Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

Preface

The first edition of this textbook, entitled *Medical-Surgical Nursing: A Nursing Process Approach,* was in many ways a groundbreaking work. The following six editions built on that achievement and further solidified the book's position as a major trendsetter for the practice of adult health nursing. Now in its eighth edition, "Iggy" charts an essential course for the future of adult nursing practice—a course reflected in its current title: *Medical-Surgical Nursing: Patient-Centered Collaborative Care.* The focus of this new edition continues to be to help students learn how to provide safe, quality care that is patient-centered, evidence-based, and collaborative. In addition to print formats as single- and two-volume texts, this edition is now available in a variety of electronic formats, including Pageburst on VST, Pageburst on Kno, and e-book formats for Kindle, Nook, and other e-readers.

The book's subtitle was carefully chosen to emphasize the nurse's role in providing care in collaboration with the patient, family, and members of the interdisciplinary team in both acute care and community-based settings. The Institute of Medicine (IOM), The Joint Commission, the Quality and Safety Education for Nurses (QSEN) Institute, and the 2010 IOM *Future of Nursing* report have called for all health professionals to coordinate and deliver evidence-based patient care as a collaborative care team.

Key Themes for the 8th Edition

The key themes for this edition strengthen the book's focus on safety, quality care, and clinical judgment to best prepare the student for collaborative patient-centered practice in medical-surgical health settings. Each theme is outlined and described below.

- **New Focus on Concepts.** Enhanced compatibility with the concept-based nursing curriculum in pre-licensure programs and a conceptual approach to teaching and learning is the key feature that sets this edition apart. To help students connect previously-learned concepts with new information in the text, six Concept Overviews introduce groups of content units. These unique features review basic concepts learned in nursing fundamentals courses—such as oxygenation and protection—to help students make connections between foundational concepts and patient care for medical-surgical conditions. The Concept Overviews are now even more accessible with color sidebars to identify these pages. For continuity and reinforcement, a list of more specific Priority Nursing Concepts has been added at the beginning of each chapter. This placement is designed to help students better understand the role of the nurse when caring for patients with selected health problems. When these concepts are explicated in the body of each chapter, they are presented in small capital letters (e.g., OXYGENATION) to help students relate and apply essential concepts to provide more focused nursing care. Nursing Concepts and Clinical Judgment Reviews at the end of most chapters apply these same concepts to the health problems presented in the chapter.
- **Improved Focus on the Core Body of Knowledge and QSEN Competencies.** This edition not only continues to emphasize need-to-know content for the RN level of practice, but also includes an increased emphasis on Quality and Safety Education for Nurses (QSEN) Institute core competencies. Clinical practice settings emphasize the essential need for safe practices and quality improvement to provide collaborative patient-centered care that is evidence-based. Many hospitals and other health care agencies have formally adopted these QSEN competencies as core values and goals for patient care. To help prepare students for the work environment as new graduates, as well as to highlight the integration of safety and quality into all nursing actions, this edition incorporates an enhanced focus on these competencies.
- **Emphasis on Patient Safety.** Patient safety is emphasized throughout this edition, not only in the narrative but also in **Nursing Safety**

Priority boxes that enable students to immediately identify the most important care needed for patients with specific health problems. These highlighted features are further classified as Action Alerts, Drug Alerts, or Critical Rescue. We also continue to include our leading-edge Best Practice for Patient Safety & Quality Care charts to emphasize the most important nursing care. Highlighted yellow text also demonstrates the application of The Joint Commission's National Patient Safety Goals initiative (http://www.jointcommission.org/standards_information/npsgs.aspx) and Core Measures content into every day nursing practice.

- **Focus on Patient-Centered Care.** Patient-centered care is enhanced in the eighth edition in several ways. The eighth edition continues to use the term "patient" instead of "client" throughout. Although the use of these terms remains a subject of discussion among nursing educators, we have not defined the patient as a dependent person. Rather, the patient can be an individual, a family, or a group—all of whom have rights that are respected in a mutually trusting nurse-patient relationship. Most health care agencies and professional organizations use "patient" in their practice and publications. In addition, most nursing organizations support the term.
- **New Focus on Gender Considerations.** To increase our emphasis on patient-centered care, we delineated **Gender Health Considerations** rather than restricting our emphasis on Women's Health Considerations as we did in previous editions. To further expand that focus on differences in patient values, preferences, and beliefs, we have added new, cutting-edge **Chapter 73, Care of Transgender Patients,** dedicated to transgender patient care. Along with other individuals in the lesbian, gay, bisexual, and questioning population, the health needs of transgender patients have gained national attention through their inclusion in *Healthy People 2020* and The Joint Commission's standards. This new chapter provides tools to help prepare students and faculty to care for transgender patients who are considering or who have undergone the gender transition process.
- **Emphasis on Evidence-Based Practice.** The updated **Chapter 5, Evidence-Based Practice in Medical-Surgical Nursing** (written by evidence-based practice (EBP) experts Dr. Rona F. Levin and Fay Wright), discusses the importance of *using best current evidence in nursing practice* and how to locate and use this evidence to improve patient care. This chapter, along with the **Evidence-Based Practice boxes** throughout the book, offers a solid foundation in this essential aspect of nursing practice. Each box summarizes a useful research

article and explains the implications of its findings for practice and further research, as well as a rating of the level of evidence based on a well-respected scale.

- **New Focus on Quality Improvement.** The QSEN Institute and clinical practice agencies require that all nurses have *quality improvement* knowledge and skills. To help prepare students for that role, this edition includes new and unique **Quality Improvement boxes.** Each box summarizes a quality improvement project published in the health care literature and the implications of the project's success in improving nursing care. The inclusion of these boxes, in addition to disseminating information and research, helps students understand that quality improvement has its underpinnings in practice change at the "grass roots" level. It also emphasizes the role of the bedside nurse in identifying potential solutions to practice problems.
- **Refocused Emphasis on Clinical Judgment.** Stressing the importance of clinical judgment skills, including an enhanced emphasis on prioritization and delegation, helps to best prepare students for practice and the NCLEX® Examination. As in the seventh edition, the eighth edition emphasizes the importance of nursing judgment to make timely and appropriate clinical decisions and prioritize care. To help achieve that focus, all-new case-based **Clinical Judgment Challenges** (formerly called "Decision-Making Challenges"), based primarily on the QSEN core competencies, have been integrated throughout the text. Selected Clinical Judgment Challenges highlight ethical dilemmas and delegation and supervision issues. These exercises provide clinical situations in which students can use on-the-spot nursing judgment to help prepare them for the fast-paced world of medical-surgical nursing and become competent nurses. Suggested answer guidelines for these Clinical Judgment Challenges are provided on the book's Evolve website (http://evolve.elsevier.com/Iggy/). In addition, Dr. Christine Tanner's clinical judgment framework (Tanner, 2006) is used to help students apply selected concepts in the **Nursing Concepts and Clinical Judgment Reviews** at the end of most chapters. The components of this model include that clinical nurses use nursing judgment to provide safe, quality care by:
  - Noticing
  - Interpreting
  - Responding
  - Reflecting
- **Emphasis on Preparation for the NCLEX® Examination.** An enhanced emphasis on the NCLEX Examination and consistency with the 2013

NCLEX-RN® test plan has been refined in this edition. Like the seventh edition, the eighth edition also emphasizes "readiness"—readiness for the NCLEX® Examination, readiness for major emergencies such as those we see with all-too-frequent mass casualty events, readiness for safe drug administration, and readiness for the new and continually unfolding world of genetics and genomics. An increased number of new **NCLEX® Examination Challenges** are interspersed throughout the text to allow students the opportunity for practice in test-taking and decision-making. Answers to these Challenges are provided in the back of the book, and their rationales are provided on the Evolve website (http://evolve.elsevier.com/Iggy). As the NCLEX® Examination becomes more challenging, it is more critical than ever that students be ready to pass the licensure exam on the first try. To help both students and faculty achieve that outcome, chapter-opening **Learning Outcomes** are now more consistent with the competencies outlined in the detailed 2013 NCLEX-RN Test Plan. The eighth edition also continues to include an innovative end-of-chapter feature called **Get Ready for the NCLEX® Examination!** This unique and effective learning aid consists of a list of **Key Points** *organized by Client Needs Category* as found in the NCLEX-RN® Test Plan. Relevant QSEN competency categories are identified for selected Key Points.

- **Expanded Content on Community-Based Care.** Expanded coverage on this important nursing area, including long-term care, is included in this edition. A recent editorial article in the journal *Medical-Surgical Nursing* stated that the future of medical-surgical nurses will change to an increased role in care coordination and transition management between acute care and community-based care (Lattavo, 2014). To help students prepare for this new role, the eighth edition of our text expands coverage of community-based care, including essential collaborative management that is needed in home, long-term, rehabilitation, and ambulatory settings.
- **Collaborative Problems and NANDA-I Nursing Diagnoses.** This edition also features an improved delineation of **NANDA-I nursing diagnoses and collaborative patient problems.** As health care becomes increasingly more collaborative, nurses need to be able to communicate with other members of the health care team, including the patient and family. To help students learn how to facilitate that communication, the eighth edition identifies patient problems and specifies which actual and potential problems are NANDA-I nursing diagnoses and which are collaborative health problems.

Clinical Currency and Accuracy

To ensure the book's currency and accuracy, we listened to students and faculty who have used the previous editions, focusing on their impressions of and experiences with the book. We reviewed documents crafted by a variety of health care organizations, including the Institute of Medicine (IOM), The Joint Commission (TJC), and the Institute for Healthcare Improvement (IHI). Recent nursing education publications were also examined, such as those authored by the National League for Nursing (NLN), the American Association of Colleges of Nursing (AACN), and Dr. Patricia Benner and her colleagues in their book *Educating Nurses: A Call for Radical Transformation* (2010). A thorough nursing education literature search of best current evidence helped us validate best practices and national health care trends to help shape the focus of the eighth edition.

We also commissioned in-depth reviews of every chapter by a dedicated panel of instructors and clinicians across the United States, and we used their reviews to guide us in revising the chapters into their final form. A well-respected interventional radiologist ensured the accuracy of selected diagnostic testing procedures and associated patient care.

The results of these efforts are reflected in the eighth edition's:

- Strong, consistent focus on NCLEX-RN® Examination preparation, clinical judgment, patient-centered collaborative care, pathophysiology, drug therapy, evidence-based clinical practice, and community-based care
- Foundation of relevant research and best practice guidelines
- Emphasis on the critical "need to know" information that beginning nurses must master to provide safe patient care

With today's knowledge explosion, it is easy for a book to become larger with each new edition. However, today's nursing students have a limited time to absorb and begin to apply the information essential for medical-surgical nursing care. Therefore in this eighth edition we eliminated some of the content found in previous foundation courses or other specialty textbooks. We limited our discussions to how this content is *used* in adult nursing and focused on content that was "need to know" for safe, patient-centered, quality nursing practice.

Outstanding Readability

Today's students need to be able to read information once and understand it; they do not have time to repeatedly read the same information. To achieve this level of readability, the text employs a direct-address style (wherever appropriate) that speaks directly to the reader, and sentences are as short as possible without sacrificing essential content. In addition, we ensured that this new edition has improved consistency of difficulty level from chapter to chapter.

Reading level is highly influenced by the length of sentences and the length of words. Although we can control the length of the sentences, medical terms are often 4 to 5 syllables long and tend to skew a chapter's reading level. Nevertheless, the result of our efforts is a med-surg text of consistently outstanding readability. The average reading level is 10th to 11th grade. It is important to note that reducing the reading level of this edition did not reduce the quality or depth of content that students need to know. Instead, the content is clear, focused, and accessible.

Ease of Access

To make the text as easy to use as possible, we have maintained the previous editions' approach of smaller chapters of more uniform length. Consistent with our focus on the "need to know," we eliminated some of the less foundational content in the first unit of the last edition and added one new chapter. The more focused eighth edition contains 74 chapters.

The overall presentation of the eighth edition has been updated, including more recent and high-quality photographs for realism, and design change features to improve content access. The design of the eighth edition includes better placement of display elements (e.g., figures, tables, boxes, and charts) for a chapter flow that enhances text reading without splintering content or confusing the reader. Additional ease-of-access features for this edition include tabbed markings for the glossary, index, illustration credits, and bibliography for quick reference. To increase the smoothness of flow and reader concentration, side-turned tables and charts have been reduced throughout the text, as have tables and charts covering multiple pages. Tables and charts now feature an alternating pattern of light and dark shading to ensure essential content for a specific topic or characteristic is not confused with another topic or characteristic.

We also have maintained the unit structure of previous editions, with vital body systems (cardiovascular, respiratory, and neurologic) appearing earlier in the book. In these three units we continue to provide complex care content in separate chapters that discuss managing critically ill patients with coronary artery disease, respiratory health problems, and neurologic health problems.

To help break up long blocks of text and also to highlight key information, we continue to include streamlined yet eye-catching headings, bulleted lists, tables, charts, and in-text highlights. Key Terms are in boldface color type and are defined in the text to foster the learning of need-to-know vocabulary. A glossary is located in the back of the book. Chapter bibliographies have been moved to the back of the book to save space in chapters for need-to-know content. These current bibliographic resources include research articles, nationally accepted clinical guidelines, and other sources of evidence when available for each chapter. Classic sources from before 2011 are noted with an asterisk (*).

A Patient-Centered Collaborative Care Approach

As in all previous editions, we take a collaborative care approach to patient care. We believe that in the real world of health care, nurses, patients, and other health care providers (including physicians, advanced-practice nurses, and physician's assistants) *share* responsibility for the management of patient problems. Thus we present patient care in a collaborative care framework. In this framework we make no *artificial* distinctions between medical treatment and nursing care. Instead, under each Patient-Centered Collaborative Care heading we discuss how the nurse coordinates care and interacts with members of the health care team as appropriate for the patient's health problems, including health promotion and illness prevention.

This edition includes newly redesigned patient-centered Concept Maps that underscore this collaborative care approach. Each Concept Map contains a case scenario. It then shows how a selected complex health problem is addressed. Each Concept Map spells out the steps of the nursing process and related concepts to illustrate the relationships among disease processes, priority patient problems, collaborative management, and more.

Although our approach is collaborative, the text is first and foremost a *nursing* text. We therefore use a nursing process approach as a tool to organize discussions of patient health problems and their management. Discussions of *major* health problems follow a full nursing process format using this structure:

[Health problem]
Pathophysiology
  Etiology (and Genetic Risk when appropriate)
  Incidence and Prevalence
Health Promotion and Maintenance (when appropriate)
Patient-Centered Collaborative Care
  Assessment
  Analysis
  Planning and Implementation
    [Collaborative Intervention Statement (based on priority patient problems)]
    Planning: Expected Outcomes
    Interventions
  Community-Based Care
    Home Care Management
    Self-Management Education

Health Care Resources

Evaluation: Outcomes

The Analysis sections list the priority patient problems (collaborative problems and nursing diagnoses) associated with major health problems and disorders. This eighth edition uses official NANDA-I nursing diagnosis language where it applies; however, most health care agencies prefer to identify collaborative patient problems or needs as the basis for the interdisciplinary plan of care rather than being restricted to NANDA-I language, which addresses primarily nursing-oriented patient problems. With its more flexible interweaving of NANDA-I diagnoses and collaborative patient problems or needs, the eighth edition more closely aligns with the language of clinical practice. The nursing diagnoses used in this edition are the 2012-2014 NANDA-I diagnoses—the most recently approved diagnoses at the time of publication of this edition. Health Promotion and Maintenance sections are found in selected discussions.

Discussions of less common or less complex disorders, although not given this complete subhead structure, nonetheless follow the same basic format: a discussion of the problem itself (including pertinent information on pathophysiology) followed by a section on patient-centered collaborative care of patients with the disorder. To demonstrate our commitment to providing the content foundational to nursing education and consistent with the recommendations of Benner and colleagues through the Carnegie Foundation for the Future of Nursing Education, we highlight throughout this edition essential pathophysiologic concepts that are key to understanding the basis for collaborative management.

Integral to this collaborative care approach is a clear delineation of just who is responsible for what. When a responsibility is primarily the nurse's, the text says so. When a decision must be made jointly by the patient, nurse, physician, and physical therapist, for example, this is clearly stated. When different health care practitioners in different care settings might be involved in the patient's care, this is stated.

Organization

The 74 chapters of *Medical-Surgical Nursing: Patient-Centered Collaborative Care* are grouped into 16 units. Unit 1, Foundations for Medical-Surgical Nursing, lays the foundation for the health care concepts incorporated throughout the text. Unit 2 consists of three chapters on concepts of emergency and trauma care and disaster preparedness.

Unit 3 consists of three chapters on the management of patients with fluid, electrolyte, and acid-base imbalances. Chapters 11 and 12 review key assessments and related patient care in a clear, concise discussion. The chapter on infusion therapy (Chapter 13) is supplemented with an online Fluids & Electrolytes Tutorial on the companion Evolve website.

Unit 4 presents the perioperative nursing content that medical-surgical nurses need to know. This content provides a solid foundation to help the student better understand the collaborative care required for the surgical patient regardless of surgical setting. Even more emphasis is placed on continuous assessment during the perioperative period to prevent complications and improve outcomes in this era of increased ambulatory care.

Unit 5 provides core content on health problems related to immune system function. This content includes normal inflammation and the immune response, altered cell growth and cancer development, and interventions for patients with connective tissue disease, HIV infection, and other immunologic disorders, cancers, and infections.

The remaining 11 units, subdivided and introduced by the six Concept Overviews, cover medical-surgical content by body system. Each of these units begins with an Assessment chapter and continues with one or more Nursing Care chapters for patients with selected health problems in that body system. This framework is familiar to students who learn the body systems in preclinical foundational science courses such as anatomy and physiology.

Multinational, Multicultural, Multigenerational Focus

To reflect the increasing diversity of our society, *Medical-Surgical Nursing: Patient-Centered Collaborative Care* takes a multinational, multicultural, and multigenerational focus. Addressing the needs of both U.S. and Canadian readers, we have included examples of trade names of drugs available in the United States and in Canada. Drugs that are available only in Canada are designated with a  symbol. When appropriate, we identify specific Canadian health care resources, including their websites. In many areas, Canadian health statistics are combined with those of the United States for provide an accurate "North American" picture.

To help nurses provide quality care for patients whose preferences, beliefs, and values may differ from their own, numerous **Cultural Considerations** and **Gender Health Considerations boxes** highlight important aspects of culturally competent care throughout the text. In addition, a new chapter (Chapter 73) is dedicated to the special health care needs of transgender patients.

Increases in life expectancy and the "graying" of the baby-boom generation add up to a steadily increasing older adult population. To help equip nurses for this challenge, the eighth edition continues to provide thorough coverage of the care of older adults. Chapter 2 offers content on the role of the nurse and health care team in promoting health for older adults in the community. It also provides coverage of common health problems that older adults may have in the health care setting, such as falls and inadequate nutrition. The text includes many **Nursing Focus on the Older Adult charts.** Laboratory values and drug dosages typical for older patients are also included throughout the book. Charts specifying normal physiologic changes to expect in the older population are found in each Assessment chapter. In addition, **Considerations for Older Adults boxes** are included throughout the text to emphasize key points to consider when caring for these patients.

Additional Learning Aids

As in previous editions, the eighth edition continues to include a rich array of learning aids geared toward adult learners to help students quickly identify and understand key information and to serve as study aids.

- Written in "patient-friendly" language, **Patient and Family Education: Preparing for Self-Management charts** provide the types of instructions that nurses must learn to provide to patients and their families to help them cope with life changes caused by illness.
- **Laboratory Profile charts** summarize important information on laboratory tests commonly used to evaluate health problems. Information typically includes normal ranges of laboratory values (including differences for older adults, when appropriate) and the possible significance of abnormal findings.
- **Common Examples of Drug Therapy charts** summarize important information about commonly used drugs. Most charts include both U.S. and Canadian trade names for typically used drugs, usual dosages (including dosages for older patients, as appropriate), and nursing interventions with rationales.
- **Key Features charts** highlight the clinical manifestations of important health problems based on pathophysiologic concepts.
- **Evidence-Based Practice boxes**, provided in many chapters, give synopses of recent nursing research articles and other scientific articles applicable to nursing. Each box provides a brief summary of the research, its level of evidence (LOE), and a brief commentary with implications for nursing practice and future research. The purpose of this feature is to help students identify the strengths and weaknesses of the research and to see how research guides nursing practice.
- New to this edition, **Quality Improvement boxes** offer anecdotes of recent nursing articles that focus on this important QSEN competency. These features, similar to the Evidence-Based Practice boxes, provide a brief summary of the research with commentary on the implications for nursing practice and research.
- As in the previous editions, **Home Care Assessment charts** serve as a convenient summary of essential assessment points for patients who need follow-up home health nursing care.
- Subtypes of **Clinical Judgment Challenges** (CJCs) emphasize the six QSEN core competencies: Patient-Centered Care, Teamwork and Collaboration, Evidence-Based Practice, Quality Improvement, Safety, and Informatics.

