diffuse plaque in the arteries of the donor heart. The cause is thought to involve a combination of immunologic and non-immunologic processes that result in vascular endothelial injury and an inflammatory

response (Eisen, 2014). Because the heart is denervated, patients do not usually experience angina. Regularly scheduled exercise tolerance tests and angiography are required to identify CAV. Only a small percentage of patients with CAV benefit from revascularization procedures like balloon angioplasty or coronary artery bypass surgery. Stents are beginning to show some promise in managing these patients. Retransplantation may be done in select patients.

To delay the development of CAV, encourage patients to follow lifestyle changes similar to those with primary CAD (see Chapter 38). The physician may prescribe a calcium channel blocker such as diltiazem (Cardizem) to prevent coronary spasm and closure. Stress the importance of strict adherence to nutritional modifications and drug regimens. Teach the patient the importance of participating in a regular exercise program. Collaborate with the physical therapist to plan the most appropriate exercise plan for the patient.

Discharge planning involves a collaborative, interdisciplinary approach. Patients require extensive health teaching for self-management and community resources for support. Counseling and support groups can help patients cope with their fear of organ rejection. Drug therapy adherence is crucial to prevent this problem. Continuing community-based care for patients with a heart transplant is similar to that for heart failure as discussed on p. 689.

Nursing Concepts and Clinical Judgment Review

What might you NOTICE if a patient is experiencing inadequate gas exchange and tissue perfusion as a result of heart failure?

- Report of shortness of breath, especially on exertion
- Report of dizziness
- Report of weight gain within days
- Syncope
- Dyspnea on exertion
- Report of palpitations
- Report of fatigue and weakness
- Disorientation or acute confusion (especially in older adults)
- Peripheral or abdominal ascites

What should you INTERPRET and how should you RESPOND to a patient experiencing inadequate gas exchange and tissue perfusion as a result of heart failure?

Perform and interpret physical assessment, including:

- Taking vital signs
- Monitoring oxygen saturation by pulse oximetry
- Performing a complete cardiovascular assessment
- Performing a complete respiratory assessment (listen for crackles or wheezes)
- Weighing patient
- Assessing cognition
- Assessing for pain or other symptoms

Respond by:

- Seeing health care provider immediately or calling 911 if patient is not in hospital setting …OR
- Notifying physician or Rapid Response Team in hospital setting
- Raising the head of the bed to a sitting position
- Giving oxygen
- Maintaining or starting IV line
- Administering furosemide IV push (IVP) as prescribed
- Monitoring intake and output
- Giving ACE inhibitors or ARBs as prescribed IV or orally

On what should you REFLECT?

- Observe patient for increased urinary output.
- Monitor for decreased respiratory distress.
- Continue to monitor for improvement.
- Think about the possible cause(s) of the patient's heart failure.
- Think about your response to the patient.
- Develop a teaching plan for the patient to help prevent worsening or recurrent acute episodes of heart failure.

Safe and Effective Care Environment

- Provide information about continuing care for patients with heart failure (HF) after discharge to the community.
- Assess whether patients with end-stage HF have advance directives. If not, provide information about them.
- Collaborate with members of the health care team when developing and implementing a plan of care for patients with heart failure. **Teamwork and Collaboration** QSEN
- Teach patients about community support groups and resources such as the American Heart Association.

Health Promotion and Maintenance

- Provide teaching about self-management at home for patients with HF (see Table 35-4).
- Monitor older adults who are taking digoxin for manifestations of toxicity. Monitor potassium levels to check for hypokalemia (see Chart 35-5). **Safety** QSEN
- Teach patients taking ACE inhibitors or ARBs to change positions slowly to avoid orthostatic hypotension, especially older adults. **Safety** QSEN
- Teach the patient with valvular dysfunction, cardiac infection, or cardiomyopathy the necessity of taking preventive antibiotic therapy before any invasive procedure. **Evidence-Based Practice** QSEN

Psychosocial Integrity

- Assess the patient for depression resulting from altered self-concept and anxiety.
- Assess the patient's coping skills. **Patient-Centered Care** QSEN

Physiological Integrity

- Assess the patient for manifestations of right- and left-sided HF (see Charts 35-1 and 35-2).
- Weigh daily and record intake and output of patients with HF.
- Assess for early signs and symptoms of pulmonary edema (e.g.,

crackles in the lung bases, dyspnea at rest, disorientation, confusion), especially in older adults. **Safety** QSEN

- Assess for symptoms of worsening HF: rapid weight gain (3 lb in a week), a decrease in exercise tolerance lasting 2 to 3 days, cold symptoms (cough) lasting more than 3 to 5 days, nocturia, development of dyspnea or angina at rest, or unstable angina. **Safety** QSEN
- Monitor the HF patient on beta blockers carefully for hypotension and bradycardia. **Safety** QSEN
- Monitor the pulse of patients taking digoxin before administration, and report to the health care provider a pulse that is not within the desired parameters.
- Monitor for manifestations of pulmonary edema as listed in Chart 35-3.
- Place the patient in a sitting position and provide oxygen therapy at a high flow rate (unless otherwise contraindicated) if pulmonary edema is suspected. **Evidence-Based Practice** QSEN
- Recognize that home care nurses perform and document focused physical assessments for cardiac patients as delineated in Chart 35-4. **Informatics** QSEN
- Monitor the patient with valvular dysfunction for atrial fibrillation, which may lead to hemostasis and mural thrombi. Monitor for an irregularly irregular cardiac rhythm, and administer warfarin as indicated.
- Document neurovascular status frequently because emboli from valvular disease may cause strokes. **Informatics** QSEN
- Differentiate major types of cardiomyopathy as described in Table 35-5.
- Observe for symptoms of heart transplant rejection as listed in Chart 35-10.
- Provide care for patients with pericarditis as outlined in Chart 35-9.

CHAPTER 36

Care of Patients with Vascular Problems

Donna D. Ignatavicius

PRIORITY CONCEPTS

- Perfusion
- Clotting
- Pain
- Inflammation

Learning Outcomes

Safe and Effective Care Environment

1. Collaborate with interdisciplinary health care team members when providing care for patients with perfusion and clotting problems.
2. Prioritize care for patients with hypertension.

Health Promotion and Maintenance

3. Identify risk factors for vascular problems.
4. Teach patients about lifestyle modifications to prevent vascular problems.

Physiological Integrity

5. Explain the inflammation process that is associated with the development of arteriosclerosis and atherosclerosis.
6. Interpret essential laboratory data related to risk for atherosclerosis.
7. Discuss the role of nutrition therapy in the management of patients with arteriosclerosis.
8. Describe the differences between essential and secondary

hypertension.

9. Develop an evidence-based plan of care for a patient with essential hypertension.
10. Document a teaching plan for patients receiving drug therapy for hypertension.
11. Compare common assessment findings present in patients with peripheral arterial and peripheral venous disease.
12. Identify when venous thromboembolism (VTE) and complications of VTE occur.
13. Plan evidence-based nursing interventions to help prevent VTE.
14. Explain the nurse's role in monitoring patients who are receiving anticoagulants.
15. Compare assessment findings associated with Raynaud's phenomenon and Buerger's disease.

 http://evolve.elsevier.com/Iggy/

The *peripheral* vascular system is essential for transporting blood to and from distal tissues in the extremities. When peripheral blood vessels are diseased or damaged, especially in the legs, arterial blood flow is impaired, preventing distal areas like the feet from having adequate perfusion. The result can be ischemia and necrosis (cell death). Venous disease causes blood to back up into the distal areas and can lead to edema and thromboses (clots) that can become emboli, a life-threatening complication.

Arteriosclerosis and Atherosclerosis

Pathophysiology

Arteriosclerosis is a thickening, or hardening, of the arterial wall that is often associated with aging. **Atherosclerosis,** a type of arteriosclerosis, involves the formation of plaque within the arterial wall and is the leading risk factor for cardiovascular disease. Usually the disease affects the larger arteries, such as coronary artery beds; aorta; carotid and vertebral arteries; renal, iliac, and femoral arteries; or any combination of these.

The exact pathophysiology of atherosclerosis is not known, but the condition is thought to occur from blood vessel damage that causes inflammation (see the discussion of inflammation in Chapter 17) (Fig. 36-1). After the vessel becomes inflamed, a fatty streak appears on the intimal surface (inner lining) of the artery. Through the process of cellular proliferation, collagen migrates over the fatty streak, forming a fibrous plaque. The fibrous plaque is often elevated and protrudes into the vessel lumen, partially or completely obstructing blood flow through the artery. Plaques are either stable or unstable. Unstable plaques are prone to rupture and are often clinically silent until they rupture (McCance et al., 2014).

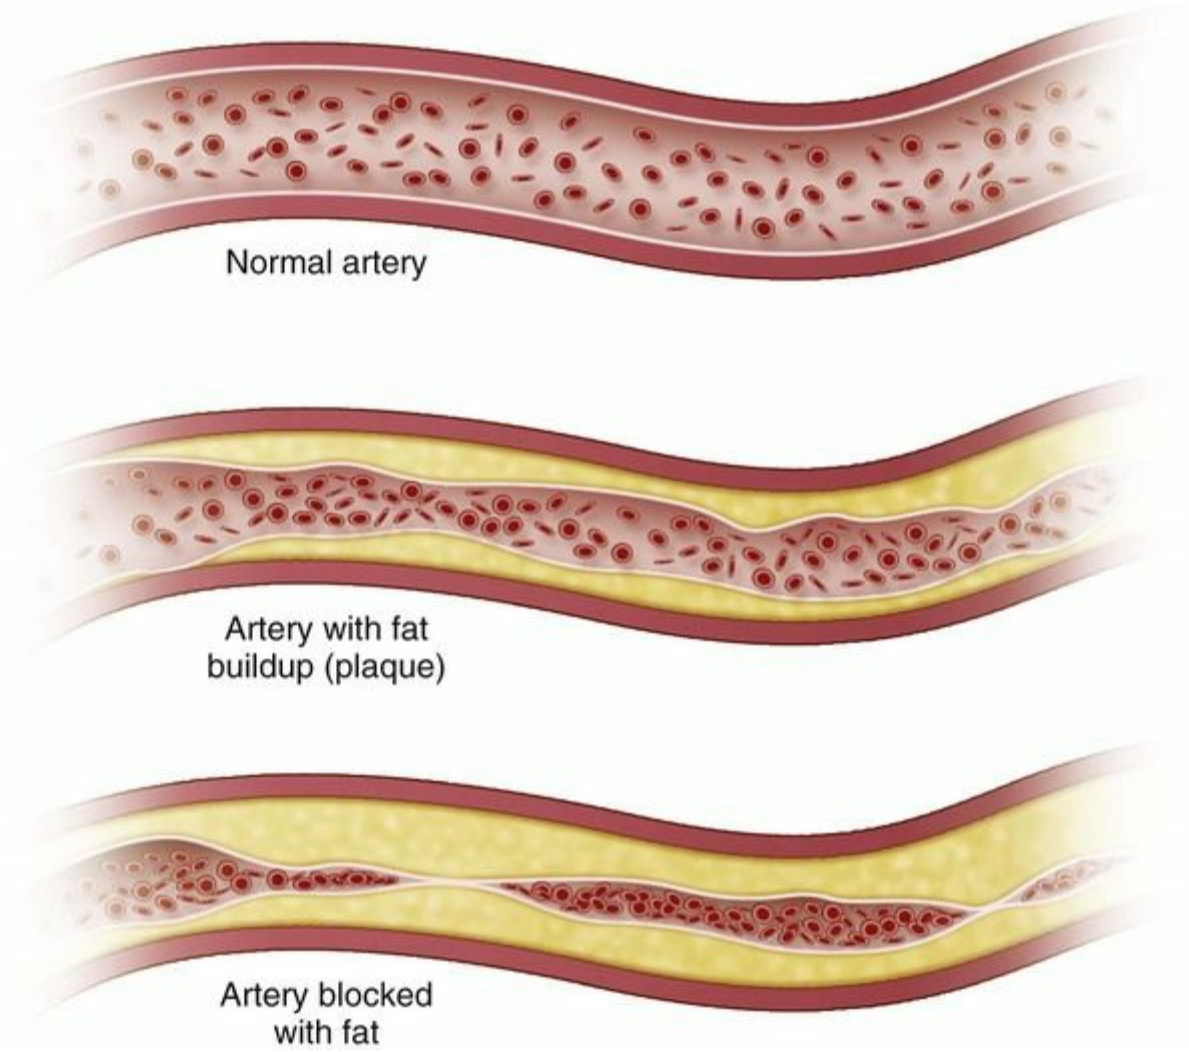

FIG. 36-1 Pathophysiology of atherosclerosis.

In the final stage, the fibrous plaques become calcified, hemorrhagic, ulcerated, or thrombosed and affect all layers of the vessel. The rate of progression of the process may be influenced by genetic factors; certain chronic diseases (e.g., diabetes mellitus); and lifestyle habits, including smoking, eating habits, and level of exercise.

When *stable* plaque ruptures, thrombosis (blood clot) and constriction obstruct the vessel lumen, causing inadequate perfusion and oxygenation to distal tissues. *Unstable* plaque rupture causes more severe damage. After the rupture occurs, the exposed underlying tissue causes platelet adhesion and rapid thrombus formation. The thrombus may suddenly block a blood vessel, resulting in ischemia and infarction (e.g., myocardial infarction) (McCance et al., 2014).

Endothelial (intimal) injury of the major arteries of the body can be caused by many factors. Elevated levels of **lipids** (fats) like low-density lipoprotein cholesterol (LDL-C) and decreased levels of high-density lipoprotein cholesterol (HDL-C) can cause chemical injuries to the vessel wall. (Chapter 33 discusses lipids in detail.) Chemical injury can also be

caused by elevated levels of toxins in the bloodstream, which may occur with renal failure or by carbon monoxide circulating in the bloodstream from cigarette smoking. The vessel wall can be weakened by the natural process of aging or by diseases such as hypertension.

Genetic predisposition and diabetes have a major effect on the development of atherosclerosis. Some patients have familial **hyperlipidemia,** an elevation of serum lipid levels. In these people, the liver makes excessive cholesterol and other fats. However, some people with hereditary atherosclerosis have a normal blood cholesterol level. The reason for the development and progression of plaque in these patients is not understood (McCance et al., 2014).

Adult patients of any age with severe diabetes mellitus frequently have premature and severe atherosclerosis from microvascular damage. The premature atherosclerosis occurs because diabetes promotes an increase in LDL-C and triglycerides (lipids) in plasma. In addition, arterial damage may result from the effect of hyperglycemia.

Other factors are indirectly related to atherosclerosis development. A list of risk factors is found in Table 36-1.

TABLE 36-1

Risk Factors for Atherosclerosis

• Low HDL-C • High LDL-C • Increased triglycerides • Genetic predisposition • Diabetes mellitus • Obesity
• Sedentary lifestyle • Smoking • Stress • African-American or Hispanic ethnicity • Older adult

HDL-C, High-density lipoprotein cholesterol; *LDL-C,* low-density lipoprotein cholesterol.

It is not known exactly how many people have atherosclerosis, but small plaques are almost always present in the arteries of young adults. The incidence can be better quantified by assessing the number of cardiovascular diseases (CVDs) that result from atherosclerosis. An estimated 81 million U.S. adults have one or more types of CVD (Go et al., 2013). About half of those with CVD are older than 60 years, and many more are middle-aged. The number of people affected by atherosclerosis is likely to increase as the population ages.

Patient-Centered Collaborative Care

Assessment

Physical Assessment/Clinical Manifestations.

The assessment of a patient with atherosclerosis includes a complete cardiovascular assessment because associated heart disease is often present. Because of the high incidence of hypertension in patients with atherosclerosis, assess the blood pressure in both arms.

Palpate pulses at all of the major sites on the body, and note any differences. *Palpate each carotid artery separately to prevent blocking blood flow to the brain!* Also feel for temperature differences in the lower extremities, and check capillary filling. Prolonged capillary filling (>3 seconds in young to middle-aged adults; >5 seconds in older adults) generally indicates poor circulation, *although this indicator is not the most reliable indicator of perfusion.* An extremity in a person with severe atherosclerotic disease may be cool or cold with a diminished or absent pulse.

Many patients with vascular disease have a bruit in the larger arteries, which can be heard with a stethoscope or Doppler probe. A **bruit** is a turbulent, swishing sound, which can be soft or loud in pitch. It is heard as a result of blood trying to pass through a narrowed artery. A bruit is considered abnormal, but it does not indicate the severity of disease. Bruits often occur in the carotid, aortic, femoral, and popliteal arteries.

Nursing Safety Priority QSEN

Critical Rescue

A decrease in intensity or a complete loss of a pulse in a patient with atherosclerosis may indicate an arterial occlusion (blockage) in the area supplied by the artery. Immediately report pulselessness to the health care provider and document for emergency management (described later in this chapter under Acute Peripheral Arterial Occlusion).

Laboratory Assessment.

Patients with atherosclerosis often have elevated lipids, including cholesterol and triglycerides. Total serum *cholesterol* levels should be below 200 mg/dL. Elevated cholesterol levels are confirmed by HDL and LDL measurements. Increased low-density lipoprotein cholesterol (LDL-C) ("bad" cholesterol) levels indicate that a person is at an increased risk for atherosclerosis. Low high-density lipoprotein cholesterol (HDL-C) ("good" cholesterol) levels also indicate an increased risk. In general, a

desirable LDL-C level is one below 130 mg/dL for healthy people and below 70 mg/dL for those diagnosed with CVD or who are diabetic. A desirable HDL-C level is 45 mg/dL or above for men and 55 mg/dL for women (Pagana & Pagana, 2014). These values differ based on age and comorbidities.

Triglyceride level may also be elevated with atherosclerosis and is an emerging lipid risk factor by the classic Adult Treatment Panel Report No. 3 (ATP III) released by the National Heart, Lung, and Blood Institute (National Cholesterol Education Program, 2002). A level of 160 mg/dL or above indicates **hypertriglyceridemia** in men**.** Women should have a level below 135 mg/dL (Pagana & Pagana, 2014). Elevated triglycerides are considered a marker for other lipoproteins. They also suggest metabolic syndrome**,** which increases the risk for coronary heart disease (see Table 38-1 and discussion in Chapter 38).

Interventions

Atherosclerosis progresses for years before clinical manifestations occur. Adults who are at risk for the disease can often be identified through cholesterol screening and history. Because of the high incidence in the United States, low-risk people 20 years of age and older are advised to have their total serum cholesterol level evaluated at least once every 5 years. More frequent measurements are suggested for people with multiple risk factors and those older than 40 years.

People with multiple risk factors are grouped into high-risk patient categories termed "coronary heart disease equivalents." These groups include:

- Patients with diabetes but without signs of vascular disease
- Patients with a Framingham Heart Study 10-year absolute risk score of over 20% for coronary heart disease events
- Patients identified with multiple metabolic risk factors

People within these groups are at the same risk level as those who already have vascular disease.

Interventions for patients with atherosclerosis or those at high risk for the disease focus on lifestyle changes. Teach patients about the need to make daily changes by avoiding or minimizing modifiable risk factors. *Modifiable risk factors* are those that can be changed or controlled by the patient, such as smoking, weight management, and exercise. Nutrition is one of the most important parts of the risk-reduction plan. Chapter 38 describes how to manage modifiable risk factors in detail in the Health Promotion and Maintenance section, p. 759. If lipoprotein levels do not improve after lifestyle changes, the health care provider may prescribe

drug therapy to lower cholesterol and/or triglycerides.

Nutrition Therapy.

The American College of Cardiology and American Heart Association (ACC/AHA) recently published new dietary recommendations for lowering LDL-C levels (Eckel et al., 2014). These recommendations were based on the best current evidence from randomized controlled trials and include:

- Consume a dietary pattern that emphasizes intake of vegetables, fruits, and whole grains.
- Consume low-fat dairy products, poultry, fish, legumes, nontropical (e.g., canola) vegetable oils, and nuts.
- Limit intake of sweets, sugar-sweetened beverages, and red meats.
- Aim for a dietary pattern that includes 5% to 6% of calories from saturated fat.
- Reduce percent of calories from *trans* fat.

These guidelines are similar to the Dietary Approaches to Stop Hypertension (DASH), which also recommend daily sodium, potassium, and fiber amounts (National Heart, Lung, and Blood Institute, 2012). In collaboration with the dietitian as needed, teach the patient about the types of fat content in food. Meats and eggs contain mostly saturated fats and are high in cholesterol. Instruct patients about increasing dietary fiber to 30 g each day, which is consistent with DASH guidelines.

Physical Activity.

The ACC/AHA also recommends that adults engage in aerobic physical activity 3 or 4 times a week to reduce LDL-C levels. Each session should last for 40 minutes on average and involve moderate-to-vigorous physical activity (Eckel et al., 2014).

Drug Therapy.

For patients with elevated total and LDL-C levels that do not respond adequately to dietary intervention, the health care provider prescribes a cholesterol-lowering agent. Drug choice and dosing depend on the serum cholesterol level, the degree to which the level needs to be decreased, and the patient's age (Stone et al., 2014). Because most of these drugs can produce major side effects, they are generally given only when nonpharmacologic management has been unsuccessful.

A class of drugs known as *3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors (statins)* successfully reduces total cholesterol in most patients when used for an extended period. Examples

include lovastatin (Mevacor), simvastatin (Zocor), and pitavastatin (Livalo), which lower both LDL-C and triglyceride levels (Table 36-2).

TABLE 36-2

Commonly Used Drugs for Lowering LDL-C Levels

HMG-CoA Reductase Inhibitors (Statins)	Combination Drugs
• Lovastatin (Mevacor) • Atorvastatin (Lipitor) • Simvastatin (Zocor) • Fluvastatin (Lescol) • Rosuvastatin (Crestor) • Pravastatin (Pravachol) • Pitavastatin (Livalo)	• Ezetimibe and simvastatin (Vytorin) • Amlodipine and atorvastatin (Caduet) • Niacin and lovastatin (Advicor)

HMG-CoA, 3-hydroxy-3-methylglutaryl coenzyme A.

The American College of Cardiology/American Heart Association recently published new recommendations for treatment of high cholesterol to reduce atherosclerotic cardiovascular disease (ASCVD) in adults (Stone et al., 2014). These evidence-based recommendations are highlighted in Table 36-3.

TABLE 36-3

Selected 2013 ACC/AHA Recommendations for the Treatment of Serum Cholesterol to Reduce Atherosclerotic Cardiovascular Disease Risk in Adults

Primary Prevention
• All people with LDL-C equal to or greater than 190 mg/dL should be evaluated for secondary causes of hyperlipidemia and treated with statin therapy. • Adults with diabetes mellitus who are 40 to 75 years of age should be treated with high-intensity statin therapy. • Adults 40 to 75 years of age with LDL-C of 70 to 189 mg/dL without clinical signs of ASCVD or diabetes should be treated with moderate- to high-intensity statin therapy.
Secondary Prevention
• High-intensity statin therapy should be initiated or continued as first-line treatment in adults 75 years of age or younger who have clinical manifestations of ASCVD, unless contraindicated. • In people older than 75 years, the potential for ASCVD risk-reduction benefits, adverse drug effects, and drug-drug interactions should be evaluated.

ASCVD, Atherosclerotic cardiovascular disease; *LDL-C,* low-density lipoprotein cholesterol.

Data from Stone, N.J., Robinson, J., Lichtenstein, A.H., Merz, N.B., Blum, C.B., Eckel, R.H., et al. (2014). 2013 ACC/AHA guidelines on the treatment of blood cholesterol to reduce atherosclerotic cardiovascular risk in adults: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. *Circulation*, *129*(25 Suppl 2), S1-S45.

Nursing Safety Priority QSEN

Drug Alert

Statins reduce cholesterol synthesis in the liver and increase clearance of LDL-C from the blood. Therefore they are contraindicated in patients with active liver disease or during pregnancy because they can cause muscle myopathies and marked decreases in liver function. Statins also

have the potential for interactions with other drugs, such as warfarin, cyclosporine, and selected antibiotics. Statins are discontinued if the patient has muscle cramping or elevated liver enzyme levels. Some patients also report abdominal bloating, flatulence, diarrhea, and/or constipation as side effects of these drugs. Remind patients to have laboratory testing follow-up as prescribed by their health care provider (Lilley et al., 2014).

Teach patients taking statin drugs, especially those taking atorvastatin, lovastatin, and simvastatin, to *avoid grapefruit and grapefruit juice in their diet*. Grapefruit contains a group of chemicals called *furanocoumarins* that bind to and inactivate the enzyme *CYP3A4.* This enzyme is important for metabolism of many drugs, including statins. If it is inactivated, too much of the statin drug can remain in the patient's bloodstream, causing possible kidney failure, heart failure, GI bleeding, or even death (Bailey et al., 2013).

A different type of lipid-lowering agent, ezetimibe (Zetia), may be used in place of or in combination with statin-type drugs. This drug inhibits the absorption of cholesterol through the small intestine. Vytorin is a combination drug containing ezetimibe and simvastatin. This drug works two ways—by reducing the absorption of cholesterol and by decreasing the amount of cholesterol synthesis in the liver. Other statin combinations have been developed to improve lipid levels, such as Advicor—a combination of niacin and lovastatin. Aspirin and pravastatin are combined as Pravigard. Amlodipine (Norvasc) and atorvastatin are combined as Caduet to decrease blood pressure while decreasing triglycerides (TGs), increasing HDL, and lowering LDL. Combining drugs may improve adherence for the patient who is often taking multiple drugs.

Complementary and Alternative Therapies.

Nicotinic acid or niacin (Niaspan), a B vitamin, may lower LDL-C and very-low-density lipoprotein (VLDL) cholesterol levels and increase HDL-C levels in some patients, although the evidence supporting its use is lacking. It is used as a single agent or in combination with an acid-binding resin drug or a statin. Low doses are recommended because many patients experience flushing and a very warm feeling all over. Higher doses can result in an elevation of hepatic enzymes.

Lovaza (omega-3 ethyl esters) is approved by the Food and Drug Administration (FDA) as an adjunct to diet to reduce TGs that are greater than 500 mg/dL. This drug also decreases plaque growth and

inflammation and reduces clot formation.

NCLEX Examination Challenge

Health Promotion and Maintenance

A client diagnosed with atherosclerosis has been prescribed lovastatin (Mevacor). Which statement by the client indicates a need for further teaching?

A "I won't need to change my diet because now I'm taking a pill."
B "I'll follow up with my nurse practitioner on a regular basis."
C "I need to quit smoking as soon as I possibly can."
D "I shouldn't drink grapefruit juice while on this drug."

Hypertension

Hypertension, or high blood pressure (BP), is the most common health problem seen in primary care settings and can cause stroke, myocardial infarction (heart attack), kidney failure, and death if not treated early and effectively. The Eighth Joint National Committee (JNC 8) on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure recently published its *2014 Evidence-Based Guidelines for the Management of High Blood Pressure in Adults* based on the results of randomized controlled trials, the gold standard for establishing recommendations for best clinical practice (James et al., 2014). These new guidelines replace the JNC 7 recommendations and hypertension classifications.

According to JNC 8, in the general population ages 60 years and older, the desired BP is below 150/90. For people younger than 60 years, the desired BP is below 140/90. Patients whose blood pressures are above these desired goals should be treated with drug therapy (James et al., 2014). Adult patients with specific risk factors for developing hypertension should be treated at any age, as described later under Drug Therapy.

❖ Pathophysiology

To best understand the pathophysiology of hypertension, a review of normal blood pressure and how it is normally maintained is essential.

Mechanisms That Influence Blood Pressure.

The systemic arterial blood pressure is a product of cardiac output (CO) and total peripheral vascular resistance (PVR). Cardiac output is determined by the stroke volume (SV) multiplied by heart rate (HR) (CO = SV × HR). Control of peripheral vascular resistance (i.e., vessel constriction or dilation) is maintained by the autonomic nervous system and circulating hormones, such as norepinephrine and epinephrine. Consequently, any factor that increases peripheral vascular resistance, heart rate, or stroke volume increases the systemic arterial pressure. Conversely, any factor that decreases peripheral vascular resistance, heart rate, or stroke volume decreases the systemic arterial pressure and can cause decreased perfusion to body tissues.

Stabilizing mechanisms exist in the body to exert an overall regulation of systemic arterial pressure and to prevent circulatory collapse. Four control systems play a major role in maintaining blood pressure:

- The arterial baroreceptor system
- Regulation of body fluid volume

• The renin-angiotensin-aldosterone system
• Vascular autoregulation

Arterial baroreceptors are found primarily in the carotid sinus, aorta, and wall of the left ventricle. They monitor the level of arterial pressure and counteract a rise in arterial pressure through vagally mediated cardiac slowing and vasodilation with decreased sympathetic tone. Therefore reflex control of circulation elevates the systemic arterial pressure when it falls and lowers it when it rises. Why baroreceptor control fails in hypertension is not clear (McCance et al., 2014).

Changes *in fluid volume* also affect the systemic arterial pressure. For example, if there is an excess of sodium and/or water in a person's body, the blood pressure rises through complex physiologic mechanisms that change the venous return to the heart, producing a rise in cardiac output. If the kidneys are functioning adequately, a rise in systemic arterial pressure produces diuresis (excessive voiding) and a fall in pressure. Pathologic conditions change the pressure threshold at which the kidneys excrete sodium and water, thereby altering the systemic arterial pressure.

The *renin-angiotensin-aldosterone* system also regulates blood pressure (see discussion in Chapter 11). The kidney produces renin, an enzyme that acts on angiotensinogen (a plasma protein substrate) to split off angiotensin I, which is converted by an enzyme in the lung to form angiotensin II. Angiotensin II has strong vasoconstrictor action on blood vessels and is the controlling mechanism for aldosterone release. Aldosterone then works on the collecting tubules in the kidneys to reabsorb sodium. Sodium retention inhibits fluid loss, thus increasing blood volume and subsequent blood pressure.

Inappropriate secretion of renin may cause increased peripheral vascular resistance in patients with hypertension. When the blood pressure is high, renin levels should decrease because the increased renal arteriolar pressure usually inhibits renin secretion. However, for most people with essential hypertension, renin levels remain normal.

The process of *vascular autoregulation,* which keeps perfusion of tissues in the body relatively constant, appears to be important in causing hypertension. However, the exact mechanism of how this system works is poorly understood.

Classifications of Hypertension.

Hypertension can be essential (primary) or secondary. **Essential hypertension** is the most common type and is not caused by an existing health problem. However, a number of risk factors can increase a

person's likelihood of becoming hypertensive. Continuous BP elevation in patients with essential hypertension results in damage to vital organs by causing medial hyperplasia (thickening) of the arterioles. As the blood vessels thicken and perfusion decreases, body organs are damaged. These changes can result in myocardial infarctions, strokes, peripheral vascular disease (PVD), or kidney failure.

Specific disease states and drugs can increase a person's susceptibility to hypertension. A person with this type of elevation in blood pressure has **secondary hypertension.**

Malignant hypertension is a severe type of elevated blood pressure that rapidly progresses. A person with this health problem usually has symptoms such as morning headaches, blurred vision, and dyspnea and/or symptoms of uremia (accumulation in the blood of substances ordinarily eliminated in the urine). Patients are often in their 30s, 40s, or 50s with their systolic blood pressure greater than 200 mm Hg. The diastolic blood pressure is greater than 150 mm Hg or greater than 130 mm Hg when there are pre-existing complications. Unless intervention occurs promptly, a patient with malignant hypertension may experience kidney failure, left ventricular heart failure, or stroke.

Etiology and Genetic Risk.

Essential hypertension can develop when a patient has any one or more of the risk factors listed in Table 36-4.

TABLE 36-4

Etiology of Hypertension

Essential (Primary)	Secondary

• Family history of hypertension
• African-American ethnicity
• Hyperlipidemia
• Smoking
• Older than 60 years or postmenopausal
• Excessive sodium and caffeine intake
• Overweight/obesity
• Physical inactivity
• Excessive alcohol intake
• Low potassium, calcium, or magnesium intake
• Excessive and continuous stress
	• Kidney disease
	• Primary aldosteronism
	• Pheochromocytoma
	• Cushing's disease
	• Coarctation of the aorta
	• Brain tumors
	• Encephalitis
	• Pregnancy
	• Drugs:
	  • Estrogen (e.g., oral contraceptives)
	  • Glucocorticoids
	  • Mineralocorticoids
	  • Sympathomimetics

Kidney disease is one of the most common causes of *secondary* hypertension. Hypertension can develop when there is any sudden damage to the kidneys. Renovascular hypertension is associated with narrowing of one or more of the main arteries carrying blood directly to

the kidneys, known as *renal artery stenosis (RAS).* Many patients have been able to reduce the use of their antihypertensive drugs when the narrowed arteries are dilated through angioplasty with stent placement.

Dysfunction of the adrenal medulla or the adrenal cortex can also cause secondary hypertension. *Adrenal-mediated hypertension* is due to primary excesses of aldosterone, cortisol, and catecholamines. In *primary aldosteronism,* excessive aldosterone causes hypertension and hypokalemia (low potassium levels). It usually arises from benign adenomas of the adrenal cortex. *Pheochromocytomas* are tumors that originate most commonly in the adrenal medulla and result in excessive secretion of catecholamines, resulting in life-threatening high blood pressure. In *Cushing's syndrome,* excessive glucocorticoids are excreted from the adrenal cortex. The most common cause of Cushing's syndrome is either adrenocortical hyperplasia or adrenocortical adenoma (tumor).

Drugs that can cause secondary hypertension include estrogen, glucocorticoids, mineralocorticoids, sympathomimetics, cyclosporine, and erythropoietin. The use of estrogen-containing oral contraceptives is likely the most common cause of secondary hypertension in women. Drugs that cause hypertension are discontinued to reverse this problem.

Incidence and Prevalence.

Hypertension is a worldwide epidemic. In the United States, one in every three adults has high blood pressure or is being treated for hypertension (Go et al., 2013). The disease can shorten life expectancy.

Gender Health Considerations

Patient-Centered Care QSEN

A higher percentage of men than women have hypertension until age 45 years. From 45 to 54 years, women have a slightly higher percentage of hypertension than men. After age 54 years, women have a much higher percentage of the disease (Go et al., 2013). The causes for these differences are not known.

Cultural Considerations

Patient-Centered Care QSEN

The prevalence of hypertension in African Americans in the United States is among the highest in the world and is constantly increasing. When compared with Euro-Americans, they develop high BP earlier in

life, making them much more likely to die from strokes, heart disease, and kidney disease (Go et al., 2013). The exact reasons for these differences are not known, but genetics and environmental factors may play a role. Efforts to raise awareness of hypertension through education within African-American communities, including the importance of receiving treatment and controlling blood pressure, have been somewhat successful. Geographic differences still exist (Go et al., 2013).

Health Promotion and Maintenance

Control of hypertension has resulted in major decreases in cardiovascular morbidity and mortality. The U.S. *Healthy People 2020* campaign includes a number of objectives related to hypertension to decrease cardiovascular mortality (Table 36-5).

TABLE 36-5

Meeting *Healthy People 2020* Objectives

Heart Disease and Stroke
Selected objectives retained from *Healthy People 2010:*
• Increase the proportion of adults with high blood pressure who are taking action to help control their blood pressure. • Increase the proportion of adults who have had their blood pressure measured within the preceding 2 years and can state whether their blood pressure was normal or high.
Selected objectives retained but modified from *Healthy People 2010:*
• Reduce the proportion of persons in the population with hypertension. • Increase the proportion of adults with prehypertension who meet the recommended guidelines for: a. Body mass index (BMI) b. Saturated fat consumption c. Sodium intake d. Physical activity e. Moderate alcohol consumption • Increase the proportion of adults with hypertension who meet the [above] recommended guidelines.
New objectives for *Healthy People 2020:*
• Increase the proportion of adults with hypertension who are taking the recommended medications to decrease their blood pressure.

Data from www.healthypeople.gov/2020.

The *2013 ACA/AHA Guidelines on Lifestyle Management to Reduce Cardiovascular Risk* outlines evidence-based dietary and exercise practices to help lower blood pressure (Eckel et al., 2014). These guidelines are similar to the Dietary Approaches to Stop Hypertension (DASH) and include:

- Consume a dietary pattern that emphasizes intake of vegetables, fruits, and whole grains.
- Consume low-fat dairy products, poultry, fish, legumes, nontropical vegetable oils, and nuts.
- Limit intake of sweets, sugar-sweetened beverages, and red meats.
- Lower sodium intake to no more than 2400 mg per day; a limit of

1500 mg of sodium per day is preferred.
- Engage in aerobic physical activity 3 or 4 times a week. Each session should last for 40 minutes on average and involve moderate-to-vigorous physical activity.

In addition to following specific dietary and physical activity guidelines, teach patients ways to decrease other modifiable risk factors for hypertension, such as smoking and excessive alcohol intake. Risk factor prevention and lifestyle changes are discussed in more detail in Chapter 38.

Patient-Centered Collaborative Care

Assessment

History.

During history taking, review the patient's risk factors for hypertension. Collect data on the patient's age; ethnic origin or race; family history of hypertension; average dietary intake of calories, sodium- and potassium-containing foods, and alcohol; and exercise habits. Also assess any past or present history of kidney or cardiovascular disease and current use of drug therapy or illicit drugs.

Physical Assessment/Clinical Manifestations.

When a diagnosis of hypertension is made, most people have no symptoms. However, some patients experience headaches, facial flushing (redness), dizziness, or fainting as a result of the elevated blood pressure. Obtain blood pressure readings in both arms. Two or more readings may be taken at each visit (Fig. 36-2). Some patients have high blood pressure due to anxiety associated with visiting a health care provider. Be sure to take an accurate blood pressure by using an appropriate-size cuff. Anderson et al. (2010) found that forearm blood pressure measurements are as accurate as upper arm blood pressures, especially in patients who are obese.

FIG. 36-2 Blood pressure screening during history and physical examination.

To detect postural (orthostatic) changes, take readings with the patient in the supine (lying) or sitting position and at least 2 minutes later when standing. **Orthostatic hypotension** is a decrease in blood pressure (20 mm Hg systolic and/or 10 mm Hg diastolic) when the patient changes position from lying to sitting.

Funduscopic examination of the eyes to observe vascular changes in the retina is done by a skilled health care practitioner. The appearance of the retina can be a reliable index of the severity and prognosis of hypertension.

Physical assessment is helpful in diagnosing several conditions that produce secondary hypertension. The presence of abdominal bruits is typical of patients with renal artery stenosis. Tachycardia, sweating, and pallor may suggest a pheochromocytoma (adrenal medulla tumor). Coarctation of the aorta is evidenced by elevation of blood pressure in the arms, with normal or low blood pressure in the lower extremities. Femoral pulses are also delayed or absent.

Psychosocial Assessment.

Assess for psychosocial stressors that can worsen hypertension and

affect the patient's ability to adhere to treatment. Evaluate job-related, economic, and other life stressors, as well as the patient's response to these stressors. Some patients may have difficulty coping with the lifestyle changes needed to control hypertension. Be sure to assess past coping strategies.

Diagnostic Assessment.

Although no laboratory tests are diagnostic of essential hypertension, several laboratory tests can assess possible causes of secondary hypertension. Kidney disease can be diagnosed by the presence of protein and red blood cells in the urine, elevated levels of blood urea nitrogen (BUN), and elevated serum creatinine levels. The creatinine clearance test directly indicates the glomerular filtration ability of the kidneys. The normal value is 107 to 139 mL/min for men and 87 to 107 mL/min for women (Pagana & Pagana, 2014). Decreased levels indicate acute or chronic kidney disease.

Urinary test results are positive for the presence of catecholamines in patients with a pheochromocytoma (tumor of the adrenal medulla). An elevation in levels of serum corticoids and 17-ketosteroids in the urine is diagnostic of Cushing's disease.

No specific x-ray studies can diagnose hypertension. Routine chest radiography may help recognize cardiomegaly (heart enlargement).

An electrocardiogram (ECG) determines the degree of cardiac involvement. Left atrial and ventricular hypertrophy is the first ECG sign of heart disease resulting from hypertension. Left ventricular remodeling can be detected on the 12-lead ECG (see Chapter 38 for discussion of remodeling).

◆ Analysis

The priority collaborative problems for patients with hypertension include:

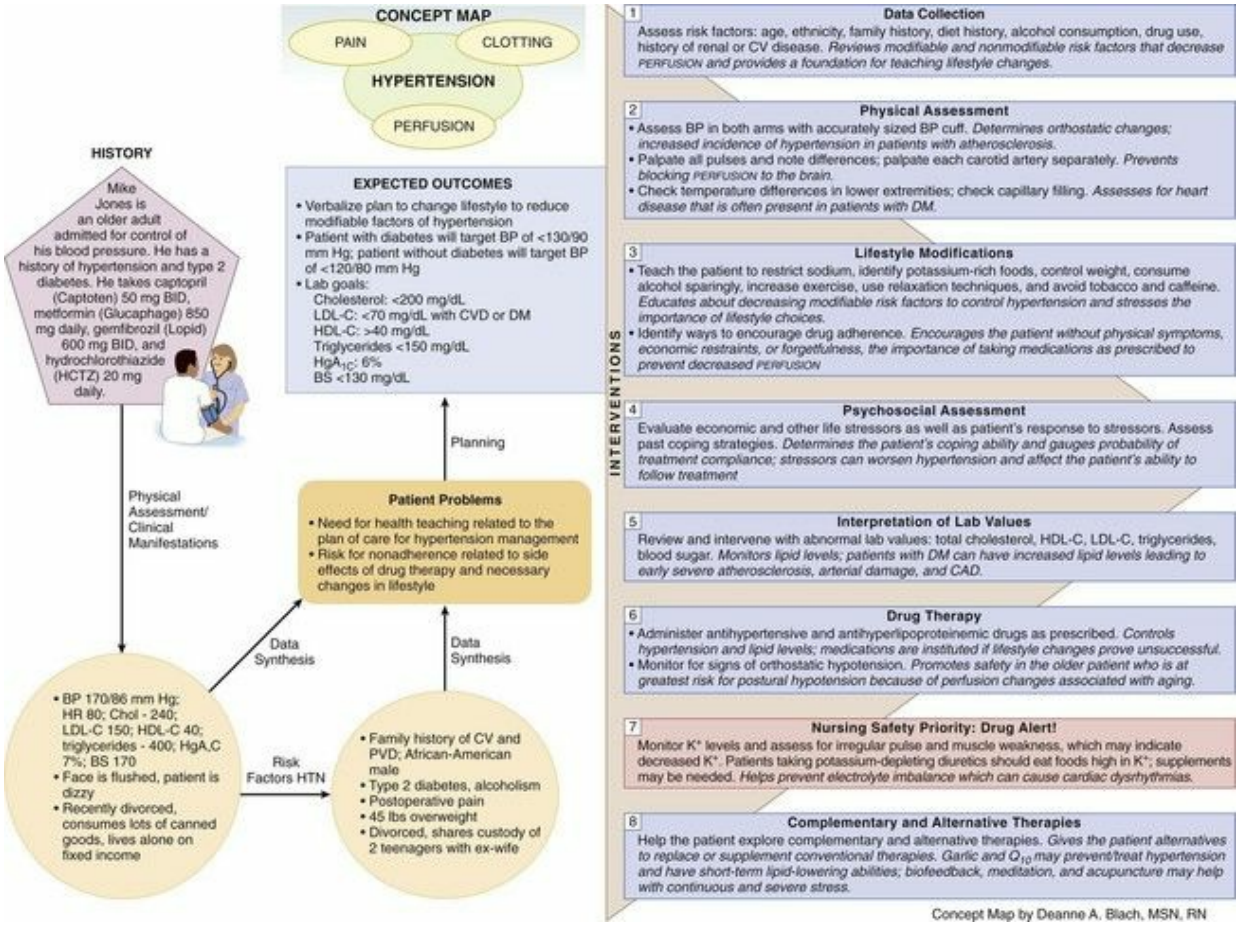
1. Need for health teaching related to the plan of care for hypertension management
2. Risk for nonadherence related to side effects of drug therapy and necessary changes in lifestyle

◆ Planning and Implementation

Health Teaching

Planning: Expected Outcomes.

The patient with hypertension is expected to verbalize his or her individualized plan of care for hypertension (see the Concept Map on Hypertension).



Interventions.

Lifestyle changes are considered the foundation of hypertension control. If these changes are unsuccessful, the primary care provider considers the use of antihypertensive drugs. There is no surgical treatment for essential hypertension. However, surgery may be indicated for certain causes of secondary hypertension, such as kidney disease, coarctation of the aorta, and pheochromocytoma.

Lifestyle Changes.

In collaboration with the health care team, teach the patient to (Baldwin, 2011):

- Restrict sodium intake in the diet per the ACA/AHA guidelines
- Reduce weight, if overweight or obese
- Use alcohol sparingly (no more than 1 drink a day for women and 2 drinks a day for men [1 drink = 12 oz. beer, 5 oz. wine, or 1.5 oz. liquor

such as vodka or gin.])
- Exercise 3 or 4 days a week for 40 minutes each day per the ACA/AHA guidelines
- Use relaxation techniques to decrease stress
- Avoid tobacco and caffeine

Strategies to help patients make these changes are discussed in Chapter 38.

Complementary and Alternative Therapies.

Garlic and coenzyme Q_{10} have been used for a number of health problems, but evidence to support their use to prevent hypertension is controversial. Evidence by consensus and case reports does support garlic's cholesterol-lowering ability and its ability to decrease blood pressure in patients with hypertension (National Center for Complementary and Alternative Medicine, 2013). Teach patients to check with their health care provider before starting garlic or any herbal therapy because of possible side effects and interactions with other herbs, foods, or drugs. Garlic can damage the liver and cause bleeding in some patients, especially if they have invasive procedures such as surgery.

Some patients have also had success with biofeedback, meditation, and acupuncture as part of their overall management plan. These methods may be most useful as adjuncts for patients who experience continuous and severe stress.

Drug Therapy.

Drug therapy is individualized for each patient, with consideration given to culture, age, other existing illness, severity of blood pressure elevation, and cost of drugs and follow-up. Once-a-day drug therapy is best, especially for the older adult, because the more doses required each day, the higher the risk that a patient will not follow the treatment regimen. However, many patients with hypertension need two or more drugs to adequately control blood pressure.

In the largest hypertensive trial done to date, Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT), the use of diuretics has been practically unmatched in preventing the cardiovascular complications of hypertension. The *2014 Evidence-Based Guidelines for the Management of High Blood Pressure in Adults* presented by JNC 8 recommends the use of one or more of these four classes of drugs: thiazide-type diuretics, calcium channel blockers (CCBs),

angiotensin-converting enzyme inhibitors (ACEIs), and angiotensin II receptor blockers (ARBs). Patients who do not respond to these first-line drugs may be placed on an aldosterone receptor antagonist (blocker), beta-adrenergic blocker, or renin inhibitor. Examples of commonly used drug classes for hypertension are listed in Chart 36-1. JNC 8 recommendations for pharmacologic management are summarized in Table 36-6.

chart 36-1 Common Examples of Drug Therapy

Hypertension Management

DRUG/USUAL DOSAGE	PURPOSE/ACTION	NURSING INTERVENTIONS	RATIONALES
Diuretics			
Hydrochlorothiazide (HCTZ) (Microzide, Oretic, Urozide 🍁) 25-100 mg orally daily	Low-ceiling diuretic that inhibits Na^+, Cl^-, and water reabsorption in the distal tubules of the kidney.	Teach patient to eat foods high in K^+ and have follow-up laboratory tests to monitor electrolyte levels.	Drug causes K^+ and Mg^{2+} excretion.
		Teach older adults to rise slowly from chair or bed.	Drug causes diuresis, which can cause orthostatic hypotension.
		Use with caution for patients with diabetes.	Drug can affect glucose control.
		Use with caution for patients with gout.	Drug can cause uric acid retention.
Furosemide (Lasix, Furoside 🍁) 40-600 mg orally daily	High-ceiling diuretic that inhibits Na^+, Cl^-, and water reabsorption in the kidney's loop of Henle.	Report to the health care provider weakness or dizziness or new-onset confusion.	Drug can cause hypovolemia, dehydration, and hypokalemia.
		Same as for HCTZ, except safer to give to patients with diabetes and gout.	Same as for HCTZ.
Spironolactone (Aldactone, Novo-Spiroton 🍁) 50-400 mg orally daily	Acts on distal tubules of kidneys to inhibit reabsorption of Na^+ in exchange for K^+.	Teach patients to *decrease* intake of foods high in potassium and have follow-up laboratory tests for electrolyte levels.	Drug causes K^+ retention in the body.
		Teach patients to report weakness and irregular pulse to health care provider.	These symptoms may indicate hyperkalemia.
Calcium Channel Blockers			
Verapamil (Calan, Nu-Verap 🍁) Up to 480 mg orally in 3 divided doses; *Extended-release* form (ER) also available as 240-480 mg orally daily	Interferes with flux of calcium ions to cause vasodilation, which lowers blood pressure (BP).	Monitor pulse and blood pressure before taking each day; do not take without contacting health care provider if pulse is less than 60 or systolic BP is below 100 mm Hg.	Drug slows SA and AV conduction in the heart, thus decreases heart rate; vasodilation causes decreased blood pressure.
		Teach patients and their families that patients should avoid grapefruit juice and grapefruits when taking calcium channel blockers.	Grapefruit and its juice can enhance the action of the drug causing organ dysfunction or death.
Amlodipine (Norvasc) 5-10 mg orally daily	Same as above for verapamil.	Same as above for verapamil, but safe to drink grapefruit juice.	Same as above for verapamil, but safe to drink grapefruit juice.
Angiotensin-Converting Enzyme (ACE) Inhibitors			
Lisinopril (Prinivil, Zestril) 10-80 mg orally daily	Blocks action of ACE in converting angiotensin I to angiotensin II (vasoconstrictor).	Report nagging cough to health care provider.	Cough is a common and annoying side effect, and drug should be discontinued if it occurs.
		Monitor blood pressure carefully, especially orthostatic checks; remind patients to move slowly from sitting to standing to prevent dizziness and possible falls. Do not give drug without checking with health care provider if systolic blood pressure is below 100.	Drug prevents vasoconstriction by angiotensin II, resulting in vasodilation and decreased blood pressure.
Enalapril (Vasotec) 10-40 mg orally daily or in divided doses; also available in IV form	Same as above for lisinopril.	Monitor blood pressure as described above for lisinopril.	Same as above for lisinopril.
Angiotensin II Receptor Blockers (ARBs)			
Valsartan (Diovan) 80-320 mg orally daily	Blocks binding of angiotensin II to receptor sites in vascular smooth muscle and adrenal glands.	Teach patients to avoid foods high in potassium.	ARBs can cause hyperkalemia, especially when combined with other antihypertensive drugs.
		Monitor blood pressures to ensure that hypotension does not occur. Do not take drug without checking with a health care provider if systolic BP is below 100.	Vasodilation causes decreased blood pressure.
Losartan (Cozaar) 25-100 mg orally daily or in divided doses twice a day	Same as above for valsartan.	Same as above for valsartan.	Same as above for valsartan.
	Aldosterone Receptor Antagonists		
Eplerenone (Inspra) 25-50 mg orally daily	Blocks aldosterone binding at receptor sites in kidney, heart, blood vessels, and brain to inhibit sodium reabsorption by the kidneys.	Teach patients to follow up with laboratory tests as scheduled; decrease intake of high-potassium foods.	Drug can cause increases in K^+ and triglycerides and a decreased Na^+.
		Avoid taking the drug with grapefruit, grapefruit juice, and St. John's wort.	Grapefruit, grapefruit juice, and St. John's wort increase the risk for adverse drug events (including death) when taking eplerenone due to enhancing the drug's action.
		Avoid taking the drug with itraconazole (Sporanox) and ketoconazole (Nizoral).	These drugs interact with eplerenone.
		Check with the pharmacist about interactions with other drugs or herbs that the patient is taking.	Drug interacts with many other drugs and herbs and is either not prescribed or drug dosage is adjusted.
Beta-Adrenergic Blockers			

DRUG/USUAL DOSAGE	PURPOSE/ACTION	NURSING INTERVENTIONS	RATIONALES
Metoprolol (Toprol, Toprol XL, Lopressor, Betaloc) 100-400 mg orally daily or in divided doses (one dose daily for XL form)	Cardioselective drugs block beta$_1$ receptors in the heart and peripheral blood vessels.	Monitor carefully for orthostatic hypotension; teach patients to rise slowly from the sitting position to prevent dizziness; do not take drug without contacting the health care provider if systolic BP is below 100.	Orthostatic hypotension is a common adverse effect of the drug and can contribute to falls and confusion, especially in older adults.
		Monitor pulse rate every day; do not take drug without contacting the health care provider if pulse is below 60.	The beta$_1$-blocking action of the drug decreases the rate, contractility, and output of the heart.
		Teach the patient that the drug can cause fatigue, depression, and sexual dysfunction; report any of these problems to the health care provider.	The drug has many side and adverse effects because of its potent action.
		Use the drug with caution in patients who are diabetic.	Because of the sympathetic blocking action of the drug, glucose production may be affected.
Atenolol (Tenormin, Apo-Atenol) 50-100 mg orally daily	Same as above for metoprolol.	Same as above for metoprolol.	Same as above for metoprolol.
Renin Inhibitors			
Aliskiren (Tekturna) 150-300 mg orally daily	Inhibits renin production, which prevents conversion of angiotensinogen to angiotensin I; decreased vasoconstriction, peripheral resistance, and cardiac output result.	Teach patients that side effects (cough and diarrhea) are not common; in a few cases, respiratory distress has occurred.	Drug is relatively safe with few side effects.

AV, Atrioventricular; **SA,** sinoatrial.

TABLE 36-6

Selected 2014 Evidence-Based Recommendations for the Management of High Blood Pressure in Adults (JNC 8)

- In the general population ages 60 years and older, start drug therapy to lower blood pressure at systolic blood pressure (SBP) equal to or greater than 150 mmHg or diastolic blood pressure (DBP) equal to or greater than 90 mmHg. The goal is to decrease blood pressure (BP) to below 150/90.
- In the general population younger than 60 years, start drug therapy to lower blood pressure at SBP equal to or greater than 140 mmHg or DBP equal to or greater than 90 mmHg. The goal is to decrease blood pressure to below 140/90.
- In people ages 18 years and older with chronic kidney disease (CKD), start drug therapy to lower BP to less than 140/90.
- In the general *nonblack* population, including those with diabetes mellitus, initial drug therapy should include a thiazide-type diuretic, calcium channel blocker (CCB), angiotensin-converting enzyme inhibitor (ACEI), or angiotensin receptor blocker (ARB).
- In the general *black* population, including those with diabetes mellitus, initial drug therapy should include a thiazide-type diuretic or CCB.
- If the goal BP is not reached within a month of treatment, increase drug dosage or add a second drug from one of the recommended classes.

Data from James, P.A., Oparil, S., Carter, B.L., Cushman, W.C., Dennison-Himmelfarb, C., Handler, J., et al. (2014). 2014 evidence-based guidelines for the management of high blood pressure in adults: Report from the panel members appointed to the Eighth National Committee (JNC 8). *Journal of the American Medical Association, 311*(5), 507-520. Retrieved December 2013, from http://jama.jamanetwork.com/article.aspx?articleid=1791497.

Diuretics.

Diuretics are the first type of drugs for managing hypertension. Three basic types of diuretics are used to decrease blood volume and lower blood pressure in order of how commonly they are typically prescribed:

- Thiazide (low-ceiling) diuretics, such as hydrochlorothiazide (HydroDIURIL, Microzide, Oretic, Urozide), inhibit sodium, chloride, and water reabsorption in the distal tubules while promoting potassium, bicarbonate, and magnesium excretion. However, they decrease calcium excretion, which helps prevent kidney stones and bone loss. Because of the low cost and high effectiveness of thiazide-type diuretics, they are usually the drugs of choice for patients with

uncomplicated hypertension. These drugs can be prescribed as a single agent or in combination with other classes of drugs.

Nursing Safety Priority QSEN

Drug Alert

Teach men that they may experience decreased libido (desire for sex) and decreased sexual performance when taking thiazides. Thiazides should be used with caution in patients with diabetes mellitus because they can interfere with serum glucose control. Caution is also indicated for patients with gout or a history of significant hyponatremia (decreased serum sodium level) because these problems can worsen when thiazides are taken.

- Loop (high-ceiling) diuretics, such as furosemide (Lasix, Furoside) and torsemide (Demadex), inhibit sodium, chloride, and water reabsorption in the ascending loop of Henle and promote potassium excretion.

Considerations for Older Adults

Patient-Centered Care QSEN

Loop diuretics are not used commonly for older adults because they can cause dehydration and orthostatic hypotension. These complications increase the patient's risk for falls. Teach families to monitor for and report patient dizziness, falls, or confusion to the health care provider as soon as possible and discontinue the medication.

- Potassium-sparing diuretics, such as spironolactone (Aldactone, Novospiroton), triamterene (Dyrenium), and amiloride (Midamor), act on the distal renal tubule to inhibit reabsorption of sodium ions in exchange for potassium, thereby *retaining* potassium in the body. When used, they are typically in combination with another diuretic or antihypertensive drug to *conserve* potassium.

Frequent voiding caused by any type of diuretic may interfere with daily activities. Teach patients to take their diuretic in the morning rather than at night to prevent nocturia (voiding during the night).

Nursing Safety Priority QSEN

Drug Alert

The most frequent side effect associated with *thiazide and loop diuretics* is hypokalemia (low potassium level). Monitor serum potassium levels, and assess for irregular pulse, dysrhythmias, and muscle weakness, which may indicate hypokalemia. Teach patients taking potassium-depleting diuretics to eat foods high in potassium, such as bananas, potatoes, and orange juice. Most people also need a potassium supplement to maintain adequate serum potassium levels.

Assess for hyperkalemia (high potassium level) for patients taking potassium-sparing diuretics, such as spironolactone. Like hypokalemia, an increased potassium level can also cause weakness, irregular pulse, and cardiac dysrhythmias. In some cases, patients may have painful muscle spasms (cramping) in their legs. These electrolyte imbalances are described in detail in Chapter 11.

Other Antihypertensive Drugs.

Calcium channel blockers, such as verapamil hydrochloride (Calan, Nu-Verap) and amlodipine (Norvasc), lower blood pressure by interfering with the transmembrane flux of calcium ions. This results in vasodilation, which *decreases* blood pressure. These drugs also block SA and AV node conduction, resulting in a decreased heart rate. Calcium channel blockers are most effective in older adults and African Americans (Go et al., 2013).

Some calcium channel blockers (CCBs), especially felodipine (Plendil, Renedil) and nifedipine (Adalat, Apo-Nifed), react with grapefruit and grapefruit juice. Grapefruit contains a group of chemicals called *furanocoumarins* that bind to and inactivate the enzyme *CYP3A4.* This enzyme is important for metabolism of many drugs, including some CCBs. If it is inactivated, too much of the CCB drug can remain in the patient's bloodstream causing possible kidney failure, heart failure, GI bleeding, or even death (Bailey et al., 2013).

A newer CCB, clevidipine butyrate (Cleviprex), is available only in IV form and must be administered using an infusion pump. This drug is indicated when oral therapy is not possible and is most often used for hypertensive urgency or severe hypertension. The most common side effects are headache and nausea. Monitor the patient's blood pressure frequently to check for hypotension. A dosage increase of 1 to 2 mg/hr generally produces an additional 2– to 4–mm Hg decrease in systolic blood pressure (Lilley et al., 2014).

Angiotensin-converting enzyme inhibitors (ACE inhibitors or ACEIs), known as the "pril" drugs, are also used as single or combination agents in the

treatment of hypertension. These drugs block the action of the angiotensin-converting enzyme as it attempts to convert angiotensin I to angiotensin II, one of the most powerful vasoconstrictors in the body. This action also decreases sodium and water retention and lowers peripheral vascular resistance, both of which lower blood pressure. ACE inhibitors include captopril (Capoten), lisinopril (Prinivil, Zestril), and enalapril (Vasotec). *The most common side effect of this group of drugs is a nagging, dry cough*. Teach patients to report this problem to their health care provider as soon as possible. If a cough develops, the drug is discontinued.

Nursing Safety Priority QSEN

Drug Alert

Instruct the patient receiving an ACE inhibitor for the first time to get out of bed slowly to avoid the severe hypotensive effect that can occur with initial use. Orthostatic hypotension may occur with subsequent doses, but it is usually less severe. If dizziness continues or there is a significant decrease in the systolic blood pressure (more than a change of 20 mm Hg), notify the health care provider or teach the patient to notify his or her provider. *The older patient is at the greatest risk for postural hypotension because of the cardiovascular changes associated with aging.*

Angiotensin II receptor antagonists, also called *angiotensin II receptor blockers (ARBs)* or the *-sartan drugs,* make up a group of drugs that selectively block the binding of angiotensin II to receptor sites in the vascular smooth muscle and adrenal tissues by competing directly with angiotensin II but not inhibiting ACE. Examples of drugs in this group are candesartan (Atacand), valsartan (Diovan), losartan (Cozaar), and azilsartan (Edarbi). ARBs can be used alone or in combination with other antihypertensive drugs. These drugs are excellent options for patients who report a nagging cough associated with ACE inhibitors. In addition, these drugs do not require initial adjustment of the dose for older adults or for any patient with renal impairment. Like the ACEs, the ARBs are not as effective in African Americans unless these drugs are taken with diuretics or another category such as a beta blocker or calcium channel blocker (Go et al., 2013).

Aldosterone receptor antagonists block the hypertensive effect of the mineralocorticoid hormone *aldosterone.* Aldosterone increases sodium

reabsorption by the kidney and is a significant contributor to hypertension, cardiac and vascular remodeling, and heart failure. Eplerenone (Inspra) lowers blood pressure by blocking aldosterone binding at the mineralocorticoid receptor sites in the kidney, heart, blood vessels, and brain. Generally well tolerated, eplerenone has dose-related adverse effects of hypertriglyceridemia, hyponatremia, and hyperkalemia. Teach patients taking eplerenone to avoid grapefruit or grapefruit juice in their diet to prevent severe complications, including death. Using ACE inhibitors or ARBs at the same time increases the risk for hyperkalemia. Therefore monitor potassium levels carefully, initially every 2 weeks for the first few months and then monthly thereafter.

Nursing Safety Priority QSEN

Drug Alert

When taking eplerenone, itraconazole (Sporanox) and ketoconazole (Nizoral) should not be taken. Drug interactions are common. Patients taking erythromycin, fluconazole (Diflucan), saquinavir (Fortovase), and verapamil (Calan) can take eplerenone but with a reduction in dosage by half to 25 mg daily. Teach patients that grapefruit juice and the popular herb *St. John's wort* can also increase the chance of adverse effects. Similar to all antihypertensives, remind patients not to get up quickly, drive, or climb stairs until they adjust to the effects of the drug.

Beta-adrenergic blockers, identified by the ending -olol, are categorized as cardioselective (working only on the cardiovascular system) and non-cardioselective. Cardioselective beta blockers, affecting only $beta_1$ receptors, may be prescribed to lower blood pressure by blocking beta receptors in the heart and peripheral vessels. By blocking these receptors, the drugs decrease heart rate and myocardial contractility. Teach patients about common side effects of beta blockers, including fatigue, weakness, depression, and sexual dysfunction. The potential for side effects depends on the "selective" blocking effects of the drug. Atenolol (Tenormin, Apo-Atenol), bisoprolol (Zebeta), and metoprolol (Lopressor, Toprol, Toprol-XL, Betaloc) are cardioselective beta blockers given for hypertension.

Patients with diabetes who take beta blockers may not have the usual manifestations of hypoglycemia because the sympathetic nervous system is blocked. The body's responses to hypoglycemia such as gluconeogenesis may also be inhibited by certain beta blockers.

Beta blockers are often the drug of choice for hypertensive patients with ischemic heart disease (IHD) because the heart is the most common target of end-organ damage with hypertension. If this drug is not tolerated, a long-acting calcium channel blocker can be used. In patients with unstable angina or myocardial infarction (MI), beta blockers or calcium channel blockers should be used initially in combination with ACE inhibitors or ARBs, with addition of other drugs if needed to control the blood pressure (see Chapter 38).