An Integrated Multimedia Resource Based on Proven Strategies for Student Engagement and Learning

Medical-Surgical Nursing: Patient-Centered Collaborative Care, 8th edition, is the centerpiece of a comprehensive package of electronic and print learning resources that break new ground in the application of proven strategies for student engagement, learning, and evidence-based educational practice. This integrated multimedia resource actively engages the student in problem solving and practicing clinical decision-making skills.

Resources for Instructors

For the convenience of faculty, all Instructor Resources are available on a streamlined, secure instructor area of the Evolve website (http://evolve.elsevier.com/Iggy/). Included among these Instructor Resources are the reorganized ***TEACH for Nurses*** **Lesson Plans.** These Lesson Plans focus on the most important content from each chapter and provide innovative strategies for student engagement and learning. Lesson Plans are provided for each chapter and are categorized into several parts:

Learning Outcomes
Teaching Focus
Key Terms
Nursing Curriculum Standards
  QSEN
  Concepts
  BSN Essentials
Student Chapter Resources
Instructor Chapter Resources
Teaching Strategies

Additional Instructor Resources provided on the Evolve website include:

- A completely revised, updated, high-quality **Test Bank** consisting of more than 1750 items, both traditional multiple-choice and NCLEX-RN® "alternate" item types. Each question is coded for correct answer, rationale, cognitive level, NCLEX Integrated Process, NCLEX Client Needs Category, and new Keywords to facilitate question searches. Page references are provided for Remembering (Knowledge)- and Understanding (Comprehension)-level questions. (Questions at the

Applying [Application] and above cognitive level require the student to draw on understanding of multiple or broader concepts not limited to a single textbook page, so page cross references are not provided for these higher-level critical thinking questions.) The Test Bank is provided in the Evolve Assessment Manager and in ExamView and ParTest formats.

- An electronic **Image Collection** containing all images from the book (approximately 550 images), delivered in a format that makes incorporation into lectures, presentations, and online courses easier than ever.
- **PowerPoint Presentations**—a revised collection of more than 2000 slides corresponding to each chapter in the text and highlighting key content with integrated images and Unfolding Case Studies. Audience Response System Questions (three discussion-oriented questions per chapter for use with iClicker and other audience response systems) are included in these slide presentations. Answers and rationales to the Audience Response System Questions and Unfolding Case Studies are found in the "Notes" section of each slide.

Also available for adoption and separate purchase:

- Corresponding chapter-by-chapter to the textbook, ***Elsevier Adaptive Quizzing (EAQ)*** integrates seamlessly into your course to help students of all skill levels focus their study time and effectively prepare for class, course exams, and the NCLEX® certification exam. ***EAQ*** is comprised of a bank of high-quality practice questions that allows students to advance at their own pace—based on their performance—through multiple mastery levels for each chapter. A comprehensive dashboard allows students to view their progress and stay motivated. The educator dashboard, grade book, and reporting capabilities enable faculty to monitor the activity of individual students, assess overall class performance, and identify areas of strength and weakness, ultimately helping to achieve improved learning outcomes.
- *Simulation Learning System (SLS) for Medical-Surgical Nursing* is an online toolkit designed to help you effectively incorporate simulation into your nursing curriculum, with scenarios that promote and enhance the clinical decision-making skills of students at all levels. It offers detailed instructions for preparation and implementation of the simulation experience, debriefing questions that encourage critical thinking, and learning resources to reinforce student comprehension. Modularized simulation scenarios correspond to Elsevier's leading medical-surgical nursing texts, reinforcing students' classroom knowledge base, synthesizing lecture and clinicals, and offering

remediation content that's critical to debriefing.

Resources for Students

Resources for students include a revised, updated, and retitled Clinical Nursing Judgment Study Guide, a Clinical Companion, Elsevier Adaptive Learning (EAL), Virtual Clinical Excursions (VCE), and Evolve Learning Resources.

The ***Clinical Nursing Judgment Study Guide*** has been completely revised and updated and features a fresh emphasis on clinical decision making, priorities of delegation, management of care, and pharmacology.

The pocket-sized ***Clinical Companion*** is a handy clinical resource that retains its easy-to-use alphabetical organization and streamlined format. It includes "Critical Rescue," "Drug Alert," and "Action Alert" highlights throughout based on the Nursing Safety Priority features in the textbook. National Patient Safety Goals highlights have been expanded as a QSEN feature, focusing on one of six QSEN core competencies, while still underscoring the importance of observing vital patient safety standards. This "pocket-sized Iggy" has been tailored to the special needs of students preparing for clinicals and clinical practice.

Corresponding chapter-by-chapter to the textbook, ***Elsevier Adaptive Learning (EAL)*** combines the power of brain science with sophisticated, patented Cerego algorithms to help students to learn faster and remember longer. It's fun, it's engaging, and it's constantly tracking student performance and adapting to deliver content precisely when it's needed to ensure core information is transformed into lasting knowledge.

Virtual Clinical Excursions, featuring an updated and easy-to-navigate "virtual" clinical setting, is once again available for the eighth edition. This unique learning tool guides students through a virtual clinical environment and helps them "learn by doing" in the safety of a "virtual" hospital.

Also available for students is a dynamic collection of Evolve Student Resources, available at http://evolve.elsevier.com/Iggy/. The Evolve Student Resources include the following:

- Review Questions for the NCLEX® Examination
- Answer Guidelines for NCLEX® Examination and Clinical Judgment Challenges
- Interactive Case Studies
- Concept Maps (digital versions of the 12 Concept Maps from the text)
- Concept Map Creator (a handy tool for creating customized Concept

Maps)
- Fluid & Electrolyte Tutorial (a complete self-paced tutorial on this perennially difficult content)
- Key Points (downloadable expanded chapter reviews for each chapter)
- Audio Glossary
- Audio Clips and Video Clips
- Content Updates

In summary, *Medical-Surgical Nursing: Patient-Centered Collaborative Care,* 8th edition, together with its fully integrated multimedia ancillary package, provides the tools you will need to equip nursing students to meet the challenges of nursing practice both now and in an emerging healthcare environment that may look very different from today's. The only elements that remain to be added to this package are those that you alone can provide—your diligence, your commitment, your innovation, *your nursing expertise.*

Donna D. Ignatavicius

M. Linda Workman

Dedication

To all the nursing educators who are passionate about teaching and all the nursing students who are passionate about learning.

Also, to my husband, Charles, who has endured countless hours of loneliness while I've worked on this project and to Stephanie, my daughter, who has educated me about the LGBTQ community's special needs. Thank you!

Donna

To students everywhere.

To John, still my one.

Linda

About the Authors

Donna D. Ignatavicius received her diploma in nursing from the Peninsula General School of Nursing in Salisbury, Maryland. After working as a charge nurse in medical-surgical nursing, she became an instructor in staff development at the University of Maryland Medical Center. She then received her BSN from the University of Maryland School of Nursing. For 5 years she taught in several schools of nursing while working toward her MS in Nursing, which she received in 1981. Donna then taught in the BSN program at the University of Maryland, after which she continued to pursue her interest in gerontology and accepted the position of Director of Nursing of a major skilled-nursing facility in her home state of Maryland. Since that time, she has served as an instructor in several associate degree nursing programs. Through her consulting activities and faculty development workshops, Donna has gained national recognition in nursing education. She is currently the President of DI Associates, Inc. (http://www.diassociates.com/), a company dedicated to improving health care through education and consultation for faculty. In recognition of her contributions to the field, she was inducted as a charter Fellow of the prestigious Academy of Nursing Education in 2007.

M. Linda Workman, a native of Canada, received her BSN from the University of Cincinnati College of Nursing and Health. After serving in the U.S. Army Nurse Corps and working as an Assistant Head Nurse and Head Nurse in civilian hospitals, Linda earned her MSN from the University of Cincinnati College of Nursing and a PhD in Developmental Biology from the University of Cincinnati College of Arts and Sciences. Linda's 30-plus years of academic experience include teaching at the diploma, associate degree, baccalaureate, and master's levels. Her areas of teaching expertise include medical-surgical nursing, physiology, pathophysiology, genetics, oncology, and immunology. Linda has been recognized nationally for her teaching expertise and was inducted as a Fellow into the American Academy of Nursing in 1992. She received Excellence in Teaching awards at the University of Cincinnati and at Case Western Reserve University. She is a former American Cancer Society Professor of Oncology Nursing and held an endowed chair in oncology for 5 years. In addition to authoring several textbooks and serving as a consult for major universities, she is Senior Volunteer Faculty at the College of Nursing, University of Cincinnati.

Acknowledgments

Publishing a textbook and ancillary package of this depth and breadth would not be possible without the combined efforts of many people. Stephanie M. Ignatavicius assisted with literature searches. For this eighth edition, we welcomed three section editors to assist in our revision process: Meg Blair, Cherie Rebar, and Chris Winkelman. Each of these nursing educators worked with us on our seventh edition as contributors and/or ancillary material authors. For this eighth edition they updated and reviewed selected units of the text to provide their expertise.

Our contributing authors once again provided consistently excellent manuscripts in a timely fashion. Special thanks to Deanne Blach, who revised our Concept Maps, and Dr. Richard Lintner, who again provided expertise in interventional radiologic procedures and associated care. Our reviewers—expert clinicians and instructors from around the United States and Canada—provided invaluable suggestions and encouragement throughout the book's development.

The staff of Elsevier/Saunders once again provided us with crucial guidance and support throughout the planning, writing, revision, and production of the eighth edition. In particular, Executive Content Strategist Lee Henderson worked closely with us from the early stages of this edition to help us hone and focus our revision plan, and Lee coordinated the project from start to finish. Senior Content Development Specialist Rae Robertson then worked with us step-by-step to bring the eighth edition from vision to publication. Rae, Julia Curcio, and Kelly McGowan held the reins of our complex ancillary package and worked with a gifted group of writers and content experts to provide an outstanding library of resources to complement and enhance the text. Special thanks to Content Coordinators/Content Development Specialists Courtney Daniels and Samantha Taylor, who not only managed the *Clinical Companion* but also handled the countless administrative details associated with a project of this size.

Senior Project Manager Jodi Willard was once again a joy to work with. If, as is said, the mark of a good editor is that her work is invisible to the reader, then Jodi is the consummate editor. Her unwavering attention to detail, flexibility, and conscientiousness not only helped to make this edition the most consistently readable ever, but also made the entire production process incredibly smooth.

Special thanks also to Publishing Services Manager Debbie Vogel. For

four editions now, Debbie has worked quietly behind the scenes to help bring the book to publication precisely on schedule and with a very high level of quality.

Designer Margaret Reid is responsible for the beautiful cover and the new interior design of the eighth edition. The praise of a book designer's work is often unsung, but Margaret's work on this edition has cast important features in exactly the right light, with neither too much nor too little emphasis, making this edition not only practical and easy to read, but also beautiful.

Our acknowledgments would not be complete without recognizing our dedicated team of Educational Solutions Consultants and other key members of the Sales and Marketing staff who helped to put this book into your hands.

Finally, we wish to thank John Danaher (President, Education) and Loren Wilson (Senior Vice President and General Manager, Content) for their ongoing vision, direction, and support for state-of-the-art educational resources for nurses.

PRIORITY CONCEPTS

- Safety
- Patient-Centered Care
- Teamwork and Collaboration
- Evidence-Based Practice
- Quality Improvement
- Informatics

Learning Outcomes

Safe and Effective Care Environment

1. Briefly describe the scope of medical-surgical nursing.
2. Explain the current priority focus on patient safety and quality of care.
3. Identify the purpose and function of the Rapid Response Team (RRT).
4. Differentiate the six core Quality and Safety Education for Nurses (QSEN) competencies that health care professionals need to provide safe, patient-centered health care.
5. Identify six major ethical principles that help guide decision making and clinical judgment.
6. Communicate patient values, preferences, and expressed needs to other members of the health care team for effective collaboration.
7. Outline the five rights of the delegation and supervision process.
8. Describe the SBAR procedure for successful hand-off communication in health care agencies.
9. Describe the nurse's role in the systematic quality improvement process.

10. Identify three ways that informatics and technology are used in health care.

 http//evolve.elsevier.com/Iggy/

Medical-surgical nursing, sometimes called *adult health nursing*, is a specialty practice area in which nurses promote, restore, or maintain optimal health for patients from 18 to older than 100 years of age (Academy of Medical-Surgical Nurses [AMSN], 2012). A separate chapter on care of older adults is part of this textbook because the majority of medical-surgical patients are older than 65 years (see Chapter 2). To be consistent with the most recent health care literature, the authors use the term *patient* rather than *client* (except in NCLEX Examination Challenge questions). The *family* refers to the patient's relatives and significant others in the patient's life.

Scope of Medical-Surgical Nursing Practice

The practice of medical-surgical nursing requires "specialized knowledge and clinical skills to manage actual or potential health problems that affect individuals, their significant others, and the community" (AMSN, 2012, p. 4). Therefore medical-surgical nursing is practiced in many types of health care settings, such as acute care facilities, skilled nursing facilities, home care agencies, and ambulatory care clinics. The role of the nurse in these settings includes care coordinator, caregiver, patient educator, and patient and family advocate (Fig. 1-1).

FIG. 1-1 A medical-surgical nurse providing care in an acute care hospital.

The nursing process and critical thinking are tools that help the medical-surgical nurse make decisions using clinical judgment while being respectful of the patient's and family's cultural diversity, age, gender, and lifestyle choices (AMSN, 2012). Most fundamentals textbooks have information on cultural diversity and competence. This textbook presents many *Clinical Judgment Challenges* and *NCLEX Examination Challenges* to help you practice how to use clinical judgment to make appropriate decisions for diverse patients.

Medical-surgical health problems occur when a patient's basic needs are not met. These needs, also called *concepts,* were introduced in your fundamentals of nursing course. This textbook builds on those concepts but focuses most on the role of nurses in safely meeting biologic (physiologic) needs for patients with selected medical-surgical health problems. Discussions of psychosocial (emotional), cultural, and spiritual needs are presented when appropriate to describe a holistic

approach to patient care. For example, *Cultural Considerations* features highlight important content related to culture.

To further build a bridge between your basic fundamentals course and medical-surgical nursing care, several special features at the beginning of each textbook section review these selected concepts:

- Protection
- Oxygenation and Tissue Perfusion
- Mobility, Sensory Perception, and Cognition
- Nutrition, Metabolism, and Bowel Elimination
- Urinary Elimination
- Sexuality

Then, at the beginning of each chapter, a priority list highlights additional nursing concepts that apply to specific content in the chapter. These concepts are also emphasized in the concept maps for selected health problems. In addition to specified nursing concepts for each chapter, the QSEN core competency areas (professional nursing concepts) are integrated throughout the text.

Priority Focus on Safety and Quality of Care

Nurses who practice medical-surgical nursing must have a broad knowledge base to meet the needs of patients. Rapid advances in technology, massive increases in available knowledge, and dramatic changes in the health care delivery system require that medical-surgical nurses use expert clinical judgment *to ensure patient safety as the priority in practice.*

Health care errors by physicians, nurses, and other health care professionals have been widely publicized for the past 20 years. Many of these errors have resulted in patient deaths and injuries and increased health care costs. As a result of these errors, a number of national and international organizations have implemented new programs and standards to combat this growing problem.

In 2000, the Institute of Medicine (IOM) stated in its *To Err Is Human: Building a Safer Health Care System* publication that between 44,000 and 98,000 patient *deaths* result each year from preventable errors in acute care hospitals. The report identified several factors that contributed to these findings and motivated other national bodies to examine ways they could improve patient safety and quality care. One of these groups, The Joint Commission (TJC), requires that health care organizations create a culture of safety and encourage patients and families to become safety partners in protecting patients from harm.

The Joint Commission is one of several national organizations that offer peer evaluation for accreditation every 3 years for all types of U.S. health care agencies that meet their standards. Although acute care hospitals are accredited more often than other types of settings, many home care agencies, nursing homes, and ambulatory care centers are also TJC-accredited. Some agencies chose accreditation by organizations other than TJC (e.g., DNV Healthcare), but safety is a major focus for all of them.

In 2002, TJC published its first annual **National Patient Safety Goals (NPSGs).** These goals require health care organizations to focus on specific priority safety practices, many of which involve establishing nursing and health system approaches to care. Since that time, TJC continues to add new goals each year. NPSGs address high-risk issues such as safe drug administration, health care–associated infections, and communication effectiveness among health care team members. When appropriate, this textbook highlights related NPSGs. A complete list of these 2015 goals can be found on the TJC website at www.jointcommission.org.

Protecting Five Million Lives from Harm

As a result of the IOM report and other data from national studies, the Institute for Healthcare Improvement (IHI) concluded that there are millions of health care errors in U.S. hospitals each year. In 2004, the IHI and its partner health care organizations launched the *100,000 Lives Campaign*—an effort to save patient lives over an 18-month targeted time frame. Six interventions for quality improvement changes in care were implemented by partnering health care agencies (Table 1-1). As a result of this project, an estimated 122,000 patient lives were saved!

TABLE 1-1

IHI Interventions to Save Patient Lives and Prevent Patient Harm

INTERVENTIONS TO SAVE PATIENT LIVES	INTERVENTIONS TO PREVENT PATIENT HARM
Deploy Rapid Response Teams.	Prevent harm from High-Alert Drugs (e.g., anticoagulants, insulin, opioids).
Provide reliable, evidence-based care for acute myocardial infarction.	Reduce surgical complications.
Prevent central line infections.	Prevent pressure ulcers.
Prevent adverse drug events (ADEs).	Reduce methicillin-resistant *Staphylococcus aureus* (MRSA) infections.
Prevent surgical site infections (SSIs).	Provide reliable, evidence-based care for congestive heart failure.
Prevent ventilator-associated pneumonia (VAP).	Get boards of health care organizations to support measures to promote safe patient care.

IHI, Institute for Healthcare Improvement.

The next IHI objective was to *protect patients from five million incidents of medical harm* over a 2-year period (December 2006 to December 2008) (Institute for Healthcare Improvement [IHI], 2005). **Medical harm** refers not only to physician incidents but also to errors caused by *all* members of the health care team or system that lead to patient injury or death. To meet this IHI objective, six interventions for changes in care were added to the original list. As seen in Table 1-1, many of these interventions are within the scope of nursing practice and are therefore emphasized throughout this textbook. Some interventions, such as pressure ulcer prevention and adverse drug event reduction, are also part of TJC's NPSGs.

One of the most successful IHI initiatives was the creation of the Rapid Response Team (RRT), also called the *Medical Emergency Team (MET).* **Rapid Response Teams** save lives and decrease the risk for harm by providing care to patients *before* a respiratory or cardiac arrest occurs. Although the RRT does not replace the Code Team who responds to patient arrests, it intervenes rapidly when needed for those who are *beginning* to clinically decline.

Nursing Safety Priority QSEN

Critical Rescue

Early clinical changes in condition occur in most patients for up to 48 hours before a "Code Blue." Therefore observe for, document, and report early indicators of patient decline, including decreasing blood pressure, increasing heart rate, increasing pain, and changes in mental status.

Members of an RRT are critical care experts who are on-site and available at any time. Although membership varies among facilities, the team may consist of an intensive care unit (ICU) nurse, respiratory therapist, **intensivist** (physician who specializes in critical care), and/or **hospitalist** (family practice physician or internist employed by the hospital). In other hospitals, acute care nurse practitioners or medical residents may be part of the team. The team responds to emergency calls, usually from nurses, according to established agency protocols and policies. Patient families may also activate the RRT. Outcome data demonstrate that the RRT approach to emergency care reduces medical complications and decreases the number of cardiac and respiratory arrests (Bogert et al., 2010).

TJC's NPSGs also include the need for early intervention for patients who are clinically changing. They require each health care organization to establish criteria for patients, families, or staff to call for additional assistance in response to an actual or perceived change in the patient's condition. NPSGs are highlighted in yellow throughout this text as they apply to the content.

Quality and Safety Education for Nurses Core Competencies

The IOM published many reports during the past 15 years suggesting ways to improve patient safety and quality care. One of its reports, *Health Professions Education: A Bridge to Quality,* identified five broad core competencies for health care professionals to ensure patient safety and quality care (Institute of Medicine [IOM], 2003). All of these competencies are interrelated and include:

- Provide patient-centered care.
- Collaborate with the interdisciplinary health care team.
- Implement evidence-based practice.
- Use quality improvement in patient care.
- Use informatics in patient care.

Several years later, the QSEN initiative, now called the *QSEN Institute,*

validated the IOM competencies for nursing practice and added safety as a separate competency to emphasize its importance. In addition, the QSEN project team created specific knowledge, skills, and attitudes (KSAs) needed to develop each core competency, using a Delphi research approach. More information about the QSEN Institute can be found on its website at www.qsen.org. QSEN core competency areas are identified in the Key Points at the end of each chapter of this text as appropriate.

This text also highlights the QSEN competencies in its *Clinical Judgment Challenges.* Teaching/learning activities to help students develop specific KSAs can be found in the *Instructor Resources* on the Evolve website and accompanying *Clinical Nursing Judgment Study Guide.* Each QSEN competency is briefly described in the following six sections.