Renin inhibitors are effective for mild to moderate hypertension. Aliskiren (Tekturna) is an example and can be used alone or with a thiazide diuretic. Renin is an enzyme produced in the kidneys that causes vasoconstriction, increases peripheral resistance, and increases cardiac output. The result is an increase in blood pressure. Renin inhibitors prevent renin from producing this action. Side effects are minimal and not common, although respiratory distress may occur.

NCLEX Examination Challenge

Physiological Integrity

A client is prescribed enalapril (Vasotec) for control of hypertension. What health teaching will the nurse provide before the client begins therapy?
A "You may develop a higher pulse rate."
B "You may notice some swelling in your feet."
C "You may develop a nagging cough."
D "Your diet should include foods high in sodium."

Promoting Adherence to the Plan of Care

Planning: Expected Outcomes.

The patient with hypertension is expected to adhere to the plan of care, including making necessary lifestyle changes.

Interventions.

Patients who require medications to control essential hypertension usually need to take them for the rest of their lives. Some patients stop taking them because they have no symptoms and have troublesome side effects.

In the hospital setting, collaborate with the pharmacist, as needed, to discuss the outcomes of therapy with the patient, including potential

side effects. Assist the patient in tailoring the therapeutic regimen to his or her lifestyle and daily schedule.

Patients who do not adhere to antihypertensive treatment are at a high risk for target organ damage and **hypertensive crisis,** a severe elevation in blood pressure (greater than 180/120), which can cause organ damage in the kidneys or heart (target organs) (Chart 36-2). Patients in hypertensive crisis are admitted to critical care units, where they receive IV antihypertensive therapy such as nitroprusside (Nipride), nicardipine (Cardene IV), fenoldopam (Corlopam), or labetalol (Normodyne). These drugs act quickly as vasodilators to decrease blood pressure (BP) by no more that 25% within 2 to 6 hours. Provide oxygen to the patient, and monitor oxygen saturation levels. When the patient's blood pressure stabilizes, oral antihypertensive drugs are given (Day, 2011).

Chart 36-2 Best Practice for Patient Safety & Quality Care QSEN

Emergency Care of Patients with Hypertensive Urgency or Crisis

Assess

- Severe headache
- Extremely high blood pressure (BP)
- Dizziness
- Blurred vision
- Shortness of breath
- Epistaxis (nosebleed)
- Severe anxiety

Intervene

- Place patient in a semi-Fowler's position.
- Administer oxygen.
- Start IV of 0.9% normal saline (NS) solution slowly to prevent fluid overload (which would increase blood pressure).
- Administer IV beta blocker or nicardipine (Cardene IV) or other infusion drug as prescribed; when stable, switch to oral antihypertensive drug.
- Monitor BP every 5 to 15 minutes until the diastolic pressure is below 90 and not less than 75; then monitor BP every 30 minutes to ensure that BP is not lowered too quickly.
- Observe for neurologic or cardiovascular complications, such as

seizures; numbness, weakness, or tingling of extremities; dysrhythmias; or chest pain (possible indicators of target organ damage).

Community-Based Care

Home Care Management.

Hypertension is a chronic illness. Allow patients to verbalize feelings about the disease and its treatment. Emphasize that their involvement in the collaborative plan of care can lead to control of the disease and can prevent complications.

Some patients do not adhere to their drug therapy regimen at home because they have no symptoms or they simply forget to take their drugs. Others may think they are not sick enough to need medication. Some patients may assume that once their blood pressure returns to normal levels, they no longer need treatment. They may also stop taking their drugs because of side effects or cost. Develop a plan with the patient and family, and identify ways to encourage adherence to the plan of care.

Self-Management Education.

Health teaching is essential to help patients become successful in managing their blood pressure. Provide oral and written information about the indications, dosage, times for administration, side effects, and drug interactions for antihypertensives. Stress that medication must be taken as prescribed; when all of it has been consumed, the prescription must be renewed on a continual basis. Suddenly stopping drugs such as beta blockers can result in angina (chest pain), myocardial infarction (MI), or rebound hypertension. Urge patients to report unpleasant side effects such as excessive fatigue, cough, or sexual dysfunction. In many instances, an alternative drug can be prescribed to minimize certain side effects.

Teach the patient to obtain an ambulatory blood pressure monitoring (ABPM) device for use at home so that the pressure can be checked. Evaluate the patient's and family's ability to use this device. If weight reduction is a desired outcome, suggest having a scale in the home for weight monitoring. For patients who do not want to self-monitor, are not able to self-monitor, or have “white-coat” syndrome when they go to their health care provider (causing elevated BP), continuous ABPM may be used. The monitor is worn for 24 hours or longer while patients perform their normal daily activities. Blood pressure is automatically taken every 15 to 30 minutes and recorded for review later. The advantage

of this technique is that the health care provider can view the changes in BP readings throughout the 24-hour period to get a picture of a true BP value. Research strongly supports 24-hour ambulatory blood pressure monitoring as a first-line procedure to determine the need for antihypertensive therapy (Verdecchia et al., 2009).

Instruct the patient about sodium restriction, weight maintenance or reduction, alcohol restriction, stress management, and exercise. If necessary, also explain about the need to stop using tobacco, especially smoking.

Health Care Resources.

A home care nurse may be needed for follow-up to monitor the blood pressure. Evaluate the patient's or family's ability to obtain accurate BP measurements, and assess adherence with treatment. The American Heart Association (www.aha.org), the Red Cross, or a local pharmacy may be used for free blood pressure checks if patients cannot buy equipment to monitor their blood pressure. Health fairs are also available in most locations.

Evaluation: Outcomes

Evaluate the care of the patient with hypertension on the basis of the identified patient problems. The expected outcomes are that the patient will:

- Verbalize understanding of the plan of care, including drug therapy and any necessary lifestyle changes
- Report adverse drug effects, such as coughing, dizziness, or sexual dysfunction, to the health care provider immediately
- Consistently adhere to the plan of care, including regular follow-up health care provider visits

Clinical Judgment Challenge

Patient-Centered Care; Teamwork and Collaboration; Evidence-Based Practice QSEN

A nursing home administrator reports having severe headache and facial flushing for the past 3 weeks. He does not smoke but is overweight. Both of his parents have hypertension and cardiac disease. One of his nurses takes his blood pressure, which is 210/116. He states that he will see his primary care provider as soon as possible. At the physician's office, his heart rate is 88 beats/min, blood pressure is

190/110, and respiratory rate is 24 breaths/min.

1. What additional information will you need from his past and current family and personal history?
2. What physical assessment data will you collect as the office nurse?
3. What type of drug therapy may be prescribed for this patient? What are your nursing responsibilities when giving these drugs?
4. What health teaching will you provide for the patient? What evidence do you have to support your answer?
5. What members of the health care team may be involved in this patient's care?
6. What community resources are available to assist this patient to self-manage his hypertension?

Peripheral Arterial Disease

Peripheral vascular disease (PVD) includes disorders that change the natural flow of blood through the arteries and veins of the peripheral circulation, causing decreased perfusion to body tissues. It affects the legs much more frequently than the arms. Generally, a diagnosis of PVD implies arterial disease (peripheral arterial disease [PAD]) rather than venous involvement. Some patients have both arterial and venous disease. The cost of the disease is very high and is expected to increase as baby boomers age and obesity in the United States continues to be a major health problem.

Pathophysiology

PAD is a result of systemic atherosclerosis. It is a chronic condition in which partial or total arterial occlusion (blockage) decreases perfusion to the extremities. The tissues below the narrowed or obstructed arteries cannot live without an adequate *oxygen* and nutrient supply. PAD in the legs is sometimes referred to as *lower extremity arterial disease (LEAD).*

Obstructions are classified as inflow or outflow, according to the arteries involved and their relationship to the inguinal ligament (Fig. 36-3). *Inflow* obstructions involve the distal end of the aorta and the common, internal, and external iliac arteries. They are located above the inguinal ligament. *Outflow* obstructions involve the femoral, popliteal, and tibial arteries and are below the superficial femoral artery (SFA). Gradual inflow occlusions may not cause significant tissue damage. Gradual outflow occlusions typically do.

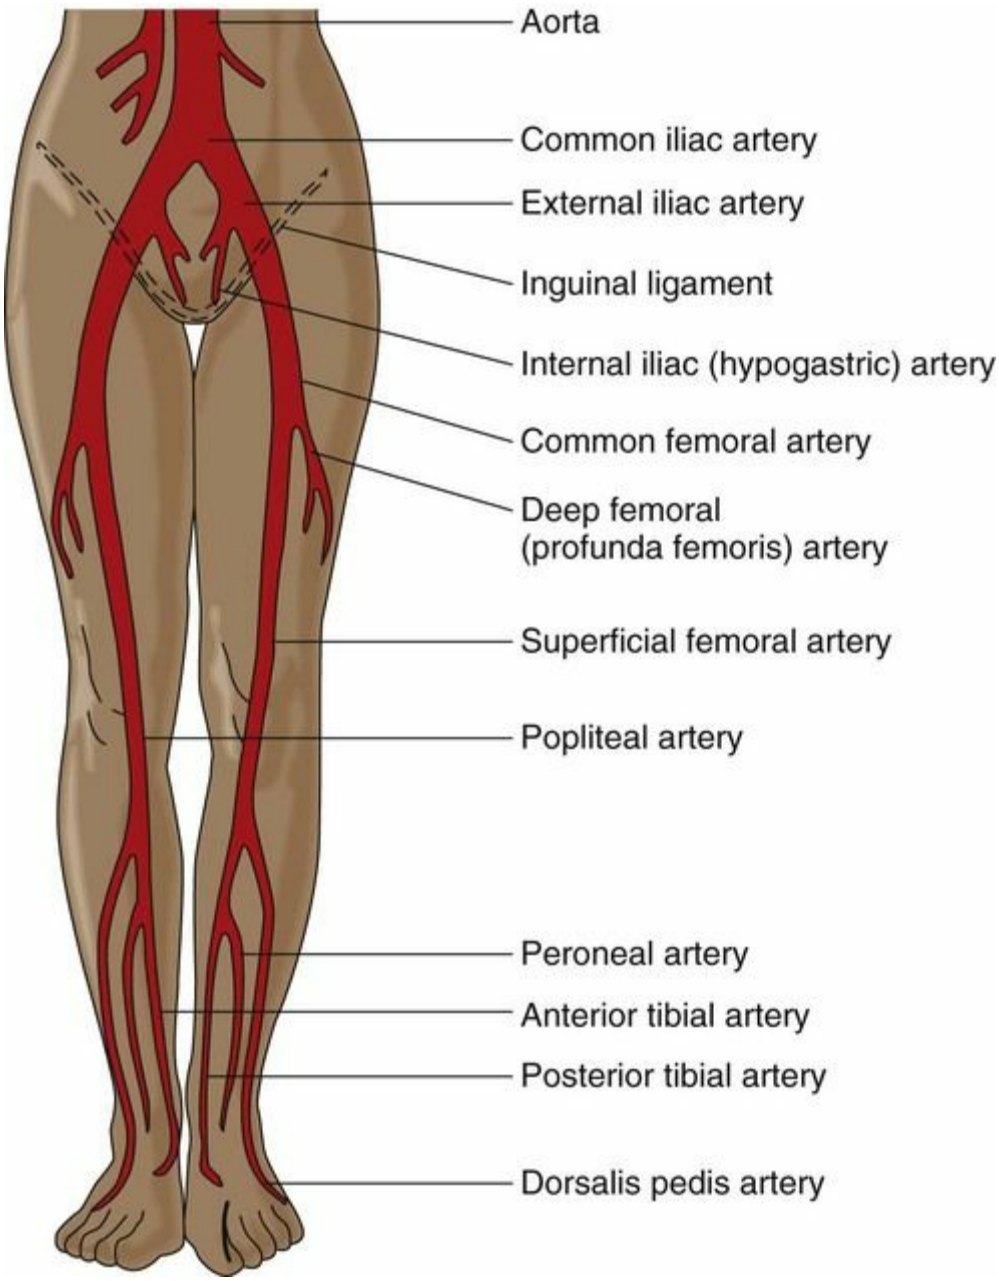


FIG. 36-3 Common locations of inflow and outflow lesions.

Atherosclerosis is the most common cause of chronic arterial obstruction; therefore the risk factors for atherosclerosis apply to PAD as well. Common risk factors include hypertension, hyperlipidemia, diabetes mellitus, cigarette smoking, obesity, high cholesterol and lipid levels, and familial predisposition. Advancing age also increases the risk for disease related to atherosclerosis. Patients with PAD have an increased risk for developing chronic angina, MI, or stroke and are much more likely to die within 10 years compared with those who do not have the disease (Go et al., 2013).

About 10 to 12 million people in the United States have PAD, most of them older than 65 years. African Americans are affected more often than any other group, most likely because they have many risk factors

such as diabetes and hypertension (Go et al., 2013).

Patient-Centered Collaborative Care

Assessment

The clinical course of chronic PAD can be divided into four stages (Chart 36-3). Patients do not experience symptoms in the early stages of disease. Most patients are not diagnosed until they develop leg pain.

Chart 36-3 Key Features

Chronic Peripheral Arterial Disease

Stage I: Asymptomatic

- No claudication is present.
- Bruit or aneurysm may be present.
- Pedal pulses are decreased or absent.

Stage II: Claudication

- Muscle pain, cramping, or burning occurs with exercise and is relieved with rest.
- Symptoms are reproducible with exercise.

Stage III: Rest Pain

- Pain while resting commonly awakens the patient at night.
- Pain is described as numbness, burning, toothache-type pain.
- Pain usually occurs in the distal portion of the extremity (toes, arch, forefoot, or heel), rarely in the calf or the ankle.
- Pain is relieved by placing the extremity in a dependent position.

Stage IV: Necrosis/Gangrene

- Ulcers and blackened tissue occur on the toes, the forefoot, and the heel.
- Distinctive gangrenous odor is present.

Physical Assessment/Clinical Manifestations.

Most patients initially seek medical attention for a classic leg pain known as **intermittent claudication** (a term derived from a word meaning "to limp"). Usually they can walk only a certain distance before a cramping, burning muscle discomfort or pain forces them to stop. The pain stops after rest. When patients resume walking, they can walk the same

distance before it returns. Thus the pain is considered reproducible. As the disease progresses, they can walk only shorter and shorter distances before pain recurs. Ultimately, it may occur even while at rest.

Rest pain, which may begin while the disease is still in the stage of intermittent claudication, is a numbness or burning sensation, often described as feeling like a toothache that is severe enough to awaken patients at night. It is usually located in the toes, the foot arches, the forefeet, the heels, and, rarely, in the calves or ankles. Patients can sometimes get pain relief by keeping the limb in a dependent position (below the heart). Those with rest pain often have advanced disease that may result in limb loss.

Patients with **inflow disease** have discomfort in the lower back, buttocks, or thighs. Patients with *mild* inflow disease have discomfort after walking about two blocks. This discomfort is not severe but causes them to stop walking. It is relieved with rest. Patients with *moderate* inflow disease experience pain in these areas after walking about one or two blocks. The discomfort is described as being more like pain, but it eases with rest most of the time. *Severe* inflow disease causes severe pain after walking less than one block. These patients usually have rest pain.

Patients with **outflow disease** describe burning or cramping in the calves, ankles, feet, and toes. Instep or foot discomfort indicates an obstruction below the popliteal artery. Those with *mild* outflow disease experience discomfort after walking about five blocks. This discomfort is relieved by rest. Patients with *moderate* outflow disease have pain after walking about two blocks. Intermittent rest pain may be present. Those with *severe* outflow disease usually cannot walk more than one-half block and usually experience rest pain. They may hang their feet off the bed at night for comfort and report more frequent rest pain than do those with inflow disease.

Specific findings for PAD depend on the severity of the disease. Observe for loss of hair on the lower calf, ankle, and foot; dry, scaly, dusky, pale, or mottled skin; and thickened toenails. With severe arterial disease, the extremity is cold and gray-blue (cyanotic) or darkened. Pallor may occur when the extremity is elevated. Dependent **rubor** (redness) may occur when the extremity is lowered (Fig. 36-4). Muscle atrophy can result from prolonged chronic arterial disease.

FIG. 36-4 Dependent rubor in the left leg of a patient with peripheral arterial disease.

Cultural Considerations

Patient-Centered Care QSEN

Only severe cyanosis is evident in the skin of dark-skinned patients. To detect cyanosis, assess the skin and nail beds for a dull, lifeless color. The soles of the feet and the toenails are less pigmented and allow detection of cyanosis or duskiness in the lower extremities.

Palpate all pulses in both legs. The most sensitive and specific indicator of arterial function is the quality of the posterior tibial pulse, because the pedal pulse is not palpable in a small percentage of people.

The strength of each pulse should be compared bilaterally.

Note early signs of ulcer formation or complete ulcer formation, a complication of PAD. Arterial and venous stasis ulcers differ from diabetic ulcers (Chart 36-4). Initially, **arterial ulcers** are painful and develop on the toes (often the great toe), between the toes, or on the upper aspect of the foot. With prolonged occlusion, the toes can become gangrenous. Typically, the ulcer is small and round with a "punched out" appearance and well-defined borders. Skin lesions are discussed in further detail in Chapter 25.

Chart 36-4 Key Features

Lower Extremity Ulcers

FEATURE	ARTERIAL ULCERS	VENOUS ULCERS	DIABETIC ULCERS
History	Patient reports claudication after walking about 1-2 blocks Rest pain usually present Pain at ulcer site Two or three risk factors present	Chronic nonhealing ulcer No claudication or rest pain Moderate ulcer discomfort Patient reports of ankle or leg swelling	Diabetes Peripheral neuropathy No reports of claudication
Ulcer location and appearance	End of the toes Between the toes Deep Ulcer bed pale, with even edges Little granulation tissue	Ankle area Brown pigmentation Ulcer bed pink Usually superficial, with uneven edges Granulation tissue present	Plantar area of foot Metatarsal heads Pressure points on feet Deep Pale, with even edges Little granulation tissue
			
Other assessment findings	Cool or cold foot Decreased or absent pulses Atrophy of skin Hair loss Pallor with elevation Dependent rubor Possible gangrene When acute, neurologic deficits noted	Ankle discoloration and edema Full veins when leg slightly dependent No neurologic deficit Pulses present May have scarring from previous ulcers	Pulses usually present Cool or warm foot Painless
Treatment	Treat underlying cause (surgical, revascularization) Prevent trauma and infection Patient education, stressing foot care	Long-term wound care (Unna boot, damp-to-dry dressings) Elevate extremity Patient education Prevent infection	Rule out major arterial disease Control diabetes Patient education regarding foot care Prevent infection

Imaging Assessment.

Magnetic resonance angiography (MRA) is commonly used to assess blood flow in the peripheral arteries. A contrast medium such as gadolinium is

used to help visualize blood flow through peripheral arteries. This test is often the only one used to diagnose PAD, although a computed tomography angiography (CTA) may also be performed.

Other Diagnostic Assessment.

Using a Doppler probe, *segmental systolic blood pressure measurements* of the lower extremities at the thigh, calf, and ankle are an inexpensive, noninvasive method of assessing PAD. Normally, blood pressure readings in the thigh and calf are higher than those in the upper extremities. With the presence of arterial disease, these pressures are lower than the brachial pressure.

With *inflow* disease, pressures taken at the thigh level indicate the severity of disease. Mild inflow disease may cause a difference of only 10 to 30 mm Hg in pressure on the affected side compared with the brachial pressure. Severe inflow disease can cause a pressure difference of more than 40 to 50 mm Hg. The ankle pressure is normally equal to or more than the brachial pressure.

To evaluate *outflow* disease, compare ankle pressure with the brachial pressure, which provides a ratio known as the **ankle-brachial index (ABI).** The value can be derived by dividing the ankle blood pressure by the brachial blood pressure. *An ABI of less than 0.90 in either leg is diagnostic of PAD. Patients with diabetes are known to have a falsely elevated ABI.*

Doppler-derived maximal systolic acceleration is a newer technique that has demonstrated successful evaluations of peripheral arterial disease in patients with diabetes (Van Tongeren et al., 2010).

Exercise tolerance testing (by chemical stress test or treadmill) may give valuable information about claudication (muscle pain) without rest pain. The technician obtains resting pulse volume recordings and asks the patient to walk on a treadmill until the symptoms are reproduced. At the time of symptom onset or after about 5 minutes, the technician obtains another pulse volume recording. Normally, there may be an increased waveform with minimal, if any, drop in the ankle pressure. In patients with arterial disease, the waveforms are decreased (dampened) and there is a decrease in the ankle pressure of 40 to 60 mm Hg for 20 to 30 seconds in the affected limb. If the return to normal pressure is delayed (longer than 10 minutes), the results suggest abnormal arterial flow in the affected limb.

Plethysmography can also be performed to evaluate arterial flow in the lower extremities. The measurement provides graphs or tracings of arterial flow in the limb. If an occlusion is present, the waveforms are

decreased to flattened, depending on the degree of occlusion.

Interventions

Collaborative management of PAD may include nonsurgical interventions and/or surgery. The patient must first be assessed to determine if the altered tissue perfusion is due to arterial disease, venous disease, or both.

Nonsurgical Management.

Exercise, positioning, promoting vasodilation, drug therapy, and invasive nonsurgical procedures are used to increase *arterial* flow to the affected leg(s).

Using Exercise and Positioning.

Exercise may improve arterial blood flow to the affected leg through buildup of the collateral circulation. **Collateral circulation** provides blood to the affected area through smaller vessels that develop and compensate for the occluded vessels. Exercise is individualized for each patient, but people with severe rest pain, venous ulcers, or gangrene should not participate. Others with PAD can benefit from exercise that is started gradually and slowly increased. Instruct the patient to walk until the point of claudication, stop and rest, and then walk a little farther. Eventually, he or she can walk longer distances as collateral circulation develops. Collaborate with the health care provider and physical therapist in determining an appropriate exercise program. Exercise rehabilitation has been used to relieve symptoms but requires a motivated patient. Supervised sessions are generally not reimbursed by health care insurance.

Positioning to promote circulation has been somewhat controversial. Some patients have swelling in their extremities. Teach them to avoid raising their legs above the heart level because extreme elevation slows arterial blood flow to the feet. In severe cases, patients with PAD and swelling may sleep with the affected leg hanging from the bed or sit upright in a chair for comfort.

Nursing Safety Priority QSEN

Action Alert

Instruct all patients with the disease to avoid crossing their legs and avoid wearing restrictive clothing (e.g., garters to hold up nylon

stockings, particularly common among older women), which interfere with blood flow. Teach them the importance of inspecting their feet daily for color or other changes.

Promoting Vasodilation.

Vasodilation can be achieved by providing warmth to the affected extremity and preventing long periods of exposure to cold. Encourage the patient to maintain a warm environment at home and to wear socks or insulated shoes at all times. *Caution him or her to never apply direct heat to the limb such as with the use of heating pads or extremely hot water. Sensitivity is decreased in the affected limb. Burns may result.*

Encourage patients to prevent exposure of the affected limb to the cold because cold temperatures cause vasoconstriction (decreasing of the diameter of the blood vessels) and therefore decrease arterial perfusion. Patients should also drink adequate fluids to prevent increased blood viscosity.

Emotional stress, caffeine, and nicotine also can cause vasoconstriction. *Emphasize that complete abstinence from smoking or chewing tobacco is essential to prevent vasoconstriction.* The vasoconstrictive effects of each cigarette may last up to 1 hour after the cigarette is smoked.

NCLEX Examination Challenge

Physiological Integrity

The nurse is caring for a client with lower extremity peripheral arterial disease. Which statement made by the client regarding self-management requires further health teaching?

A "I need to quit smoking as soon as I can."
B "I will elevate my legs above the level of my heart."
C "I will use a heating pad to promote circulation."
D "I will avoid crossing my legs at all times."

Drug Therapy.

For patients with chronic PAD, prescribed drugs include hemorheologic and antiplatelet agents. Pentoxifylline (Trental) is a hemorheologic agent that increases the flexibility of red blood cells. It decreases blood viscosity by inhibiting platelet aggregation and decreasing fibrinogen and thus increases blood flow in the extremities. Many patients report limited improvement in their daily lives after taking pentoxifylline.

However, those with extremely limited endurance for walking have reported improvement to the point that they can perform some activities (e.g., walk to the mailbox or dining room) that were previously impossible.

Antiplatelet agents, such as aspirin (acetylsalicylic acid, Ancasal) and clopidogrel (Plavix), are commonly used. Aspirin 325 or 81 mg daily may be recommended for patients with chronic PAD. However, clopidogrel is better than aspirin for reducing the risk for myocardial infarction (MI), ischemic stroke, and vascular death. Patients with PAD and no contraindications to antiplatelet therapy should receive either aspirin or clopidogrel. Some patients receive both drugs (dual antiplatelet therapy).

Remind patients not to eat grapefruit or drink grapefruit juice while on clopidogrel. Grapefruit contains a group of chemicals called *furanocoumarins* that bind to and inactivate the enzyme *CYP3A4.* This enzyme is important for metabolism of many drugs, including clopidogrel. If it is inactivated, too much of the drug can remain in the patient's bloodstream causing possible kidney failure, heart failure, GI bleeding, or even death (Bailey et al., 2013).

Patients who experience disabling intermittent claudication may also benefit from phosphodiesterase inhibitors such as cilostazol (Pletal). This drug can also increase HDL-C levels. Teach patients taking the drug that it may cause headaches and GI disturbances, especially flatulence (gas) and diarrhea.

Controlling hypertension can improve tissue perfusion by maintaining pressures that are adequate to perfuse the periphery but not constrict the vessels. Teach about the effect of blood pressure on the circulation, and instruct in methods of control. For example, patients taking beta blockers may have drug-related claudication or a worsening of symptoms. The health care provider closely monitors those who are receiving beta blockers. If the patient has high serum lipids, lipid-lowering drugs such as statins are used (see earlier discussion of statins under Drug Therapy for Atherosclerosis, p. 712).

Invasive Nonsurgical Procedures.

A nonsurgical but invasive approach for improving arterial flow is the use of **percutaneous vascular intervention,** also called **percutaneous transluminal coronary angioplasty (PTCA).** This procedure requires an arterial puncture in the patient's groin. One or more arteries are dilated with a balloon catheter advanced through a cannula, which is inserted into or above an occluded or stenosed artery. When the procedure is

successful, it opens the vessel and improves arterial blood flow. Patients who are candidates for percutaneous procedures such as PTA must have occlusions or stenoses that are accessible to the catheter. Reocclusion may occur, and the procedure may be repeated. Some patients are occlusion-free for up to 3 to 5 years, whereas others may experience reocclusion within a year.

During percutaneous vascular intervention, intravascular stents (wire meshlike devices) are usually inserted to ensure adequate blood flow in a stenosed vessel. Candidates for stents are patients with stenosis of the common or external iliac arteries. Stents are also available to effectively treat superficial femoral artery disease. Patients have these procedures in same-day surgery or ambulatory care centers.

Another arterial technique to improve blood flow to ischemic legs in people with PAD is mechanical rotational abrasive **atherectomy.** The Rotablator device is designed to scrape plaque from inside the artery while minimizing damage to the vessel surface.

Nursing Safety Priority QSEN

Critical Rescue

The priority for nursing care following a PTA or atherectomy is to observe for bleeding at the arterial puncture site, which is sealed with a special collagen plug. Monitor for manifestations of impending hypovolemic shock, including a decrease in blood pressure, increased pulse rate, and decreased urinary output. Perform frequent checks of the distal pulses in both legs to ensure adequate perfusion and oxygenation.

Most patients receive anticoagulant or antiplatelet therapy, such as heparin or clopidogrel (Plavix), before and/or during the procedure. An antiplatelet drug may also be prescribed for 1 to 3 months or longer after the procedure to prevent arterial clotting.

Surgical Management.

Patients with severe rest pain or claudication that interferes with the ability to work or threatens loss of a limb become surgical candidates. **Arterial revascularization** is the surgical procedure most commonly used to increase arterial blood flow in an affected limb.

Surgical procedures are classified as *inflow* or *outflow.* Inflow procedures involve bypassing arterial occlusions above the superficial femoral arteries (SFAs). Outflow procedures involve surgical bypassing

of arterial occlusions at or below the SFAs. For those who have both inflow and outflow problems, the inflow procedure (for larger arteries) is done before the outflow repair.

Inflow procedures include aortoiliac, aortofemoral, and axillofemoral bypasses. Outflow procedures include femoropopliteal and femorotibial bypasses. Inflow procedures are more successful, with less chance of reocclusion or postoperative ischemia. Outflow procedures are less successful in relieving ischemic pain and are associated with a higher incidence of reocclusion.

Graft materials for bypasses are selected on an individual basis. For outflow procedures, the preferred graft material is the patient's own **(autogenous)** saphenous vein. However, some patients experience coronary artery disease and may need this vein for coronary artery bypass. When the saphenous vein is not usable, the cephalic or basilic arm veins may be used. Grafts made of synthetic materials have also been used when autogenous veins were not available.

Preoperative Care.

Preparing the patient for surgery is similar to procedures described for general or epidural anesthesia (see Chapter 14). Documentation of vital signs and peripheral pulses provides a baseline of information for comparison during the postoperative phase. Depending on the surgical procedure, the patient may have one or more IV lines, urinary catheter, central venous catheter, and/or arterial line. To prevent postoperative infection, antibiotic therapy is typically given before the procedure.

Operative Procedures.

The anesthesia provider places the patient under general, epidural, or spinal anesthesia. Epidural or spinal induction is preferred for older adults to decrease the risk for cardiopulmonary complications in this age-group. If arterial bypass is to be accomplished by autogenous grafts, the surgeon removes the veins through an incision. The blocked artery is then exposed through an incision, and the replacement vein or synthetic graft material is sutured above and below the occlusion to increase blood flow around the occlusion.

For conventional open *aortoiliac* and *aortofemoral* bypass (AFB) surgery, the surgeon makes a midline incision into the abdominal cavity to expose the abdominal aorta, with additional incisions in each groin (Fig. 36-5). Graft material is tunneled from the aorta to the groin incisions, where it is sutured in place.

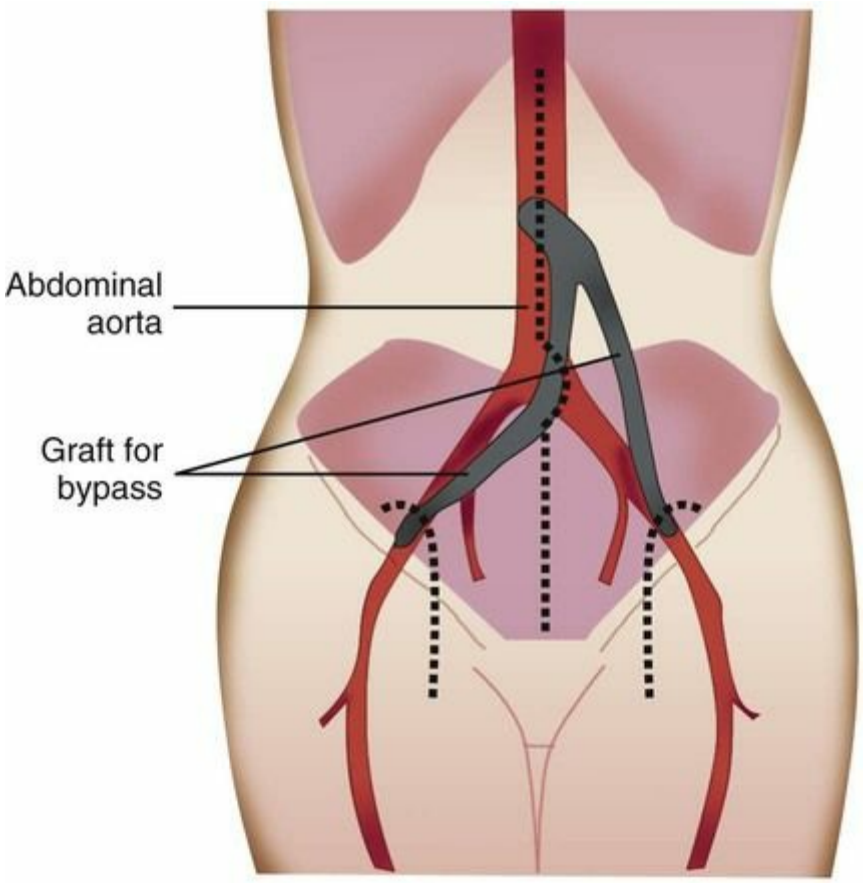

FIG. 36-5 In aortoiliac and aortofemoral bypass surgery, a midline incision into the abdominal cavity is required, with an additional incision in each groin.

In an open *axillofemoral* bypass (Fig. 36-6), the surgeon makes an incision beneath the clavicle and tunnels graft material subcutaneously with a catheter from the chest to the iliac crest, into a groin incision, where it is sutured in place. Neither the thoracic nor the abdominal cavity is entered. For that reason, the axillofemoral bypass is used for high-risk patients who cannot tolerate a procedure requiring abdominal surgery.

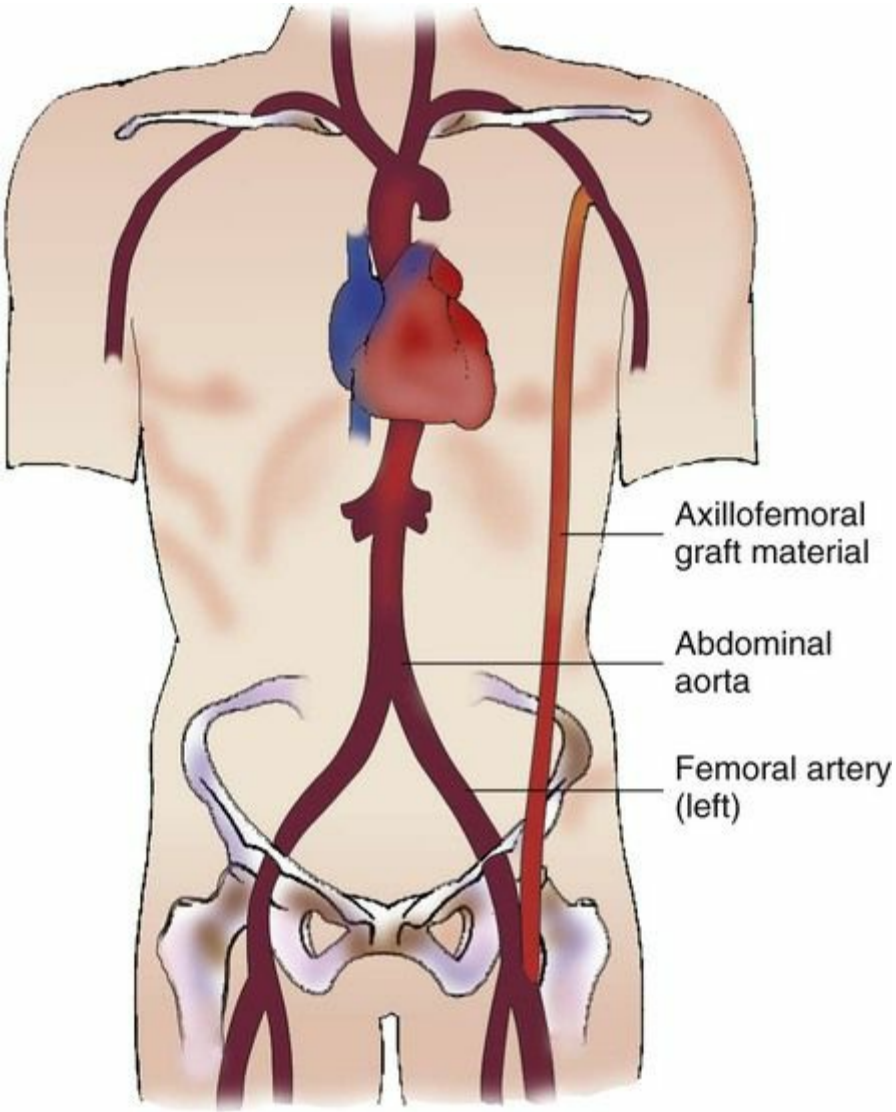

FIG. 36-6 An axillofemoral bypass graft

Minimally invasive surgical techniques are beginning to be performed by vascular surgeons in large urban medical centers using robotic-assisted laparoscopic procedures. These newer surgical techniques require extensive training and do not shorten surgical time.

Postoperative Care.

Thorough and ongoing nursing assessment for postoperative arterial revascularization patients is crucial to detect complications. Deep breathing every 1 to 2 hours and using an incentive spirometer are essential to prevent respiratory complications.

Patients who have undergone conventional aortoiliac or aortofemoral bypass are NPO status for at least 1 day after surgery to prevent nausea and vomiting, which could increase intra-abdominal pressure. Those who have undergone bypass surgery of the lower extremities not involving the aorta or abdominal wall (femoropopliteal or femorotibial bypass) may remain NPO until the first postoperative day, when they are allowed clear

liquids.

Warmth, redness, and edema of the affected extremity are often expected outcomes of surgery as a result of increased arterial perfusion. Immediately postoperatively, the operating suite or postanesthesia care unit (PACU) nurse marks the site where the distal (dorsalis pedis or posterior tibial) pulse is best palpated or heard by Doppler ultrasonography. This information is communicated to the nursing staff on the critical care unit where the patient will be sent. "Hand-off" reporting is essential to promote safety and quality care (as required by The Joint Commission's National Patient Safety Goals).

To promote graft patency, monitor the patient's blood pressure and notify the surgeon if the pressure increases or decreases beyond the patient's baseline. Hypotension may indicate hypovolemia, which can increase the risk for clotting. Range of motion of the operative leg is usually limited, with no bending of the hip and knee. Consult with the surgeon on a case-by-case basis regarding limitations of movement, including turning. Patients having open procedures may be restricted to bedrest for 24 hours or longer after surgery to prevent disruption of the suture lines. Patients having minimally invasive surgical (MIS) procedures may be ambulatory and eat within the day of surgery. Pain and surgical complications tend to occur less often in patients who have MIS procedures.

Nursing Safety Priority QSEN

Critical Rescue

Graft occlusion (blockage) is a postoperative emergency that can occur within the first 24 hours after arterial revascularization. Monitor the patient for and report severe continuous and aching pain, which may be the first indicator of postoperative graft occlusion and ischemia. Many people experience a throbbing pain caused by the increased blood flow to the extremity. Because this sensation is different from ischemic pain, be sure to assess the type of pain that is experienced. Pain from occlusion may be masked by patient-controlled analgesia (PCA). Some patients have ischemic pain that is not relieved by PCA.

Monitor the patency of the graft by checking the extremity every 15 minutes for the first hour and then hourly for changes in color, temperature, and pulse intensity. Compare the operative leg with the unaffected one. *If the operative leg feels cold; becomes pale, ashen, or cyanotic; or has a decreased or absent pulse, contact the surgeon immediately!*

Emergency **thrombectomy** (removal of the clot), which the surgeon may perform at the bedside, is the most common treatment for acute graft occlusion. Thrombectomy is associated with excellent results in prosthetic grafts. Results of thrombectomy in autogenous vein grafts are not as successful and often necessitate graft revision and even replacement.

Local intra-arterial thrombolytic (clot-dissolving) therapy with an agent such as tissue plasminogen activator (t-PA) or an infusion of a platelet inhibitor such as abciximab (ReoPro) may be used for acute graft occlusions. This therapy is provided in select settings in which health care providers are experts in its use. Other antiplatelet drugs such as the glycoprotein IIb/IIIa inhibitors *tirofiban (Aggrastat)* and *eptifibatide (Integrilin)* may be used as alternatives. The physician considers these therapies when the surgical alternative (e.g., thrombectomy with or without graft revision or replacement) carries high morbidity or mortality rates or when surgery for this type of occlusion has traditionally yielded poor results. Closely assess the patient for manifestations of bleeding if thrombolytics are used.

Graft or wound infections can be life threatening. Use sterile technique when providing incisional care, and observe for symptoms of infection. Assess the area for induration, erythema, tenderness, warmth, edema, or drainage. Also monitor for fever and leukocytosis (increased serum white blood cell count). Notify the surgeon promptly if any of these symptoms occur.

Patients having conventional open bypass procedures are usually hospitalized for 5 to 7 days. Those having MIS procedures usually have shorter stays of 2 or 3 days.

Community-Based Care

Peripheral arterial disease (PAD) is a chronic, long-term problem with frequent complications. Patients may benefit from a case manager who can follow them across the continuum of care. The desired outcome is that the patient can be maintained in the home.

Management at home often requires an interdisciplinary team approach, including several home care visits. Chart 36-5 outlines the assessment highlights for home care patients with peripheral vascular disease (PVD).

Chart 36-5 Home Care Assessment

The Patient with Peripheral Vascular Disease

Assess tissue perfusion to affected extremity(ies), including:

- Distal circulation, sensation, and motion
- Presence of pain, pallor, paresthesias, pulselessness, paralysis, poikilothermy (coolness)
- Ankle-brachial index

Assess adherence to therapeutic regimen, including:

- Following foot care instructions
- Quitting smoking
- Maintaining dietary restrictions
- Participating in exercise regimen
- Avoiding exposure to cold and constrictive clothing

Assess ability to manage wound care and prevent further injury, including:

- Use of compression stockings or compression pumps as directed
- Use of various dressing materials
- Signs and symptoms to report to nurse

Assess coping ability of patient and family members.

Assess home environment, including:

- Safety hazards, especially related to falls

Instruct patients on methods to promote vasodilation. Teach them to avoid raising their legs above the level of the heart unless venous stasis is also present. Provide written and oral instructions on foot care and methods to prevent injury and ulcer development (Chart 36-6).

Chart 36-6 Patient and Family Education: Preparing for Self-Management

Foot Care for the Patient with Peripheral Vascular Disease

- Keep your feet clean by washing them with a mild soap in room-temperature water.
- Keep your feet dry, especially the ankles and between the toes.
- Avoid injury to your feet and ankles. Wear comfortable, well-fitting shoes. Never go without shoes.
- Keep your toenails clean and filed. Have someone cut them if you cannot see them clearly. Cut your toenails straight across.
- To prevent dry, cracked skin, apply a lubricating lotion to your feet.
- Prevent exposure to extreme heat or cold. Never use a heating pad on your feet.

- Avoid constricting garments.
- If a problem develops, see a podiatrist or physician.
- Avoid extended pressure on your feet or ankles, such as occurs when you lean against something.

Patients who have had surgery require additional instruction on incision care (see Chapter 16). Encourage all patients to avoid smoking and to limit dietary fat intake to 5% to 6% of the total daily calories (Eckel et al., 2014). Remind them to drink adequate fluids to prevent dehydration.

Patients with chronic arterial obstruction may fear recurrent occlusion or further narrowing of the artery. They often fear that they might lose a limb or become debilitated in other ways. Indeed, chronic PAD may worsen, especially in those with diabetes mellitus. Reassure them that participation in prescribed exercise, nutrition therapy, and drug therapy, along with cessation of smoking, can limit further formation of atherosclerotic plaques.

Patients with arterial compromise may need assistance with ADLs if activity is limited by pain. They may need to limit or avoid stair climbing, depending on the severity of disease. Patients who have undergone surgery or need to limit activity usually need temporary help with daily activities by the family or other caregiver.

Patients who must limit activity because of PAD may benefit from the assistance of a home care aide. Those who have undergone surgery may require a home care nurse to assist with incision care. In collaboration with the case manager, arrange for home care resources before discharge.

Acute Peripheral Arterial Occlusion

Pathophysiology

Although chronic peripheral arterial disease (PAD) progresses slowly, the onset of **acute arterial occlusions** is sudden and dramatic. An **embolus** (piece of clot that travels and lodges in a new area) is the most common cause of peripheral occlusions, although a local thrombus may be the cause. Occlusion may affect the upper extremities, but it is more common in the lower extremities. Emboli originating from the heart are the most common cause of acute arterial occlusions. Most patients with an embolic occlusion have had an acute myocardial infarction (MI) and/or atrial fibrillation within the previous weeks.

Patient-Centered Collaborative Care

Patients with an acute arterial occlusion describe severe pain below the level of the occlusion that occurs even at rest. The affected extremity is cool or cold, pulseless, and mottled. Small areas on the toes may be blackened or gangrenous due to lack of perfusion. *Those with acute arterial insufficiency often present with the "six P's" of ischemia:*

- Pain
- Pallor
- Pulselessness
- Paresthesia
- Paralysis
- Poikilothermy (coolness)

The health care provider must initiate treatment promptly to avoid permanent damage or loss of an extremity. Anticoagulant therapy with unfractionated heparin (UFH, Hepalean) is usually the first intervention to prevent further clot formation. A bolus of up to 10,000 units may be prescribed. The patient may undergo angiography.

A surgical *thrombectomy* or *embolectomy* with local anesthesia may be performed to remove the occlusion. The physician makes a small incision, which is followed by an **arteriotomy** (a surgical opening into an artery). A catheter is inserted into the artery to retrieve the embolus. It may be necessary to close the artery with a synthetic or autologous (patient's own blood vessel) patch graft.

Nursing Safety Priority QSEN

Critical Rescue

After an arterial thrombectomy, observe the affected extremity for improvement in color, temperature, and pulse every hour for the first 24 hours or according to the postoperative surgical protocol. Monitor patients for manifestations of new thrombi or emboli, especially pulmonary emboli (PE). Chest pain, dyspnea, and acute confusion (older adults) typically occur in patients with PE. Notify the health care provider or Rapid Response Team immediately if these symptoms occur.

pain should significantly diminish after the surgical procedure, although mild incisional pain remains. Watch closely for complications caused by reperfusing the artery after thrombectomy or embolectomy, which include spasms and swelling of the skeletal muscles. Swelling of the skeletal muscles can result in compartment syndrome.

Compartment syndrome occurs when tissue pressure within a confined body space becomes elevated and restricts blood flow. The resulting ischemia can lead to tissue damage and eventually tissue death. Assess the motor and sensory function of the affected extremity. Monitor for increasing pain, swelling, and tenseness. Report any of these symptoms to the health care provider immediately. **Fasciotomy** (surgical opening into the tissues) may be necessary to prevent further injury and save the limb.

The use of *systemic thrombolytic therapy* for acute arterial occlusions has been disappointing because bleeding complications often outweigh the benefits obtained. Catheter-directed intra-arterial thrombolytic therapy with *fibrinolytics,* such as alteplase (Activase) or t-PA, has emerged as an alternative to surgical treatment in selected settings. A catheter is placed percutaneously (through the skin) into the artery with or without ultrasound guidance by the vascular surgeon or interventional radiologist. The tip of the catheter is embedded in the clot to directly deliver the thrombolytic infusion for 24 to 36 hours until the clot dissolves.

During infusion, monitor the patient for complications such as bleeding and hemorrhagic stroke. Maintain a normal blood pressure for the patient by monitoring fluids to prevent a potential stroke. As the clot dissolves, the patient typically experiences severe pain that requires patient-controlled analgesia (PCA).

Nursing Safety Priority QSEN

Drug Alert

When *fibrinolytics* are given, assess for signs of bleeding, bruising, or hematoma. For patients receiving any *platelet inhibitor,* monitor platelet counts for the first 3, 6, and 12 hours after the start of the infusion or per agency protocol. If the platelet count decreases to below 100,000/mm^3, the infusion needs to be readjusted or discontinued. If any of these complications occur, notify the physician or Rapid Response Team immediately.

Aneurysms of Central Arteries

Pathophysiology

An **aneurysm** is a permanent localized dilation of an artery, which enlarges the artery to at least 2 times its normal diameter. It may be described as *fusiform* (a diffuse dilation affecting the entire circumference of the artery) or *saccular* (an outpouching affecting only a distinct portion of the artery). Aneurysms may also be described as *true* or *false*. In true aneurysms, the arterial wall is weakened by congenital or acquired problems. False aneurysms occur as a result of vessel injury or trauma to all three layers of the arterial wall. *Dissecting aneurysms* differ from aneurysms in that they are formed when blood accumulates in the wall of an artery.

Aneurysms tend to occur at specific anatomic sites (Fig. 36-7), most commonly in the abdominal aorta. They often occur at a point where the artery is not supported by skeletal muscles or on the lines of curves or flexion in the arterial tree. This chapter discussed aneurysms of the central arteries. Brain aneurysms are discussed in Chapter 45.

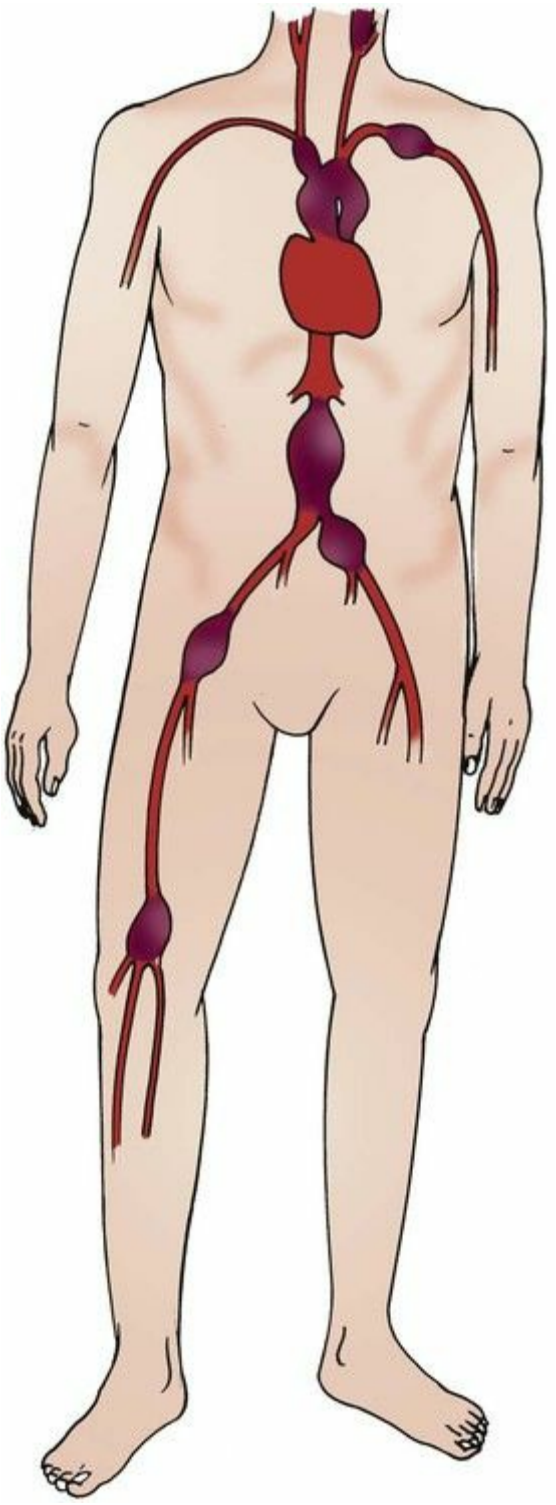

FIG. 36-7 Common anatomic sites of arterial aneurysms.

An aneurysm forms when the middle layer (media) of the artery is weakened, producing a stretching effect in the inner layer (intima) and outer layers of the artery. As the artery widens, tension in the wall increases and further widening occurs, thus enlarging the aneurysm and increasing the risk for arterial rupture. Elevated blood pressure can also increase the rate of aneurysmal enlargement and risk for early rupture. When *dissecting* aneurysms occur, the aneurysm enlarges, blood is lost, and blood flow to organs is diminished.

Abdominal aortic aneurysms (AAAs) account for most aneurysms, are commonly asymptomatic, and frequently rupture. Most of these are located between the renal arteries and the aortic bifurcation (dividing area).

Thoracic aortic aneurysms (TAAs) are not quite as common and are frequently misdiagnosed. They are typically discovered when advanced imaging is used to assess other conditions. TAAs commonly develop between the origin of the left subclavian artery and the diaphragm. They are located in the descending, ascending, and transverse sections of the aorta. They can also occur in the aortic arch and are very difficult to manage surgically.

Aneurysms can cause symptoms by exerting pressure on surrounding structures or by rupturing. *Rupture is the most frequent complication and is life threatening because abrupt and massive hemorrhagic shock results.* Thrombi within the wall of an aneurysm can also be the source of emboli in distal arteries below the aneurysm.

Atherosclerosis is the most common cause of aneurysms, with hypertension, hyperlipidemia, and cigarette smoking being contributing factors. Age, gender, and family history also play a role (McCance et al., 2014). Syphilis (a sexually transmitted disease), Marfan syndrome (a connective tissue disease), and Ehlers-Danlos syndrome (a rare genetic disorder) are other causes of AAAs. Chronic inflammation (aortitis) and blunt trauma, usually from motor vehicle crashes, can cause aneurysms in the descending thoracic aorta (Hiratzka et al., 2010).

Patient-Centered Collaborative Care

Assessment

Most patients with abdominal or thoracic aneurysms are asymptomatic when their aneurysms are first discovered by routine examination or during an imaging study performed for another reason. However, a few patients do have symptoms that bring them to their health care provider or the emergency department.

Physical Assessment/Clinical Manifestations.

Assess patients with a known or suspected *abdominal aortic aneurysm (AAA)* for abdominal, flank, or back pain. Pain is usually described as steady with a gnawing quality, unaffected by movement, and lasting for hours or days.

A pulsation in the upper abdomen slightly to the left of the midline between the xyphoid process and the umbilicus may be present. A

detectable aneurysm is at least 5 cm in diameter. *Auscultate for a bruit over the mass, but avoid palpating the mass because it may be tender and there is risk for rupture!* If expansion and impending rupture of an AAA are suspected, assess for severe pain of sudden onset in the back or lower abdomen, which may radiate to the groin, buttocks, or legs.

Patients with a rupturing AAA are critically ill and are at risk for hypovolemic shock due to hemorrhage. Clinical manifestations include hypotension, diaphoresis, decreased level of consciousness, oliguria (scant urine output), loss of pulses distal to the rupture, and dysrhythmias. Retroperitoneal hemorrhage is manifested by hematomas in the flanks (lower back). Rupture into the abdominal cavity causes abdominal distention.

When *a thoracic aortic aneurysm* is suspected, assess for back pain and manifestations of compression of the aneurysm on adjacent structures. Signs include shortness of breath, hoarseness, and difficulty swallowing. TAAs are not often detected by physical assessment, but occasionally a mass may be visible above the suprasternal notch. Assess the patient with suspected rupture of a thoracic aneurysm for sudden and excruciating back or chest pain. Hypovolemic shock also occurs with TAA.

Imaging Assessment.

Computed tomography (CT) scanning with contrast is the standard tool for assessing the size and location of an abdominal or thoracic aneurysm. *Ultrasonography* is also used.

Interventions

The size of the aneurysm and the presence of symptoms determine patient management. The nurse's role is to perform frequent patient assessments, including blood pressure, pulse, and peripheral circulation checks.

Nonsurgical Management.

The desired outcome of nonsurgical management is to monitor the growth of the aneurysm and maintain the blood pressure at a normal level to decrease the risk for rupture. Patients with hypertension are treated with antihypertensive drugs to decrease the rate of enlargement and the risk for early rupture.

For those with small or asymptomatic aneurysms, frequent ultrasound or CT scans are necessary to monitor the growth of the aneurysm. Emphasize the importance of following through with scheduled tests to

monitor the growth. Also explain the clinical manifestations of aneurysms that need to be promptly reported.

Surgical Management.

Surgical management of an aneurysm may be an elective or an emergency procedure. *For patients with a rupturing abdominal aortic or a thoracic aneurysm, emergency surgery is performed.* Patients with smaller aneurysms that are producing symptoms are advised to have elective surgery. Those with smaller aneurysms that are not causing symptoms are treated nonsurgically until symptoms occur or the aneurysm enlarges.

The most common surgical procedure for AAA has traditionally been a resection or repair **(aneurysmectomy).** However, the mortality rate for elective resection is high and markedly increases for emergency surgery. Endovascular stent grafts have improved mortality rates and shortened the hospital stay for select patients who need AAA repair.

The repair of AAAs with **endovascular stent grafts** is the procedure of choice for almost all patients on an elective or emergent basis. Stents (wirelike devices) are inserted percutaneously (through the skin), avoiding abdominal incisions and therefore decreasing the risk for a prolonged postoperative recovery. Postoperative care is similar to care required after an arteriogram (angiogram).

Different designs of endovascular stent grafts are used, depending on the anatomic involvement of the aneurysm. The stent graft is flexible with either Dacron or polytetrafluoroethylene (PTFE) material. It is inserted through a skin incision into the femoral artery by way of a catheter-based system. The catheter is advanced to a level above the aneurysm away from the renal arteries. The graft is released from the catheter, and the stent graft is placed with a series of hooks. This procedure is done in collaboration with the vascular surgeon, interventional radiologist, operating suite team, and, at some centers, vascular medicine physician.

Complications for stent repair include:

- Conversion to open surgical repair
- Bleeding
- Aneurysm rupture
- Peripheral embolization
- Misplacement of the stent graft

The endovascular repair of AAAs has decreased the length of hospital stay for patients requiring repair of abdominal aneurysms. However, the patient needs to be closely monitored, in the hospital and at home, for

the development of complications after the procedure. Expert nursing care is required to allow for early identification of problems, and complications require timely surgical intervention. In addition, coordination and collaboration with the health care team are required for discharge planning and follow-up care for patients at home.

Community-Based Care

Most patients are discharged to home after aneurysm repair. However, in the absence of family or other support systems, the postoperative patient may be discharged to a transitional care or long-term care facility for rehabilitation.

If discharged to home, the patient must follow instructions regarding activity level and incisional care. Because stair climbing may be restricted initially, he or she may need a bedside commode if the bathroom is inaccessible. Teach the patient who has undergone surgical repair about activity restrictions, wound care, and pain management. Patients may not perform activities that involve lifting heavy objects (usually more than 15 to 20 pounds [6.8 to 9.1 kg]) for 6 to 12 weeks postoperatively. Advise them to use caution for activities that involve pulling, pushing, or straining. Those who usually engage in vigorous activities should discuss them with their health care provider. Most patients are restricted from driving a car for several weeks after discharge.

For patients who have not undergone surgical aneurysm repair, the teaching plan emphasizes the importance of compliance with the schedule of frequent ultrasound scanning to monitor the size of the aneurysm.

Nursing Safety Priority QSEN

Action Alert

Teach patients receiving treatment for hypertension about the importance of continuing to take prescribed drugs. Instruct them about the signs and symptoms that must promptly be reported to the health care provider, which include:

- Abdominal fullness or pain or back pain
- Chest or back pain
- Shortness of breath
- Difficulty swallowing or hoarseness

In collaboration with the case manager or social worker, assess the

availability of transportation to and from appointments for patients needing ultrasound monitoring. Those who have undergone surgery may require the services of a home care nurse for initial assistance with dressing changes. A home care aide may be needed to assist with ADLs, depending on the patient's support system.

Aneurysms of the Peripheral Arteries

Although femoral and popliteal aneurysms are not common, they may be associated with an aneurysm in another location of the arterial tree (see Fig. 36-7). To detect a popliteal aneurysm, assess for a pulsating mass in the popliteal space. To detect a femoral aneurysm, observe a pulsatile mass over the femoral artery. *To prevent its rupture, do not palpate the mass!* Evaluate both extremities because more than one femoral or popliteal aneurysm may be present.

The patient may have symptoms of limb ischemia (decreased perfusion), including diminished or absent pulses, cool to cold skin, and pain. pain also may be present if an adjacent nerve is compressed. The recommended treatment for either type of aneurysm, regardless of the size, is surgery because of the risk for thromboembolic complications.

To treat a femoral aneurysm, the surgeon removes the aneurysm and restores circulation using a synthetic or an autogenous saphenous vein graft-stent repair. Most surgeons prefer to bypass rather than resect a popliteal aneurysm.

After surgery, monitor for lower limb ischemia. Palpate pulses below the graft to assess graft patency. Often, Doppler ultrasonography is necessary to assess blood flow when pulses are not palpable. *Report sudden development of pain or discoloration of the extremity immediately to the physician because it may indicate graft occlusion.*

Aortic Dissection

Pathophysiology

Aortic dissection was previously referred to as a *dissecting aneurysm.* However, because this condition is more accurately described as a *dissecting hematoma,* the term *aortic dissection* is more commonly used. Aortic dissection is not common but is a life-threatening problem.

Aortic dissection is thought to be caused by a sudden tear in the aortic intima, opening the way for blood to enter the aortic wall. Degeneration of the aortic media may be the primary cause for this condition, with hypertension being an important contributing factor. It is often associated with connective tissue disorders such as Marfan syndrome. It occurs also in middle-aged and older people, peaking in adults in their 50s and 60s. Men are more commonly affected than women (Hiratzka et al., 2010).

The circulation of any major artery arising from the aorta can be impaired in patients with aortic dissection; therefore this condition is highly lethal and represents an emergency situation. Although the ascending aorta and descending thoracic aorta are the most common sites, dissections can also occur in the abdominal aorta and other arteries.

Patient-Centered Collaborative Care

Assessment

The most common symptom is pain. It is described as "sharp," "tearing," "ripping," and "stabbing" and tends to move from its point of origin. Depending on the site of dissection, the patient may feel pain in the anterior chest, back, neck, throat, jaw, or teeth at a level of 10 on a 0-to-10 pain intensity scale.

Diaphoresis (excessive sweating), nausea, vomiting, faintness, and apprehension are also common. Blood pressure is usually elevated unless complications such as cardiac tamponade or rupture have occurred. In these cases, the patient becomes rapidly hypotensive. A decrease or absence of peripheral pulses is common, as is aortic regurgitation, which is characterized by a musical murmur best heard along the right sternal border. Neurologic deficits such as an altered level of consciousness, paraparesis, and strokes also can occur.

Chest x-ray, computed tomography (CT), magnetic resonance imaging (MRI), and aortic angiography may be used to confirm the diagnosis.

However, MRI scanning is very time-consuming and may not be the test of choice. Transthoracic echocardiography (TTE) or transesophageal echocardiography (TEE) may be performed at the bedside for patients who cannot be moved (Braverman, 2010).

Interventions

The expected outcomes for emergency care for a patient with an aortic dissection are elimination of pain and reduction of systolic blood pressure to 100 to 120 mm Hg. Make sure that the patient has two large-bore IV catheters to infuse 0.9% sodium chloride and give medication. Insert an indwelling urinary catheter. The physician prescribes IV morphine sulfate to relieve pain and an IV beta blocker, such as esmolol (Brevibloc), to lower heart rate and blood pressure (Carlson, 2012). If this regimen is not effective, nicardipine hydrochloride (Cardene) or other antihypertensive may be used.

Subsequent treatment depends on the location of the dissection. Patients receive continued medical treatment for uncomplicated distal dissections and surgical treatment for proximal dissections. For those receiving long-term medical treatment, the systolic blood pressure must be maintained at or below 130 to 140 mm Hg. Beta blockers (e.g., propranolol) and calcium channel antagonists (e.g., amlodipine) are prescribed to assist with blood pressure maintenance once the patient is stabilized.

Patients having surgical intervention for a proximal dissection typically require cardiopulmonary bypass (CPB) (see Chapter 38). The surgeon removes the intimal tear and sutures edges of the dissected aorta. Usually a synthetic graft is used.

Other Arterial Health Problems

Fewer health problems affect peripheral and central arteries. Examples of some of these problems are summarized in Table 36-7.