Patient-Centered Care

To be competent in patient-centered care, the medical-surgical nurse recognizes "the patient or designee as the source of control and full partner in providing compassionate and coordinated care based on respect for [the] patient's preferences, values, and needs" (Quality and Safety Education for Nurses [QSEN], 2011). The KSAs for competence in patient-centered care focus on communication, compassion, culture, patient education and empowerment, and respect for patients and their families (Table 1-2).

TABLE 1-2

Examples of Knowledge, Skills, and Attitudes (KSAs) Needed to Develop the IOM/QSEN Patient-Centered Care Competency

KNOWLEDGE	SKILLS	ATTITUDES
Describe how diverse cultural, ethnic, and social backgrounds function as sources of patient, family, and community values.	Provide patient-centered care with sensitivity and respect for the diversity of human experience.	Recognize personally held attitudes about working with different ethnic, cultural, and social backgrounds.
Demonstrate comprehensive understanding of the concepts of pain and suffering, including physiologic models of pain and comfort.	Assess presence and extent of pain and suffering.	Recognize personally held values and beliefs about the management of pain and suffering.
Examine how the safety, quality, and cost-effectiveness of health care can be improved through the active involvement of patients and families.	Engage patients or designated surrogates in active partnerships that promote health, safety and well-being, and self-care management.	Respect patient preferences for degree of active engagement in care processes.
Explore ethical and legal implications of patient-centered care.	Facilitate informed patient consent for care.	Respect and encourage individual expression of patient values, preferences, and expressed needs.

IOM, Institute of Medicine; *QSEN*, Quality and Safety Education for Nurses.

Data from Quality and Safety Education for Nurses, 2011 (www.qsen.org).

Nurses also provide family-centered care. As an advocate for the patient and family, teach them how to be empowered and have more control over their care. To assist in this process, TJC recommends a Speak Up™ campaign to provide information to patients and families to increase their empowerment (TJC, 2011). The basic framework of the campaign urges patients and their families to:

- **S**peak up if you have questions or concerns, and if you don't understand, ask again. It's your body and you have a right to know.
- **P**ay attention to the care you are receiving. Make sure you're getting the right treatments and medications by the right health care professionals. Don't assume anything.
- **E**ducate yourself about your diagnosis, the medical tests you are undergoing, and your treatment plan.
- **A**sk a trusted family member or friend to be your advocate.
- **K**now what medications you take and why you take them. Medication errors are the most common health care errors.
- **U**se a hospital, clinic, surgery center, or other type of health care

organization that has undergone a rigorous on-site evaluation against established state-of-the-art quality and safety standards, such as that provided by TJC.

- **P**articipate in all decisions about your treatment. You are the center of the health care team.

Patient and family empowerment is one way to demonstrate respect for patients in their ability to be care partners.

Ethical Principles.

Respect for people is the basis for six essential *ethical principles* that nurses and other health care professionals should use as a guide for clinical decision making. Respect implies that patients are treated as autonomous individuals capable of making informed decisions about their care. This patient **autonomy** is also referred to as *self-determination* or *self-management.* When the patient is not capable of self-determination, you are ethically obligated to protect him or her as an advocate within the professional scope of practice, according to the American Nurses Association (ANA) Code of Ethics for Nurses (ANA, 2010).

The second ethical principle is **beneficence,** which promotes positive actions to help others. In other words, it encourages the nurse to do good for the patient. **Nonmaleficence** emphasizes the importance of preventing harm and ensuring the patient's well-being. Harm can be avoided only if its causes or possible causes are identified. As described earlier in this chapter, patient safety is currently a major national focus to prevent deaths and injuries.

Fidelity refers to the agreement that nurses will keep their obligations or promises to patients to follow through with care. **Veracity** is a related principle in which the nurse is obligated to tell the truth to the best of his or her knowledge. If you are not truthful with a patient, his or her respect for you will diminish and your credibility as a health care professional will be damaged.

Social justice, the last principle, refers to equality and fairness; that is, all patients should be treated equally and fairly, regardless of age, gender identity, sexual orientation, religion, race, ethnicity, or education. For example, a patient who cannot afford health care receives the same quality and level of care as one who has extensive insurance coverage. An older patient with dementia is shown the same respect as a younger patient who can communicate. A Hispanic patient who can communicate only in Spanish receives the same level of care as a Euro-American patient whose primary language is English. More information on ethics

and ethical principles can be found in your fundamentals textbook.

The ANA recognizes the need for nurses to provide culturally competent care, emphasizing that nurses should practice with respect and compassion to ensure the dignity and uniqueness of every person (ANA, 2010). The individual's unique values, preferences, and needs must be communicated to each member of the health care team. Some of the *Clinical Judgment Challenges* in this textbook focus on ethical issues.

Special Needs of the LGBTQ Population.

Nurses today have been made aware of cultural variations and learned how to incorporate those differences to individualize patient care. However, one group that is rarely addressed in the nursing literature is the lesbian, gay, bisexual, transgender, and queer and/or questioning (LGBTQ) population (Pettinato, 2012). This terminology is widely accepted by the LGBTQ community and is commonly used, although *LGBT* may be seen more often in health care literature. Queer and/or questioning individuals prefer not having strict labels on their sexualities or genders. Another term that may also be used is *LGBTQI* to include intersex individuals. Intersex individuals have sexual or reproductive organs that are not clearly male or female or may have a combination of both male and female organs.

Many studies provide evidence that LGBTQ individuals do not feel comfortable with or trust health care professionals because of previous discrimination (IOM, 2011). The *Healthy People 2020* initiative added a category for these individuals because of health disparities in this population and the need in the United States to improve LGBTQ health. The complete document can be found on www.healthypeople.gov/2020. This textbook includes special health needs of this population as part of its *Gender Health Considerations* features. A new chapter on transgender health has also been added to this edition of the text to help students learn about the special needs of transgender patients.

The health care system, like other facets of society, often overlooks sexualities and genders that are alternative to the standard of heterosexuality and clearly delineated maleness or femaleness. As a health care professional, it is essential to not be restricted by rigid standards of identity. A good way of rethinking concepts of sexuality and gender is to think of each as existing along a spectrum as opposed to the confinement of heterosexual/homosexual and male/female.

To begin to gain trust and show respect for the LGBTQ patient, health care professionals need to know their patient's sexual orientation and gender identity. Do not assume that every patient is heterosexual or

clearly gendered. *Include questions about gender identity and sexual activity as part of your patient's health assessment.* Table 1-3 lists recommended patient interview questions about sexual orientation, gender identity, and health care.

TABLE 1-3

Recommended Patient Interview Questions about Sexual Orientation, Gender Identity, and Health Care

• Do you have sex with men, women, both, or neither?
• Does anyone live with you in your household?
• Are you in a relationship with someone who does not live with you?
• If you have a sexual partner, have you or your partner been evaluated about the possibility of transmitting infections to each other?
• If you have more than one sexual partner, how are you protecting both of you from infections, such as hepatitis B or hepatitis C or HIV?
• Have you disclosed your gender identity and sexual orientation to your health care provider?
• If you have not, may I have your permission to provide that information to members of the health care team who are involved in your care?
• Who do you consider as your closest family members?

HIV, Human immune deficiency virus.

Teamwork and Collaboration

To provide patient- and family-centered care, the nurse "functions effectively within nursing and inter-professional teams, fostering open communication, mutual respect, and shared decision-making to achieve quality patient care" (QSEN, 2011). Therefore the KSAs for this competency emphasize the importance of communication and team functioning. Communication is an essential process for successful collaboration. **Collaboration** entails planning, implementing, and evaluating patient care together using an interdisciplinary (ID) plan of care. To help meet this purpose, health care agencies have frequent and regular ID meetings and conduct ID patient care rounds.

Electronic mail (e-mail) allows for quick communication among health care professionals to enhance collaboration and coordination of care. *However, it should not replace face-to-face and phone communication.*

Although there are many health care team members, some caregivers work more closely with nurses than others. For example, the physician or other health care provider and medical-surgical nurse collaborate frequently in a given day regarding patient care. The occupational therapist may not work as closely with the nurse unless the patient is receiving rehabilitation services. Collaboration with the rehabilitation team is discussed in Chapter 6.

One of the most important members of the ID team is the case manager (CM) or discharge planner, who is typically a nurse or social worker in health care agencies. The purpose of the **case management**

process is to provide quality and cost-effective services and resources to achieve positive patient outcomes. In collaboration with the nurse, the CM coordinates inpatient and community-based care before discharge from a hospital or other facility. Part of that process may involve communicating with other CMs who are employed by third-party health care payers (e.g., Medicare) to keep patients from being readmitted to the hospital.

Communication.

Poor communication between professional caregivers and health care agencies causes many medical errors and patient safety risks. In 2006, The Joint Commission began to require systematic strategies for improving communication. Two years later, another National Patient Safety Goal mandated that nurses communicate continuing patient care needs, such as pain management or respiratory support, to post-discharge caregivers.

To improve communication between staff members and health care agencies, procedures for hand-off communication were established. An effective procedure used in many agencies today is called *SBAR* (pronounced S-Bar). **SBAR** is a formal method of communication between two or more members of the health care team. The SBAR process includes these four steps:

- **S**ituation: Describe what is happening at the time to require this communication.
- **B**ackground: Explain any relevant background information that relates to the situation.
- **A**ssessment: Provide an analysis of the problem or patient need based on assessment data.
- **R**ecommendation: State what is needed or what the desired outcome is.

Several modifications of SBAR include I-SBAR and I-SBAR-R. In these procedures, the "I" reminds the individual to *identify* himself or herself. The last "R" stands for the *response* that the receiver provides based on the information given. Be sure to follow the established documentation and reporting protocols in your agency.

One of the most recent projects to improve communication was provided in 2010 by the Center for Transforming Health Care (www.centerfortransforminghealthcare.org). Every transition of care is potentially risky for patients because vital information needs to be communicated among caregivers and from one health care agency to another to keep patients safe. This quality improvement (QI) project recommends these targeted solutions to ensure successful

communication using the acronym ***SHARE*** as outlined in Table 1-4.

TABLE 1-4

Center for Transforming Health Care Targeted Solutions to Enhance Successful Hand-Off Communication and Collaboration: SHARE

TARGETED SOLUTION	DESCRIPTION OF SOLUTION
Standardize critical content.	Providing details of the patient's history to the receiver, emphasizing key information about the patient, and synthesizing information from various sources before passing it on.
Hardwire within your system.	Developing standardized forms, tools, and methods, such as checklists; identifying new and existing technologies to assist in successful hand-off; and stating expectations about how to conduct a successful hand-off.
Allow opportunity to ask questions.	Using critical-thinking skills when discussing a patient's case as well as sharing and receiving Information as an interdisciplinary team ("pit crew"). Receivers should expect to receive all key information about the patient, scrutinize and question the data, and exchange contact information with the sender for additional questions.
Reinforce quality and measurement.	Demonstrating leadership commitment to successful hand-offs, such as holding staff accountable, monitoring compliance with use of standardized forms, and using data to determine a systematic approach for improvement.
Educate and coach.	Teaching staff throughout the organization about what constitutes a successful hand-off, standardizing training on how to conduct a hand-off, providing performance feedback at the time of the hand-off, and making successful hand-offs an organizational priority.

Data from the Joint Commission Center for Transforming Healthcare. (2010). *Joint Commission Center for Transforming Healthcare tackles miscommunication among caregivers.* Retrieved January 15, 2013, from www.centerfortransforminghealthcare.org.

Specific examples of ways to improve communication among nurses and other health care professionals using the SHARE principles have been cited in recent nursing literature. For instance, Maxson et al. (2012) reported a process for shift reporting from one nurse to another in which both shift nurses made bedside rounds during each patient's report. In this way, the patient and family were included in the communication process and patient safety was improved (see Evidence-Based Practice box). Burns (2011) reported a pilot study on a medical unit in which the unit's nurse, hospitalist physician, and physician's nurse made patient rounds as a team to improve health team communication and increase the patient's perception of and satisfaction with his or her care.

Evidence-Based Practice QSEN

Does a Bedside Nurse Reporting Process Promote Patient Safety?

Maxson, P.M., Derby, K.M., Wrobleski, D.M., & Foss, D.M. (2012). Bedside nurse-to-nurse handoff promotes patient safety. *MEDSURG Nursing, 21,* 140-144.

Patient handoff at shift change in most hospitals has typically included a verbal or taped report, allowing nurses to communicate necessary patient information for continuity of care. Bedside handoff between shifts allows the patient and family to have an opportunity for input into the plan of care. This process helps meet the Joint Commission's National Patient Safety Goals and encourages patients to be an active part of their own care.

A convenience sample of 60 patients was used in a small study to examine the effects of bedside nurse-to-nurse handoff on a hospital unit. Thirty (30) patients were enrolled before the change in shift reporting, and 30 were enrolled after the change to bedside handoff. All nursing staff were invited to participate. Patients and staff completed surveys before and after the practice change. Fifteen nurses completed the pre- and post-survey indicating that they were more satisfied with the bedside handoff method when compared with the previous method of reporting. Patient satisfaction also increased as a result of the bedside nurse-to-nurse handoff process.

Level of Evidence: 4

This research was a small descriptive study that used a convenience sample.

Commentary: Implications for Practice and Research

Use of bedside nursing handoff increases patient and staff satisfaction and standardizes the shift report. This process also improves patient safety because both nurses see the patient during the change-of-shift period. Patients feel they are more active partners in their care and have the opportunity to ask questions and provide information during the handoff time. Additional studies using larger samples are needed to demonstrate the advantages and possible disadvantages of the shift change nurse-to-nurse handoff.

Delegation and Supervision.

As a nursing leader, you will delegate certain nursing tasks and activities to unlicensed assistive personnel (UAP), such as patient care technicians (PCTs) or patient care assistants (PCAs). **Delegation** is the process of transferring to a competent person the authority to perform a selected nursing task or activity in a selected patient care situation. This process

requires precise and accurate communication. *The nurse is always accountable for the task or activity that is delegated!*

An important process that is sometimes not consistently performed by busy medical-surgical nurses is supervision of the UAP to whom the task or activity has been delegated. **Supervision** is guidance or direction, evaluation, and follow-up by the nurse to ensure that the task or activity is performed appropriately. Examples of delegated tasks are turning and positioning, vital signs, and intake and output measurements.

Be sure to follow these five rights when you delegate and supervise a nursing task or activity to a UAP:

- *Right task:* The task is within the UAP's scope of practice and competence.
- *Right circumstances:* The patient care setting and resources are appropriate for the delegation.
- *Right person:* The UAP is competent to perform the delegated task or activity.
- *Right communication:* The nurse provides a clear and concise explanation of the task or activity, including limits and expectations.
- *Right supervision:* The nurse appropriately monitors, evaluates, intervenes, and provides feedback on the delegation process as needed.

Other activities or patient care responsibilities may be assigned by a registered nurse (RN) to another RN or to a licensed practical or vocational nurse (LPN/LVN). Each state designates which tasks may be safely delegated and assigned to nursing team members. Interventions that you can typically delegate or assign in any state are indicated throughout this text. Some of the *Clinical Judgment and NCLEX Examination Challenges* throughout this book will test your understanding of the delegation and supervision process.

Evidence-Based Practice

Evidence-based practice (EBP) is the integration of the best current evidence to make decisions about patient care. It considers the patient's preferences and values as well as one's own clinical expertise for the delivery of optimal health care (Melnyk & Fineout-Overholt, 2011; QSEN, 2011). Health care agencies follow the Core Measures developed by the Centers for Medicare & Medicaid (CMS) in collaboration with TJC to ensure that best practices are followed. Examples of Core Measures are highlighted throughout this textbook, such as those related to heart failure, stroke, and acute myocardial infarction.

The best source of evidence is research. However, available nursing research is limited and in some areas may not reflect the highest or best level of evidence. Some nursing research is designed as small, descriptive studies to explore new concepts. The findings of these studies cannot be generalized, but they provide a basis for future larger and better-controlled research.

As we did in the last edition of our text, this edition devotes a chapter to EBP (Chapter 5). In addition, *Evidence-Based Practice* boxes are found throughout the text to provide the most current research that serves as a basis for nursing practice. Each of these features presents a brief summary of the research, identifies the level (strength) of evidence using the scale in Chapter 5, and concludes with a "Commentary: Implications for Practice and Research" discussion to help you apply the findings of the study to your daily practice.

Quality Improvement

Ensuring patient and staff safety requires individual and systematic evaluation and change. To meet the **quality improvement** competency, nurses are expected to "use data to monitor the outcomes of care processes and use improvement methods to design and test changes to continuously improve the quality and safety of health care systems" (QSEN, 2011). The KSAs stress the importance of learning how to use specific QI tools, participating in root cause analyses, and impacting changes in care processes.

As a medical-surgical nurse, you will be expected to:

- Identify indicators to monitor quality and effectiveness of health care.
- Access and evaluate data to monitor the quality and effectiveness of health care.
- Recommend ways to improve care processes.
- Implement activities to improve care processes.

A new feature for this edition of our textbook is *Quality Improvement* boxes that summarize articles on QI projects and end with a "Commentary: Implications for Practice and Research" discussion. Additional information about the QI process can be found in nursing leadership and management resources.

Informatics

Informatics involves using information and technology to communicate, manage knowledge, mitigate error, and support decision making (QSEN, 2011; Yoder-Wise, 2011). The emphasis of the KSAs for informatics is

documentation, electronic data access, and data utilization.

Although most health care settings have information technology (IT) departments, nurses retrieve and use valuable information for patient care. The largest application of health care informatics is use of the electronic health record (EHR) (also called *electronic patient record [EPR]* or *electronic medical record [EMR]*) for documenting nursing and interdisciplinary care. Computers may be located at the nurses' work station or at the patient's bedside (point of care [POC]) (Fig. 1-2) or near the nurses' station. Handheld mobile devices are also popular because of their ease of use and portability.

FIG. 1-2 An electronic documentation system that is used at the bedside (point of care).

Another major purpose of informatics is for retrieval of data for the evidence-based practice process described in Chapter 5. The Internet provides ways to search for multiple sources of information very efficiently. However, all data sources must be evaluated for their credibility and reliability. Some health care agencies provide handheld

mobile devices, such as the iPod Touch™, to health care professionals for data access and team communication via text or e-mail.

New technologies for patient, staff, and resource (inventory) management are emerging in health care agencies to promote patient safety and improve efficiency. An example of these technologies is radio frequency identification (RFID). RFID allows any person or object to be tracked electronically. For example, patients wear electronic identification wristbands.

Nurses need to be involved in decisions about introducing new or advanced health care technologies into the health care agency. They should also be included in designing technology that improves the effectiveness and efficiency of health care while providing for patient and staff privacy.

Safety

As discussed earlier in this chapter, nurses play a key role in promoting safety and preventing errors, including "missed nursing care," the necessary care that should have been provided by one or more nurses. The nurse "minimizes risk of harm to patients and providers through both system effectiveness and individual performance" (QSEN, 2011). The KSAs for safety stress the importance of examining care processes (QI), integrating national patient resources, and using appropriate tools to reduce reliance on memory, such as checklists.

The National Council of State Boards of Nursing (NCSBN) published findings of an extensive study of nursing practice breakdowns (Benner et al., 2010). These results identified nine key areas where nursing practice should be improved, including:

- Medication administration
- Clearly communicating patient data and clinical assessments
- Attentiveness/surveillance of patients
- Clinical reasoning or judgment
- Prevention of errors or complications
- Intervention (carrying out nursing actions in an appropriate and timely manner)
- Interpretation of authorized provider orders
- Professional responsibility and patient advocacy
- Mandatory reporting

The research report also provided case examples and analyses to assist in the development of quality improvement processes.

Three types of *Nursing Safety Priority* boxes are found throughout this

text to emphasize the importance of safety when in daily practice. These features delineate safety based on patient need. For example, *Nursing Safety Priority: Critical Rescue* emphasizes the need for action for potential or actual life-threatening problems. *Nursing Safety Priority: Action Alert* boxes focus on the need for action but not necessarily for life-threatening situations. These safety alerts are essential, though, to ensure optimal patient outcomes. As the name implies, *Nursing Safety Priority: Drug Alert* boxes specify actions needed to ensure safety related to drug administration, monitoring, or related patient and family education.

Get Ready for the NCLEX® Examination!

Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Medical-surgical nursing is a specialty practice that requires a broad knowledge base and clinical skills to meet the needs of adult patients in a variety of settings.
- Medical-surgical nurses help meet human needs of adult patients, such as mobility and oxygenation, in a caring, respectful relationship.
- The Joint Commission requires that health care organizations create a culture of SAFETY by following the National Patient Safety Goals (NPSGs). **Safety** QSEN
- The Institute for Healthcare Improvement (IHI) interventions to save lives and prevent patient harm are listed in Table 1-1. **Safety** QSEN
- Rapid Response Teams (RRTs) save lives and decrease the risk for patient harm before a respiratory or cardiac arrest occurs. **Safety** QSEN
- Remember to always observe for slow and sudden changes in patient condition, especially changes in vital signs and mental status. **Safety** QSEN
- A vital role of the nurse is as an advocate to empower patients and their families to have control over their health care and function as safety partners.
- The six core competencies for health care professionals based on research by the Institute of Medicine (IOM) and Quality and Safety Education for Nurses (QSEN) are patient-centered care, teamwork and collaboration, evidence-based practice, quality improvement, informatics, and safety.
- Examples of the knowledge, skills, and attitudes needed for patient-centered care are found in Table 1-2. **Patient-Centered Care** QSEN
- Six essential ethical principles to consider when making clinical decisions are autonomy, beneficence, nonmaleficence, fidelity, veracity, and social justice.
- Nurses must show respect and compassion for the uniqueness of every individual to ensure patient-centered care.
- The lesbian, gay, bisexual, transgender, queer and/or questioning (LGBTQ) population typically does not trust health care professionals; use sensitive questioning about sexual orientation and gender identity as part of your interview with patients in this group (see Table 1-3). **Patient-Centered Care** QSEN

- Nurses collaborate by communicating patient's needs and preferences with members of the health care team to establish an individualized approach to care. **Teamwork and Collaboration** QSEN
- The SBAR procedure or similar established protocol is used for successful hand-off communication between caregivers and between health care agencies as part of the SHARE collaborative process (see Table 1-4).
- When delegating a nursing task to unlicensed assistive personnel (UAP), the nurse is always accountable to ensure that the task was performed safely and accurately. **Safety** QSEN
- evidence-based practice (EBP) is the integration of best current evidence to make decisions about patient care. It considers the patient's preferences and values, as well as one's own clinical expertise. **Evidence-Based Practice** QSEN
- Nurses are active participants in the systematic quality improvement process in their health care agency. **Quality Improvement** QSEN
- informatics and technology are used for patient documentation, electronic data access, and health care resource tracking. **Informatics** QSEN

CHAPTER 2

Common Health Problems of Older Adults

Donna D. Ignatavicius

PRIORITY CONCEPTS

- Nutrition
- Mobility
- Sensory Perception
- Cognition
- Elimination
- Tissue Integrity

Learning Outcomes

Safe and Effective Care Environment

1. Explain the need to collaborate with members of the health care team to help the patient/family achieve health goals.
2. Identify risk factors for falls and impaired driving ability, including problems with mobility, in older adults who live in the community or are hospitalized.
3. Explain evidence-based falls risk and prevention interventions for older adults in the hospital and community.
4. Describe best practices to promote patient safety when using restraints.

Health Promotion and Maintenance

5. Teach selected evidence-based lifestyle practices to promote healthy activities in older adults.
6. Conduct a medication assessment for potential risks for adverse drug events in older adults.

Psychosocial Integrity

7. Assess the older patient's risk for and signs of neglect and abuse.
8. Use valid and reliable assessment tools to document mental/behavioral health problems in the older adult.
9. Compare characteristics of common problems of cognition: depression, delirium, and dementia.
10. Develop a plan of care to assist the older adult to cope with relocation stress syndrome.

Physiological Integrity

11. Identify four subgroups of older adults.
12. Explain factors that contribute to nutrition-related problems among older adults in the community and inpatient facilities.
13. Describe the effects of drugs on the older adult.
14. Identify key interventions to prevent problems related to tissue integrity in older adults.

 http://evolve.elsevier.com/Iggy/

About 13% of the people in the United States are older than 65 years, but this number is expected to grow to 25% by 2050 (U.S. Census Bureau, 2013). In general, women live longer than men, although the exact reason for this difference is not known. Most patients on adult acute care and nursing home units are older than 65 years; many of these patients are discharged for home health services. Therefore nurses and other health care professionals need to know about the special needs of older adults to care for them in a variety of settings.

This chapter describes the major health issues, sometimes referred to as **geriatric syndromes,** associated with late adulthood in community and inpatient settings (Brown-O'Hara, 2013). The care of older adults (sometimes referred to as *elders*) with specific acute and chronic health problems is discussed as appropriate throughout this text. *Nursing Focus on the Older Adult* charts and *Considerations for Older Adults* boxes highlight the most important information. A brief review of major physiologic changes of aging are listed in the Assessment chapter of each body system unit. A number of gerontologic nursing textbooks and journals are available for additional information about older adult care.

Overview

Late adulthood can be divided into four subgroups:
- 65 to 74 years of age: the young old
- 75 to 84 years of age: the middle old
- 85 to 99 years of age: the old old
- 100 years of age or older: the elite old

The fastest growing subgroup is the old old, sometimes referred to as the advanced older adult population. Members of this subgroup are sometimes referred to as the "frail elderly," although a number of 85- to 95-year-olds are very healthy and do not meet the criteria for being frail. *Frailty* is a geriatric syndrome in which the older adult has unintentional weight loss, weakness and exhaustion, and slowed physical activity, including walking. Frail older adults are also at high risk for adverse outcomes (Brown-O'Hara, 2013; Rocchiccioli & Sanford, 2009).

The vast majority of older adults live in the community at home, in assisted-living facilities, or in retirement or independent living complexes. Of all older adults, only about 5% live in long-term care (LTC) facilities (mostly nursing homes) and another 10% to 15% are ill but are cared for at home. Older adults from any setting usually experience one or more hospitalizations in their lifetime. About half of all older adults will likely be admitted at some time during their life for short-term stays in a skilled unit of a LTC facility, usually for rehabilitation or complex medical-surgical follow-up care.

Other institutions also have an increase in aging adults. For example, men older than 50 years are the fastest growing group of prisoners today. Like the rest of the older population, older prisoners have multiple chronic health problems. However, these problems are often complicated by a history of alcohol and substance abuse and poor nutrition that require deliberate management strategies. Nurses who work in these settings must have expertise in care of older adults.

The number of homeless people older than 60 years is also growing. The inability to pay for housing and family/partner relationship problems are primary factors that contribute to this trend. Most homeless adults have one or more chronic health problems, including mental/behavioral health disorders (Gerber, 2013). A growing number are veterans of war.

Health Issues for Older Adults in Community-Based Settings

Health is a major concern for many older adults. Health status can affect the ability to perform ADLs and to participate in social roles. A failure to perform these activities may increase dependence on others and may have a negative effect on morale and life satisfaction. When older adults lose the ability to function independently, they often feel empty and worthless. Loss of autonomy is a painful event related to the physical and mental changes of aging.

Older adults may also experience a number of losses that can affect a sense of control over their lives, such as the death of a spouse and friends or the loss of social and work roles. Nurses need to support older adults' self-esteem and feelings of independence by encouraging them to maintain as much control as possible over their lives, to participate in decision making, and to perform as many tasks as possible.

Like younger and middle-aged adults, older adults need to practice health promotion and illness prevention to maintain or achieve a high level of wellness. Teach them the importance of promoting wellness and strategies for meeting this outcome (Chart 2-1).

Chart 2-1 Patient and Family Education: Preparing for Self-Management

Lifestyles and Practices to Promote Wellness

Health-Protecting Behaviors

- Have yearly influenza vaccinations (after October 1).
- Obtain a pneumococcal vaccination.
- Obtain a shingles vaccination.
- Have a tetanus immunization, and get a booster every 10 years.
- Wear seat belts when you are in an automobile.
- Use alcohol in moderation or not at all.
- Avoid smoking; if you do smoke, do not smoke in bed.
- Install and maintain working smoke detectors and/or sprinklers.
- Create a hazard-free environment to prevent falls; eliminate hazards such as scatter rugs and waxed floors.
- Use medications, herbs, and nutritional supplements according to your health care provider's prescription.
- Avoid over-the-counter medications unless your physician directs you to use them.

Health-Enhancing Behaviors

- Have a yearly physical examination; see your health care provider more often if health problems occur.
- Reduce dietary fat to not more than 30% of calories; saturated fat should provide less than 10% of your calories.
- Increase your daily dietary intake of complex carbohydrate– and fiber-containing food to five or more servings of fruits and vegetables and six or more servings of grain products.
- Increase calcium intake to between 1000 and 1500 mg daily; take a vitamin D supplement every day if not exposed daily to sunlight.
- Allow at least 10 to 15 minutes of sun exposure two or three times weekly for vitamin D intake; avoid prolonged sun exposure.
- Exercise regularly three to five times a week.
- Manage stress through coping mechanisms that have been successful in the past.
- Get together with people in different settings to socialize.
- Reminisce about your life through reflective discussions or journaling.

Common health issues and geriatric syndromes that often affect older adults in the community include:

- Decreased nutrition and hydration
- Decreased mobility
- Stress and loss
- Accidents
- Drug use and misuse
- Mental health/cognition problems (including substance abuse)
- Elder neglect and abuse

Decreased Nutrition and Hydration

The minimum nutritional requirements of the human body remain consistent from youth through old age, with a few exceptions. Older adults need an increased dietary intake of calcium, vitamin D, vitamin C, and vitamin A because aging changes disrupt the ability to store, use, and absorb these substances. For older adults who have a sedentary lifestyle and reduced metabolic rate, a reduction in total caloric intake to maintain an ideal body weight is needed. nutrition-related problems can occur in older adults when these needs are not met.

Many physical aging changes influence nutritional status or the ability to consume needed nutrients. Diminished senses of taste and smell often result in a loss of desire for food. Older adults have less ability to taste

sweet and salt than to taste bitter and sour. This aging change may result in an overuse of table sugar and salt to compensate. Some older adults consume numerous desserts and other sweet foods, which can cause them to become overweight or obese. Teach older adults how to balance their diets with healthy food selections. Remind them to substitute herbs and spices to season food and vary the textures of food substances to feel satisfied.

Tooth loss and poorly fitting dentures from inadequate dental care or calcium loss can also cause the older adult to avoid important nutritious foods. Unlike today, dental preventive programs were not readily available or stressed as being important when today's older adults were younger. Older people with dentition problems may eat soft, high-calorie foods such as ice cream and mashed potatoes, which lack roughage and fiber. Unless the person carefully chooses more nutritious soft foods, vitamin deficiencies, constipation, and other problems can result. The extensive use of prescribed and over-the-counter (OTC) drugs, including herbal supplements, may decrease appetite, affect food tolerances and food absorption, and cause constipation.

Constipation can reduce quality of life for older adults and cause pain, depression, anxiety, and decreased social activities (Toner & Claros, 2012). In some cases, it leads to a small or large bowel obstruction, potentially life-threatening events. Constipation is common among older adults and can be caused by multiple risk factors, including foods, drugs, and diseases.

Nursing Safety Priority QSEN

Action Alert

Teach older adults to increase fiber and fluid intake, exercise regularly, and avoid risk factors that contribute to constipation. Older adults should consume 35 to 50 g of fiber each day and drink at least 2 L a day unless medically contraindicated. Some people may also add a “colon cocktail” of equal portions of prune juice, applesauce, and psyllium (e.g., Metamucil) to their daily diet. Remind older adults to take 1 to 2 tablespoons of the mixture daily. If these measures do not prevent constipation, teach them to take a stool softener. For opioid-induced constipation (OIC), methylnaltrexone (Relistor) may be prescribed. This drug is given subcutaneously once every other day as needed and tends to have quick results (Toner & Claros, 2012).

Reduced income, chronic disease, fatigue, and decreased ability to perform ADLs are other factors that contribute to inadequate nutrition and constipation among older adults. "Fast food" is often inexpensive and requires no preparation. However, it is usually high in fat, carbohydrates, and calories but lacking in healthy nutrients. Older adults can become overweight or obese when they consume a diet high in fast food.

Other older adults may reduce their intake of food to near-starvation levels, even with the availability of programs such as food stamps (Supplemental Nutritional Assistance Program [SNAP]), community food banks, and Meals on Wheels. Many senior centers and homeless shelters offer meals, as well as group social activities. The lack of transportation, the necessity of traveling to obtain such services, and the inability to carry large or heavy groceries prevent some older adults from taking advantage of food programs. Others are too proud to accept free services.

Inadequate nutrition may also be related to loneliness. Older adults may respond to loneliness, depression, and boredom by not eating, which can lead to weight loss. Many who live alone lose the incentive to prepare or eat balanced diets, especially if they do not "feel well." Men who live at home alone are especially at risk for not eating enough calories to maintain their weight.

Nursing Safety Priority QSEN

Action Alert

Perform nutritional screening for older adults in the community who are at risk for inadequate nutrition—either weight loss or obesity. Ask the person about unintentional weight loss or gain, eating habits, appetite, prescribed and over-the-counter drugs, and current health problems. Determine contributing factors for older adults who have or are at risk for poor nutrition, such as transportation issues or loneliness. Based on these data, develop and implement a plan of care in collaboration with the registered dietitian, pharmacist, and/or case manager to manage these problems. Chapter 60 describes nutritional assessment and management of nutrition problems in detail.

Some older adults are at risk for **geriatric failure to thrive (GFTT)**—a complex syndrome including under-nutrition, impaired physical functioning, depression, and cognitive impairment (Rocchiccioli & Sanford, 2009). However, drug therapy, chronic diseases, major losses,

and poor socioeconomic status can cause these same health problems. Be sure to consider these factors when screening for GFTT. For those at risk for or who have GFTT, collaborate with the older adult and family to plan referral to his or her primary care provider for extensive evaluation. Early supportive intervention can help prevent advanced levels of deterioration.

People older than 65 years are also at risk for dehydration because they have less body water content than younger adults. In severe cases, they require emergency department visits or hospital stays.

Nursing Safety Priority QSEN

Action Alert

Older adults sometimes limit their fluid intake, especially in the evening, because of problems associated with mobility, prescribed diuretics, and urinary incontinence. *Teach older adults that fluid restrictions make them susceptible to dehydration and electrolyte imbalances (especially sodium and potassium) that can cause serious illness or death.*

Incontinence may actually increase because the urine becomes more concentrated and irritating to the bladder and urinary sphincter. Teach older adults the importance of drinking 2 liters of water a day plus other fluids as desired. Remind them to avoid excessive caffeine and alcohol because they can cause dehydration. Chapter 11 discusses fluid and electrolyte imbalances in detail.

Decreased Mobility

Exercise and activity are important for older adults as a means of promoting and maintaining mobility and overall health (Fig. 2-1). Physical activity can help keep the body in shape and maintain an optimal level of functioning. Regular exercise has many benefits for older adults in community-based settings. The advantages of maintaining appropriate levels of physical activity include:

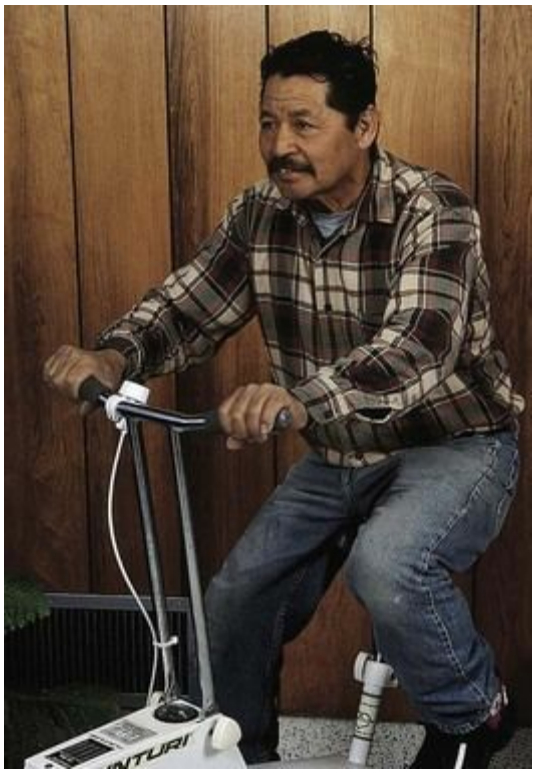

FIG. 2-1 Exercise is important to older adults for health promotion and maintenance.

- Decreased risk for falls
- Increased muscle strength and balance
- Increased mobility
- Increased sleep
- Reduced or maintained weight
- Improved sense of well-being and self-esteem
- Decreased depression symptoms
- Improved longevity
- Reduced risks for diabetes, coronary artery disease, and dementia

Assess older adults in any setting regarding their history of exercise and any health concerns they may have. For independent older adults, remind them to check with their health care provider to implement a supervised plan for regular physical activity. Teach all older adults about the value of physical activity.

For people who are homebound, focus on functional fitness, such as performing ADLs. For those who are not homebound, teach the importance of other types of exercise. Resistance exercise, for example, maintains muscle mass. Aerobic exercise, like walking, improves strength and endurance. One of the best exercises is walking at least 30 minutes, 3 to 5 times a week. During the winter, indoor shopping centers and other public places can be used. In addition, many senior centers and community centers offer exercise programs for older adults. For

those who have limited mobility, chair exercises are provided.

Swimming is also recommended but does not offer the weight-bearing advantage of walking. Weight bearing helps build bone, an especially important advantage for older women to prevent osteoporosis (see Chapter 50). Teach older adults who have been sedentary to start their exercise programs slowly and gradually increase the frequency and duration of activity over time, under the direction of their health care provider.

NCLEX Examination Challenge

Health Promotion and Maintenance

Which statement by an older adult regarding diet and exercise indicates a need for further teaching by the nurse?

A "I need to include more fiber in my diet like whole grains, raw vegetables, and fruits."

B "I just joined our local fitness center and plan to go there three times a week"

C "I will stop drinking fluids after 4 pm to prevent getting up during the night."

D "I drink prune juice every day and that keeps my bowels very regular."

Stress and Loss

Stress can speed up the aging process over time, or it can lead to diseases that increase the rate of degeneration. It can also impair the reserve capacity of older adults and lessen their ability to respond and adapt to changes in their environment.

Although no period of the life cycle is free from stress, the later years can be a time of especially high risk. Frequent sources of stress and anxiety for the older population include:

- Rapid environmental changes that require immediate reaction
- Changes in lifestyle resulting from retirement or physical incapacity
- Acute or chronic illness
- Loss of significant others
- Financial hardships
- Relocation

How people react to these stresses depends on their personal coping skills and support networks. For instance, losses leave many older adults without friends for support and help. As a result, many must rely solely on their personal resources to maintain their mental health/behavioral

health. A combination of poor physical health and social problems leaves older adults susceptible to stress overload, which can result in illness and premature death.

The ways in which people adapt to old age depend largely on the personality traits and coping strategies that have characterized them throughout their lives. Establishing and maintaining relationships with others throughout life are especially important to the older person's happiness. Even more important than having friends is the nature of the friendships. People who have close, intimate, stable relationships with others in whom they confide are more likely to cope with crisis.

Some older adults have chosen to return to work at least on a part-time basis to increase their income and socialize with other people. If a person retired between the ages of 55 and 65 years and lives into his or her 80s, funds can deplete; additional income is needed to meet basic needs, including money for prescription drugs. Although U.S. government Medicare Part A pays for inpatient hospital care, older adults pay for Medicare Part B to reimburse for 80% of most ambulatory care services, Medicare Part D for prescription drugs, and often a private Medi-Gap insurance (e.g., United or Blue Cross/Blue Shield) to cover the costs not paid for by Medicare. The premiums for these insurances are very expensive and may still require that older adults pay out-of-pocket copayments for health care services and prescription drugs.

Fortunately, most older adults are relatively healthy and live in and own their own homes. Physical and/or mental health problems may force some to relocate to a retirement center or an assisted-living facility, although these facilities can be very expensive. Others move in with family members or to apartment buildings funded and designated for seniors. Older adults usually have more difficulty adjusting to major change when compared with younger and middle-aged adults. Being admitted to a hospital or nursing home is a particularly traumatic experience. Older adults often suffer from relocation stress syndrome, also known as *relocation trauma.* **Relocation stress syndrome** is the physical and emotional distress that occurs after the person moves from one setting to another. Examples of physiologic behaviors are sleep disturbance and increased physical symptoms, such as GI distress. Examples of emotional manifestations are withdrawal, anxiety, anger, and depression. Chart 2-2 lists nursing interventions that may help decrease the effects of relocation.

Chart 2-2 Best Practice for Patient Safety & Quality

Care QSEN

Minimizing the Effects of Relocation Stress in Older Adults

- Provide opportunities for the patient to assist in decision making.
- Carefully explain all procedures and routines to the patient before they occur.
- Ask the family or significant other to provide familiar or special keepsakes to keep at the patient's bedside (e.g., family picture, favorite hairbrush).
- Reorient the patient frequently to his or her location.
- Ask the patient about his or her expectations during hospitalization or assisted-living or nursing home stay.
- Encourage the patient's family and friends to visit often.
- Establish a trusting relationship with the patient as early as possible.
- Assess the patient's usual lifestyle and daily activities, including food likes and dislikes and preferred time for bathing.
- Avoid unnecessary room changes.
- If possible, have a family member, significant other, staff member, or volunteer accompany the patient when leaving the unit for special procedures or therapies.

Family members and facility staff need to be aware that older adults need personal space in their new surroundings. Older adults need to participate in deciding how the space will be arranged and what they can keep in their new home to help offset potential feelings of powerlessness. Suggest that the patient or family bring in personal items, such as pictures of relatives and friends, favorite clothing, and valued knickknacks, to assist in making the new setting seem more familiar and comfortable. This same intervention can be carried out in a hospital setting.