TABLE 36-7

Assessment and Interventions for Other Arterial Health Problems

DISEASE/HEALTH PROBLEM	ASSESSMENT	COLLABORATIVE MANAGEMENT	NURSING CARE
Buerger's Disease	Claudication in feet and lower extremities worse at night; causes ischemia and fibrosis of vessels in extremities with increased sensitivity to cold. Ulcerations and gangrene occur on digits. Cause unknown but is associated with smoking.	Vasodilating drugs, such as nifedipine (Procardia); management of ulceration and gangrene; chronic pain management modalities.	Teach patient about smoking cessation, avoid cold by wearing gloves and warm clothes, manage stress, avoid caffeine; teach patient taking nifedipine to avoid grapefruit and grapefruit juice to prevent severe adverse effects, including possible death; teach patients on vasodilators about side effects such as facial flushing, hypotension, headaches.
Raynaud's Phenomenon/Disease	Painful vasospasms of arteries and arterioles in extremities, especially digits; causes red-white-blue skin color changes on exposure to cold or stress; cause unknown, occurs more in women, and may be autoimmune because it is associated with many rheumatic diseases like systemic lupus erythematosus.	Same as above	Same as above
Subclavian Steal	Occurs in upper extremities as result of subclavian artery occlusion or stenosis causing ischemia in the arm and pain; paresthesias and dizziness are also common; BP difference in arms and presence of subclavian bruit on the affected side.	Surgical interventions for cyanosis or unrelenting pain, such as endarterectomy, bypass, or dilation of subclavian artery.	Monitor patient closely for new signs and symptoms; postoperative, check pulses and observe for ischemic changes, including severe pain or color changes (e.g., cyanosis).
Thoracic Outlet Syndrome	Compression of subclavian artery by rib or muscle that is more common in women and those who have to keep arms moving or above their heads (e.g., golfers, swimmers); also present with trauma; causes neck, arm, and shoulder pain with numbness and possible cyanosis.	Physical therapy for exercise program, avoiding aggravating positions; surgery as last resort for severe pain.	Health teaching about avoiding activities and positions that aggravate pain; monitor for new signs and symptoms; neurovascular assessments; postoperative care if needed.

Peripheral Venous Disease

To function properly, veins must be patent (open) with competent valves. Vein function also requires the assistance of the surrounding muscle beds to help pump blood toward the heart. If one or more veins are not operating properly, they become distended and clinical manifestations occur.

Three health problems alter the blood flow in veins:

- Thrombus formation *(venous thrombosis)* can lead to pulmonary embolism (PE), a life-threatening complication. **Venous thromboembolism (VTE)** is the current term that includes both deep vein thrombosis and PE.
- Defective valves lead to *venous insufficiency* and *varicose veins,* which are not life threatening but are problematic.
- Skeletal muscles do not contract to help pump blood in the veins. This problem can occur when weight bearing is limited or muscle tone decreases.

Venous Thromboembolism

Pathophysiology

Venous thromboembolism (VTE) is one of health care's greatest challenges and includes both thrombus and embolus complications. A **thrombus** (also called a *thrombosis*) is a blood clot believed to result from an endothelial injury, venous stasis, or hypercoagulability. The thrombosis may be specifically attributable to one element, or it may involve all three elements. It is often associated with an inflammatory process. When a thrombus develops, inflammation occurs around the clot, thickening the vein wall and consequently possibly leading to embolization (the formation of an **embolus**). Pulmonary embolism (PE) is the most common type of embolus and is discussed in detail in Chapter 32.

Thrombophlebitis refers to a thrombus that is associated with inflammation. **Phlebothrombosis** is a thrombus without inflammation. Thrombophlebitis can occur in superficial veins. However, it most frequently occurs in the deep veins of the lower extremities.

Deep vein thrombophlebitis, commonly referred to as **deep vein thrombosis (DVT),** is the most common type of thrombophlebitis. Deep vein thrombophlebitis (thrombosis) is more serious than superficial thrombophlebitis because it presents a greater risk for PE. In PE, a dislodged blood clot travels to the pulmonary artery—a medical

emergency! DVT develops most often in the legs but can occur also in the upper arms as a result of increased use of central venous devices.

Thrombus formation has been associated with stasis of blood flow, endothelial injury, and/or hypercoagulability, known as **Virchow's triad.** The precise cause of these events remains unknown; however, a few predisposing factors have been identified.

The highest incidence of clot formation occurs in patients who have undergone hip surgery, total knee replacement, or open prostate surgery. Other conditions that seem to promote thrombus formation are ulcerative colitis, heart failure, cancer, oral contraceptives, and immobility. Complications of immobility occur during prolonged bedrest such as when a patient is confined to bed for an extensive illness. People who sit for long periods (e.g., on an airplane or at a computer) are also at risk. **Phlebitis** (vein inflammation) associated with invasive procedures such as IV therapy can also predispose patients to thrombosis.

A systematic literature review by Anthony (2013) found a valid and reliable model for placing patients in high- and low-risk groups for DVT. This model is highly predictive of DVT development. During the nursing assessment, one point is given for each of nine characteristics, which include:

- Active cancer, paralysis, or casting of an extremity
- Bedridden for more than 3 days
- Major surgery with general anesthesia during the previous 3 months
- Localized tenderness along the deep venous system
- Swelling of the entire leg
- Calf swelling of greater than 3 cm larger when compared with the other leg
- Pitting edema in one leg
- Dilated superficial veins in one leg
- Previously documented DVT

A score of 2 or more indicates that a DVT is likely to occur.

Millions of people in the United States are affected by deep vein thrombosis each year, and many die from pulmonary embolism. The largest number of deaths occur in older adults.

Health Promotion and Maintenance

In the *community,* if a person has a history of any type of VTE, these precautions should be taken:

- Avoid oral contraceptives.
- Drink adequate fluids to avoid dehydration.

• Exercise legs during long periods of bedrest or sitting.

The Joint Commission's VTE Core Measure Set requires that hospitals report data on 6 areas related to VTE prophylaxis and management (Table 36-8). If VTE is not prevented or adequately managed, the hospital may not be paid by the third party payer (e.g., Medicare) for the patient's care. In the *inpatient setting*, all patients must be assessed for risk for VTE on admission. For those at moderate to high risk, initiate these interventions to prevent VTE:

TABLE 36-8

Venous Thromboembolism (VTE) Core Measure Set

CORE MEASURE	ASSESSMENT OF MEASURE
VTE-1	**VTE Prophylaxis:** Number of patients who received VTE prophylaxis or have documented why no VTE prophylaxis was given the day of or the day after hospital admission or surgery
VTE-2	**ICU VTE:** Number of patients who received VTE prophylaxis on ICU admission or have documented why no VTE prophylaxis was given the day of admission, transfer, or surgery
VTE-3	**VTE Patients with Anticoagulant Overlap Therapy:** Number of patients diagnosed with confirmed VTE who received overlap of parenteral anticoagulant and warfarin
VTE-4	**VTE Patients Receiving Unfractionated Heparin:** Number of patients receiving heparin with dosages/platelet count monitoring by protocol or nomogram
VTE-5	**VTE Warfarin Therapy Discharge Instructions:** Number of patients who received written instructions that address these four criteria: • Compliance issues • Dietary advice • Follow-up monitoring • Information about potential for adverse drug reactions/interactions
VTE-6	**Hospital-Acquired Potentially Preventable VTE:** Number of patients who developed VTE while hospitalized

ICU, Intensive care unit.

Data from www.jointcommission.org/venous_thromboembolism/.

• Patient education
• Leg exercises
• Early ambulation
• Adequate hydration
• Graduated compression stockings
• Intermittent pneumatic compression, such as sequential compression devices (SCDs)
• Venous plexus foot pump
• Anticoagulant therapy

Patient-Centered Collaborative Care

Assessment

People with DVT may have symptoms or may be asymptomatic. *The classic signs and symptoms of DVT are calf or groin tenderness and pain and sudden onset of unilateral swelling of the leg.* pain in the calf on dorsiflexion of the foot (positive Homans' sign) appears in only a small percentage of

patients with DVT, and false-positive findings are common (Anthony, 2013). *Therefore checking a Homans' sign is not advised because it is an unreliable tool!* Examine the area described as painful, comparing this site with the other limb. *Gently* palpate the site, observing for **induration** (hardening) along the blood vessel and for warmth and edema. Redness may also be present (Fig. 36-8).

FIG. 36-8 Deep vein thrombosis (DVT) of lower left leg.

Although diagnostic tests are available, physical examination findings are often adequate for diagnosis. If a definitive diagnosis is lacking from physical assessment findings alone, diagnostic tests may be performed.

The preferred diagnostic test for DVT is *venous duplex ultrasonography,* a noninvasive ultrasound that assesses the flow of blood through the veins of the arms and legs. *Doppler flow studies* may also be useful in the diagnosis, but they are more sensitive in detecting proximal rather than distal DVT. Normal venous circulation creates audible signals, whereas thrombosed veins produce little or no sound. The accuracy of the scanning depends on the technical skill of the health care professional performing the test. If the test is negative but a DVT is still suspected, a venogram may be needed to make an accurate diagnosis.

Impedance plethysmography assesses venous outflow and can detect most DVTs that are located above the popliteal vein. It is not helpful in

locating clots in the calf and is less sensitive than Doppler studies.

Magnetic resonance direct thrombus imaging (MRI), another noninvasive test, is useful in finding a DVT in the proximal deep veins and is better than traditional venography in finding DVT in the inferior vena cava or pelvic veins.

A d-dimer test is a global marker of coagulation activation and measures fibrin degradation products produced from fibrinolysis (clot breakdown). The test is used for the diagnosis of DVT when the patient has few clinical signs and stratifies patients into a high-risk category for reoccurrence. Useful as an adjunct to noninvasive testing, a negative d-dimer test can exclude a DVT without an ultrasound.

Physical and diagnostic assessment of patients with pulmonary embolism is described in Chapter 32.

Interventions

The focus of managing thrombophlebitis is to prevent complications such as pulmonary emboli, prevent further thrombus formation, and prevent an increase in size of the thrombus. Patients with deep vein thrombosis (DVT) may be hospitalized for treatment, although this practice is changing as a result of the use of newer drugs.

Nonsurgical Management.

DVT is usually treated medically using a combination of rest and drug therapy. Prevention of DVT and other types of venous thromboembolism (VTE) is crucial for patients at risk. Preventive measures are listed on p. 730 in the Health Promotion and Maintenance section.

Rest.

Supportive therapy for DVT has typically included bedrest and elevation of the extremity. However, a review and synthesis of the literature showed that outcomes are not different if the patient is allowed to ambulate (Gay et al., 2009). Ambulation did not cause pulmonary embolus, and the DVT did not worsen any more with ambulation than with bedrest. Allowing patients to ambulate may decrease their fear and anxiety about dislodging the clot and life-threatening complications.

Teach the patient to elevate his or her legs when in bed and chair. To help prevent chronic venous insufficiency, instruct patients with active and resolving DVT to wear knee- or thigh-high sequential or graduated compression stockings for an extended period. Be sure to select the correct stocking size for the patient according to the sizing chart provided.

Some health care providers prescribe intermittent or continuous warm, moist soaks to the affected area. *To prevent the thrombus from dislodging and becoming an embolus, do not massage the affected extremity.* Monitor all patients for signs and symptoms of pulmonary embolism (PE), which include shortness of breath, chest pain, and acute confusion (in older adults). Emboli may also travel to the brain or heart, but these complications are not as common as PE. Chapter 32 describes PE manifestations in detail.

Drug Therapy.

Anticoagulants are the drugs of choice for actual DVT and for patients at risk for DVT. However, these drugs are known to cause medical complications and even death. Therefore The Joint Commission's National Patient Safety Goals (NPSGs) include the need for agencies to reduce the likelihood of patient harm associated with the use of anticoagulant therapy.

The conventional treatment has been IV unfractionated heparin followed by oral anticoagulation with warfarin (Coumadin). However, unfractionated heparin can be problematic because each patient's response to the drug is unpredictable and hospital admission is usually required for laboratory monitoring and dose adjustments. The use of low–molecular-weight heparin (LMWH) has changed the management of both DVT and PE.

Unfractionated Heparin Therapy.

Some patients with a confirmed diagnosis of an existing blood clot are started on a regimen of IV unfractionated heparin (UFH, Hepalean) therapy. UFH is an anticoagulant agent that at low doses interacts with antithrombin III to produce selective inhibition of clotting factors IIa (thrombin) and Xa. At higher doses, it inhibits practically all clotting factors. The ultimate result is inhibition of fibrin formation. The health care provider prescribes UFH to prevent the formation of further clots, which often develop in the presence of an existing clot, and to prevent enlargement of the existing clot. Over a long period, the existing clot is slowly absorbed by the body.

Before UFH administration, a baseline prothrombin time (PT), activated partial thromboplastin time (APTT or aPTT), international normalized ratio (INR), complete blood count (CBC) with platelet count, urinalysis, stool for occult blood, and creatinine level are required. Notify the physician if the platelet count is below 100,000 to 120,000/mm^3,

depending on agency protocol.

UFH is initially given in a bolus IV dose of about 80 to 100 units/kg of body weight in a prefilled syringe or 5000 units followed by continuous infusion via an infusion pump. The infusion is regulated by a reliable electronic pump that protects against accidental free flow of solution. The physician or clinical pharmacist prescribes concentrations of UFH (in 5% dextrose in water) and the number of units or milliliters per hour needed to maintain a therapeutic aPTT (usually 18-20 units/kg/hr or at least 30,000 units over 24 hours). aPTT is measured at least daily, and results are reported to the health care provider as soon as results are available to allow adjustment of heparin dosage. Therapeutic levels of aPTTs are usually $1\frac{1}{2}$ to 2 times normal control levels.

Nursing Safety Priority QSEN

Critical Rescue

Notify the physician if the aPTT value is greater than 70 seconds, or follow hospital protocol for reporting critical laboratory values. Assess patients for signs and symptoms of bleeding, which include hematuria, frank or occult blood in the stool, ecchymosis (bruising), petechiae, an altered level of consciousness, or pain. If bleeding occurs, stop the anticoagulant immediately and call the health care provider or Rapid Response Team!

UFH can also decrease platelet counts. Mild reductions are common and are resolved with continued heparin therapy. Severe platelet reductions, although rare, result from the development of antiplatelet bodies within 6 to 14 days after the beginning of treatment. Platelets aggregate into "white clots" that can cause thrombosis, usually in the form of an acute arterial occlusion. The provider discontinues heparin administration if severe **heparin-induced thrombocytopenia (HIT)** (platelet count <150,000), or "white clot syndrome," occurs. Low–molecular-weight heparin is used more commonly today because of the complications involved with unfractionated heparin.

Bivalirudin (Angiomax), lepirudin (Refludan), and argatroban injection are *highly selective direct thrombin inhibitors* that may be used as alternatives to heparin or for patients who have had HIT. Like heparin, these drugs increase the risk for bleeding. Monitor hemoglobin, hematocrit, aPTT, platelet count, urinalysis, fecal occult blood test, and blood pressure for indications of this complication. An oral

anticoagulant like warfarin (Coumadin) may also be substituted for heparin if necessary.

Ensure that protamine sulfate, the antidote for heparin, is available if needed for excessive bleeding. Chart 36-7 highlights information important to nursing care and patient education associated with anticoagulant therapy.

Chart 36-7 Best Practice for Patient Safety & Quality Care QSEN

The Patient Receiving Anticoagulant Therapy

- Carefully check the dosage of anticoagulant to be administered, even if the pharmacy prepared the drug.
- Monitor the patient for signs and symptoms of bleeding, including hematuria, frank or occult blood in the stool, ecchymosis, petechiae, altered mental status (indicating possible cranial bleeding), or pain (especially abdominal pain, which could indicate abdominal bleeding).
- Monitor vital signs frequently for decreased blood pressure and increased pulse (indicating possible internal bleeding).
- Have antidotes available as needed (e.g., protamine sulfate for heparin; vitamin K for warfarin [Coumadin, Warfilone]).
- Monitor activated partial thromboplastin time (aPTT) for patients receiving unfractionated heparin. Monitor prothrombin time (PT)/international normalized ratio (INR) for patients receiving warfarin or low–molecular-weight heparin (LMWH).
- Apply prolonged pressure over venipuncture sites and injection sites.
- When administering *subcutaneous* heparin, apply pressure over the site and do not massage.
- Teach the patient going home while taking an anticoagulant to:
  - Use only an electric razor
  - Take precautions to avoid injury; for example, do not use tools such as hammers or saws, where accidents commonly occur
  - Report signs and symptoms of bleeding, such as blood in the urine or stool, nosebleeds, ecchymosis, or altered mental status
  - Take the prescribed dosage of drug at the precise time that it was prescribed to be taken
  - Not stop taking the drug abruptly; the physician usually tapers the anticoagulant gradually

To *prevent* DVT, unfractionated heparin may be given in low doses

subcutaneously for high-risk patients, especially after orthopedic surgery. Commonly used alternatives to unfractionated heparin include:

- Low–molecular-weight heparin (e.g., enoxaparin [Lovenox]) (drug class of choice after orthopedic surgery)
- Selective factor Xa inhibitors (e.g., fondaparinux [Arixtra]; rivaroxaban [Xarelto] used most often for orthopedic surgery)
- Warfarin (Coumadin, Warfilone)

Low–Molecular-Weight Heparin.

Subcutaneous low–molecular-weight heparins (LMWHs) such as enoxaparin (Lovenox), dalteparin (Fragmin), and ardeparin (Normiflo) have a consistent action and are preferred for prevention and treatment of DVT. Danaparoid (Orgaran) is also classified as an LMWH but is actually a heparinoid. LMWHs bind less to plasma proteins, blood cells, and vessel walls, resulting in a longer half-life and more predictable response. These drugs inhibit thrombin formation because of reduced factor IIa activity and enhanced inhibition of factor Xa and thrombin.

Some patients taking LMWH may be safely managed at home with visits from a home care nurse. Candidates for home therapy must have stable DVT or PE, low risk for bleeding, adequate renal function, and normal vital signs. They must be willing to learn self-injection or have a family member, friend, or home care nurse administer the subcutaneous injections.

Some health care providers place the patient on a regimen of IV unfractionated heparin (UFH) for several days and then follow up with an LMWH. In this case, the UFH is discontinued at least 30 minutes before the first LMWH injection. The usual dose of enoxaparin is 1 mg/kg of body weight, not to exceed 90 mg, and is repeated every 12 hours. If the patient's creatinine level is greater than 2 mg/dL (indicating renal insufficiency), the health care provider lowers the dose. Dalteparin can be given once daily at 200 units/kg of body weight and does not require dose adjustment for renal insufficiency. The usual dose of ardeparin is 50 units/kg of body weight and is given every 12 hours.

Assess all stools for occult blood. The aPTTs are not checked on an ongoing basis because the doses of LMWH are not adjusted.

Warfarin Therapy.

If the patient is receiving continuous UFH, warfarin (Coumadin), an oral anticoagulant, may be *added* at least 5 days later. Patients receiving LMWH are placed on the oral drug after the first dose. This anticoagulant drug overlap is necessary because heparin and warfarin work differently.

Warfarin works in the liver to inhibit synthesis of the four vitamin K–dependent clotting factors and takes 3 to 4 days before it can exert therapeutic anticoagulation. The heparin continues to provide therapeutic anticoagulation until this effect is achieved. IV heparin is then discontinued.

According to the National Patient Safety Goals, therapeutic levels of warfarin must be monitored by measuring the international normalized ratio (INR) at frequent intervals. Because prothrombin times are often inconsistent and misleading, the INR was developed. Most laboratories report both results. Most patients receiving warfarin should have an INR between 1.5 and 2.0 to prevent future DVT and to minimize the risk for stroke or hemorrhage (Pagana & Pagana, 2014). For patients with additional cardiovascular problems or pulmonary embolus, the desired INR is higher, up to 3.5 or 4.0. The health care provider specifies the desired INR level to obtain. Be aware of the critical value for INR according to agency policy (ranges between 4.5 and 6.0). Notify the health care provider immediately if your patient's INR is at a critical value.

After obtaining the patient's baseline INR, warfarin therapy should be started with low doses, at least 5 mg, and gradually titrated up according to the INR. Patients usually receive this drug for 3 to 6 months or longer after an episode of DVT if no precipitating factors were discovered, with recurrence, or if there are continuing risk factors.

Nursing Safety Priority QSEN

Drug Alert

For patients taking warfarin, assess for any bleeding, such as hematuria or blood in the stool. *Ensure that vitamin K, the antidote for warfarin, is available in case of excessive bleeding* (see Chart 36-7). Report any bleeding to the health care provider, and document in the patient's health record. Teach patients to avoid foods with high concentrations of Vitamin K, especially dark green leafy vegetables. These foods interfere with the action of warfarin.

NCLEX Examination Challenge

Physiological Integrity

The nurse is providing care to a client who has started warfarin after being diagnosed with a deep vein thrombosis. What health teaching will the nurse provide to the client related to self-management of warfarin

therapy?
A "You must have your partial thromboplastin time checked every 2 weeks."
B "Massage the injection site after the warfarin is injected."
C "Eat plenty of dark green leafy vegetables while taking warfarin."
D "Report any signs of bleeding to your primary care provider."

Thrombolytic Therapy.

Thrombolytic therapy using fibrinolytics is not commonly prescribed unless it is the treatment of last resort.

Surgical Management.

A deep vein thrombus is rarely removed surgically unless there is a massive occlusion that does not respond to medical treatment and the thrombus is of recent (1 to 2 days) onset. **Thrombectomy** is a common surgical procedure for removing the clot. Preoperative and postoperative care of patients undergoing thrombectomy is similar to the care for those undergoing arterial surgery (see pp. 723-725 in the Peripheral Arterial Disease section).

For patients with recurrent deep vein thrombosis (DVT) or pulmonary emboli that do not respond to medical treatment and for patients who cannot tolerate anticoagulation, **inferior vena cava filtration** may be indicated. The surgeon usually inserts a filter device, or "umbrella," into the femoral vein. The device is meant to trap emboli in the inferior vena cava before they progress to the lungs. Holes in the device allow blood to pass through, thus not significantly interfering with the return of blood to the heart. There are several new filter brands available and designed to allow for removal if and when DVT risks diminish.

Preoperative care is similar to that provided for patients receiving local anesthesia (see Chapter 14). If they have recently been taking anticoagulants, collaborate with the physician about interrupting this therapy in the preoperative period to avoid hemorrhage.

Postoperatively, inspect the groin insertion site for bleeding and signs or symptoms of infection. Other postoperative nursing care is similar to that for any patient undergoing local anesthesia (see Chapter 16).

Community-Based Care

Patients recovering from thrombophlebitis or DVT are ambulatory when they are discharged from the hospital. The primary focus of planning for discharge is to educate the patient and family about anticoagulation

therapy.

Teach patients recovering from DVT to stop smoking and avoid the use of oral contraceptives to decrease the risk for recurrence. Alternative forms of birth control may be used. Most patients are discharged on a regimen of warfarin (Coumadin, Warfilone) or low–molecular-weight heparin (LMWH). The VTE Core Measures and the Joint Commission's National Patient Safety Goals require that the patients be given written discharge instructions about anticoagulant therapy that address:

- Drug compliance issues (need to take drug as prescribed)
- Dietary advice (e.g., foods to avoid)
- Follow-up monitoring (e.g., Coumadin clinic, INR testing)
- Information about potential for adverse drug reactions/interactions (e.g., bleeding, bruising)

Instruct patients and their families to avoid potentially traumatic situations, such as participation in contact sports. Provide written and oral information about the signs and symptoms of bleeding (see Chart 36-7). Reinforce the need to report any of these manifestations to the health care provider immediately.

The anticoagulant effect of warfarin may be reversed by omitting one or two doses of the drug or by the administration of vitamin K. In case of injury, teach patients to apply pressure to bleeding wounds and to seek medical assistance immediately. Encourage them to carry an identification card or wear a medical alert bracelet that states that they are taking warfarin or any other anticoagulant.

Instruct patients to tell their dentist and other health care providers before receiving treatment or prescriptions that they are taking warfarin. Prothrombin times are affected by many prescription and over-the-counter drugs such as NSAIDs. Teach patients to avoid high-fat and vitamin K–rich foods, such as cabbage, cauliflower, broccoli, asparagus, turnips, spinach, kale, fish, and liver (Chart 36-8). Remind them to drink adequate fluids to stay well hydrated, avoid alcohol (which can cause dehydration), and avoid sitting for prolonged periods.

Chart 36-8 Patient and Family Education: Preparing for Self-Management

Foods and Drugs That Interfere with Warfarin (Coumadin)

Eat small amounts of foods rich in vitamin K each day, including any of these:

- Broccoli

- Cauliflower
- Spinach
- Kale
- Other green leafy vegetables
- Brussels sprouts
- Cabbage
- Liver

If possible, avoid:

- Allopurinol
- NSAIDs
- Acetaminophen
- Vitamin E
- Histamine blockers
- Cholesterol-reducing drugs
- Antibiotics
- Oral contraceptives
- Antidepressants
- Thyroid drugs
- Antifungal agents
- Other anticoagulants
- Corticosteroids
- Herbs, such as St. John's wort, garlic, ginseng, *Ginkgo biloba*

If possible, in collaboration with the case manager (CM) or other discharge planner, arrange for the patient to obtain a device to self-monitor INR at home. Some insurance companies do not pay for the INR monitoring device. Clinical studies show that self-monitoring of the INR and self-adjusting of anticoagulation therapy result in better anticoagulation control, improve patient satisfaction, and improve quality of life (Michaels & Regan, 2013). The device used to self-monitor is similar to a glucometer for glucose testing and requires a fingerstick blood sample applied to a test strip or plastic cuvette, which is then inserted into the machine. Self-monitoring can be used either for the testing alone or for self-management, in which the patient uses the test results to adjust drug dosages based on a dosing protocol. If the patient cannot use a monitoring device, teach a family member or other caregiver how to perform the procedure. If the patient lives alone, collaborate with the CM to arrange for follow-up laboratory appointments to have blood drawn at frequent intervals—usually every week until the patient's values are stabilized. Communication with the primary care provider is essential while patients are receiving warfarin.

Patients receiving subcutaneous LMWH injections at home need instruction on self-injection. Teach the appropriate caregiver and family members or friends, if necessary, to administer the injections.

Patients who have experienced DVT may fear recurrence of a thrombus. They may also be concerned about treatment with warfarin and the risk for bleeding. Assure them that the prescribed treatment will help resolve this problem and that ongoing assessment of prothrombin times and INR values decreases the risks for bleeding.

Venous Insufficiency

Pathophysiology

Venous insufficiency occurs as a result of prolonged venous hypertension that stretches the veins and damages the valves. Valvular damage can lead to a backup of blood and further venous hypertension, resulting in edema and decreased tissue perfusion. With time, this stasis (stoppage) results in venous stasis ulcers, swelling, and cellulitis.

The veins cannot function properly when thrombosis occurs or when valves are not working correctly. Venous hypertension can occur in people who stand or sit in one position for long periods (e.g., teachers, office personnel). Obesity can also cause chronically distended veins, which lead to damaged valves. Thrombus formation can contribute to valve destruction. Chronic venous insufficiency also often occurs in patients who have had thrombophlebitis. In severe cases, venous ulcers develop.

Venous leg ulcers are a major cause of death, pain, and health care costs. Most venous ulcer care is delivered in the community setting by home care nurses or through self-management.

Patient-Centered Collaborative Care

Assessment

Venous insufficiency may result in edema of both legs. There may be **stasis dermatitis** or reddish brown discoloration along the ankles, extending up to the calf. In people with long-term venous insufficiency, **stasis ulcers** often form. They can result from the edema or from minor injury to the limb. Ulcers typically occur over the malleolus, more often medially (inner ankle) than laterally (outer ankle). The ulcer usually has irregular borders. In general, these ulcers are chronic and difficult to heal (see Chart 36-4). Many people live with ulcers for years, and recurrence is common. Some may lose one or both legs if ulcers are not controlled.

Interventions

The focus of treating venous insufficiency is to decrease edema and promote venous return from the affected leg. Patients are not usually hospitalized for venous insufficiency alone unless it is complicated by an ulcer or another disorder is occurring at the same time.

Nonsurgical Management.

Treatment of chronic venous insufficiency is nonsurgical unless it is complicated by a venous stasis ulcer that requires surgical débridement. The desired outcomes of managing venous stasis ulcers are to heal the ulcer, prevent infection, and prevent stasis with recurrence of ulcer formation. Collaborate with the wound care nurse or wound, ostomy, and continence nurse (WOCN) to make recommendations for ulcer care. A dietitian can suggest dietary supplements, such as zinc and vitamins A and C, as well as high-protein foods, to promote wound healing.

Patients with chronic venous insufficiency wear graduated compression stockings, which fit from the middle of the foot to just below the knee or to the thigh. Stockings should be worn during the day and evening. Explain the purpose and importance of wearing the compression stockings. Be sure to use the sizing chart that comes with the stockings to select the best fit. Teach patients to not roll them down and to report if they become too tight or uncomfortable.

Teach the patient to elevate his or her legs for at least 20 minutes 4 or 5 times per day. When the patient is in bed, remind him or her to elevate the legs above the level of the heart (Chart 36-9).

Chart 36-9 Patient and Family Education: Preparing for Self-Management

Venous Insufficiency

Graduated Compression Stockings (GCSs)

- Wear stockings as prescribed, usually during the day and evening.
- Put the stockings on upon awakening and before getting out of bed.
- When applying the stockings, do not "bunch up" and apply like socks. Instead, place your hand inside the stocking and pull out the heel. Then place the foot of the stocking over your foot and slide the rest of the stocking up. Be sure that rough seams on the stocking are on the outside, not next to your skin.
- Do not push stockings down for comfort, because they may function

like a tourniquet and further impair venous return.
- Put on a clean pair of stockings each day. Wash them by hand (not in a washing machine) in a gentle detergent and warm water.
- If the stockings seem to be "stretched out," replace them with a new pair.

Dos and Don'ts

- Elevate your legs for at least 20 minutes 4 or 5 times a day. When in bed, elevate your legs above the level of your heart.
- Avoid prolonged sitting or standing.
- Do not cross your legs. Crossing at the ankles is acceptable for short periods.
- Do not wear tight, restrictive pants. Avoid girdles and garters.

Coordinate with the physician about the use of intermittent sequential pneumatic compression or foot plexus pumps for patients with past or present venous stasis ulcers. If an open venous ulcer is present, the device may be applied over a dressing such as an Unna boot. Instruct the patient to apply the pump as directed during the period of healing. Because of the high incidence of venous ulcer recurrence, encourage patients with chronic venous insufficiency whose ulcers have healed to continue compression therapy for life.

Venous stasis ulcers are slightly more manageable than ulcers resulting from arterial disease. They are chronic in nature, with some patients having the same ulcer for years. Ulcers often heal, only to recur in the same area several years later.

Two types of occlusive dressings are used for venous stasis ulcers: oxygen-permeable dressings and oxygen-impermeable dressings. Because the role of atmospheric oxygen in wound healing is controversial, opinions vary with regard to which type of dressing is preferred. An oxygen-permeable polyethylene film and an oxygen-impermeable hydrocolloid dressing (e.g., DuoDERM) are common. Hydrocolloid dressings are left in place for a minimum of 3 to 5 days for best effect. Use medical aseptic technique when changing dressings. If the wound is infected, use Contact Precautions in addition to Standard Precautions.

Artificial skin products can be used for difficult-to-heal venous leg ulcers. These first-generation products are very expensive but are laying the foundation in the field, with costs anticipated to come down in the future. Except for cultured epithelial autografts, artificial skins are only temporary. Artificial skin serves as a biologic cover to secrete growth

factors to promote more growth factor secretion from the patient's own skin to speed the wound healing process.

If the patient is ambulatory, an **Unna boot** may be used. An Unna boot dressing is constructed of gauze that has been moistened with zinc oxide. Apply the boot to the affected limb, from the toes to the knee, after the ulcer has been cleaned with normal saline solution. It is then covered with an elastic wrap and hardens like a cast. This promotes venous return and prevents stasis. The Unna boot also forms a sterile environment for the ulcer. The physician or advanced practice nurse changes the boot about once a week. Instruct the patient to report increased pain, which indicates that the boot may be too tight.

The health care provider may prescribe topical agents, such as Accuzyme, to chemically débride the ulcer, eliminating necrotic tissue and promoting healing. Remind patients that they may temporarily feel a burning sensation when the agent is applied. If an infection or cellulitis develops, systemic antibiotics are necessary.

Surgical Management.

Surgery for chronic venous insufficiency is not usually performed because it is not successful. Attempts at transplanting vein valves have had limited success. Surgical débridement of venous ulcers is similar to that performed for arterial ulcers.

NCLEX Examination Challenge

Health Promotion and Maintenance

The nurse is caring for a client with chronic venous stasis ulcers. Which statement by the client indicates a need for further health teaching?
A "I'll wear compression stockings at night."
B "I'll keep my affected leg above my heart."
C "I'll eat protein and vitamin C foods to help heal the ulcer"
D "I'll change my dressing every 3 to 5 days as needed."

Community-Based Care

The desired outcome for the patient with chronic venous insufficiency is to be managed in the home. For patients with frequent acute complications and repeated hospital admissions, case management can help meet appropriate clinical and cost outcomes.

Help patients plan for opportunities and facilities that allow for

elevation of the lower extremities in and outside the home. In addition, collaborate with the wound specialist to plan care of the ulcers at home.

If the physician prescribes graduated compression stockings, teach patients to apply these stockings before they get out of bed in the morning and to remove them just before going to bed at night (see Chart 36-9). Also advise them that they will probably need to wear these stockings for the rest of their lives.

To improve circulation and aid in weight reduction, collaborate with the physical therapist to prescribe an exercise program on an individual basis. Encourage all patients to maintain an optimal weight and consult with the dietitian to plan a weight-reduction diet.

Patients with venous stasis disease, especially those with venous stasis ulcers, may require long-term emotional support to assist them in meeting long-term needs. They may also need assistance in coping with necessary lifestyle adjustments, such as possible changes in occupation.

Patients with venous stasis ulcers may need the assistance of a home care nurse to perform dressing changes. Those with Unna boots need weekly transportation to their health care provider for dressing changes. Collaborate with the case manager to arrange for a sequential compression device in the home if the health care provider prescribes one.

Varicose Veins

Pathophysiology

Varicose veins are distended, protruding veins that appear darkened and tortuous. They can occur in anyone, but they are common in adults older than 30 years whose occupations require prolonged standing or heavy physical activity. Varicose veins are frequently seen also in patients with systemic problems (e.g., heart disease), obesity, high estrogen states, and a family history of varicose veins.

Both *superficial* and *deep* veins can become distended. As the vein wall weakens and dilates, venous pressure increases and the valves become incompetent (defective), causing venous reflux (Armstrong, 2013). The incompetent valves enhance the vessel dilation, and the veins become tortuous and distended. The severity of the disease depends on the extent of the distention and reflux. **Telangiectasias** (spider veins) are dilated *intradermal* veins less than 1 to 3 mm in diameter that are visible on the skin surface. Most patients are not bothered by them but may consider them unattractive. Most telangiectasias do not develop into the more severe varicose vein disease.

More advanced disease causes venous distention (bulging), edema, a feeling of fullness in the legs, and pruritus (itching). As a result, signs and symptoms of venous insufficiency may occur, including venous stasis ulcers, brown pigmentation from extravasated red blood cells (also called *skin staining*), and pain.

Varicose veins and reflux are diagnosed by simple ultrasonography or duplex ultrasonography. Informal assessments of venous reflux can be made with the patient lying down to determine the direction of flow within a vein. For the duplex ultrasound procedure, the patient is upright and BP cuffs are placed at the thigh, calf, and ankle. The cuffs are serially inflated and deflated while the scanner tests for reflux. A reflux time greater than 0.5 second in the saphenous vein is considered abnormal (Armstrong, 2013).

Patient-Centered Collaborative Care

The overall purpose of management for patients with varicose veins is to improve and maintain optimal venous return to the heart and prevent disease progression. Conservative measures are the treatment of choice, including the three *E*s: **e**lastic compression hose, **e**xercise, and **e**levation. Graduated compression stockings (GCSs) rely on graduated external pressure to improve venous return by applying pressure to the muscles. They are available in many grades or strengths, ranging from 8 to 50 mm Hg pressure. Exercise increases venous return by helping the muscles pump blood back to the heart. Teach patients to avoid high-impact exercises such as horseback riding and running. Daily walks and ankle flexion exercises while sitting are common exercises that are helpful in promoting circulation. Elevating the extremities as much as possible allows gravity to work with the valves in promoting venous return and prevent reflux.

Patients who continue to have pain or unsightly veins despite using the three Es may opt for more invasive approaches. Surgical ligation and/or removal of veins ("stripping") were the procedures of choice for many years. Sclerotherapy to occlude the affected vessel is also an option.

However, newer, less-invasive treatments are more common today. They are less painful and have a shorter recovery time. A common procedure is an endovenous ablation, which occludes the varicose vein, most commonly the saphenous vein. Using ultrasound guidance, the clinician advances a catheter into the vein and injects an anesthetic agent around it. Then the vessel is ablated (occluded) while the catheter is slowly removed. The two modalities for ablation are (1) endovenous laser

treatment (EVLT) using laser heat and (2) radiofrequency ablation (RFA) using a radiofrequency heating element.

After the procedure, teach the patient the importance of using a GCS or other form of compression (such as elastic compression bandages) for 24 hours a day, except for showers, for at least the first week. Follow-up ultrasonography ensures that the treated vein is closed. The patient is monitored carefully for the first 6 to 8 weeks to determine how healing has progressed. Some patients require continued use of the three Es for many years, depending on the severity of their disease.

Assess the affected limb for vascular status, including any changes in color or temperature of the leg. Monitor for pain, edema, and paresthesias that could indicate complications such as DVT or nerve damage. Nerve damage is usually temporary and minimal; it usually resolves within a few months (Armstrong, 2013).

Vascular Trauma

Many types of trauma can result in vascular injury. Vascular injuries include punctures, lacerations, and transections. Acute blunt or penetrating trauma may result in a false aneurysm or hematoma. Arteriovenous fistulas may be seen after penetrating injuries. The more common causes of penetrating injuries to the blood vessels are gunshot and knife wounds.

Blunt trauma can result from high-speed automobile crashes as a result of the shearing force of rapid deceleration. Vascular trauma can also occur during arterial puncture for arteriographic or hemodynamic studies in which a dissection, hematoma, or occlusive lesion occurs.

The history and physical examination aid in establishing the diagnosis of vascular injury. Ask the patient or family about the mechanism of injury, the site of injury, the amount of blood loss, and symptoms present after the injury. Assess for circulatory, sensory, and motor impairment. Be aware that, despite significant trauma, impairment may not be apparent, especially if deep vessels have been injured. Arteriography can provide essential information about the vascular injury.

Management of vascular injuries is often initiated in a hospital emergency department. Careful patient triage is crucial. The most important principles in the management of vascular trauma are establishing a patent airway, controlling bleeding, and restoring blood flow. Emergency or urgent surgical intervention is needed for ischemia to maximize successful revascularization.

The method of repair varies with the type of vascular injury. Techniques

include vein bypass grafting, lateral suture repair, thrombectomy (excision of blood clot), resection with end-to-end anastomosis, and vein patch grafting. Vascular repair can sometimes be done via angiographic access (covered stent sealing an injury or embolizing a branch artery where appropriate).

Nursing Concepts and Clinical Judgment Review

What might you NOTICE if the patient is experiencing inadequate gas exchange and tissue perfusion as a result of vascular problems?

- Redness and swelling in lower leg (venous)
- Pallor, cyanosis (darkened), mottling, or rubor in lower leg (arterial)
- Report of pain/cramping in lower legs or hands (at rest or during activity)
- Ulcers on ankles, feet, or digits
- Pulsating mass in abdomen (abdominal aortic aneurysm)
- Decreased level of consciousness (LOC), diaphoresis, decreased urine output (rupturing aortic aneurysm)

What should you INTERPRET and how should you RESPOND to a patient experiencing inadequate gas exchange and tissue perfusion as a result of peripheral vascular disease?

Perform and interpret physical assessment, including:

- Taking vital signs
- Assessing peripheral pulses
- Assessing capillary refill
- Checking for sensation and temperature
- Completing a pain assessment
- Assessing ulcer

Respond by:

- Notifying physician immediately or calling Rapid Response Team if aortic rupture suspected
- Monitoring vital signs
- Giving oxygen if aneurysm rupture suspected
- Starting an IV line if aneurysm rupture suspected
- Documenting abnormal peripheral vascular assessment findings
- Elevating legs if swollen unless arterial blood flow is poor

On what should you REFLECT?

- Think about how you responded.

- Continue to monitor patient for changes in peripheral blood flow, including pulse assessments.
- Observe patient for decreased report of pain.

Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Plan care for the patient with atherosclerosis and hypertension, in collaboration with the health care team, including the dietitian, pharmacist, and primary health care provider as needed. **Teamwork and Collaboration** QSEN
- To reduce the risk for injury, caution patients about orthostatic hypotension when taking antihypertensive drugs. **Safety** QSEN
- Monitor blood pressure carefully in patients who have hypertension; be aware that they may develop a hypertensive crisis, a life-threatening medical emergency (see Chart 36-2).

Health Promotion and Maintenance

- In collaboration with the dietitian, assist the patient to incorporate healthy eating behaviors to lower cholesterol and saturated fats and increase fresh fruits, vegetables, and fiber in the diet. For overweight patients, assist in a weight-reduction plan. **Teamwork and Collaboration** QSEN
- Teach patients to engage in 40 minutes of moderate-to-vigorous physical activity 3 or 4 times a week to lower blood pressure and LDL-C levels.
- Assess the patient for modifiable and nonmodifiable risk factors for vascular disease, and teach health promotion behaviors to the patient and family. Pay particular attention to the patient with a family history of cardiovascular disease (see Table 36-1). **Patient-Centered Care** QSEN

Physiological Integrity

- Remember that risk factors such as smoking increase the pathophysiologic process of atherosclerosis (see Table 36-1).
- Remember that atherosclerosis occurs when fatty plaques occlude arteries and prevent adequate perfusion to vital body tissues.
- Monitor total cholesterol, HDL-C, and LDL-C levels to assess patient risk for atherosclerosis.
- Teach patients taking any of the statins in Table 36-2 to report any adverse effects including muscle cramping to their health care

provider. Monitor the patient's liver enzymes carefully.

- Teach patients to decrease saturated and *trans* fats in their diet; instruct them to consume a diet rich in fruits, vegetables, and whole grains; and instruct them to include legumes, poultry, fish, and low-fat dairy products. Remind them to limit sweets, red meats, and sugar-sweetened beverages. **Evidence-Based Practice** QSEN
- Hypertension is categorized as either essential or secondary; the risk factors and causes for each type are described in Table 36-4. Essential hypertension is called *primary hypertension* and is not caused by another health problem or drug. *Secondary hypertension* is caused by other health problems or drug therapy.
- Closely observe the patient receiving anticoagulants or fibrinolytics for signs of bleeding, and monitor appropriate laboratory values for desired outcome values (see Chart 36-7). **Safety** QSEN
- Monitor for decreased serum potassium levels when patients are taking thiazide or loop diuretics; hypokalemia could cause life-threatening cardiac dysrhythmias (see Chart 36-1). **Safety** QSEN
- Teach patients to move slowly when changing position if taking any of the antihypertensive drugs listed in Chart 36-1. **Safety** QSEN
- Recognize that clinical manifestations of peripheral vascular disease (PVD) depend on whether it affects the arteries or veins. In addition to pallor, rubor, or cyanosis, key features of chronic peripheral arterial disease are listed in Chart 36-3.
- Vasodilating drugs or surgery is used for arterial vascular diseases.
- Deep vein thrombosis (DVT) is the most common type of peripheral vascular problem. When symptoms are present, they include swelling, redness, localized pain, and warmth.
- Be aware that DVT can lead to pulmonary embolism, a life-threatening emergency!
- Teach patients to prevent VTE by leg exercises, early ambulation, adequate hydration, graduated compression stockings (GCSs), sequential compression devices (SCDs), and anticoagulant therapy.
- Monitor aPTT values for patients receiving unfractionated heparin; monitor INR for patients receiving warfarin (Coumadin). **Safety** QSEN
- Assess for venous and arterial ulcers as described in Chart 36-4.
- Teach foot care for patients with PVD as outlined in Chart 36-6.
- Teach patients about precautions for anticoagulant therapy as described in Chart 36-7. Teach about food and drugs that interfere with warfarin (Coumadin) as listed in Chart 36-8. **Evidence-Based Practice** QSEN
- Monitor for indications of aneurysm rupture: diaphoresis, nausea,

vomiting, pallor, hypotension, tachycardia, severe pain, and decreased level of consciousness. **Safety** QSEN

- Varicose veins can cause severe pain and reflux requiring the three *E*s: **e**lastic compression hose, **e**xercise, and **e**levation. Endovascular ablation can occlude the affected vessel with minimal pain and the risk for few complications. Postprocedure compression with graduated stockings or other elastic bandages is essential for this procedure to be successful.
- Raynaud's and Buerger's disease affect the digits of the fingers and toes as outlined in Table 36-7.

CHAPTER 37

Care of Patients with Shock

M. Linda Workman

PRIORITY CONCEPTS

- Perfusion
- Clotting
- Inflammation
- Infection

Learning Outcomes

Safe and Effective Care Environment

1. Evaluate patient risk for hypovolemic shock or sepsis and septic shock.
2. Apply principles of infection control to prevent infection and sepsis in susceptible patients, especially older adults.

Health Promotion and Maintenance

3. Teach all people how to prevent and recognize hypovolemic shock or sepsis.

Psychosocial Integrity

4. Reduce the psychological impact for the patient and family regarding the assessment and management of hypovolemic or septic shock.

Physiological Integrity

5. Use laboratory data and clinical manifestations of perfusion to determine the effectiveness of therapy for hypovolemic shock and sepsis.
6. Prioritize the nursing care for the patient experiencing any stage of

hypovolemic shock.

7. Prioritize the nursing care for the patient with sepsis or septic shock, especially when impaired clotting is present.

http://evolve.elsevier.com/Iggy/

Overview

All organs, tissues, and cells need a continuous supply of oxygen to function properly. The lungs first bring oxygen into the body through ventilation and gas exchange, and the cardiovascular system (heart, blood, and blood vessels) delivers oxygen by perfusion to all tissues and removes cellular wastes (Fig. 37-1). **Shock** is widespread abnormal cellular metabolism that occurs when gas exchange with oxygenation and tissue perfusion needs are not met sufficiently to maintain cell function (McCance et al., 2014). It is a condition rather than a disease and is the "whole-body" response that occurs when too little oxygen is delivered to the tissues. All body organs are affected by shock and either work harder to adapt and compensate for reduced gas exchange or perfusion (see Fig. 37-1) or fail to function because of hypoxia. Shock is a "syndrome" because the problems resulting from it occur in a predictable sequence.

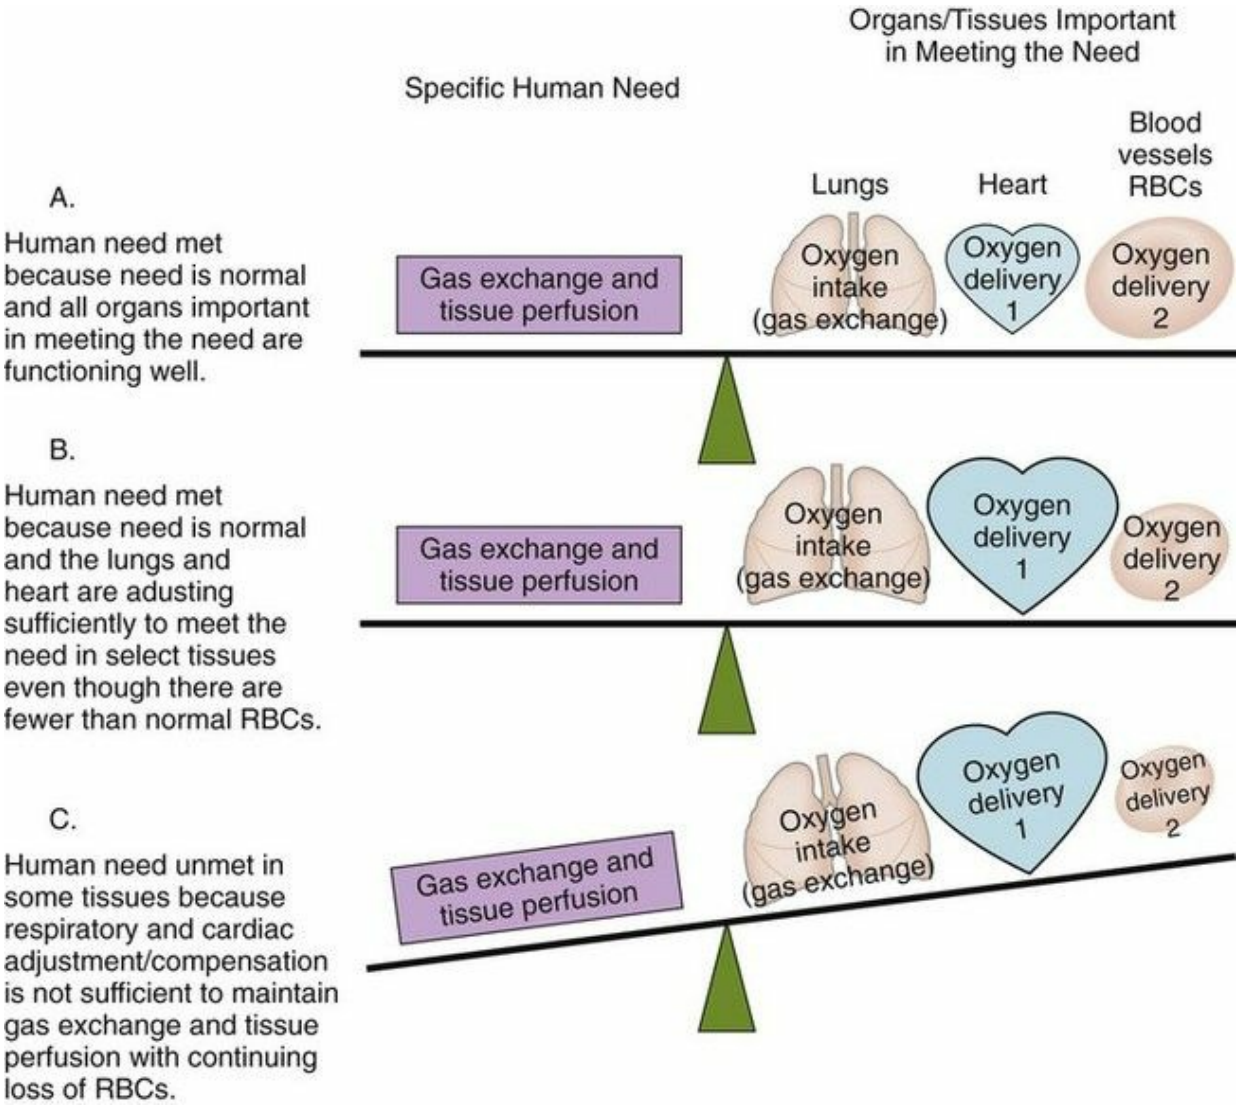

FIG. 37-1 Gas exchange and tissue perfusion affected by hypovolemic shock and adjustment/compensation. *RBCs*, Red blood cells.

Any problem that impairs oxygen perfusion to tissues and organs can start the syndrome of shock and lead to a life-threatening emergency. Shock is often a result of cardiovascular problems. Patients in acute care settings are at higher risk, but shock can occur in any setting. For example, older patients in long-term care settings are at risk for sepsis and shock related to urinary tract infections. When the body's adaptive adjustments (compensation) or health care interventions are not effective and shock progresses, severe hypoxia can lead to cell loss, multiple organ dysfunction syndrome (MODS), and death.

Shock is classified by the type of impairment causing it into the categories of hypovolemic shock, cardiogenic shock, distributive shock (which includes septic shock, neurogenic shock, and anaphylactic shock), and obstructive shock. Table 37-1 describes this classification and common causes of shock.

TABLE 37-1

Causes and Types of Shock by Functional Impairment

Hypovolemic Shock

Overall Cause

Total body fluid decreased (in all fluid compartments).

Specific Cause or Risk Factors

- Hemorrhage
  - Trauma
  - GI ulcer
  - Surgery
  - Inadequate clotting
- Hemophilia
- Liver disease
- Cancer therapy
- Anticoagulation therapy
- Dehydration
  - Vomiting
  - Diarrhea
  - Heavy diaphoresis
  - Diuretic therapy
  - Nasogastric suction
  - Diabetes insipidus

Cardiogenic Shock

Overall Cause

Direct pump failure (fluid volume not affected).

Specific Cause or Risk Factors

- Myocardial infarction
- Cardiac arrest
- Ventricular dysrhythmias
- Cardiac amyloidosis
- Cardiomyopathies
- Myocardial degeneration

Distributive Shock

Overall Cause

Fluid shifted from central vascular space (total body fluid volume normal or increased).

Specific Cause or Risk Factors

- Neural-induced
  - Pain
  - Anesthesia
  - Stress
  - Spinal cord injury
  - Head trauma
- Chemical-induced
  - Anaphylaxis
  - Sepsis
  - Capillary leak
- Burns
- Extensive trauma
- Liver impairment
- Hypoproteinemia

Obstructive Shock

Overall Cause

Cardiac function decreased by noncardiac factor (indirect pump failure). Total body fluid is not affected although central volume is decreased.

Specific Cause or Risk Factors

- Cardiac tamponade
- Arterial stenosis
- Pulmonary embolus
- Pulmonary hypertension
- Constrictive pericarditis
- Thoracic tumors
- Tension pneumothorax

Most manifestations of shock are similar regardless of what starts the process or which tissues are affected first. These manifestations result from physiologic adjustments *(compensatory mechanisms)* that the body makes in the attempt to ensure continued perfusion of vital organs. These adjustment actions are triggered by the sympathetic nervous system's stress response activating the endocrine and cardiovascular systems. Manifestations unique to any one type of shock result from specific tissue dysfunction. The common features of shock are listed in Chart 37-1.

Chart 37-1 Key Features

Shock

Cardiovascular Manifestations

- Decreased cardiac output
- Increased pulse rate
- Thready pulse
- Decreased blood pressure
- Narrowed pulse pressure
- Postural hypotension
- Low central venous pressure
- Flat neck and hand veins in dependent positions
- Slow capillary refill in nail beds
- Diminished peripheral pulses

Respiratory Manifestations

- Increased respiratory rate
- Shallow depth of respirations
- Increased Pa_{CO_2}
- Decreased Pa_{O_2}
- Cyanosis, especially around lips and nail beds

Gastrointestinal Manifestations

- Decreased motility
- Diminished or absent bowel sounds
- Nausea and vomiting
- Constipation

Pa_{CO_2}, Partial pressure of arterial carbon dioxide; Pa_{O_2}, partial pressure of arterial oxygen.

Neuromuscular Manifestations

Early

- Anxiety
- Restlessness
- Increased thirst

Late

- Decreased central nervous system activity (lethargy to coma)
- Generalized muscle weakness
- Diminished or absent deep tendon reflexes
- Sluggish pupillary response to light

Kidney Manifestations

- Decreased urine output
- Increased specific gravity
- Sugar and acetone present in urine

Integumentary Manifestations

- Cool to cold
- Pale to mottled to cyanotic
- Moist, clammy
- Mouth dry; pastelike coating present

Review of Oxygenation and Tissue Perfusion

Oxygenation with gas exchange and perfusion depend on how much oxygen from arterial blood perfuses the tissue. Perfusion is related to mean arterial pressure (MAP). The factors that influence MAP include:

- Total blood volume
- Cardiac output
- Size and integrity of the vascular bed, especially capillaries

Total blood volume and cardiac output are directly related to MAP, so increases in either total blood volume or cardiac output *raise* MAP. Decreases in either total blood volume or cardiac output *lower* MAP.

The size of the vascular bed is inversely (negatively) related to MAP. This means that increases in the size of the vascular bed *lower* MAP and decreases *raise* MAP (Fig. 37-2). The small arteries and veins connected to capillaries can increase in diameter by relaxing the smooth muscle in vessel walls **(dilation)** or decrease in diameter by contracting the muscle **(vasoconstriction)**. When blood vessels dilate and total blood volume remains the same, blood pressure decreases and blood flow is slower.

When blood vessels constrict and total blood volume remains the same, blood pressure increases and blood flow is faster.

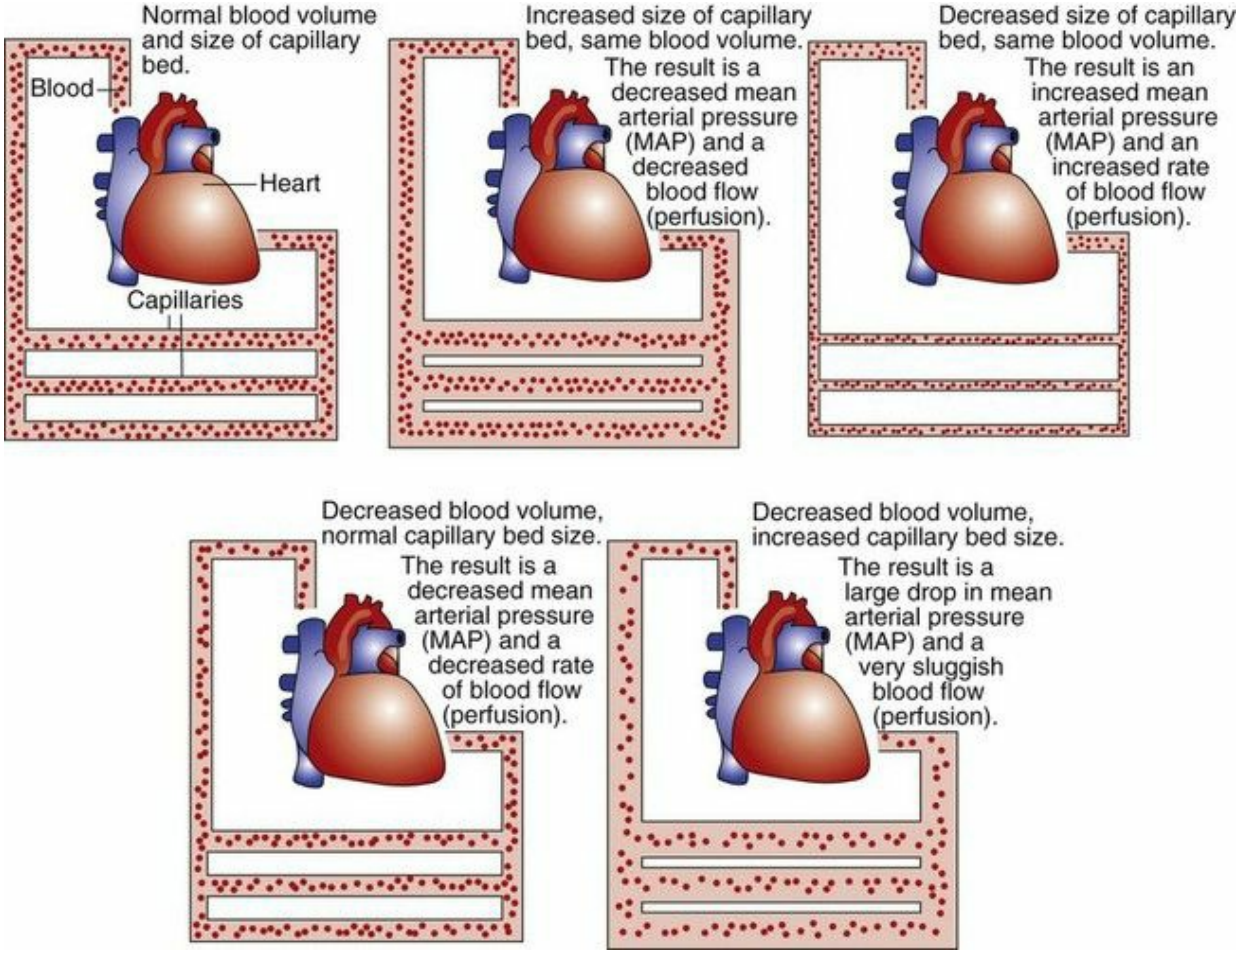

FIG. 37-2 Interaction of blood volume and the size of the capillary bed affecting mean arterial pressure (MAP).

Blood vessels are innervated by the sympathetic nervous system. Some nerves continuously stimulate vascular smooth muscle so that the blood vessels are normally partially constricted, a condition called **sympathetic tone**. Increases in sympathetic stimulation constrict smooth muscle even more, raising MAP. Decreases in sympathetic tone relax smooth muscle, dilating blood vessels and lowering MAP.

Perfusion (blood flow) to organs varies and adjusts to changes in tissue oxygen needs. The body can selectively increase blood flow to some areas while reducing flow to others. The skin and skeletal muscles can tolerate low levels of oxygen for hours without dying or being damaged. Other organs (e.g., heart, brain, liver, pancreas) do not tolerate **hypoxia** (low levels of tissue oxygenation), and a few minutes without oxygen results in serious damage and cell death.

Types of Shock

Types of shock vary because shock is a manifestation of a pathologic condition rather than a disease state (see Table 37-1). *More than one type of shock can be present at the same time.* For example, trauma caused by a car crash may trigger hemorrhage (leading to hypovolemic shock) and a myocardial infarction (leading to cardiogenic shock).

Hypovolemic shock occurs when too little circulating blood volume decreases MAP, resulting in inadequate total body perfusion and oxygenation. Common problems leading to hypovolemic shock are poor clotting with hemorrhage and dehydration. A complete discussion of the pathophysiology and management of hypovolemic shock begins on p. 741.

Cardiogenic shock occurs when the heart muscle is unhealthy and pumping is impaired. Myocardial infarction is the most common cause of direct pump failure. Other causes are listed in Table 37-1. Any type of pump failure decreases cardiac output and MAP. Chapter 38 discusses the pathophysiology and care for the person with shock from myocardial infarction.

Distributive shock occurs when blood volume is not lost from the body but is distributed to the interstitial tissues where it cannot perfuse organs. It can be caused by blood vessel dilation, pooling of blood in venous and capillary beds, and increased capillary leak. All these factors decrease mean arterial pressure (MAP) and may be started either by nerve changes *(neural-induced)* or by the presence of some chemicals *(chemical-induced).*

Neural-induced distributive shock is a loss of MAP that occurs when sympathetic nerve impulses are decreased and blood vessel smooth muscles relax, causing vasodilation and poor perfusion. Shock results when vasodilation is widespread. Problems leading to loss of sympathetic tone are listed in Table 37-1.

Chemical-induced distributive shock has three common origins: anaphylaxis, sepsis, and capillary leak syndrome. It occurs when certain body chemicals or foreign substances in the blood and vessels start widespread changes in blood vessel walls. The chemicals are usually **exogenous** (originate outside the body), but this type of shock also can be induced by substances normally found in the body, such as excessive amounts of histamine.

Anaphylaxis is an extreme type I allergic reaction. It begins within seconds to minutes after exposure to a specific allergen in a susceptible person. The result is widespread loss of blood vessel tone, with

decreased blood pressure and decreased cardiac output. Table 20-2 (in Chapter 20) lists common allergens that can cause anaphylaxis. Chapter 20 describes the pathophysiology, prevention, and care of the patient with anaphylactic shock.

Sepsis is a widespread infection that triggers whole-body inflammation. It leads to distributive shock when infectious microorganisms are present in the blood and is most commonly called **septic shock.** A complete discussion of the pathophysiology, prevention, and care for the patient with sepsis and septic shock begins on p. 748.

Capillary leak syndrome is the response of capillaries to the presence of body chemicals that enlarge capillary pores and allow fluid to shift from the capillaries into the interstitial tissues. Once in the interstitial tissue, these fluids are stagnant and cannot deliver oxygen or remove tissue waste products. Problems causing fluid shifts include severe burns, liver disorders, ascites, peritonitis, large wounds, kidney disease, hypoproteinemia, and trauma.

Obstructive shock is caused by problems that impair the ability of the normal heart to pump effectively. The heart itself remains normal, but conditions outside the heart prevent either adequate filling of the heart or adequate contraction of the healthy heart muscle. The most common cause of obstructive shock is cardiac tamponade (Table 37-1). Care of the person with cardiac tamponade is presented in Chapter 35 (pericarditis) and Chapter 38.

Although the causes and initial manifestations associated with the different types of shock vary, eventually the effects of hypotension and **anaerobic cellular metabolism** (metabolism without oxygen) result in the common key features of shock listed in Chart 37-1.