Accidents

Accidents are very common among older adults; falls are the most common. Motor vehicle crashes increase as well because of physiologic changes of aging or chronic diseases like Alzheimer's or peripheral neuropathy.

Fall Prevention

Most accidents occur at home. Teach older adults about the need to be aware of safety precautions to prevent accidents, such as falls.

Incapacitating accidents are a primary cause of decreased mobility and chronic pain in old age. Some people develop **fallophobia** (fear of falling) and avoid leaving their homes.

Home modifications may help prevent falls. Collaborate with family and significant others when recommending useful changes to prevent older adult injury. Safeguards such as handrails, slip-proof pads for rugs, and adequate lighting are essential in the home. Avoiding scatter rugs, slippery floors, and clutter is also important to prevent falls. Installing grab bars and using non-slip bathmats can help prevent falls in the bathroom. Raised toilet seats are also important. Remind older adults to avoid going out on days when steps are wet or icy and to ask for help when ambulating. To minimize sensory overload, advise the older adult to concentrate on one activity at a time.

Changes in sensory perception and mobility can create challenges for older adults in any environment. For example, **presbyopia** (farsightedness that worsens with aging) may make walking more difficult; the person is less aware of the location of each step. In addition, the older adult may have disorders that affect visual acuity, such as macular degeneration, cataracts, glaucoma, or diabetic retinopathy. Teach the person to look down at where he or she is walking and have frequent eye examinations to update glasses or contact lenses to improve vision. Drug therapy or surgery may be needed to correct glaucoma or cataracts.

A reduced sense of touch decreases the awareness of body orientation (e.g., whether the foot is squarely on the step). The decreased reaction time that commonly results from age-related changes in the neurologic system may also impair the ability to recognize or move from a dangerous setting. Chronic diseases such as peripheral neuropathy and arthritis can affect mobility and sensory perception in the older adult as well. If needed, encourage the use of visual, hearing, or ambulatory assistive devices. High costs and a fear of appearing old sometimes prevent older adults from obtaining or using hearing aids, eyeglasses, walkers, or canes.

Once an older person has been identified as being at high risk for falls, choose interventions that help prevent falls and possible serious injury. For example, for those in the community, tai chi exercise is very helpful to improve balance and functional mobility, as well as to decrease the fear of falling, especially among older women (Wooten, 2010).

Driving Safety

Motor vehicle crashes are the most common cause of injury-related death in the

young-old population—those between 65 and 74 years of age. Increased national concerns about this growing problem have prompted many states to require more frequent testing for older drivers. As one ages, reaction time and the ability to multitask decrease. Sleep disturbances, especially insomnia, are also common in older adults but are *not* part of normal aging. Some crashes occur because the person falls asleep while driving.

The older the person, the more likely he or she will have chronic diseases and the drugs needed to manage them. These health problems and treatments can contribute to motor vehicle crashes. For instance, drugs used for hypertension can cause orthostatic hypotension (low blood pressure when changing body position from a supine to sitting or standing position).

Physicians and other health care professionals play a major role in identifying driver safety issues. Yet, many are reluctant to intervene because older patients feel they will lose their independence if they cannot drive. They may also be angry and resistant to the idea of giving up perhaps their only means of transportation. As an alternative, health care professionals can recommend driving refresher courses and suggest that high-risk driving conditions, like wet roads, be avoided. Newer vehicles have some safety features to help older adults, such as large-print digital readouts for speed and other data. Chart 2-3 lists additional ways to improve older adult driver safety.

Chart 2-3 Best Practice for Patient Safety & Quality Care QSEN

Recommendations for Improving Older Adult Driver Safety

- Discuss driving ability with the patient to assess his or her perception.
- Assess physical and mental deficits that could affect driving ability.
- Consult with appropriate health care providers to treat health problems that could interfere with driving.
- Suggest community-based transportation options, if available, instead of driving.
- Discuss driving concerns with patients and their families.
- Remind the patient to wear glasses and hearing aids, if prescribed.
- Encourage driver refresher classes, often offered by AARP (formerly the American Association of Retired Persons).
- Consult a certified driving specialist for an on-road driving assessment.
- Encourage avoiding high-risk driving locations or conditions, such as

busy urban interstates and wet or icy weather conditions.
- Report unsafe drivers to the state department of motor vehicles if they continue to drive.

Drug Use and Misuse

Drug therapy for the older population is another major health issue. Because of the multiple chronic and acute health problems that occur in this age-group, drugs for older adults account for about one third of all prescription drug costs. The term **polymedicine** has been used to describe the use of many drugs to treat multiple health problems for older adults. **Polypharmacy** is the use of multiple drugs, duplicative drug therapy, high-dosage medications, and drugs prescribed for too long a period of time (Planton & Edlund, 2010). Another term, hyperpharmacy, has also been used to describe the excessive use of drugs to treat disease (Messina & Escallier, 2011).

Older adults commonly take multiple nonprescription (OTC) drugs, such as analgesics, antacids, cold and cough preparations, laxatives, and herbal/nutritional supplements, often without consulting a health care provider. Therefore this population is at high risk for adverse drug events (ADEs) directly related to the number of drugs taken and the frequency with which they are taken. Drug-drug, food-drug, drug-herb, and drug-disease interactions are common ADEs that often lead to hospital admission.

Effects of Drugs on Older Adults

Older adults often do not tolerate the standard dosage of drugs traditionally prescribed for younger adults. The physiologic changes related to aging make drug therapy more complex and challenging. These changes affect the absorption, distribution, metabolism, and excretion of drugs from the body. Even common antibiotics can lead to temporary memory loss or acute confusion. More commonly, antibiotic therapy can cause a *Clostridium difficile* infection, as discussed in Chapter 23.

Age-related changes that can potentially affect drug *absorption* from an oral route include an increase in gastric pH, a decrease in gastric blood flow, and a decrease in GI motility. Despite these changes, older adults do not have major absorption difficulties because of age-related changes alone.

Age-related changes that affect drug *distribution* include smaller amounts of total body water, an increased ratio of adipose tissue to lean

body mass, a decreased albumin level, and a decreased cardiac output. Increased adipose tissue in proportion to lean body mass can cause increased storage of lipid-soluble drugs. This leads to a decreased concentration of the drug in plasma but an increased concentration in tissue.

Drug *metabolism* often occurs in the liver. Age-related changes affecting metabolism include a decrease in liver size, a decrease in liver blood flow, and a decrease in serum liver enzyme activity. These changes can result in increased plasma concentrations of a drug (Lilley, Collins, & Snyder, 2014). Monitor liver function studies, and teach older adults to have regular physical examinations.

Changes in the kidneys can also result in high plasma concentrations of drugs. The *excretion* of drugs usually involves the renal system. Age-related changes of the renal system include decreased renal blood flow and reduced glomerular filtration rate. These changes result in a decreased creatinine clearance and thus a slower excretion time for medications. Consequently, serum drug levels can become toxic and the patient can become extremely ill or die. *Monitor renal studies, especially serum creatinine and creatinine clearance, when giving drugs to older adults!*

A creatinine clearance test measures the glomerular filtration rate of the kidneys. A commonly used formula for calculating creatinine clearance for men rather than directly measuring it is:

$$\frac{(140 - \text{Age in years}) \times \text{Lean body weight in kg}}{\text{Serum creatinine in mg/dL} \times 72}$$

For women, use this formula and multiply the answer by 0.85. A normal creatinine clearance for men is 107 to 139 mL/min and for women is 87 to 107 mL/min. Values decrease by 6.5 mL/min for each decade of life after 20 years of age (Pagana & Pagana, 2014).

When chronic disease is added to the physiologic changes of aging, drug reactions have a more dramatic effect and take longer to correct. Often a lower dose of a drug is necessary to prevent ADEs. The policy of "start low, go slow" is essential when health care providers prescribe drugs for older adults. The physiologic changes of aging are highly individual. Alterations in drug therapy should always be individualized according to the actual physiologic changes present and the occurrence and severity of chronic disease. Common ADEs are listed in Table 2-1.

TABLE 2-1

Common Adverse Drug Events (ADEs) in Older Adults

• Edema • Severe nausea and vomiting • Anorexia • Dehydration • Dysrhythmias • Fatigue • Weakness	• Dizziness • Syncope • Urinary retention • Diarrhea • Constipation/impaction • Hypotension • Acute confusion

Data from Berryman, S.N., Jennings, J., Ragsdale, S., Lofton, T., Huff, D.C., & Rooker, J.S. (2012). Beers criteria for potentially inappropriate medication use in older adults. *MEDSURG Nursing, 21,* 129-133.

Self-Administration of Drugs

Most people older than 65 years take their own medications. Because the risk for drug toxicity is considerably increased in the older population, assist patients in assuming this task responsibly. Teach patients and their caregivers, providing clear and concise directions and developing ways to assist them in overcoming difficulties with self-administration.

Older adults may make errors in self-administration or do not adhere to the drug regimen for several reasons. First, they may simply forget. In the rush of daily activities, they may not take their drugs or may take them too often because they cannot remember when or whether they have taken the medications. It is often helpful if they associate pill taking with daily events (e.g., meals) or keep a simple chart or calendar. Pill boxes are available for a daily, weekly, or monthly supply of medicine that can be placed in small compartments (Fig. 2-2). Egg cartons can be very cost-effective pill boxes. Large print on the drug label assists patients who have poor vision. Writing the drug regimen on the top of the bottle with large letters and numbers is helpful for some older adults. Colored labels or dots can also be applied. Easy-open bottle caps help older adults with limited hand mobility or strength.

FIG. 2-2 A medication system for safe self-administration.

A second reason for drug errors is poor communication with health care professionals. These problems result from poor explanations that are not understood because of educational limitations, language barriers, or difficulty with hearing and vision. Health care professionals often presume that their patients have learned the information if they have taught them about the drugs. Assist older adults in planning their drug therapy schedules as needed.

Complementary and Alternative Therapies.

A third reason for errors is the varying ways that older adults take their medications. Many people older than 65 years use a multitude of complementary and alternative therapies. Some add to their drug regimen by taking OTC drugs, which can interact with prescription drugs and cause serious problems (Vitale, 2012). For example, a patient receiving warfarin (Coumadin, Warfilone) for anticoagulation may take ibuprofen (Motrin) regularly for arthritis or garlic for hypertension. Because ibuprofen and garlic can inhibit clotting, this combination can cause serious bleeding. When obtaining a drug history, ask patients about all OTC drugs, including herbal and food supplements.

Some other older adults avoid taking their prescribed drugs. The fear of dependency or the cost of the drugs may cause many to discontinue their drug therapy too soon or not begin taking the drug. In addition, the actions or side effects of some drugs may not be desirable. For example, diuretics may cause incontinence when patients cannot get to the bathroom quickly enough. Others may think that two pills are twice as effective and, therefore, better than taking just one. Some older adults take drugs that are leftover from a previous illness or one that is borrowed from someone else. Teach patients to take their medications

exactly as prescribed by their health care providers.

Medication Assessment and Health Teaching

The *Healthy People 2020* initiative recommends that older adults be interviewed regarding their medication use and include these questions:

- Do you take five or more prescription medications?
- Do you take herbs, vitamins, or other dietary supplements, or OTC medications?
- Do you have your prescriptions filled at more than one pharmacy?
- Is more than one health care practitioner prescribing your medications?
- Do you take your medications more than once a day?
- Do you have trouble opening your medication bottles?
- Do you have poor eyesight or hearing?
- Do you live alone?
- Do you have a hard time remembering to take your medications?

The Beers Criteria for Potentially Inappropriate Medication Use in Older Adults assessment tool, simply known as the *Beers criteria*, is also very useful in screening for medication-related risks in older adults who have chronic health problems (Berryman et al., 2012). The tool lists multiple medications and related concerns. Examples of these "at-risk" drugs are listed in Table 2-2.

TABLE 2-2

Examples of Beers Criteria for Potentially Inappropriate Medication Use in Older Adults

• meperidine (Demerol) • cyclobenzaprine (Flexeril) • digoxin (Lanoxin) (Should not exceed 0.125 mg daily except for atrial fibrillation) • ticlopidine (Ticlid) • fluoxetine (Prozac) • amitriptyline (Elavil) • diazepam (Valium)	• promethazine (Phenergan) • ketorolac (Toradol) • short-acting nifedipine (e.g., Procardia) • ferrous sulfate (Iron) (Should not exceed 325 mg daily) • chlorpropamide (Diabinese) • diphenhydramine (Benadryl)

Data from Berryman, S.N., Jennings, J., Ragsdale, S., Lofton, T., Huff, D.C., & Rooker, J.S. (2012). Beers criteria for potentially inappropriate medication use in older adults. *MEDSURG Nursing, 21,* 129-133.

To reduce drug-related risks in older adults, perform a medication assessment every 6 months or more often if an acute illness or exacerbation of a chronic disease occurs. Be sure to:

- Obtain a list of all medications taken on a regular and as-needed basis; include OTC and prescribed drugs, herbs, and nutritional supplements. If a list is not available, ask the older adult or family to

gather all ointments, pills, lotions, eyedrops, inhalers, injectable solutions, vitamins, minerals, herbs, and other OTC medications and place into a bag for review.
- Highlight all medications that are part of the Beers criteria; highlight any medication for which the indication for its use is not clear, inappropriate, or could be discontinued (e.g., duplicative drug).
- Collaborate with the older adult, family, pharmacist, and primary health care provider if appropriate to determine the need for medication changes. Suggest once-a-day dosing if possible.
- Give older adults verbal and written information (at the appropriate reading level) regarding any change or new medication prescribed.
- Promote adherence to the drug therapy regimen exactly as prescribed; remind older adults to check with their primary care provider if they want to change their regimen or add an OTC medication or natural product (nutritional or herbal supplement, or probiotic).
- Encourage lifestyle changes and other nonpharmacologic interventions to help manage or prevent health problems.
- Remind older adults not to share or borrow medications.

NCLEX Examination Challenge

Physiological Integrity

A home care nurse conducts an assessment of an older woman's medications and herbal/nutritional supplements. Which supplement is most likely to cause an interaction with prescribed medications?
A Calcium
B Vitamin C
C St. John's wort
D Vitamin B complex

Mental Health/Behavioral Health Problems

Older adults are usually mentally sound and competent. Some changes in cognition have been identified as age related and are linked to specific cognitive functions rather than intellectual capacity. These changes include a decreased reaction time to stimuli and an impaired memory for recent events. *However, severe cognitive impairment, depression, hallucinations, and delusions are not common.*

Two forms of competence exist: legal competence and clinical competence. A person is **legally competent** if he or she is:
- 18 years of age or older

- Pregnant or a married minor
- A legally emancipated (free) minor who is self-supporting
- Not declared incompetent by a court of law

If a court determines that an older adult is not legally competent, a **guardian** is appointed to make health care decisions. Guardians may be family members or a person who is not related to the patient. When no one is available, a guardian may be appointed from a local Area Agency on Aging, an organization with comprehensive services and resources for older adults.

A person is **clinically competent** if he or she is legally competent and can make clinical decisions. Decisional capacity is determined by a person's ability to identify problems, recognize options, make decisions, and provide the rationale supporting the decisions. Selected behavioral/mental illnesses often affect both legal and clinical competence.

Nurses are in a unique position to teach older adults about ways to promote cognitive health. In a recent systematic literature review, Williams and Kemper (2010) found that collaborative interventions targeting cognitive training (e.g., learning a new skill), physical activity, social engagement, and nutrition were the most helpful in optimizing cognitive aging.

As older adults age, they are at increasing risk for severe mental health problems—depression, delirium, and dementia, often referred to as the *3Ds.* Many older veterans of the Korean and Vietnam wars also suffer from chronic pain, depression, post-traumatic stress disorder (PTSD), and severe anxiety. Substance abuse, especially alcoholism, is common among veterans and older adults in general. Alcoholism can contribute to cognitive decline and may be used as a coping mechanism for loss. Several mental health problems are discussed briefly here; more comprehensive discussions can be found in mental health/behavioral health textbooks.

Depression

Depression is the most common mental health/behavioral health problem among older adults in the community, affecting 15 of every 100 older adults (National Institute of Mental Health [NIMH], 2011). It increases in incidence when older adults are admitted to the hospital or nursing home. **Depression** is broadly defined as a mood disorder that can have cognitive, affective, and physical manifestations. It can be primary or secondary and can range from mild to severe, or major. As a *primary*

problem, depression is thought to result from a lack of the neurotransmitters *norepinephrine* and *serotonin* in the brain. *Secondary* depression, sometimes called *situational* depression, can result when there is a sudden change in the person's life, such as an illness or loss. Common illnesses that can cause secondary depression include stroke, arthritis, and cardiac disease. It is often underdiagnosed by physicians and is therefore undertreated.

Families and nurses are in the best position to suspect depression in an older adult. Several screening tools are available to help determine if the patient has clinical depression. The **Geriatric Depression Scale—Short Form (GDS-SF)** is a valid and reliable screening tool and is available in multiple languages. The patient selects "yes" or "no" to 15 questions, or a nurse or other health care professional can ask the questions to the patient. A score of 10 or greater is consistent with a possible diagnosis of clinical depression (Fig. 2-3). These patients are then evaluated more thoroughly by the health care provider for treatment. Without diagnosis and treatment, depression can result in:

Geriatric Depression Scale—Short Form

Choose the best answer for how you have felt over the past week:

1. Are you basically satisfied with your life? YES / **NO**
2. Have you dropped many of your activities and interests? **YES** / NO
3. Do you feel that your life is empty? **YES** / NO
4. Do you often get bored? **YES** / NO
5. Are you in good spirits most of the time? YES / **NO**
6. Are you afraid that something bad is going to happen to you? **YES** / NO
7. Do you feel happy most of the time? YES / **NO**
8. Do you often feel helpless? **YES** / NO
9. Do you prefer to stay at home, rather than going out and doing new things? **YES** / NO
10. Do you feel you have more problems with memory than most? **YES** / NO
11. Do you think it is wonderful to be alive now? YES / **NO**
12. Do you feel pretty worthless the way you are now? **YES** / NO
13. Do you feel full of energy? YES / **NO**
14. Do you feel that your situation is hopeless? **YES** / NO
15. Do you think that most people are better off than you are? **YES** / NO

Answers in bold indicate depression. Score 1 point for each bolded answer.

A score > 5 points is suggestive of depression.
A score ≥ 10 points is almost always indicative of depression.
A score > 5 points should warrant a follow-up comprehensive assessment.

FIG. 2-3 The Geriatric Depression Scale—Short Form.

- Worsening of medical conditions
- Risk for physical illness
- Alcoholism and drug abuse
- Increased pain and disability
- Delayed recovery from illness
- Suicide

Older adults with depression may have early morning insomnia, excessive daytime sleeping, poor appetite, a lack of energy, and an unwillingness to participate in social and recreational activities. The primary treatment for depression usually includes drug therapy and psychotherapy. Selective serotonin reuptake inhibitors (SSRIs) are the

first choice for drug therapy but take 2 to 3 weeks to work. They act by increasing the amount of serotonin and norepinephrine at nerve synapses in the brain.

Nursing Safety Priority QSEN

Drug Alert

Tricyclic antidepressants should not be used because they have anticholinergic properties that can cause acute confusion, severe constipation, and urinary incontinence. For older adults who may be prescribed this group of drugs, question the health care provider and request an SSRI or other treatment.

Recent research has demonstrated that reminiscence or reflective therapies also help older adults overcome feelings of depression and despair. A study by McCaffrey et al. (2010) determined that frequent walking through a large garden and reflective journaling decreased depression as measured by the Geriatric Depression Scale (see the Evidence-Based Practice box). More information about depression, including strategies for preventing depression, is available in mental health/behavioral health nursing textbooks.

Evidence-Based Practice QSEN

Do Reflective Activities Improve Symptoms of Depression and Despair in Older Adults?

McCaffrey, R., Hanson, C., & McCaffrey, W. (2010). Garden walking for depression: A research report. *Holistic Nursing Practice, 24*(5), 252-259.

Depression affects 15 of every 100 older adults at some point in their later years, which leads to physical, mental, and social dysfunction. In this mixed-method design study, the researchers created a walking guide and reflective journal entitled *Stroll for Well-Being: Garden Walks at the Morikami Museum* (Stroll) to be used by 40 community-dwelling older adults at their convenience for 12 visits over a period of 6 months. The participants were either self-diagnosed or were being treated by a health care provider for depression. The sample was 62.5% white and 12.5% African American. The remaining group was a mix of ethnic backgrounds. Most participants were educated at a high school level or higher.

The *Stroll* was structured so that they would spend about 2 hours each

at 6 stops in the Morikami Museum and Japanese Gardens. At each stop, the participants made entries into a reflective journal to share their lived experience.

Using the short-form Geriatric Depression Scale (GDS) as a quantitative measure before and after the intervention, the researchers found a statistically significant change in depression scores, with lower scores indicating less depression. For the qualitative aspect of the study, a 4-step thematic analysis of the journal entries included:

- Being forced to spend time away from pressures of the day
- A sense of the beauty of nature
- Using the gardens to provide insight and depth to the experience
- Gratitude for the beauty of nature and the "life I have led"

Level of Evidence: 4

This study is a small descriptive study but includes both quantitative and qualitative methods to study the effect of the intervention for a selected convenience sample.