Hypovolemic Shock

❖ Pathophysiology

The basic problem of hypovolemic shock is a loss of blood volume from the vascular space, resulting in a decreased mean arterial pressure (MAP) (see Fig. 37-2) and a loss of oxygen-carrying capacity from the loss of circulating red blood cells (RBCs). The reduced MAP slows blood flow, decreasing tissue perfusion. The loss of RBCs decreases the ability of the blood to oxygenate the tissue it does reach. These oxygenation and perfusion problems lead to *anaerobic* (without oxygen) cellular metabolism.

The main trigger leading to hypovolemic shock is a sustained decrease in MAP from decreased circulating blood volume. A decrease in MAP of 5 to 10 mm Hg below the patient's normal baseline value is detected by pressure-sensitive nerve receptors *(baroreceptors)* in the aortic arch and carotid sinus. This information is transmitted to brain centers, which stimulate adjustments *(compensatory mechanisms)* to help ensure continued blood flow and oxygen delivery to vital organs while limiting blood flow to less vital areas. The movement of blood into selected areas while bypassing others ("shunting") results in some shock manifestations.

If the events that caused the initial decrease in MAP are halted now, compensatory mechanisms provide adequate oxygenation and perfusion without intervention. If events continue and MAP decreases further, some tissues function under anaerobic conditions. This condition increases lactic acid levels and other harmful metabolites (e.g., protein-destroying enzymes, oxygen free radicals) (McCance et al., 2014). These substances cause acid-base imbalances with tissue-damaging effects and depressed heart muscle activity. These effects are temporary and reversible if the cause of shock is corrected within 1 to 2 hours after onset. When shock conditions continue for longer periods without help, the resulting acid-base imbalance and increased metabolites cause so much cell damage in vital organs that they are unable to perform their critical functions. When this problem, known as multiple organ dysfunction syndrome (MODS), occurs to the extent that vital organs die, recovery from shock is no longer possible (see the section on the Refractory Stage of Shock on p. 742). Table 37-2 summarizes the progression of shock.

TABLE 37-2

Adaptive Responses and Events During Hypovolemic Shock

Initial Stage

• Decrease in mean arterial pressure (MAP) of 5-10 mmHg from baseline value
• Increased sympathetic stimulation
  • Mild vasoconstriction
  • Increased heart rate

Nonprogressive Stage

• Decrease in MAP of 10-15 mmHg from baseline value
• Continued sympathetic stimulation
  • Moderate vasoconstriction
  • Increased heart rate
  • Decreased pulse pressure
• Chemical compensation
  • Renin, aldosterone, and antidiuretic hormone secretion
Increased vasoconstriction
Decreased urine output
Stimulation of the thirst reflex
• Some anaerobic metabolism in nonvital organs
  • Mild acidosis
  • Mild hyperkalemia

Progressive Stage

• Decrease in MAP of >20 mmHg from baseline value
• Anoxia of nonvital organs
• Hypoxia of vital organs
• Overall metabolism is anaerobic
  • Moderate acidosis
  • Moderate hyperkalemia
  • Tissue ischemia

Refractory Stage
• Severe tissue hypoxia with ischemia and necrosis • Release of myocardial depressant factor from the pancreas • Buildup of toxic metabolites • Multiple organ dysfunction syndrome (MODS) • Death

Stages of Shock

The syndrome of shock progresses in four stages when the conditions that cause shock remain uncorrected and poor cellular oxygenation continues. These stages are:

1. Initial stage
2. Nonprogressive stage
3. Progressive stage
4. Refractory stage

Initial Stage of Shock.

The initial (early) stage of shock is present when the patient's baseline

MAP is decreased by less than 10 mm Hg. Compensatory mechanisms are so effective at returning systolic pressure to normal during this stage that oxygen perfusion to vital organs is maintained. The cellular change in this stage is increased anaerobic metabolism in some tissues with production of lactic acid, although overall metabolism is still aerobic. The compensation responses of vascular constriction and increased heart rate are effective, and both cardiac output and MAP are maintained within the normal range. Because vital organ function is not disrupted, the manifestations of shock are difficult to detect at this stage. *A heart and respiratory rate increased from the patient's baseline level or a slight* ***increase*** *in diastolic blood pressure may be the only manifestation of this stage of shock.*

Nonprogressive Stage.

The nonprogressive (compensatory) stage of shock occurs when MAP decreases by 10 to 15 mm Hg from baseline. Kidney and hormonal compensatory mechanisms are activated because cardiovascular responses alone are not enough to maintain MAP and supply oxygen to vital organs.

The ongoing decrease in MAP triggers the release of renin, antidiuretic hormone (ADH), aldosterone, epinephrine, and norepinephrine to start kidney compensation. Urine output decreases, sodium reabsorption increases, and widespread blood vessel constriction occurs. ADH increases water reabsorption in the kidney, further reducing urine output, and increases blood vessel constriction in the skin and other less vital tissue areas. Together these actions compensate for shock by maintaining the fluid volume within the central blood vessels.

Tissue hypoxia occurs in nonvital organs (e.g., skin, GI tract) and in the kidney, but it is not great enough to cause permanent damage. Acid-base and electrolyte changes occur in response to the buildup of metabolites. Changes include **acidosis** (low blood pH) and **hyperkalemia** (increased blood potassium level).

Manifestations of this stage include changes resulting from decreased tissue perfusion. Subjective changes include thirst and anxiety. Objective changes include restlessness, tachycardia, increased respiratory rate, decreased urine output, falling systolic blood pressure, rising diastolic blood pressure, narrowing pulse pressure, cool extremities, and a 2% to 5% decrease in oxygen saturation. *Comparing these changes with the values and manifestations obtained earlier is critical to identifying this stage of shock.*

If the patient is stable and compensatory mechanisms are supported by medical and nursing interventions, he or she can remain in this stage for hours without having permanent damage. *Stopping the conditions that*

started shock and providing supportive interventions can prevent the shock from progressing. The effects of this stage are reversible when nurses recognize the problem and coordinate the health care team to start appropriate interventions.

Progressive Stage of Shock.

The progressive stage of shock occurs when there is a sustained decrease in MAP of more than 20 mm Hg from baseline. Compensatory mechanisms are functioning but can no longer deliver sufficient oxygen, even to vital organs. Vital organs develop hypoxia, and less vital organs become **anoxic** (no oxygen) and **ischemic** (cell dysfunction or death from lack of oxygen). As a result of poor perfusion and a buildup of metabolites, some tissues die.

Manifestations of the progressive stage of shock include a *worsening* of changes resulting from decreased tissue perfusion. The patient may express a sense of "something bad" (impending doom) about to happen. He or she may seem confused, and thirst increases. Objective changes are a rapid, weak pulse; low blood pressure; pallor to cyanosis of oral mucosa and nail beds; cool and moist skin; anuria; and a 5% to 20% decrease in oxygen saturation. Laboratory data at this stage may show a low blood pH, along with rising lactic acid and potassium levels.

Nursing Safety Priority QSEN

Critical Rescue

The progressive stage of shock is a life-threatening emergency. Vital organs can tolerate this situation for only a short time before developing multiple organ dysfunction syndrome (MODS) and being damaged permanently. Immediate interventions are needed to reverse the effects of this stage of shock. The patient's life usually can be saved if the conditions causing shock are corrected within 1 hour or less of the onset of the progressive stage. Continuously monitor and compare with earlier findings to assess therapy effectiveness and determine when therapy changes are needed.

Refractory Stage of Shock and Multiple Organ Dysfunction Syndrome.

The refractory stage of shock occurs when too much cell death and tissue damage result from too little oxygen reaching the tissues. Vital organs have extensive damage and cannot respond effectively to interventions,

and shock continues. So much damage has occurred with release of metabolites and enzymes that damage to vital organs continues despite interventions.

The sequence of cell damage caused by massive release of toxic metabolites and enzymes is termed **multiple organ dysfunction syndrome (MODS)**. Once the damage has started, the sequence becomes a vicious cycle as more dead and dying cells open and release metabolites. These trigger small clots (microthrombi) to form, which block tissue perfusion and damage more cells, continuing the devastating cycle. Liver, heart, brain, and kidney function are lost first. The most profound change is damage to the heart muscle.

Manifestations are a rapid loss of consciousness; nonpalpable pulse; cold, dusky extremities; slow, shallow respirations; and unmeasurable oxygen saturation. *Therapy is not effective in saving the patient's life, even if the cause of shock is corrected and MAP temporarily returns to normal.*

Etiology

Hypovolemic shock occurs when too little circulating blood volume causes a MAP decrease that prevents total body perfusion and oxygenation. Problems leading to hypovolemic shock are listed in Table 37-1.

Hypovolemic shock from external hemorrhage is common after trauma and surgery. Hypovolemic shock from internal hemorrhage occurs with blunt trauma, GI ulcers, and poor control of surgical bleeding. Hemorrhage leading to hypovolemia also can be caused by any problem that reduces the levels of clotting factors (see Table 37-1). Hypovolemia as a result of dehydration can be caused by any problem that decreases fluid intake or increases fluid loss (see Table 37-1).

Incidence and Prevalence

The exact incidence of hypovolemic shock is not known because it is a response rather than a disease. It is a common complication among hospitalized patients in emergency departments and after surgery or invasive procedures.

Health Promotion and Maintenance

Hypovolemic shock from most causes can be prevented. Teach all people to prevent dehydration by having an adequate fluid intake during exercise and when in hot, dry environments. Urge people to prevent trauma and hemorrhage by using proper safety equipment and seat belts and being aware of hazards in the home or workplace.

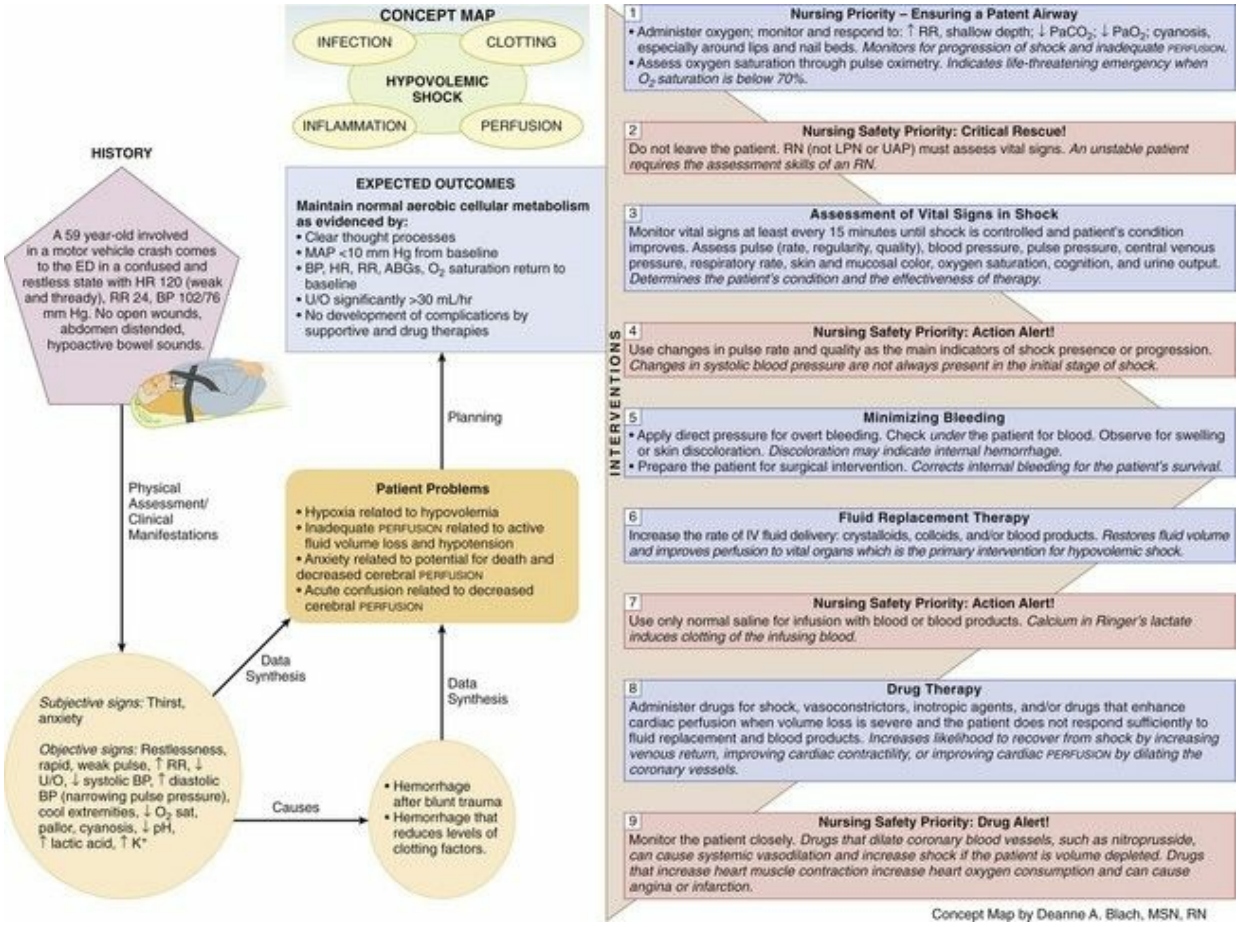
Recognizing hypovolemic shock is a major nursing responsibility. Keep in mind that just being a patient in the acute care setting is a risk factor. Also identify patients at risk for dehydration, and assess for early manifestations. This is especially important for those who have reduced cognition or reduced mobility or who are on NPO status.

Assess all patients with invasive procedures or trauma for obvious or occult impaired clotting with bleeding. Compare pulse quality and rate with baseline. Compare urine output with fluid intake. Check vital signs of patients who have persistent thirst. Assess for shock in any patient who develops a change in mental status, an increase in pain, or an increase in anxiety.

Teach patients who have invasive procedures in an ambulatory setting the manifestations of shock. Stress the importance of seeking immediate help for obvious heavy bleeding, persistent thirst, decreased urine output, light-headedness, or a sense of impending doom (a feeling that something bad is happening or going to happen).

Patient-Centered Collaborative Care

The Concept Map on p. 744 addresses assessment and nursing care issues related to hypovolemic shock.



Assessment

History.

Ask about risk factors related to hypovolemic shock. If the patient is alert, question him or her directly. If the patient is not alert, collect information from family members. *Age* is important because shock from trauma is more common in young adults and other types of shock are more common in older adults. Ask about recent illness, trauma, procedures, or chronic health problems that may lead to shock (e.g., GI ulcers, general surgery, hemophilia, liver disorders, prolonged vomiting or diarrhea). Ask about the use of drugs such as aspirin, other NSAIDs, and diuretics that may cause changes leading to hypovolemic shock.

Ask about fluid intake and output during the previous 24 hours. *Information about urine output is especially important because urine output is reduced during the first stages of shock, even when fluid intake is normal.*

Assess the patient for factors that can lead to shock. Areas to examine for poor clotting and hemorrhage include the gums, wounds, and sites of dressings, drains, and vascular accesses. Also check *under* the patient for blood. Observe for any swelling or skin discoloration that may indicate

an internal hemorrhage.

Physical Assessment/Clinical Manifestations.

Most manifestations of hypovolemic shock are caused by the changes resulting from compensatory efforts. **Compensatory mechanisms** are physiologic responses that try to keep an adequate perfusion to vital organs. Shock may be first evident as changes in cardiovascular function. As shock progresses, changes in the renal, respiratory, integumentary, musculoskeletal, and central nervous systems become evident. Ensure that vital sign measurements are accurate, and monitor them for trends indicating shock.

Nursing Safety Priority QSEN

Action Alert

Assign a registered nurse rather than a licensed practical nurse/licensed vocational nurse (LPN/LVN) or unlicensed assistive personnel (UAP) to assess the vital signs of a patient who is at risk for or suspected of having hypovolemic shock.

Cardiovascular changes that occur with hypovolemic shock start with decreased mean arterial pressure (MAP) leading to compensatory responses. Assess the central and peripheral pulses for rate and quality. In the initial stage of shock, the pulse rate increases to keep cardiac output and MAP at normal levels, even though the actual **stroke volume** (amount of blood pumped out from the heart) per beat is decreased. *Increased heart rate is the first manifestation of shock.* Because stroke volume is decreased, the peripheral pulses are difficult to palpate and are blocked with light pressure. As shock progresses, peripheral pulses may be absent.

When assessing the blood pressure (BP), consider the patient's normal baseline blood pressure. Although a blood pressure of 90/50 mm Hg may indicate severe shock in one person, it may be the normal blood pressure for another healthy adult.

Nursing Safety Priority QSEN

Action Alert

Because changes in systolic blood pressure are not always present in the initial stage of shock, use changes in pulse rate and quality as the

main indicators of shock presence or progression.

With vasoconstriction, diastolic pressure increases but systolic pressure remains the same. As a result, the difference between the systolic and diastolic pressures *(pulse pressure)* is smaller or "narrower." Monitor blood pressure for changes from baseline levels and for changes from the previous measurement. For accuracy, use the same equipment on the same extremity. Validate an abnormal electronic BP reading with a manual BP reading.

Systolic pressure decreases as shock progresses and cardiac output decreases. A reduced systolic pressure narrows the pulse pressure even further. When shock continues and interventions are not adequate, compensation fails and both systolic and diastolic pressures decrease and blood pressure is difficult to hear. Palpation or a Doppler device may be needed to detect the systolic blood pressure.

Oxygen saturation is assessed through pulse oximetry. Pulse oximetry values between 90% and 95% occur with the nonprogressive stage of shock, and values between 75% and 80% occur with the progressive stage of shock. *Any value below 70% is considered a life-threatening emergency and may signal the refractory stage of shock.*

Respiratory changes with shock are an adaptive response to help maintain oxygenation when tissue perfusion is decreased. Assess the rate and depth of respiration. Respiratory rate increases during shock to ensure that oxygen intake is increased so that it can be delivered to critical tissues. When shock progresses to the stage at which lactic acidosis is present, the respiratory depth also increases.

Kidney and urinary changes occur with shock to compensate for decreased MAP by saving body water through decreased filtration and increased water reabsorption. Assess urine for volume, color, specific gravity, and the presence of blood or protein. *Decreased urine output is a sensitive indicator of early shock. Measure urine output at least every hour. In severe shock, urine output may be absent.* Of the four vital organs (heart, brain, liver, and kidney), only the kidney can tolerate hypoxia and anoxia for up to 1 hour without permanent damage. When hypoxia or anoxia persists beyond this time, patients are at risk for acute kidney injury (AKI) and kidney failure.

Skin changes occur because of reduced blood flow in the skin. An early compensatory mechanism is skin blood vessel constriction, which reduces skin perfusion. This allows more blood to perfuse the vital organs, which cannot tolerate low oxygen levels.

Assess the skin for temperature, color, and moisture. With shock, it

feels cool or cold to the touch and is moist. Color changes appear first in oral mucous membranes and in the skin around the mouth. In dark-skinned patients, pallor or cyanosis is best assessed in the oral mucous membranes. Other color changes are noted first in the skin of the extremities and then in the central trunk area. The skin feels clammy or moist to the touch, not because sweating increases but because the normal fluid lost through the skin does not evaporate well on cool skin. As shock progresses, skin becomes mottled. Lighter-skinned patients have an overall grayish blue color and darker-skinned patients appear darker, without an underlying reddish glow.

Evaluate capillary refill time by pressing on the patient's fingernail until it blanches and then observing how fast the nail bed resumes color when pressure is released. Normally these capillaries resume color as soon as pressure is released. With shock, capillary refill is slow or may be absent. Capillary refill is not a reliable indicator for peripheral blood flow in older patients or those with anemia, diabetes, or peripheral vascular disease.

Central nervous system (CNS) changes with shock first manifest as thirst. Thirst is caused by stimulation of the thirst centers in the brain in response to decreased blood volume.

Assess the patient's level of consciousness (LOC) and orientation. CNS changes with shock are caused by cerebral hypoxia. In the initial and nonprogressive stages, patients may be restless or agitated and may be anxious or have a feeling of impending doom that has no obvious cause. As hypoxia progresses, confusion and lethargy occur. Lethargy progresses to somnolence and loss of consciousness as cerebral hypoxia worsens with shock progression.

Skeletal muscle changes during shock include weakness and pain in response to tissue hypoxia and anaerobic metabolism, which are later manifestations. Weakness is generalized and has no specific pattern. Deep tendon reflexes are decreased or absent.

Assess muscle strength by having the patient squeeze your hand and by trying to keep his or her arms flexed while you attempt to straighten them. Assess deep tendon reflexes by lightly tapping the patellar tendons and Achilles tendons with a reflex hammer and observing the degree of responsive movement.

Psychosocial Assessment.

Changes in mental status and behavior occur early in shock. Observe the patient closely, and document behavior. Assess mental status by evaluating LOC and noting whether the patient is asleep or awake. If the

patient is asleep, attempt to awaken him or her and document how easily he or she is aroused. If the patient is awake, determine whether he or she is oriented to person, place, and time. Avoid asking questions that can be answered with a "yes" or a "no" response. Consider these points during assessment:

- Is it necessary to repeat questions to obtain a response?
- Does the response answer the question asked?
- Does the patient have difficulty making word choices?
- Is the patient irritated or upset by the questions?
- Can the patient concentrate on a question long enough to answer, or is the attention span limited?

Talk with the family to determine whether the patient's behavior and cognition are typical or represent a change.

NCLEX Examination Challenge

Physiological Integrity

Which manifestations of shock are a result of compensatory mechanisms to maintain circulating blood volume?

A Edema and weight gain
B Confusion and lethargy
C Decreased urine output and thirst
D Increased pulse and respiratory rates

Laboratory Assessment.

Although no single test confirms or rules out shock, changes in laboratory data may support the diagnosis. Chart 37-2 lists laboratory changes occurring with hypovolemic shock. As shock progresses, arterial blood gas values become abnormal. The pH decreases, the partial pressure of arterial oxygen (Pa_{O_2}) decreases, and the partial pressure of arterial carbon dioxide (Pa_{CO_2}) increases. Other laboratory changes occur with specific causes of hypovolemic shock.

Chart 37-2 Laboratory Profile

Hypovolemic Shock

TEST	NORMAL RANGE FOR ADULTS	SIGNIFICANCE OF ABNORMAL FINDINGS
pH (arterial)	7.35-7.45	Decreased: insufficient tissue oxygenation causing anaerobic metabolism and acidosis
Pa_{O_2}	80-100 mm Hg	Decreased: anaerobic metabolism
Pa_{CO_2}	35-45 mm Hg	Increased: anaerobic metabolism
Lactic acid (arterial)	3-7 mg/dL	Increased: anaerobic metabolism with buildup of metabolites
	0.3-0.8 mmol/L	
Hematocrit	*Females:* 37%-47% *Males:* 42%-52%	Increased: fluid shift, dehydration
		Decreased: hemorrhage
Hemoglobin	*Females:* 12-16 g/dL *Males:* 14-18 g/dL	Increased: fluid shift, dehydration
		Decreased: hemorrhage
Potassium	3.5-5.0 mEq/L or mmol/L	Increased: dehydration, acidosis

$Paco_2$, Partial pressure of arterial carbon dioxide; *Pao_2,* partial pressure of arterial oxygen.

Pagana, K., & Pagana, T. (2014). *Mosby's manual of diagnostic and laboratory tests* (5th ed.). St. Louis: Mosby.

Hematocrit and hemoglobin levels decrease if shock is caused by poor clotting and hemorrhage. When shock is caused by dehydration or a fluid shift, hematocrit and hemoglobin levels are elevated.

Analysis

The priority NANDA-I nursing diagnoses and collaborative problems for patients with hypovolemic shock include:

- Hypoxia related to hypovolemia
- Inadequate perfusion related to active fluid volume loss and hypotension
- Anxiety related to potential for death and decreased cerebral perfusion (NANDA-I)
- Acute Confusion related to decreased cerebral perfusion (NANDA-I)

Clinical Judgment Challenge

Patient-Centered Care; Evidence-Based Practice; Safety QSEN

Your patient is a 40-year-old woman who is returned to your ambulatory care unit after having a cholecystectomy (gall bladder removal) performed as minimally invasive surgery by laparoscopy. After moving her from the stretcher to her bed, you take her vital signs. Her pulse is 118 and thready, blood pressure is 88/72, respiratory rate is 28, and pulse oxymetry is 88%. When you call her name, she opens her eyes but does not answer any questions.

1. What should you do first?
2. What manifestations of shock are present based on the information

you currently have?
3. How would you classify this stage of shock? Provide a rationale for your evaluation.
4. What other assessment data should you obtain?
5. Given the type of surgery she has undergone, where would you expect bleeding to occur and what manifestations would indicate possible bleeding?
6. She still has an IV in her left hand infusing dextrose 5% in 0.45% saline. The post-surgical orders indicate that it should be removed when she is stable. Should you remove it now? Why or why not?

Interventions

Medical and nursing interventions for patients in hypovolemic shock focus on reversing the shock, restoring fluid volume to the normal range, and preventing complications. Monitoring is critical to determine whether the patient is responding to therapy or whether shock is progressing and a change in intervention is needed. Surgery may be needed to correct the cause of shock. Chart 37-3 lists best practices for patients in hypovolemic shock.

Chart 37-3 Best Practice for Patient Safety & Quality Care QSEN

The Patient in Hypovolemic Shock

- Ensure a patent airway.
- Insert an IV catheter, or maintain an established catheter.
- Administer oxygen.
- Elevate the patient's feet, keeping his or her head flat or elevated to no more than a 30-degree angle.
- Examine the patient for overt bleeding.
- If overt bleeding is present, apply direct pressure to the site.
- Administer drugs as prescribed.
- Increase the rate of IV fluid delivery.
- Do not leave the patient.

Nonsurgical Management.

The purposes of shock management are to maintain tissue oxygenation, increase vascular volume, and support compensatory mechanisms. Oxygen therapy, fluid replacement therapy, and drug therapy are useful.

Oxygen therapy is used at any stage of shock and is delivered by mask,

hood, nasal cannula, endotracheal tube, or tracheostomy tube. It is given in liters per minute (L/min) by cannula or percentage concentration with a mask.

IV therapy for fluid resuscitation is a primary intervention for hypovolemic shock. Crystalloids and colloids are often used for volume replacement. Crystalloid solutions contain nonprotein substances (e.g., minerals, salts, sugars). Colloid solutions contain large molecules of proteins or starches (see Chapter 11).

Crystalloid fluids help maintain an adequate fluid and electrolyte balance. Two common solutions are normal saline and Ringer's lactate. Normal saline (0.9% sodium chloride in water) is a replacement solution used to increase plasma volume and can be infused with any blood product. Ringer's lactate contains sodium, chloride, calcium, potassium, and lactate. This isotonic solution expands volume, and the lactate buffers acidosis.

Nursing Safety Priority QSEN

Action Alert

Use only normal saline for infusion with blood or blood products because the calcium in Ringer's lactate induces clotting of the infusing blood.

Protein-containing colloid fluids help restore osmotic pressure and fluid volume. Blood and blood products are used when shock is caused by blood loss. These fluids include whole blood, packed red blood cells, and plasma.

Whole blood and packed red blood cells (PRBCs) increase hematocrit and hemoglobin levels along with fluid volume. PRBCs are given for moderate blood loss because they restore the red blood cell deficit and improve oxygen-carrying capacity without adding excessive fluid volume. Massive transfusion therapy, defined as 10 units of PRBCs given within the first 6 hours of severe hemorrhage, can improve outcomes and prevent death from acute traumatic coagulopathy (Day et al., 2013). See Chapter 40 for nursing care during transfusion therapy.

Plasma, an acellular blood product containing clotting factors, is given to restore osmotic pressure when hematocrit and hemoglobin levels are normal. Plasma protein fractions (e.g., Plasmanate) and synthetic plasma expanders (e.g., hetastarch [hydroxyethyl starch, Hespan]) increase volume and are used for hypovolemic shock before a cause is identified.

Drug therapy is used in addition to fluid therapy when the volume lost is severe and the patient does not respond sufficiently to fluid replacement and blood products. Drugs for shock increase venous return, improve cardiac contractility, or improve cardiac perfusion by dilating the coronary vessels. Chart 37-4 lists common drugs used to treat shock.

Chart 37-4 Common Examples of Drug Therapy

Hypovolemic Shock

DRUGS	NURSING INTERVENTIONS	RATIONALES
Vasoconstrictors	**Improve mean arterial pressure by increasing peripheral resistance, increasing venous return, and increasing myocardial contractility.**	
Dopamine (Intropin, Revimine 🍁) Norepinephrine (Levophed) Phenylephrine HCl	Assess patient for chest pain.	Drugs increase myocardial oxygen consumption.
	Monitor urine output hourly.	Higher doses decrease kidney perfusion and urine output.
	Assess blood pressure every 15 min.	Hypertension is a manifestation of overdose.
	Assess the patient for headache.	Headache is an early manifestation of drug excess.
	Assess every 30 min for extravasation; check extremities for color and perfusion.	If the drug gets into the tissues, it can cause severe vasoconstriction, tissue ischemia, and tissue necrosis.
	Assess for chest pain.	Drug can cause rapid onset of vasoconstriction in the myocardium and impair cardiac oxygenation.
Inotropic Agents	**Directly stimulate beta adrenergic receptors on the heart muscle, improving contractility**	
Dobutamine (Dobutrex) Milrinone (Primacor)	Assess for chest pain.	Drugs increase myocardial oxygen consumption and can cause angina or infarction.
	Assess blood pressure every 15 min.	Hypertension is a manifestation of overdose.
Agents Enhancing Myocardial Perfusion	**Improve myocardial perfusion by dilating coronary arteries rapidly for a short time.**	
Sodium nitroprusside (Nitropress, Nipride 🍁)	Protect drug container from light.	Light degrades drug quickly.
	Assess blood pressure at least every 15 min.	Drug can cause systemic vasodilation and hypotension, especially in older adults.

Nursing Safety Priority QSEN

Drug Alert

Monitor the patient closely because drugs that dilate coronary blood vessels, such as nitroprusside, can cause systemic vasodilation and increase shock if the patient is volume depleted. Drugs that increase heart muscle contraction increase heart oxygen consumption and can cause angina or infarction.

Monitoring vital signs and level of consciousness is a major nursing action to determine the patient's condition and the effectiveness of therapy. Monitor these vital signs:

- Pulse (rate, regularity, and quality)
- Blood pressure
- Pulse pressure
- Central venous pressure (CVP)

- Respiratory rate
- Skin and mucosal color
- Oxygen saturation
- Cognition
- Urine output

Assess these parameters at least every 15 minutes until the shock is controlled and the patient's condition improves. Hemodynamic monitoring in critical care settings includes intra-arterial monitoring, mixed venous oxygen saturation (Sv_{O_2}), pulmonary artery monitoring, and pulmonary capillary wedge pressures.

Insertion of a CVP catheter allows pressure to be monitored in the patient's right atrium or superior vena cava while providing venous access. A decrease in CVP from baseline levels reflects hypovolemic shock with reduced venous return to the right atrium.

Intra-arterial catheters allow continuous blood pressure monitoring and are an access for arterial blood sampling. They are inserted into an artery (radial, brachial, femoral, or dorsalis pedis). The catheter is attached to pressure tubing and a transducer, which converts arterial pressure into an electrical signal seen as a waveform on an oscilloscope and as a numeric value.

Surgical Management.

Surgical intervention in addition to nonsurgical management may be needed to correct the cause of shock. Such procedures include vascular repair, surgical hemostasis of major wounds, closure of bleeding ulcers, and chemical scarring (chemosclerosis) of varicosities.

Community-Based Care

Hypovolemic shock is a complication of another condition and is resolved before patients are discharged from the acute care setting. Because surgery and many other invasive procedures now occur on an ambulatory care basis, more patients at home are at increased risk for hypovolemic shock. Teach patients and family members the early manifestations of shock (increased thirst, decreased urine output, light-headedness, sense of apprehension) and to seek immediate medical attention if they appear.

NCLEX Examination Challenge

Safe and Effective Care Environment

Which change in laboratory value or clinical manifestations in a client with hypovolemic shock indicates to the nurse that current therapy may need to be changed?