Commentary: Implications for Practice and Research

Depression is usually treated with psychotherapy and drugs, which often cause adverse drug effects in older adults. When nurses care for older adults with depression, they need to recommend alternative and complementary interventions that may help relieve depressive symptoms and possibly decrease dependence on drug therapy. Using the findings of this study, it is clear that enjoying the beauty of nature and reflecting on life experiences can benefit patients who have been diagnosed with or suspect that they have depression.

Dementia

Dementia is a broad term used for a syndrome that involves a slowly progressive cognitive decline, sometimes referred to as *chronic confusion.* This syndrome represents a global impairment of intellectual function and is generally chronic and progressive. There are many types of dementia, the most common being Alzheimer's disease. Multi-infarct dementia, the second most common dementia, results from a vascular disorder. Chapter 42 discusses dementias in detail, with a focus on Alzheimer's disease.

Delirium

Whereas dementia is a chronic, progressive disorder, **delirium** is an *acute*

state of confusion. Delirium also differs from dementia in that it is often short-term and reversible within a month or less. It is often seen among older adults in a setting with which they are unfamiliar. It occurs in up to 50% of older adults who are hospitalized (Sendelbach & Guthrie, 2009). In addition to cognitive changes, some patients have physical and emotional manifestations. The types of delirium are *hyperactive, hypoactive, mixed,* and *unclassifiable. Hyperactive* patients may try to climb out of bed or become agitated, restless, and aggressive. *Hypoactive* patients are quiet, apathetic, and withdrawn. *Mixed* delirium patients have a combination of hyperactive and hypoactive manifestations. Others cannot be classified in one of these categories.

Some of the multiple factors that can cause delirium are:

- Drug therapy (especially anticholinergic and psychoactive drugs)
- Electrolyte imbalances
- Infections, especially urinary tract, pneumonia, and sepsis
- Fecal impaction or severe diarrhea
- Surgery
- Metabolic problems, such as hypoglycemia
- Neurologic disorders, such as tumors
- Circulatory, renal, and pulmonary disorders
- Nutritional deficiencies
- Hypoxemia (decreased arterial oxygen level)
- Relocation
- Major loss

Nursing Safety Priority QSEN

Action Alert

Acutely confused patients who are discharged from the hospital are at an increased risk for functional decline, falls, and incontinence at home. Therefore carefully assess older patients in any setting for acute confusion so that it can be managed.

A number of tools have been developed for point-of-care screening for delirium, including the Confusion Assessment Method (CAM), Delirium Index (DI), NEECHAM Confusion Scale, and Mini-Cog (Sendelbach & Guthrie, 2009). The CAM consists of nine open-ended questions and a diagnostic algorithm for determining delirium (Table 2-3). This screening tool is easily adaptable for computerized point-of-care charting (Swan et al., 2011).

TABLE 2-3

The Confusion Assessment Method (CAM)

1. Acute onset and fluctuating course (e.g., Is there evidence of an acute change in mental status from the patient's baseline?) 2. Inattention (e.g., Does the patient have difficulty focusing attention or keeping track of what is being said?) 3. Disorganized thinking (e.g., Is the patient's thinking and conversation disorganized or incoherent?) 4. Altered level of consciousness (e.g., Is the patient lethargic, hyperalert, or difficult to arouse?)
The diagnosis of delirium by the CAM is the presence of features 1 and 2 *and* either 3 *or* 4.

Data from Sendelbach, S., & Guthrie, P.F. (2009). Evidence-based guideline—Acute confusion/delirium: Identification, assessment, treatment, and prevention. *Journal of Gerontological Nursing, 35*(11), 11-17.

Collaborate with the health care team to remove or treat risk or causative factors for acute confusion. For example, if the patient has a low oxygen saturation level, provide supplemental oxygen therapy to increase oxygen to the brain. If the patient has a urinary tract infection (UTI), it is treated. The primary clinical manifestation of UTIs in older adults is acute confusion.

To help prevent and manage delirium, use a calm voice to frequently reorient the patient. For example, playing tapes of soothing music may have a calming effect. Providing a doll or stuffed animal to "fidget" with may prevent the patient from removing important medical tubes or equipment. Some nurses believe that providing dolls and stuffed animals is treating the adult like a child, but this intervention can sometimes be very effective when used for therapeutic purposes. If the patient has a favorite item, such as an afghan blanket or a picture, ask the family or significant others to provide it for the same purpose.

Table 2-4 highlights the major differences between delirium and dementia and lists the major nursing considerations for each. The most difficult challenge is caring for a patient who is experiencing both problems at the same time.

TABLE 2-4

Differences in the Characteristics of Delirium and Dementia

VARIABLE	DEMENTIA	DELIRIUM
Description	A chronic, progressive cognitive decline	An acute confusional state
Onset	Slow	Fast
Duration	Months to years	Hours to less than 1 month
Cause	Unknown, possibly familial, chemical	Multiple, such as surgery, infection, drugs
Reversibility	None	Usually
Management	Treat signs and symptoms	Remove or treat the cause
Nursing interventions	Reorientation not effective in the late stages; use validation therapy (acknowledge the patient's feelings, and do not argue); provide a safe environment; observe for associated behaviors, such as delusions and hallucinations	Reorient the patient to reality; provide a safe environment

Alcohol Use and Abuse

Excessive alcohol consumption increases the risk for falls and other accidents, affects mood and cognition, and leads to complications of chronic diseases like diabetes mellitus, hypertension, and gastroesophageal reflux disease (GERD). Isolation, depression, and delirium can result from alcohol abuse. The National Institute on Alcohol Abuse and Alcoholism (NIAAA) recommends that people older than 65 years have no more than one alcoholic drink a day or seven drinks in a week (NIAAA, 2011).

The Short Michigan Alcoholism Screening Test—Geriatric Version (SMAST-G) is often used by nurses and other health care professionals in ambulatory care settings to detect alcohol abuse or alcoholism. The 10 yes/no question test is available in English and Spanish and can be either self-administered or administered by a clinician. Examples of questions on the tool are:

- Do you drink to take your mind off your problems?
- When you feel lonely, does having a drink help?

A "yes" answer is worth one point. A total score of two or more points indicates that the person has a problem with alcohol.

Other screening tools for alcohol misuse in older adults include the CAGE questionnaire and the Alcohol-Related Problems Survey (ARPS)

and the Short ARPS (shARPS). The acronym *CAGE* comes from four questions:

- Have you ever tried to **c**ut down on your drinking?
- Have people **a**nnoyed you by criticizing your drinking?
- Have you ever felt bad or **g**uilty about your drinking?
- Have you ever had a drink first thing in the morning to settle your nerves to get rid of a hangover (**e**ye-opener)?

The ARPS and shARPS were created specifically for use with older adults. In a classic study by Fink et al. (2002), these tools were shown to be more sensitive than the SMAST-G and CAGE screening tests in identifying older adults at risk for alcohol abuse. Those who were identified as non-hazardous and harmful drinkers by the ARPS tool were not identified by other tools. These groups were not diagnosed as having alcoholism but were at risk for this problem.

Clinical Judgment Challenge

Patient-Centered Care; Safety QSEN

A 67-year-old man recently lost his wife after being married for 42 years. He met his wife shortly after he returned from Vietnam as a combat soldier. He visits his physician and reports decreased appetite, moodiness, and extreme fatigue, even though he sleeps 10 to 12 hours a night. When giving his medical history, he admits that he drinks 4 or 5 beers and smokes marijuana almost every day.

1. What do you think caused this man's new symptoms and why?
2. As this man's office nurse, what other assessment data do you need to collect? What screening tools might you use?
3. For what safety issues is this older adult at risk and why?
4. With whom might you collaborate to develop his plan of care?

Elder Neglect and Abuse

Another problem for some older adults is neglect and abuse, both verbal and physical. Some older adults are more vulnerable to these problems than others, especially widows who may have difficulty being assertive. Elder abuse and neglect is a serious problem that affects an estimated 2 million older adults each year (U.S. Census Bureau, 2013). Older persons who are neglected or abused are often physically dependent. The abuser is often a family member who becomes frustrated or distraught over the burden of caring for the older adult. Unfortunately, only a few cases of elder abuse are reported (Stark, 2012).

Prolonged caregiving by a family member is a new and unexpected role for adult children, usually women. This new role may result in role fatigue, conflict, and strain. As a result, **neglect** can occur when a caregiver fails to provide for an older adult's basic needs, such as food, clothing, medications, or assistance with ADLs. The caregiver refuses to let other people, like nursing assistants or home care nurses, into the home. Whether intentional or unintentional, neglect accounts for almost half of all cases of actual elder abuse.

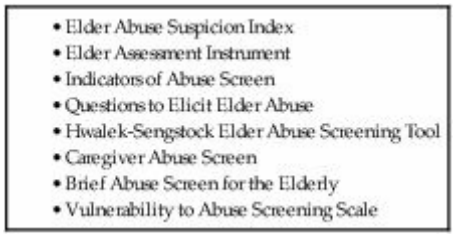
Physical abuse is the use of physical force that results in bodily injury, especially in the "bathing suit" zone (abdomen, buttocks, genital area, upper thighs). Examples of physical abuse are hitting, burning, pushing, and molesting the patient. Sedating the older adult is also abusive. **Financial abuse** occurs when the older adult's property or resources are mismanaged or misused; this is more common than physical abuse. **Emotional abuse** is the intentional use of threats, humiliation, intimidation, and isolation toward older adults.

Carefully assess the patient for signs of abuse, such as bruises in clusters or regular patterns; burns, commonly to the buttocks or the soles of the feet; unusual hair loss; or multiple injuries, especially fractures. If the older adult is too weak or has no other resources or support systems, he or she may not admit that abuse is occurring. Neglect may be manifested by pressure ulcers, contractures, dehydration or malnutrition, urine burns, excessive body odor, and listlessness. Depression and dementia are common in community older adults who are abused or neglected.

Be sure to screen for abuse and neglect of older adults using an appropriate assessment tool. Table 2-5 lists tools that can be used by nurses and other health care professionals to screen for elder abuse and neglect (Stark, 2012). The older adult should be referred to the appropriate service when there is:

TABLE 2-5

Examples of Elder Abuse Screening Tools



- Evidence of mistreatment without sufficient clinical explanation

- Report by an older adult of being abused or neglected
- A belief by the health care professional that there is a high risk for or probable abuse, neglect, abandonment, or exploitation

All states in the United States and other Western countries have laws requiring health care professionals to report suspected elder abuse. In the community, if physical abuse or neglect is suspected, notify the local Adult Protective Services agency. In a hospital or nursing home, notify the social worker or case manager, who then will report the problem to the appropriate agency.

Health Care Issues for Older Adults in Hospitals and Long-Term Care Settings

Older adults who are admitted to hospitals and long-term care settings such as nursing homes have special needs and potential health problems. Many of these problems are similar to those seen among community older adults as discussed in this chapter. The Joint Commission and other agencies have addressed some of the most common problems seen in older adults. In addition, since 1996, the Hartford Institute for Gerontological Nursing has worked to ensure that all hospitalized patients 65 years of age and older be given quality care.

Cultural Considerations

Patient-Centered Care QSEN

The health of Hispanic older adults continues to lag behind that for non-Hispanic whites due to a number of factors, such as language barriers, inadequate health insurance, and lack of health care access. To add to this health disparity, most nurses and other health care professionals are not trained in the language or culture of Hispanic older adults. Some older Hispanic patients may have beliefs and values that conflict with traditional Western health care views. Be respectful of these differences and incorporate them into your patient's plan of care. Become educated about the Hispanic culture and learn to speak basic medical Spanish to foster communication and trust (Strunk et al., 2013).

Gender Health Considerations

Patient-Centered Care QSEN

Significant health disparities are also associated with the lesbian, gay, bisexual, transgender, and questioning (LGBTQ) older adult population. Compared with heterosexual adults, LGBTQ older adults are at an elevated risk for disability from chronic disease and mental distress (Fredriksen-Goldsen, 2011). When admitted to the hospital or nursing home, they may hide their gender identity and sexual orientation from the nurse and other health care providers because of fear of rejection, discrimination, or lack of adequate health care.

Do not assume that your older patients or visitors are heterosexual. Establish a safe and trusting relationship with the patient and discuss sexual orientation and gender issues in a private setting to emphasize

confidentiality. Do not force patients to answer any questions with which they feel uncomfortable. Teach direct caregivers, such as nursing assistants, that they may observe patients with sexual organs that conflict with the patient's gender identity. If this situation occurs, remind them not to be offensive or judgmental but, rather, carry out the task as planned. Chapter 73 in this text describes care of transgender patients in detail.

Nurses may not be aware that the needs of older adults differ from those of younger adults. Some health care systems have designated Acute Care of the Elderly (ACE) units with geriatric resources nurses and geriatric clinical nurse specialists. The patients are cared for by geriatricians who specialize in the care of older adults.

Other hospitals have developed interdisciplinary programs system-wide to meet the special needs of older patients. The incentive for these new programs is the Nurses Improving Care for Healthsystem Elders (NICHE) project, which continues to generate evidence-based practice guidelines for older adult care.

The purpose of all of these programs and units is to focus on the special health care issues or geriatric syndromes seen in the older population (Brown-O'Hara, 2013). The **Fulmer SPICES** framework was developed as part of the NICHE project and identifies six serious "marker conditions" that can lead to longer hospital stays, higher medical costs, and even deaths. These conditions are:

- **S**leep disorders
- **P**roblems with eating or feeding
- **I**ncontinence
- **C**onfusion
- **E**vidence of falls
- **S**kin breakdown

Each of these problems is briefly described here and also is discussed in more detail in other parts of this chapter and the textbook. Other problems, such as depression and constipation, are also common in older hospitalized patients. Rather than being fully comprehensive, the SPICES framework is intended to be an easy tool that has been called "geriatric vital signs" (Fulmer, 2007).

Problems of Sleep, Nutrition, and Continence

Sleep disorders are common in hospitalized patients, especially older adults. Adequate rest is important for healing, as well as for physical and

mental functioning. Pain, chronic disease, environmental noise and lighting, and staff conversations are a few of the many contributing factors to insomnia in the acute and long-term care setting. Assess the patient, and ask how he or she is sleeping. If the patient is not able to answer, observe for restlessness and other behaviors that could indicate lack of adequate rest. Manage the patient's pain by giving pain medication before bedtime. Attempt to keep patients awake during the day to prevent insomnia. Keep staff conversations as quiet as possible and away from patients' rooms. Dim the lights to make the patient area as dark as possible. Avoid making loud noises such as slamming doors. Postpone treatments until waking hours or early morning if they can be delayed safely. If possible, place a "Do not Disturb" sign on the patient's door to avoid unnecessary interruptions in sleep.

Problems with eating and feeding prevent the older patient from receiving adequate nutrition. Malnutrition is common among older adults and is associated with poor clinical outcomes, including death. In a study by Volkert et al. (2010), nutrition-related problems were present in half of 205 older patients admitted to a community hospital, but only 8.3% of them received enteral nutrition supplements. The researchers concluded that nutritional screenings and standard protocols should be implemented for older patients in all hospitals. Nurses need to perform nutritional screenings on the first day of patient admission, including a thorough nutritional history, weight, height, and body mass index (BMI) calculation. Chapter 60 describes nutritional screening in more detail.

Collaborate with the registered dietitian (RD) about the patient's nutritional status as needed to achieve health goals. Consider cultural preferences, and determine what foods the patient likes. Manage symptoms such as pain, nausea, and vomiting. If the patient has difficulty chewing or swallowing, coordinate a plan of care with the speech-language pathologist and dietitian. If there are no dietary restrictions, encourage family members or friends to bring in food that the patient might enjoy. Additional interventions to prevent nutrition-related problems are discussed in Chapter 60.

Urinary and bowel elimination *issues* vary in type and severity and may be caused by many factors, including acute or chronic disease, ADL ability, and available staff. Assess the patient to identify causes for incontinence or retention. *These problems are not physiologic changes of aging but are very common in both the hospital and long-term care setting.* Place the patient on a toileting schedule or a bowel or bladder training program, if appropriate. Delegate and supervise this activity to unlicensed assistive personnel. Chapters 6 and 66 discuss bladder training in detail; Chapter

6 describes bowel training as well. Constipation was described earlier in this chapter.

Confusion, Falls, and Skin Breakdown

Acute and chronic confusion affect many older patients in both the hospital and nursing home. Whereas chronic confusion states such as dementia are not reversible, acute confusion, or delirium, may be avoidable and is often reversible when the cause is resolved or removed (see Table 2-4). For example, avoiding multiple drugs and promoting adequate sleep can help prevent acute confusion. Help the patient by reorienting him or her to reality as much as needed. Keep the patient as comfortable as possible; for example, provide interventions to control pain. Delirium is discussed earlier in this chapter. Chapter 42 describes dementia in detail.

NCLEX Examination Challenge

Physiological Integrity

An older adult returns to the orthopedic unit after an open reduction, internal fixation surgery for a fractured hip. Upon admission, she is combative and screaming profane language. What is the nurse's first action?
A Increase the client's rate of intravenous fluids.
B Give the client IV morphine stat.
C Start oxygen via mask at 6 L/min.
D Assess for risk factors that could cause her behaviors.

The most common accident among older patients in a hospital or nursing home setting is falling. A **fall** is an unintentional change in body position that results in the patient's body coming to rest on the floor or ground. Some falls result in serious injuries such as fractures and head trauma. The Joint Commission's **National Patient Safety Goals (NPSGs)** require that all inpatient health care settings have admission and daily fall risk assessment tools and a fall reduction program for patients who are at high risk.

Assess all older patients for risk for falls. Many evidence-based assessment tools, such as the Morse Fall Scale, STRATIFY, and the Hendrich II Fall Risk Model (HIIFRM), have been developed to help the nurse focus on factors that increase an older person's risk for falling. Some of these tools also recommend selected interventions depending on the patient's fall risk score (Swartzell et al., 2013). Chart 2-4 lists some

of the common risk factors that should be assessed and evidence-based, collaborative interventions for preventing falls in high-risk patients. *A recent history of falling is the single most important predictor for falls.*

Chart 2-4 Best Practice for Patient Safety & Quality Care QSEN

Assessing Risk Factors and Preventing Falls in Older Adults

Assess for the presence of these risk factors:

- History of falls
- Advanced age (>80 years)
- Multiple illnesses
- Generalized weakness or decreased mobility
- Gait and postural instability
- Disorientation or confusion
- Use of drugs that can cause increased confusion, mobility limitations, or orthostatic hypotension
- Urinary incontinence
- Communication impairments
- Major visual impairment or visual impairment without correction
- Alcohol or other substance abuse
- Location of patient's room away from the nurses' station (in the hospital or nursing home)
- Change of shift or mealtime (in the hospital or nursing home)

Implement these nursing interventions for all patients, regardless of risk:

- Monitor the patient's activities and behavior as often as possible, preferably every 30 to 60 minutes.
- Teach the patient and family about the fall prevention program to become safety partners.
- Remind the patient to call for help before getting out of bed or a chair.
- Help the patient to get out of bed or a chair if needed; lock all equipment, such as beds and wheelchairs, before transferring patients.
- Teach patients to use the grab bars when walking in the hall without assistive devices or when using the bathroom.
- Provide or remind the patient to use a walker or cane for ambulating if needed; educate him or her on how to use these devices.
- Remind the patient to wear eyeglasses or a hearing aid if needed.
- Help the incontinent patient to toilet every 1 to 2 hours.
- Clean up spills immediately.

- Arrange the furniture in the patient's room or hallway to eliminate clutter or obstacles that could contribute to a fall.
- Provide adequate lighting at all times, especially at night.
- Observe for side effects and toxic effects of drug therapy.
- Orient the patient to the environment.
- Keep the call light and patient care articles within reach; ensure that the patient can use the call light.
- Place the bed in the lowest position with the brakes locked.
- Place objects that the patient needs within reach.
- Ensure that adequate handrails are present in the patient's room, bathroom, and hall.
- Have the physical therapist assess the patient for mobility and safety.

For patients at a high risk for falls:

- Implement all assessments and interventions listed above.
- Relocate the patient for best visibility and supervision.
- Encourage family members or significant other to stay with the patient.
- Collaborate with other members of the health care team, especially the rehabilitative services.
- Use technologic devices to alert staff to patients getting out of bed, such as mattress sensor pads and chair alarms.
- Use low beds or futon-type beds to prevent injury if the patient falls out of bed.

Toileting-related falls are very common, especially at night (Tzeng & Yin, 2012). Older patients often have **nocturia** (urination at night) and get out of bed to go to the bathroom. They may forget to ask for assistance and may subsequently fall as a result of disorientation in the darkness in an unfamiliar environment. In some cases, they may crawl over the siderail, which can make the fall more serious. Because of this, full or split siderails are used far less often in both hospitals and nursing homes. In both settings, siderails are classified as restraints unless the use of rails helps patients increase mobility.

A **restraint** is any device or drug that prevents the patient from moving freely and must be prescribed by a health care provider. In 1990, the federal government enforced a law that gives nursing home residents the right to be restraint free. Removing physical restraints from nursing home residents has reduced serious injuries, although falls and minor injuries have increased in some cases. Mattresses placed on floors next to patient beds or "low beds" have helped reduce injury.

Hospitals have also reduced the use of physical restraints. The Joint Commission has specific standards that limit the use of physical

restraints in hospitals and nursing homes. Chemical restraints (psychoactive drugs) such as haloperidol (Haldol) have sometimes been used in place of physical restraints.

Experts agree that older adults should not be placed in a physical restraint or sedated just because they are old. Use alternatives before applying any type of restraint (Chart 2-5). However, if all other interventions (e.g., reminding patients to call for assistance when needed; asking a family member to stay with patients) are not effective in fall prevention, a physical restraint may be required for a limited period. Applying a restraint is a serious intervention and should be analyzed for its risk versus its benefit. Check the patient in a restraint every 30 to 60 minutes, and release the restraint at least every 2 hours for turning, repositioning, and toileting. Physical restraints such as vests have caused serious injury and even death. *If restraint is needed, use the least restrictive device first. Be sure to follow your facility's policy and procedure for using restraints.*

Chart 2-5 Best Practice for Patient Safety & Quality Care QSEN

Using Restraint Alternatives

- If the patient is acutely confused, reorient him or her to reality as often as possible.
- If the patient has dementia, use validation to reaffirm his or her feelings and concerns.
- Check the patient often, at least every hour.
- If the patient pulls tubes and lines, cover them with roller gauze or another protective device; be sure that IV insertion sites are visible for assessment.
- Keep the patient busy, with an activity, pillow or apron, puzzle, or art project.
- Provide soft, calming music.
- Place the patient in an area where he or she can be supervised. (If the patient is agitated, do not place him or her in a noisy area.)
- Turn off the television if the patient is agitated.
- Ask a family member or friend to stay with the patient at night.
- Help the patient to toilet every 2 to 3 hours, including during the night.
- Be sure that the patient's needs for food, fluids, and comfort are met.
- If agency policy allows, provide the patient with a pet visit.
- Provide familiar objects or cherished items that the patient can touch.

• Document the use of all alternative interventions.
• If a restraint is applied, use the least restrictive device (e.g., mitts rather than wrist restraints, a roller belt rather than a vest).

Chemical restraints are often overused in hospital settings. Examples include:
• Antipsychotic drugs
• Antianxiety drugs
• Antidepressant drugs
• Sedative-hypnotic drugs

The most potent group of psychoactive drugs is the antipsychotics. These drugs are appropriate only for the control of certain behavioral problems, such as delusions, acute psychosis, and schizophrenia. Typical antipsychotic drugs include haloperidol (Haldol, Peridol) and thiothixene (Navane). These drugs should not be used to treat anxiety or induce sedation.

Nursing Safety Priority QSEN

Drug Alert

Closely monitor older adults receiving antipsychotics for adverse drug events (ADEs). Assess patients for:
• Anticholinergic effects, the most common problem, causing constipation, dry mouth, and urinary retention
• Orthostatic hypotension, which increases the patient's risk for falls and fractures
• Parkinsonism, including tremors, bradycardia, and a shuffling gait
• Restlessness and the inability to stay still in any one position
• Hyperglycemia and diabetes mellitus, which occur more with drugs like risperidone (Risperdal) and quetiapine (Seroquel)

If any of these ADEs occur, notify the health care provider immediately.

Skin breakdown, especially pressure ulcers, is a major tissue integrity problem among older adults in hospitals and nursing homes. In some cases, these wounds cause death from infection. Therefore prevention is the best approach. The Joint Commission's NPSGs require that all health care agencies have a program to prevent agency-associated pressure ulcers. The program should include these evidence-based interventions:
• Nutritional support

• Avoidance of skin injury from friction or shearing forces
• Repositioning and support surfaces
• A plan to increase mobility and activity level, when appropriate
• Skin cleansing and use of moisture barriers

Assess older adults for their risk for pressure ulcers, using an assessment tool such as the Braden Scale for Predicting Pressure Sore Risk (see Chapter 25). Implement evidence-based interventions to prevent agency-acquired pressure ulcers and maintain tissue integrity. Coordinate these interventions with members of the health care team, including the dietitian and wound care specialist.

Nursing Safety Priority QSEN

Action Alert

Supervise unlicensed assistive personnel (UAP) for frequent turning and repositioning for the patient who is immobile. Assess the skin every 8 hours for reddened areas that do not blanch. Remind UAP to keep the skin clean and dry. Use pressure-relieving mattresses, and avoid briefs or absorbent pads that can cause skin irritation and excess moisture. Chapter 25 describes in detail additional interventions for prevention and management of pressure ulcers.

Skin tears are also common in older adults, especially the old-old group and those who are on chronic steroid therapy. Teach UAP to use extreme caution when handling these patients. Use a gentle touch, and report any open areas. Avoid bruising because older adults have increased capillary fragility.

Care Transition from the Hospital or Long-Term Care Setting to Home

Some older adults and their families experience a breakdown in communication and coordination of care when transitioning from the hospital or long-term care (LTC) setting (nursing home) to the home setting. If the transition is not optimal, older adults experience high readmission rates and an increase in visits to the emergency department or health care provider's office.

A qualitative study by Dossa et al. (2012) showed that health care professionals, especially nurses, did not communicate effectively as they prepared for the discharge of older adults. Care was not coordinated

among health care professionals, which led to confusion for the older adult and family caregivers. To help prevent these problems, the authors recommended that a system needs to be in place to address patients' communication needs. The system should include follow-up phone calls after discharge to home and having one case manager to coordinate care during and after the transition from the inpatient agency to home. A home care nurse or other health care professional can serve as a "health coach" to ensure understanding of discharge instructions, consistent follow-up appointments, and a designated emergency contact for the patient and family. Discharge instructions should be easy to read, in large print, and accurate. Continuity of care for high quality transition between settings is essential to achieve positive outcomes for older adults.

Get Ready for the NCLEX® Examination!

Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Collaborate with members of the health care team when providing care to older adults in the community or inpatient setting. For example, consult with the registered dietitian for problems with nutrition; consult with the pharmacist to discuss the patient's drug regimen. **Teamwork and Collaboration** QSEN
- Assess all older adults for risk factors for impaired driving ability, such as decreased mobility, sensory perception, and cognition (see Chart 2-3).
- Assess older adults in the community and inpatient settings for falls risk factors (e.g., cognitive decline and vision impairment) and implement interventions as delineated in Chart 2-4. **Safety** QSEN
- Physical and chemical restraints should not be used for older adults until all other alternatives have been tried (see Chart 2-5).
- Follow The Joint Commission's National Patient Safety Goals and federal/state standards when using patient restraints to maintain patient safety. **Safety** QSEN

Health Promotion and Maintenance

- Teach older adults about the benefits of regular physical exercise.
- Provide information regarding community resources for older adults to help them meet their basic needs.
- Teach health promotion practices as listed in Chart 2-1.
- Conduct a medication assessment for potential risks in older adults using the Beers criteria.

Psychosocial Integrity

- Depression is the most common yet most underdiagnosed and undertreated mental health/behavioral health disorder among older adults.
- Delirium is acute confusion; dementia is chronic confusion (see Tables 2-3 and 2-4). Confusion is not part of the normal aging process.
- Screen older adults for alcohol abuse or alcoholism, and refer those with identified problems to appropriate resources. **Evidence-Based Practice** QSEN

- Screen older adults for neglect and abuse, which are serious problems; family caregivers are usually the abusers (see Table 2-5). **Safety** QSEN
- Relocation stress syndrome is the reaction of an older adult when transferred to a different environment; ways to minimize this problem are listed in Chart 2-2.

Physiological Integrity

- The four subgroups of the older adult population are the young old, middle old, old old, and elite old.
- The biggest concern regarding accidents among older adults in both the community and inpatient setting is falls. **Safety** QSEN
- Physiologic changes of aging predispose older adults to toxic effects of medication; drugs are absorbed, metabolized, and distributed more slowly than in younger people. They are also excreted more slowly by the kidneys.
- Medication use in older adults is often a problem when they commit errors when self-medicating, avoid needed medications, or have problems understanding their medication regimen. **Evidence-Based Practice** QSEN
- Follow The Joint Commission's National Patient Safety Goals and best practice guidelines to prevent agency-acquired pressure ulcers.
- Promote sleep and rest for older adults to decrease the incidence of delirium and to prevent falls.
- Use the SPICES assessment tool for identifying serious health problems that can be prevented or managed early.

CHAPTER 3

Assessment and Care of Patients with Pain

Chris Pasero and Donna D. Ignatavicius

PRIORITY CONCEPTS

- Pain
- Cognition
- Sensory Perception

Learning Outcomes

Safe and Effective Care Environment

1. Identify the role of the nurse as an advocate for patients with acute pain or chronic cancer or non-cancer pain.
2. Explain the importance of collaborating with the health care team in developing the pain management plan of care.

Health Promotion and Maintenance

3. Develop a teaching plan for patients to include complementary and alternative therapies for pain management.
4. Incorporate special considerations for older adults related to pain assessment and management.
5. Describe how to provide patient-centered care by respecting patients' preferences, values, and beliefs regarding pain and its management.

Psychosocial Integrity

6. Discuss the attitudes and knowledge of patients and their families regarding pain assessment and management.
7. Explain the importance of assessing expectations of patient and family for relief of pain, discomfort, or suffering.

Physiological Integrity

8. Demonstrate comprehensive understanding of the concepts of pain and suffering, including physiologic models of pain and comfort.
9. Perform a complete pain assessment, and document per agency policy.
10. Compare and contrast the characteristics of the major types of pain and examples of each.
11. Explain the role of the three analgesic groups in pain management.
12. Differentiate between addiction, pseudoaddiction, tolerance, and physical dependence.
13. Develop a plan of care to prevent common side effects of opioid analgesics.
14. Compare the advantages and disadvantages of drug administration routes.
15. Describe the benefits and limitations of selected safety-enhancing technologies used in pain management.
16. Prioritize care for the patient receiving patient-controlled analgesia.
17. Outline care for a patient receiving epidural analgesia.
18. Identify the importance of incorporating nonpharmacologic interventions into the patient's plan of care as needed to control pain.

 http://evolve.elsevier.com/Iggy/

Overview

Pain is a universal, complex, and personal experience that everyone has at some point in life. It is the most common reason people seek medical care and the number-one reason people take medication. Unrelieved pain can alter or diminish quality of life more than any other single health-related problem. Despite more than 30 years of education and dissemination of guideline recommendations, the failure to adequately manage pain remains a major health problem worldwide.

In response to mandates by many professional organizations and The Joint Commission (TJC), many hospitals and other health care agencies in the United States have implemented interdisciplinary pain initiatives to help ensure patients receive the best possible treatment. Some hospitals address this by establishing pain resource nurse (PRN) programs. As the name implies, one or more nurses per clinical unit are trained to serve as a resource to other members of the health care team in managing pain. Other hospitals have a formal team or pain service consisting of one or more nurses, pharmacists, case managers, and/or physicians. In larger facilities, pain services may specialize by type of pain (e.g., acute pain service or pain and palliative care team). Although a large part of the team's plan may center on drug therapy, these groups also recommend nonpharmacologic measures when appropriate.

Scope of the Problem

Pain is a major economic problem and a leading cause of disability that hampers the lives of many people, especially older adults. Chronic non-cancer pain, such as osteoarthritis, rheumatoid arthritis, diabetic neuropathy, and post-stroke pain syndrome, is the most common cause of long-term disability, affecting millions of Americans and others throughout the world.

Pain is inadequately treated in all health care settings. Populations at the highest risk in medical-surgical nursing are older adults, substance abusers, and those whose primary language differs from that of the health care professional. Older adults in nursing homes are at especially high risk because many residents are unable to report their pain. In addition, there often is a lack of staff members who have been trained to manage pain in the older adult population.

Inadequate pain management can lead to many adverse consequences affecting the patient and family members (Table 3-1). Therefore nurses have a legal and ethical responsibility to ensure that patients receive adequate pain control. Many professional organizations, including the American Society for Pain Management Nursing (ASPMN), the American Pain Society (APS), and TJC state that patients in all health care settings, including home care, have a right to effective pain management.

TABLE 3-1

Impact of Unrelieved Pain

Physiologic Impact	Quality-of-Life Impact
• Prolongs stress response • Increases heart rate, blood pressure, and oxygen demand • Decreases GI motility • Causes immobility • Decreases immune response • Delays healing • Poorly managed acute pain increases risk for development of chronic pain	• Interferes with ADLs • Causes anxiety, depression, hopelessness, fear, anger, and sleeplessness • Impairs family, work, and social relationships **Financial Impact** • Costs Americans billions of dollars per year • Increase shospital length of stay • Leads to lost income and productivity

Patients rely on nurses and other health care professionals to adequately assess and manage their pain. As the coordinator of patient care, be sure to accurately document your assessments and actions, including patient and caregiver teaching. Communication and collaboration among the patient and members of the interdisciplinary health care team about the patient's pain, expectations, and progress toward control are equally important.

Definitions of Pain

Pain is defined as an unpleasant sensory and emotional experience associated with actual or potential tissue damage. McCaffery (1968) offered a more personal definition when she stated that pain is whatever the experiencing person says it is and exists whenever he or she says it exists. This has become the clinical definition of pain worldwide and reflects an understanding that the patient is the authority on the pain and the *only* one who can describe the experience. *In other words, self-report is always the most reliable indication of pain.* Nurses who approach pain from this perspective can help the patient achieve effective management by advocating for proper control. If the patient cannot provide self-report, a variety of other methods, such as observation of behavioral indicators, are used to assess the pain (see later in this chapter).

Categorization of Pain by Duration

Pain is often described as being acute or chronic based on its duration (Table 3-2). *Acute pain* is usually short-lived, whereas *chronic pain* can last a person's lifetime. *Acute pain* often results from sudden, accidental trauma (e.g., fractures, burns, lacerations) or from surgery, ischemia, or acute inflammation. *Chronic pain or persistent pain* is further divided into two subtypes. *Chronic cancer pain* is pain associated with cancer and is usually the result of tissue changes from tumor growth. *Chronic non-cancer pain* is associated with past or ongoing tissue damage, such as chronic back or neck pain or osteoarthritis pain. *Non-cancer pain is the most common type of chronic pain.*

TABLE 3-2

Characteristics of Acute Pain and Chronic Pain

ACUTE	CHRONIC* (OR PERSISTENT)
• Has short duration • Usually has a well-defined cause • Decreases with healing • Is usually reversible • Initially serves a biologic purpose (warning sign to withdraw from painful stimuli or seek help) • When prolonged, serves no useful purpose • Ranges from mild to severe intensity • May be accompanied by anxiety and restlessness • When unrelieved, can increase morbidity and mortality and prolong hospital length of stay	• Usually lasts longer than 3 months • May or may not have well-defined cause • Usually begins gradually and persists • Serves no useful purpose • Ranges from mild to severe intensity • Often accompanied by multiple quality-of-life and functional adverse effects, including depression, fatigue, financial burden, and increased dependence on family, friends, and the health care system • Can impact the quality of life of family members and friends

*Includes chronic cancer pain and chronic non-cancer pain.

Acute Pain

Almost everyone experiences acute pain at some time. Brief **acute pain** serves a biologic purpose in that it acts as a warning signal by activating the sympathetic nervous system and causing various physiologic responses. Although not consistent in all people, when acute pain is severe, you may see responses similar to those found in "fight-or-flight" reactions, such as increased vital signs, sweating, and dilated pupils. Most people protect themselves by drawing away from the painful stimulus. Behavioral signs may include restlessness (especially among cognitively impaired older adults who sometimes fidget and pick at clothing), an inability to concentrate, apprehension, and overall distress of varying degrees. These heightened physiologic and behavioral responses are often referred to as the *acute pain model*. It is important to remember that the response to pain is highly individual and that humans quickly adapt physiologically and behaviorally to pain. Be careful not to expect certain responses when assessing any type of pain. *The absence of*

the physiologic and behavioral responses does not mean the absence of pain.

Acute pain is usually temporary, has a sudden onset, and is easily localized. The pain is typically confined to the injured area and may subside with or without treatment. As the injured area heals, the sensory perception of pain changes and, in most cases, diminishes and resolves. Both the caregiver and the patient can see an end to the pain, which usually makes coping somewhat easier.

Pain that accompanies surgery is one of the most common examples of acute pain, but it is not always well managed. *The response to pain after surgery is highly individual and variable*. There is no evidence that shows one type of surgery is consistently more or less painful than another. Usually, poorly managed postoperative pain is a result of inadequate drug (analgesic) therapy. Poorly managed and prolonged acute pain serves no useful purpose and has many adverse effects including inability of the patient to participate in the recovery process with subsequent increased disability. The severity of early postoperative pain may be a predictor of long-term pain. Those who experience unrelieved severe postoperative pain are at high risk for the development of chronic persistent postsurgical pain (Pasero, 2011).

Chronic Pain

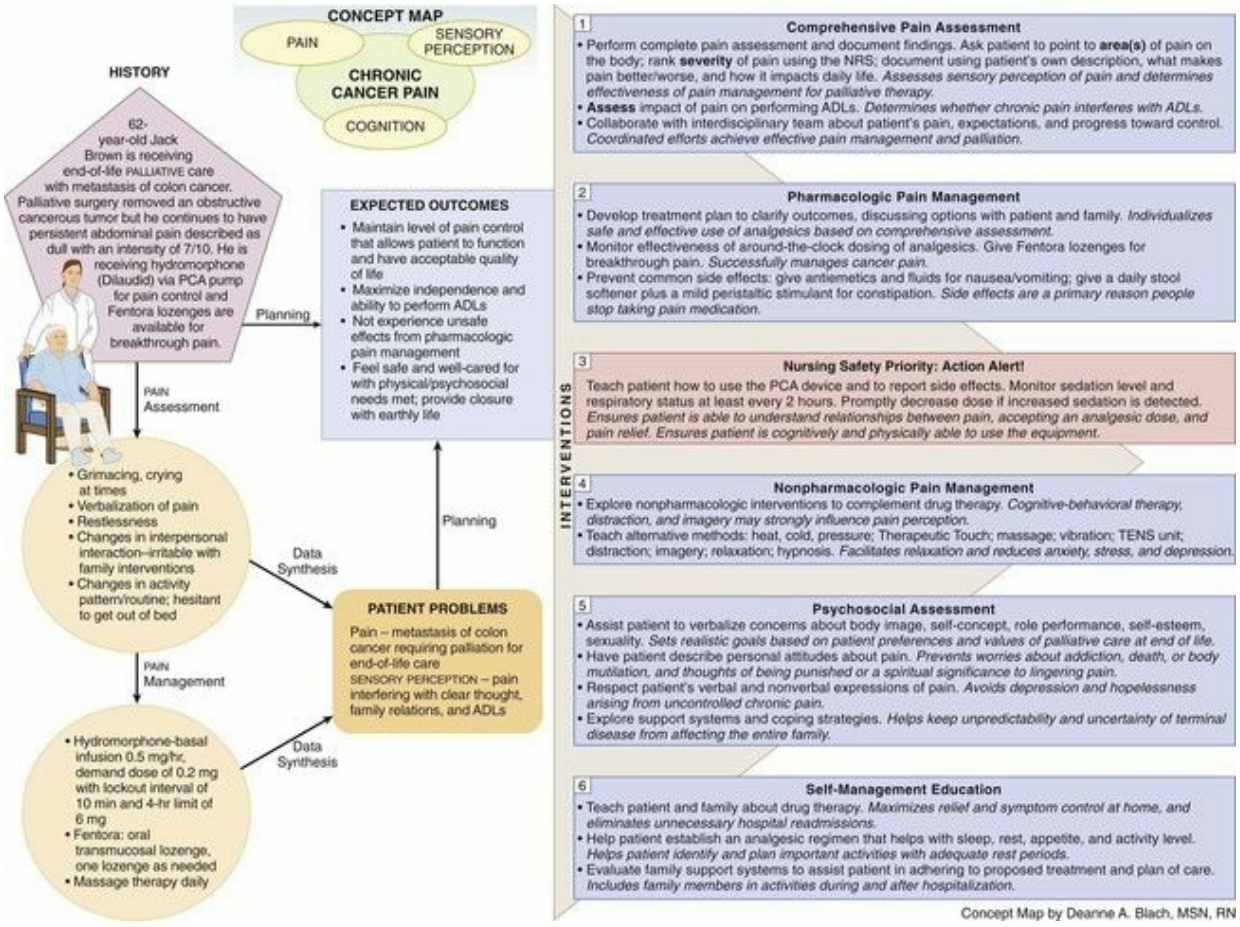
Chronic pain (also called *persistent pain*) is often defined as pain that lasts or recurs for an indefinite period, usually for more than 3 months. The onset is gradual, and the character and quality of the pain often change over time. *Chronic pain serves no biologic purpose.* Because it persists for an extended period, it can interfere with personal relationships and performance of ADLs. Chronic pain can also result in emotional and financial burdens, depression, and hopelessness for patients and their families. It is important to remember that the body adapts to persistent pain, and thus vital signs, such as pulse and blood pressure, may actually be lower than normal in people with chronic pain. *Although many characteristics of chronic pain are similar in different patients, be aware that each patient is unique and requires a highly individualized plan of care.*

Chronic Cancer Pain

Many patients with cancer report pain at the time of diagnosis, which increases in advanced stages of the disease. Most cancer pain can be successfully managed by giving adequate amounts of oral opioids around the clock, yet patients with cancer are often inadequately treated for what can be persistent, excruciating pain and suffering.