A Urine output increases from 5 mL/hour to 6 mL/hour
B Pulse pressure decreases from 28 mm Hg to 22 mm Hg
C Serum potassium level increases from 3.6 mEq/L to 3.9 mEq/L
D Core body temperature increases from 98.2° F (36.8° C) to 98.8° F (37.1° C)

Sepsis and Septic Shock

❖ Pathophysiology

Sepsis leading to septic shock is a complex type of distributive shock that usually begins as a bacterial or fungal infection and progresses to a critical emergency over a period of days. The progression of sepsis to septic shock is outlined in Fig. 37-3. *As progression occurs, the pathologic problems occur faster and to a greater degree. Thus control of sepsis and prevention of severe sepsis and septic shock are easier to achieve early in the process. Failure to recognize and intervene in early sepsis is a major factor for progression to septic shock and death.*

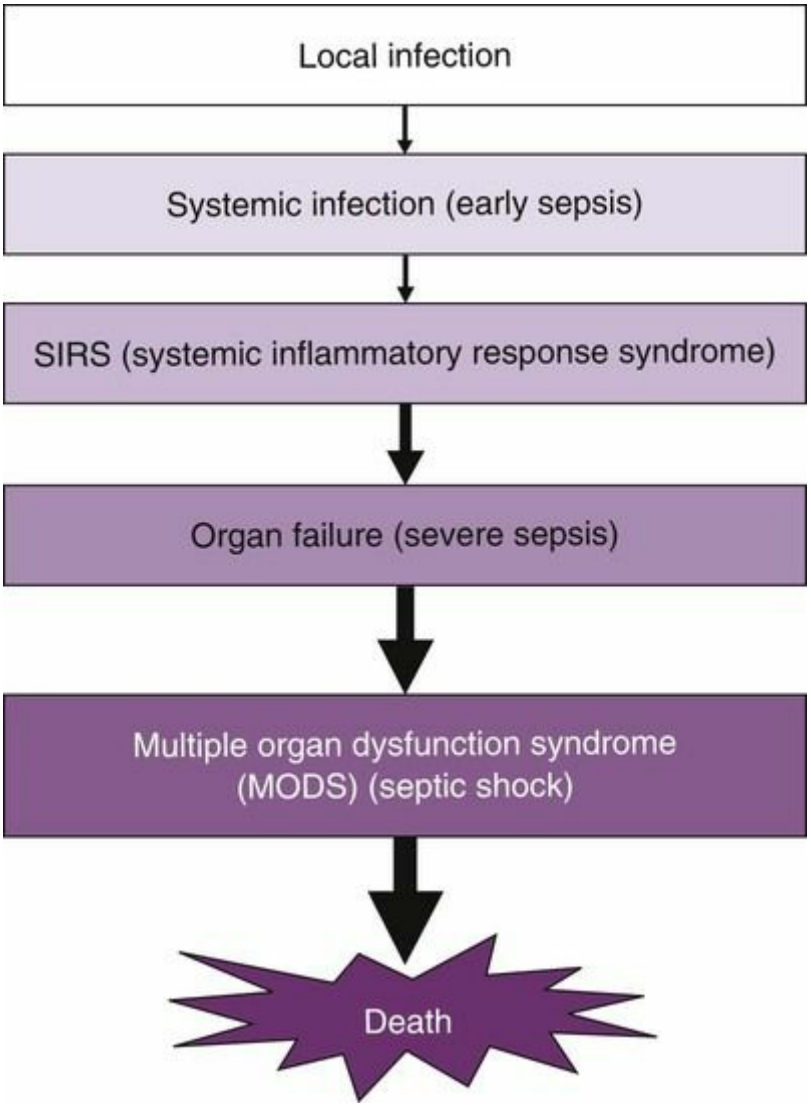


FIG. 37-3 Common progression of events leading to septic shock and multiple organ dysfunction syndrome (MODS).

Infection

When infection is confined to a local area, it should not lead to sepsis and shock. In the person whose immune system and inflammatory responses are effective, the presence of organism invasion first starts a helpful, local response of inflammation to confine and eliminate the organism and to prevent the infection from becoming worse or widespread.

The white blood cells (WBCs) in the area of invasion secrete cytokines to trigger local inflammation and bring more WBCs to kill the invading organisms. The results of this response constrict the small veins and dilate the arterioles in the area, which increases perfusion to locally infected tissues.

Capillary leak occurs, allowing plasma to leak into the tissues. This response causes swelling. The duration of inflammation depends on the size and severity of the infection, but usually it subsides within a few days, when the infection has been managed by these responses. A benefit of inflammation is that it is limited only to the area of infection and stops as soon as it is no longer needed. The patient does not have fever, tachycardia, decreased oxygen saturation, or reduced urine output.

Sepsis and Systemic Inflammatory Response Syndrome

Sepsis is the presence of infection systemic manifestations (Dellinger et al., 2013). Infectious organisms have entered the bloodstream. As their numbers increase, widespread inflammation, known as ***s**ystemic **i**nflammatory **r**esponse **s**yndrome (SIRS)*, is triggered as a result of infection escaping local control. With the organisms and their toxins in the bloodstream and entering other body areas, inflammation is an enemy, leading to extensive hormonal, tissue, and vascular changes and oxidative stress that further impair oxygenation and tissue perfusion. The WBCs produce many pro-inflammation cytokines, especially interleukin-1 (IL-1), interleukin-6 (IL-6), and tumor necrosis factor-alpha (TNF-A or TNF-α) (Abbas et al., 2012). (See Chapter 17 for a discussion of cytokines.) As a result, there is widespread vasodilation and blood pooling (Schell-Chaple & Lee, 2014). The patient has mild hypotension, a low urine output, and an increased respiratory rate. These responses result in a hypodynamic state with decreased cardiac output. Body temperature varies depending on the duration of the sepsis and on WBC function. Some patients have a low-grade fever and others have a high fever. Still others may have a below-normal body temperature. Fever and hypotension result from SIRS. The reduced urine output and increased respiratory rate are compensatory responses to impaired oxygenation and perfusion. Often the patient has the elevated WBC count expected

with a systemic infection.

Inappropriate clotting with microthrombi forming in some organ capillaries causes hypoxia and reduces organ function. This problem is hard to detect, but if sepsis is stopped at this point, the organ damage is completely reversible. The microthrombi increase hypoxic conditions, which then generate more toxic metabolites. These damage more cells and increase the production of pro-inflammatory cytokines, leading to an amplification of SIRS and a vicious repeating cycle of poor oxygenation and perfusion (Fig. 37-4). Although these manifestations are subtle, they indicate sepsis and SIRS and will progress unless intervention begins now.

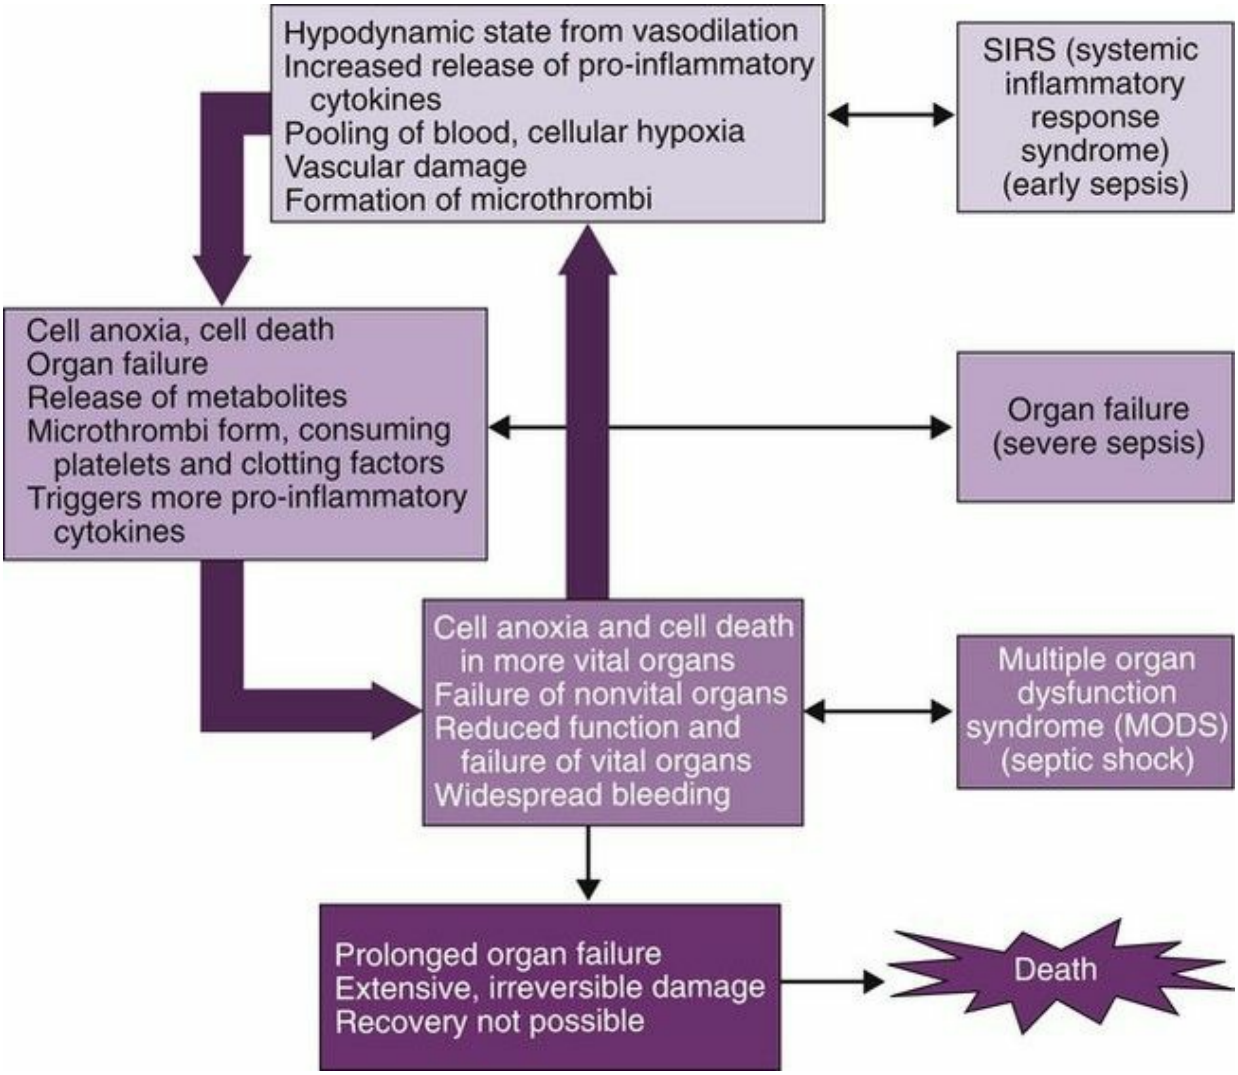

FIG. 37-4 Vicious cycle of systemic inflammatory response syndrome (SIRS) and multiple organ dysfunction syndrome (MODS) in septic shock.

Unfortunately, this early hypodynamic state has a relatively short duration and manifestations are so subtle that the condition is often

missed or misdiagnosed. When early sepsis and SIRS are identified and treated aggressively at this stage, the cycle of progression is stopped and the outcome is good. When sepsis and SIRS are not identified and treated at this stage, it progresses to severe sepsis, which is much harder to control. Nurses, as well as all other health care professionals, have a responsibility to identify cues that indicate sepsis before it becomes severe (Kleinpell et al., 2013). Identifying criteria have been established (Table 37-3) and must be used to ensure interventions are instituted at this stage.

TABLE 37-3

Sepsis with Systemic Inflammatory Response Syndrome (SIRS) Criteria

Suspected or identified infection with some of the following:

- Temperature of more than 101° F (38.3° C) or less than 96.8° F (36° C)
- Heart rate of more than 90 beats per minute
- Respiratory rate of more than 20 breaths per minute
- Abnormal WBC count (>12,000/mm³ or <4000/mm³)
- Normal WBC count with >10% bands
- Plasma C-reactive protein >2 standard deviations above normal
- Plasma prolactin >2 standard deviations above normal
- Arterial hypotension (SBP <90 mmHg; MAP <70 mmHg)
- Arterial hypoxemia (Pa_{O_2}/Fi_{O_2} <300)
- Urine output <0.5 mL/kg/hr for 2 hours despite adequate fluid resuscitation
- Creatinine increase >0.5 mg/dL
- INR >1.5 or aPTT >60
- Absent bowel sounds
- Platelet count <100,000/mm³
- Total bilirubin >4 mg/dL
- Elevated lactic acid (lactate) levels
- Decreased capillary refill or presence of mottling
- Hyperglycemia (plasma glucose >140 mg/dL or 7.7 mmol/L) in absence of diabetes
- Unexplained change in mental status
- Significant edema or positive fluid balance

aPTT, Activated partial thromboplastin time; *Fio_2,* fraction of inspired oxygen; *INR,* international normalized ratio; *MAP,* mean arterial pressure; *Pao_2,* partial pressure of arterial oxygen; SBP, systolic blood pressure; *WBC,* white blood cell.

Adapted from Dellinger, R.P., Levy, M., Rhodes, A., Annane, D., Gerlach, H., Opal, S.M., et al. (2013). Surviving sepsis campaign: International guidelines for management of severe sepsis and septic shock: 2012. *Critical Care Medicine, 41*(2), 580-637.

Nursing Safety Priority QSEN

Critical Rescue

Notify the health care provider or the Rapid Response Team for any patient who has vital signs or other conditions that meet the sepsis with SIRS criteria.

Severe Sepsis

Severe sepsis is sepsis plus sepsis-induced organ dysfunction or tissue hypoperfusion (Dellinger et al., 2013). It represents the progression of sepsis with an amplified SIRS (see Fig. 37-4). All tissues are involved and are hypoxic to some degree. Some organs are experiencing cell death and dysfunction at this time. Microthrombi formation is widespread with clots forming where they are not needed. This process uses up or consumes much of the available platelets and clotting factors, a condition known as *disseminated intravascular coagulation (DIC).* The amplified SIRS and cytokine release increase capillary leakiness, injure cells, and increase cell metabolism. Damage to endothelial cells reduces anticlotting actions and triggers the formation of even more small clots, increasing DIC. Anaerobic metabolism continues, and cell uptake of oxygen is poor. The continued stress response triggers the continued release of glucose from the liver and causes hyperglycemia. The more severe the response, the higher the blood glucose level (Kleinpell et al., 2013; Schell-Chaple & Lee, 2014).

Despite the severity of this stage and the fact that it may be present for 24 hours or more, it is often missed. One of the reasons it may be missed is that the cardiac function is hyperdynamic in this phase. The pooling of blood and the widespread capillary leak stimulate the heart, and cardiac output is *increased* with a more rapid heart rate and an elevated systolic blood pressure. In addition, the patient's extremities may feel warm and there is little or no cyanosis. Even though the patient may "look" better, the pathologic changes occurring at the tissue level are serious and have caused significant damage. The WBC count at this time may no longer be elevated. The reason for this is that a prolonged sepsis stage may have exceeded the bone marrow's ability to keep producing and releasing new mature neutrophils and other WBCs. The WBC count may be extremely low, especially the segmented neutrophils (segs).

Clinical manifestations of this stage include a lower oxygen saturation, rapid respiratory rate, decreased to absent urine output, and a change in the patient's cognition and affect. Appropriate and aggressive interventions at this stage can still prevent septic shock, although mortality after a patient reaches this stage is much higher than for sepsis and SIRS. *At this point, the down-hill course leading to septic shock is extremely rapid.*

Septic Shock

Septic shock is sepsis-induced hypotension persisting despite adequate fluid resuscitation. It is the stage of sepsis and SIRS when multiple organ

dysfunction syndrome (MODS) with organ failure is evident and poor clotting with uncontrolled bleeding occurs (see Fig. 37-4). *Even with appropriate intervention, the death rate among patients in this stage of sepsis is very high* (Dellinger et al., 2013). Severe hypovolemic shock and hypodynamic cardiac function are present as a result of an inability of the blood to clot because the platelets and clotting factors were consumed earlier. Vasodilation and capillary leak continue from vascular endothelial cell disruption, and cardiac contractility is poor from cellular ischemia. The clinical manifestations resemble the late stage of hypovolemic shock.

Etiology

The major cause of sepsis is a bacterial infection that escapes local control, although in immunocompromised patients, fungal infections also cause sepsis. Common organisms causing sepsis include gram-negative bacteria (*Pseudomonas aeruginosa, Escherichia coli,* and *Klebsiella pneumoniae*) and gram-positive bacteria (*Staphylococcus* and *Streptococcus*). Patients especially at risk for sepsis are those who are immunocompromised in any way and those who have central lines. Central lines in place even for short periods create a direct access point for microorganisms and can lead to central line–associated bloodstream infections (CLABSIs) (Dumont & Nesselrodt, 2012; Earhart, 2013). Table 37-4 lists some of the health problems that increase the risk for sepsis and septic shock.

TABLE 37-4

Conditions Predisposing to Sepsis and Septic Shock

• Malnutrition • Immunosuppression • Large, open wounds • Mucous membrane fissures in prolonged contact with bloody or drainage-soaked packing • GI ischemia • Exposure to invasive procedures • Cancer • Older than 80 years
• Infection with resistant microorganisms • Receiving cancer chemotherapy • Alcoholism • Diabetes mellitus • Chronic kidney disease • Transplantation recipient • Hepatitis • HIV/AIDS

AIDS, Acquired immune deficiency syndrome; *HIV,* human immune deficiency virus.

Incidence and Prevalence

Sepsis and septic shock are common events in the United States and throughout the world (Dellinger et al., 2013). Although sepsis management has improved, the incidence is increasing as a result of more drug-resistant organisms and the fact that patients are discharged from the hospital "quicker and sicker" (Lopez-Bushnell et al., 2014). Sepsis takes time to develop, and the patient may be discharged before manifestations are obvious.

Health Promotion and Maintenance

Prevention is the best management strategy for sepsis and septic shock. Evaluate all patients for their risk for sepsis, especially older adults because the death rate from sepsis in people older than 65 years is nearly twice that of younger adults. Table 37-4 lists some of the health problems that increase the risk for septic shock. Use aseptic technique during invasive procedures and when working with nonintact skin and mucous membranes in immunocompromised patients. Remove indwelling urinary catheters and IV access lines as soon as they are no longer needed. Ensure that patients receiving mechanical ventilation are weaned from the ventilator as soon as possible (Kleinpell et al., 2013).

Because sepsis can be a complication of many conditions found in acute care settings, always consider its possibility. *Early detection of sepsis before progression to septic shock is a major nursing responsibility.* The nurse is the health care professional most in contact with the patient and is in a unique position to detect subtle changes in appearance and behavior that can indicate sepsis. Use the assessment techniques described below for changes in vital signs, laboratory findings, appearance, and behavior to identify early any characteristics of sepsis and sepsis progression at least every shift for potentially infected, seriously ill patients (Kleinpell & Schorr, 2014). Using an evidence-based protocol to identify patients in the emergency department who may be in early sepsis on admission can improve the timing of implementing an appropriate sepsis bundle intervention (see the Quality Improvement box).

Quality Improvement QSEN

Improving Nurse Recognition of Sepsis Indicators in the Emergency Department

Kilburn, F., Baily, P., & Price, D. (2013). Sepsis: Recognizing the next event. *Nursing2013, 43*(10), 14-16.

After prevention, the greatest positive factor for surviving sepsis is

early recognition of the condition, which leads to implementation of the evidence-based interventions through early goal-directed therapy (EGDT). Recognition of the condition while patients are being seen in the emergency department (ED) can be challenging; however, delay of diagnosis significantly increases the risk for death (Dellenger et al., 2013). One rural Midwestern emergency department found that of the 42 patients admitted through the ED who were diagnosed after admission with sepsis or systemic inflammatory response syndrome (SIRS), 21 had two or more defining criteria while in the ED. Of these 21, only 3 were actually recognized and diagnosed in the ED. The Quality Management department determined that the greatest obstacle to early recognition of SIRS or sepsis was the seven-page assessment document that, although comprehensive, was time-consuming and minimally used by the ED nurses.

The stakeholders in the process developed a shorter, clearer, and more user-friendly SIRS and sepsis protocol consisting of a recognition and treatment order set based on the 2012 sepsis guidelines. In the first 3 months after developing this tool and incorporating it into the triage nurse admission data set, there was a 37% increase in the recognition of patients meeting SIRS and sepsis criteria in the ED.

Commentary: Implications for Practice and Research

Evidence-based practice has demonstrated that early recognition of patients with SIRS or sepsis is the first step in improving survival from this devastating condition. The implementation of a more user-friendly protocol in one ED has improved the step of recognition at one facility. Research measuring the final survival and cost outcomes based on speed of implementing EGDT is needed to determine how well early recognition is turned into early intervention through communication and teamwork.

Early detection can be made by patients and families, as well as by health care personnel. This is especially important for patients discharged to home after invasive procedures or surgery. Teach patients the manifestations of local infection (local redness, pain, swelling, purulent drainage, loss of function) and of early sepsis (fever, urine output less than intake, light-headedness). Teach them how to use a thermometer and to take the temperature twice a day and whenever they are not feeling well. Urge those with manifestations of early sepsis to immediately contact their health care provider. Teach them that if antibiotics are prescribed, to take these drugs as prescribed and to

complete the entire course.

Patient-Centered Collaborative Care

Assessment

Sepsis and septic shock differ from other types of shock in many ways. The entire syndrome may occur over many hours to days, and the manifestations are less obvious. The chance for recovery is good when the patient is recognized as having sepsis with SIRS and appropriate interventions are started within 6 hours. Septic shock, on the other hand, has a rapid downhill course and chances for recovery are relatively poor. Nurses identifying patients in the earlier stages of sepsis can make the greatest difference in survival.

History.

Age is important because sepsis develops more easily among older, debilitated patients who are immunosuppressed (Touhy & Jett, 2014). Chart 37-5 lists factors that increase the older adult's risk for shock. Ask about the patient's medical history including recent illness, trauma, invasive procedures, or chronic conditions that may lead to sepsis. Check which drugs the patient has used in the past week. Some drugs may directly cause changes leading to shock. Also, a drug regimen may indicate a disorder or problem that can contribute to sepsis. These drugs include aspirin, corticosteroids, antibiotics, and cancer therapy drugs.

Chart 37-5 Nursing Focus on the Older Adult

Risk Factors for Shock

Hypovolemic Shock

- Diuretic therapy
- Diminished thirst reflex
- Immobility
- Use of aspirin-containing products
- Use of complementary therapies such as *Ginkgo biloba*
- Anticoagulant therapy

Cardiogenic Shock

- Diabetes mellitus
- Presence of cardiomyopathies

Distributive Shock

- Diminished immune response
- Reduced skin integrity
- Presence of cancer
- Peripheral neuropathy
- Strokes
- Being in a hospital or extended-care facility
- Malnutrition
- Anemia

Obstructive Shock

- Pulmonary hypertension
- Presence of cancer

Physical Assessment/Clinical Manifestations.

Manifestations of sepsis and septic shock occur over many hours, and some change during the progression. See Table 37-3 for a listing of specific manifestations and laboratory changes that often occur with sepsis and septic shock.

Cardiovascular changes differ in the different stages of sepsis and septic shock. Cardiac output and blood pressure are low in early sepsis and very low in septic shock. In severe sepsis, cardiac output is higher as are heart rate and blood pressure, although this is an indication of a worsening condition rather than an improvement. Increased cardiac output is reflected by tachycardia, increased stroke volume, a normal systolic blood pressure, and a normal central venous pressure (CVP). Increased cardiac output and vasodilation make the skin color appear normal with pink mucous membranes, and the skin is warm to the touch. This situation is temporary, and eventually the cardiac output is greatly reduced.

With progression, disseminated intravascular coagulation (DIC) occurs as a result of excessive clotting with formation of thousands of small clots in the tiny capillaries of the liver, kidney, brain, spleen, and heart. DIC reduces perfusion and oxygenation and decreases oxygen saturation, causing hypoxia and ischemia.

The huge number of small clots uses clotting factors and fibrinogen faster than they can be produced, which eventually leads to poor clotting. This increases the risk for hemorrhage, which occurs in the septic shock stage. Coupled with the continued capillary leak, the bleeding causes hypovolemia and a dramatic decrease in cardiac output, blood pressure,

and pulse pressure. The manifestations of this phase are the same as those of the later stages of hypovolemic shock.

Respiratory changes are first caused by compensatory mechanisms that try to maintain oxygenation with a rate increase. As tissue hypoxia becomes more profound and acidosis is present, the depth of respiration also increases. The lungs are susceptible to damage, and the complication of acute respiratory distress syndrome (ARDS) may occur in septic shock. ARDS in septic shock is caused by the continued systemic inflammatory response syndrome (SIRS) increasing the formation of oxygen free radicals, which damage lung cells. *ARDS in a patient with septic shock has a high mortality rate.*

Skin changes differ at different stages of sepsis. In the hyperdynamic stage, the skin is warm and no cyanosis is evident. With progression to septic shock and compromised circulation, the skin is cool and clammy with pallor, mottling, or cyanosis. In DIC, petechiae and ecchymoses can occur anywhere. Blood may ooze from the gums, other mucous membranes, and venipuncture sites, as well as around IV catheters.

A kidney/urinary change of low urine output compared with fluid intake indicates shock. When a patient who has no known kidney or bladder problem suddenly starts having a low urine output, be suspicious of severe sepsis or septic shock. Reduced output is caused by capillary leak, low circulating volume, and hormonal changes. Kidney function decreases, and serum creatinine levels increase.

Psychosocial Assessment.

The indicator that patients may be in the beginning of severe sepsis is often a change in affect or behavior. Compare the patient's current behavior, verbal responses, and general affect with those assessed earlier in the day or the day before. They may seem just slightly different in their reactions to greetings, comments, or jokes. They may be less patient than usual or act restless or fidgety. Patients may make statements such as “I feel as if something is wrong, but I don't know what.” If behavior is changed from prior assessments, consider the possibility of severe sepsis and shock.

Laboratory Assessment.

No single laboratory test confirms the presence of sepsis and septic shock, although the hallmark of sepsis is an increasing serum lactate level, a normal or low total white blood cell (WBC) count, and a decreasing segmented neutrophil level with a rising band neutrophil level (left shift, see Chapter 17). The presence of bacteria in the blood

supports the diagnosis of sepsis although this finding may not be present. Obtain specimens of urine, blood, sputum, and any drainage for culture to identify the causative organisms. Blood cultures should be taken before antibiotic therapy is started provided that this action does not delay antibiotic therapy by more than 45 minutes (Dellinger et al., 2013). Other abnormal laboratory findings that occur with septic shock include changes in the white blood cell (WBC) count; the differential leukocyte count may show a left shift. Hematocrit and hemoglobin levels usually do not change until late in septic shock. At that point, the hematocrit and hemoglobin levels, fibrinogen levels, and platelet count are low from disseminated intravascular coagulation (DIC). The serum lactate level is above normal, and the serum bicarbonate levels are lower than normal. Unfortunately, these parameters may take time to change and cannot be relied on as sensitive indicators of the patient's worsening condition.

Another indicator of sepsis and septic shock is a low blood level of activated protein C. Protein C is an enzyme that prevents inappropriate clot formation. It is activated when it binds to healthy vascular endothelial cells. In severe sepsis, the injured endothelial cells cannot activate protein C and thousands of small clots form in the capillaries of vascular organs. Decreasing levels of activated protein C indicate the beginning of severe sepsis even before other manifestations are evident.

Other biologic indicators of severe sepsis and septic shock are changes in plasma d-dimer levels and cytokine (interleukin-6 [IL-6] and interleukin-10 [IL-10]) levels. Plasma d-dimer levels rise during sepsis as the fibrin in clots is broken down. IL-6 is a pro-inflammatory cytokine, and IL-10 is an anti-inflammatory cytokine. In sepsis, IL-6 levels rise and IL-10 levels either remain normal or decrease. These indicators have a lag time, and changes may not be present soon enough to identify sepsis with SIRS before severe sepsis or septic shock develops.

Because the results of blood cultures may not be available until the patient's condition has progressed to severe sepsis or septic shock, other biomarkers for sepsis and SIRS are needed to help identify the condition when it can be managed and cured. Two such markers are increasing lactic acid levels and increasing prolactin levels.

The actual diagnosis of sepsis is difficult to make, yet the best outcome depends on an early diagnosis and the implementation of appropriate aggressive interventions within 6 hours. In general, sepsis is considered to exist when an infection is present along with some of the additional established criteria listed in Table 37-3.

NCLEX Examination Challenge

Safe and Effective Care Environment

Which clinical manifestation in a client alerts the nurse to the probability of septic shock instead of hypovolemic shock?
A Hypotension
B Pale, clammy skin
C Decreased urine output
D Oozing of blood at the IV site

Planning and Implementation

The priority problem for patients with septic shock is potential for multiple organ dysfunction syndrome (MODS).

Planning: Expected Outcomes.

With appropriate interventions, the patient with sepsis or septic shock is expected to have normal aerobic cellular metabolism. Indicators include:

- Arterial blood gases (pH, Pa_{O_2}, and Pa_{CO_2}) within the normal range
- Maintenance of a urine output of at least 20 mL/hr
- Maintenance of mean arterial blood pressure within 10 mm Hg of baseline
- Absence of multiple organ dysfunction syndrome (MODS)

Interventions.

Interventions for sepsis and septic shock focus on identifying the problem as early as possible, correcting the conditions causing it, and preventing complications. The use of a sepsis resuscitation bundle for treatment of sepsis within 6 hours is the standard of practice. A *bundle* is a group of two or more specific interventions that have been shown to be effective when applied together or in sequence. The sepsis management bundle is presented in Table 37-5. Target outcomes of implementing the bundle are obtaining and maintaining a central venous pressure of 8 mm Hg or higher, central venous oxygen saturation of at least 70%, and return of lactic acid levels to normal (Kleinpell et al., 2013).

TABLE 37-5

Bundles for Resuscitation and Management of Severe Sepsis

Surviving Sepsis Care Bundle
Within the first 3 hours of suspecting severe sepsis:
1. Measure serum lactate levels. 2. Obtain blood cultures *before* administering antibiotics. 3. Administer broad-spectrum antibiotics. 4. If either hypotension or a serum lactate level greater than 4 mmol/L (36 mg/dL) is present, administer 30 mL/kg crystalloids intravenously.
Within 6 hours of initial manifestations of suspected septic shock:
5. Administer prescribed vasopressors for hypotension that does not respond to initial fluid resuscitation measures to maintain MAP ≥65 mm Hg. 6. If arterial hypotension persists despite fluid volume resuscitation (indicating septic shock) or lactic acid remains ≥4 mmol/L (36 mg/dL), institute these assessments: • Measure central venous pressure. • Measure central venous oxygen saturation. 7. Re-measure lactic acid (lactate) level if initial value was elevated.

MAP, Mean arterial pressure.

Data from Dellinger, R.P., Levy, M., Rhodes, A., Annane, D., Gerlach, H., Opal, S.M., et al. (2013). Surviving sepsis campaign: International guidelines for management of severe sepsis and septic shock: 2012. *Critical Care Medicine, 41*(2), 580-637; Kleinpell, R., Aitken, L., & Schorr, C. (2013). Implications of the new international sepsis guidelines for nursing care. *American Journal of Critical Care, 22*(3), 212-222.

Oxygen therapy is useful whenever poor tissue perfusion and poor oxygenation are present. Oxygen is delivered in the same ways as for hypovolemic shock. However, the patient with septic shock is more likely to be mechanically ventilated. Care of the patient being mechanically ventilated is discussed in detail in Chapter 32.

Drug therapy to enhance cardiac output and restore vascular volume is essentially the same as that used in hypovolemic shock (see Chart 37-4). In addition, drug therapy is needed to combat sepsis, adrenal insufficiency, hyperglycemia, and clotting problems.

Although septic shock can be caused by any organism, the most common agents are gram-negative bacteria. In accordance with the recommendations of The Joint Commission's National Patient Safety Goals (NPSGs), IV antibiotics with known activity against gram-negative bacteria are given before organisms are identified, preferably within 1 hour of a sepsis diagnosis. Multiple drugs with wide activity are prescribed, based on the site of infection and the most common geographic infections, until the actual causative organism is known.