Most cancer pain is the result of tumor growth, including nerve compression, invasion of tissue, and/or bone metastasis, an extremely painful condition. Cancer treatments also can cause *acute pain* (e.g., from repetitive blood draws and other procedures, surgery, and toxicities from chemotherapy and radiation therapy).

Patients with cancer pain generally have pain in two or more areas of the body but usually talk about only the primary area. Be sure to perform a complete pain assessment to ensure an effective plan of care (see the Concept Map).



Chronic Non-Cancer Pain

Chronic non-cancer pain is a global health problem, occurring most often in people older than 65 years. This type of pain was formerly called *chronic nonmalignant* pain. However, most experts, and certainly patients who suffer daily, believe that all pain is malignant. There are many sources and types of chronic non-cancer pain. Among the most common are neck, shoulder, and low back pain following injury. Chronic conditions, such as diabetes, rheumatoid arthritis, Crohn's disease, and

interstitial cystitis, often are associated with chronic pain. People who have had a stroke or are paralyzed may report persistent pain as a result of central nervous system (CNS) damage. Sometimes the exact cause of the pain is unclear as with fibromyalgia.

Categorization of Pain by Underlying Mechanisms

Pain is more commonly categorized as either nociceptive (normal pain processing) or neuropathic (abnormal pain processing) (Table 3-3). The duration of nociceptive and neuropathic pain can be either acute (short-lived) or chronic (persistent), and a person can have both types.

TABLE 3-3

Physiologic Sources of Nociceptive Pain and Neuropathic Pain

PHYSIOLOGIC STRUCTURE	CHARACTERISTICS OF PAIN	SOURCES OF ACUTE POSTOPERATIVE PAIN	SOURCES OF CHRONIC PAIN SYNDROMES
Nociceptive Pain (normal pain processing)			
Somatic Pain			
Cutaneous or superficial: skin and subcutaneous tissues	Sharp, burning	Incisional pain, pain at insertion sites of tubes and drains, wound complications, orthopedic procedures, skeletal muscle spasms	Bony metastases, osteoarthritis and rheumatoid arthritis, low back pain, peripheral vascular diseases
Deep somatic: bone, muscle, blood vessels, connective tissues	Dull, aching, cramping		
Visceral Pain			
Organs and the linings of the body cavities	Poorly localized Diffuse, deep cramping or splitting, sharp, stabbing	Chest tubes, abdominal tubes and drains, bladder distention or spasms, intestinal distention	Pancreatitis, liver metastases, colitis, appendicitis
Neuropathic Pain (abnormal pain processing)			
Peripheral or central nervous system: nerve fibers, spinal cord, and higher central nervous system	Poorly localized Shooting, burning, fiery, shocklike, sharp, painful numbness	Phantom limb pain, postmastectomy pain, nerve compression	HIV-related pain, diabetic neuropathy, postherpetic neuralgia, chemotherapy-induced neuropathies, cancer-related nerve injury, radiculopathies

HIV, Human immune deficiency virus.

Nociceptive Pain

The classic *gate control theory* is credited with stimulating intense research that led to discoveries that form the basis of what is known about pain transmission today. According to this theory, a gating mechanism exists in the spinal cord. It was proposed that when the gate is open, pain impulses ascend to the brain where the person perceives that pain is present (Pasero & McCaffery, 2011). When the gate is closed, the impulses are blocked and pain is not perceived. It is no longer necessary to discuss pain transmission in terms of theories because much is known today about this phenomenon, known as *nociception.*

Nociception is the term that is used to describe how pain becomes a conscious experience. It involves the *normal functioning of physiologic systems* that process noxious stimuli with the ultimate result being that the stimuli are perceived to be painful. In short, nociception means "normal" pain transmission and is generally discussed in terms of four processes: transduction, transmission, perception, and modulation (Fig.

3-1). Although it is helpful to consider nociception in the context of these four processes, it is important to understand that they do not occur as four separate and distinct entities. They are continuous, and the processes overlap as they flow from one to another.

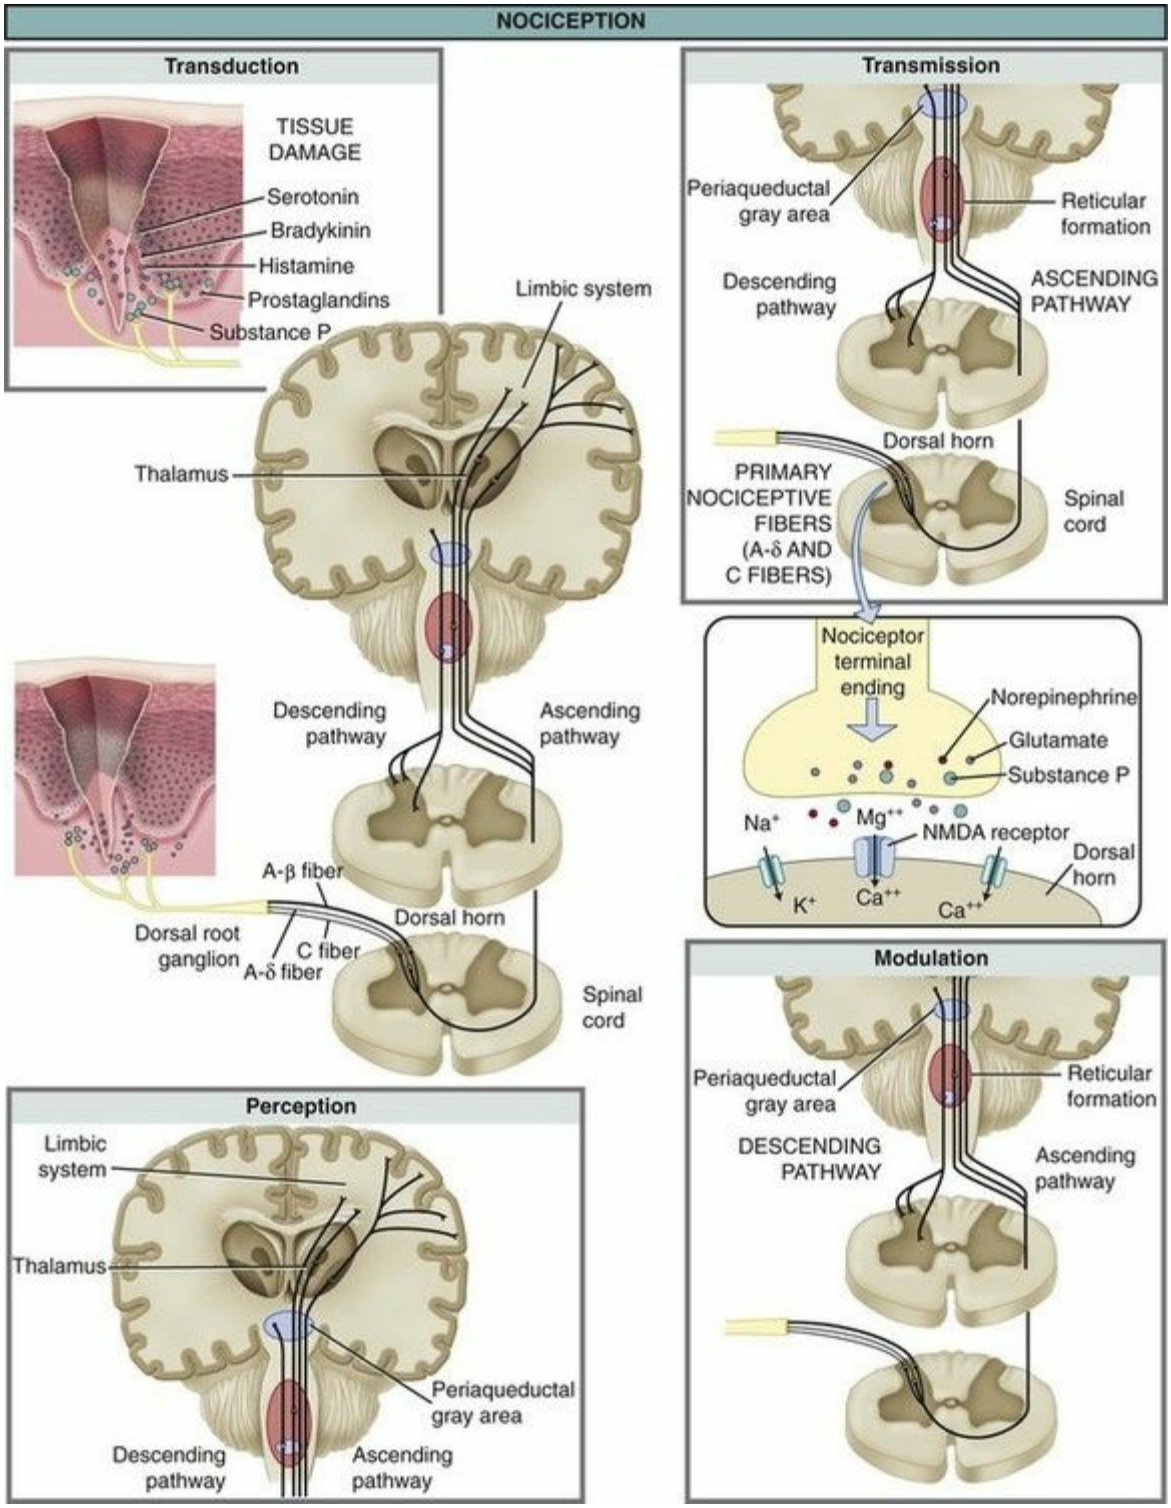


FIG. 3-1 Nociception.

Transduction is the first process of nociception and refers to the means by which noxious events activate neurons that exist throughout the body

(skin, subcutaneous tissue, and visceral, or somatic, structures) and have the ability to respond selectively to specific noxious stimuli. These neurons are called *nociceptors.* When they are stimulated directly, a number of excitatory compounds (e.g., serotonin, bradykinin, histamine, substance P, and prostaglandins) are released that further activate more nociceptors (see Fig. 3-1) (Yaksh & Wallace, 2011).

Transmission is the second process involved in nociception. Nociceptors have small-diameter axons—either A-delta or C fibers (see Fig. 3-1). Effective transduction generates an electric signal (action potential) that is transmitted in these nerve fibers from the periphery toward the CNS. *A-delta fibers* are lightly myelinated and faster conducting than unmyelinated C fibers. The endings of A-delta fibers detect thermal and mechanical injury. The sensory perception accompanying A-delta fiber activation is sharp and well-localized and leads to an appropriately rapid protective response, such as reflex withdrawal from the painful stimuli. *C fibers* are unmyelinated or poorly myelinated slow conductors and respond to mechanical, thermal, and chemical stimuli. Activation after acute injury yields a poorly localized (more widely distributed) typically aching or burning pain. In contrast to the intermittent nature of A-delta sensations, C fibers usually produce more continuous pain.

Perception is the third broad process involved in nociception. Perception, which may be viewed as the end result of the neural activity associated with transmission of information about noxious events, involves the conscious awareness of pain (see Fig. 3-1). It requires the activation of higher brain structures, including the cortex, and involves both awareness and the occurrence of emotions and drives associated with pain. The physiology of pain perception is very poorly understood but presumably can be targeted by therapies that activate higher cortical functions to achieve pain control or coping. Cognitive-behavioral therapy and specific approaches such as distraction and imagery (discussed later in the chapter) have been developed based on evidence that brain processes can strongly influence pain perception.

Modulation of afferent input generated in response to noxious stimuli happens at every level from the periphery to the cortex (see Fig. 3-1). The neurochemistry of modulation is complex and not yet fully understood, but it is known that multiple peripheral and central systems and dozens of neurochemicals are involved. For example, the endogenous opioids (endorphins) are found throughout the peripheral nervous system (PNS) and CNS and, like the exogenous opioids administered therapeutically, they inhibit neuronal activity by binding to opioid receptors. Other central inhibitory neurotransmitters important in the modulation of pain

include serotonin and norepinephrine, which are released in the spinal cord and brainstem by the descending fibers of the modulatory system to inhibit pain.

Nociceptive pain is the result of actual or potential tissue damage or inflammation and is often categorized as being somatic or visceral. *Somatic pain* arises from the skin and musculoskeletal structures, and *visceral pain* arises from organs. Examples include pain-associated trauma, surgery, burns, and tumor growth.

Neuropathic Pain

Neuropathic pain is a descriptive term used to refer to pain that is believed to be sustained by a set of mechanisms that is driven by damage to or dysfunction of the PNS and/or CNS. In contrast to nociceptive pain, which is sustained by ongoing activation of essentially *normal* neural systems, neuropathic pain is sustained by the *abnormal* processing of stimuli. Whereas nociceptive pain involves tissue damage or inflammation, neuropathic pain may occur in the absence of either.

It is not clear why noxious stimuli result in neuropathic pain in some people and not in others and why some treatments work in some and not in others. Neuropathic pain is difficult to treat and often resistant to first-line analgesics. Asking patients to describe it is the best way to identify the presence of neuropathic pain. Common distinctive descriptors include “burning,” “shooting,” “stabbing,” and feeling “pins and needles.” Much is unknown about what causes and maintains neuropathic pain; it is the subject of intense ongoing research.

Patient-Centered Collaborative Care

Pain Assessment

All accepted guidelines identify the patient's self-report as the gold standard for assessing the existence and intensity of pain (Pasero & McCaffery, 2011). Because pain is such a private and personal experience, it may be difficult for the person to describe or explain it to others. However, subjective descriptions of the experience and measurement of pain intensity are more reliable and accurate than observable qualities of pain. The amount of pain and responses to it vary from person to person; therefore interpreting it solely on actions or behaviors can be misleading and is not recommended. Patients may report pain in the absence of any observable or documented physiologic changes.

Although nurses are entitled to their doubts and opinions about a patient's pain, those doubts and opinions cannot be allowed to interfere with appropriate patient care. The nurse's primary role in pain management is to advocate for patients by *accepting* their reports of pain and acting promptly to relieve it, while respecting patients' preferences and values (Quality and Safety Education for Nurses [QSEN], 2011).

To be patient-centered, always respect the patient's verbal and nonverbal expressions of pain without making judgments or inferences about the reality of it. If patients perceive that health care professionals doubt the existence of their pain, mistrust and other negative feelings can arise and interfere with a therapeutic nurse-patient relationship.

The Comprehensive Pain Assessment

A comprehensive pain assessment should be conducted during the initial interview with the patient, with each new report of pain, and whenever indicated by changes in the patient's condition or treatment plan during the course of care. Pain assessment at these intervals serves as the foundation for developing and evaluating the effectiveness of the treatment plan. Remember that patients' personal preferences and values affect how they report their history. *When culturally appropriate, be sure to include families and significant others in this information-gathering process to be family-centered.*

Components of a comprehensive pain assessment and tips on how to elicit the information from the patient include:

- *Location(s):* Ask the patient to state or point to the area(s) of pain on the body. Sometimes allowing patients to make marks on a body diagram is helpful in gaining this information (Fig. 3-2). Patients may present

with more than one specific painful site. Encourage those who cannot identify the painful areas and state that they "hurt all over" to focus on parts of the body that are not painful. Ask them to begin with the hand and fingers of one extremity and identify the presence or absence of pain. By focusing attention on selected areas of the body, the patient is assisted in better localizing painful areas. People who state that they hurt everywhere often begin to realize that some parts of the body are not painful. Identifying painful areas helps the patient understand the origin of the pain. This understanding is particularly important for those with cancer, because every new pain often raises the suspicion of metastasis (spread of disease). The pain may have other causes, such as immobility or constipation. Pain may be described as belonging to one of four categories related to its location:

McGill-Melzack
PAIN QUESTIONNAIRE

Patient's name _____ Age _____
File No. _____ Date _____
Clinical category (e.g., cardiac, neurologic)
Diagnosis: _____
_____
_____
Analgesic (if already administered):
1. Type _____
2. Dosage _____
3. Time given in relation to this test _____
Patient's intelligence: circle number that represents best estimate.
1 (low) 2 3 4 5 (high)

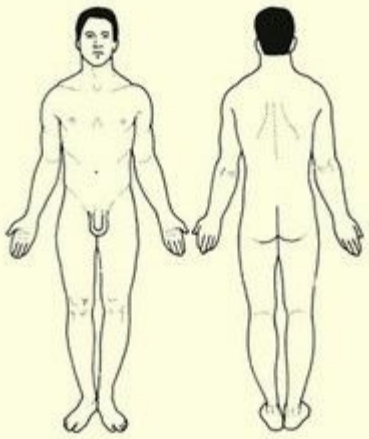
This questionnaire has been designed to tell us more about your pain. Four major questions we ask are
1. Where is your pain?
2. What does it feel like?
3. How does it change with time?
4. How strong is it?

It is important that you tell us how your pain feels now. Please follow the instructions at the beginning of each part.

© R. Melzack, Oct. 1970

Part 1. Where Is Your Pain?

Please mark, on the drawings below, the areas where you feel pain. Put E if external, or I if internal, near the areas you mark. Put EI if both external and internal.



Part 2. What Does Your Pain Feel Like?

Some of the words below describe your *present* pain. Circle *ONLY* those words that best describe it. Leave out any category that is not suitable. Use only a single word in each appropriate category — the one that applies best.

1	6	11	16
Flickering	Tugging	Tiring	Annoying
Quivering	Pulling	Exhausting	Troublesome
Pulsing	Wrenching	12	Miserable
Throbbing	7	Sickening	Intense
Beating	Hot	Suffocating	Unbearable
Pounding	Burning	13	17
2	Scalding	Fearful	Spreading
Jumping	Searing	Frightful	Radiating
Flashing	8	Terrifying	Penetrating
Shooting	Tingling	14	Piercing
3	Itchy	Punishing	18
Pricking	Smarting	Grueling	Tight
Boring	Stinging	Cruel	Numb
Drilling	9	Vicious	Drawing
Stabbing	Dull	Killing	Squeezing
Lancinating	Sore	15	Tearing
4	Hurting	Wretched	19
Sharp	Aching	Blinding	Cool
Cutting	Heavy		Cold
Lacerating	10		Freezing
5	Tender		20
Pinching	Taut		Nagging
Pressing	Rasping		Nauseating
Gnawing	Splitting		Agonizing
Cramping			Dreadful
Crushing			Torturing

Part 3. How Does Your Pain Change With Time?

1. Which word or words would you use to describe the *pattern* of your pain?

1	2	3
Continuous	Rhythmic	Brief
Steady	Periodic	Momentary
Constant	Intermittent	Transient

2. What kind of things *relieve* your pain?

3. What kind of things *increase* your pain?

Part 4. How Strong Is Your Pain?

People agree that the following 5 words represent pain of increasing intensity. They are:

1	2	3	4	5
Mild	Discomforting	Distressing	Horrible	Excruciating

To answer each question below, write the number of the most appropriate word in the space beside the question.

1. Which word describes your pain right now? ____
2. Which word describes it at its worst? ____
3. Which word describes it when it is least? ____
4. Which word describes the worst toothache you ever had? ____
5. Which word describes the worst headache you ever had? ____
6. Which word describes the worst stomachache you ever had? ____

FIG. 3-2 The McGill-Melzack Pain Questionnaire.

1. Localized pain is confined to the site of origin.
2. Projected pain is diffuse around the site of origin and is not well localized.
3. Referred pain is felt in an area distant from the site of painful stimuli.
4. Radiating pain is felt along a specific nerve or nerves.

- *Intensity:* Ask the patient to rate the severity of the pain using a reliable and valid assessment tool. Various self-report scales have been

developed to help patients communicate pain intensity. Once a scale is selected, be sure to use the *same* scale over time for that patient, and assess intensity both with and without activity. See Table 3-4 for strategies that can be used to teach patients and their families how to use a pain rating scale. The most common intensity rating scales are:

TABLE 3-4

Teaching Patients and Their Families How to Use APain Rating Scale*

Step 1. Show the pain rating scale to the patient and family, and explain its primary purpose.
Example: "This is a pain rating scale that many of our patients use to help us understand their pain and to set goals for pain relief. We will ask you regularly about pain, but any time you have pain you must let us know so that we can help control it. We don't always know when you hurt."
Step 2. Explain the parts of the pain rating scale. If the patient does not like it or understand it, switch to another scale (e.g., vertical presentation, VDS, or faces).
Example: "On this pain rating scale, 0 means no pain and 10 means the worst possible pain. The middle of the scale, around 5, means moderate pain. A 2 or 3 would be mild pain, but 7 or higher means severe pain."
Step 3. Discuss pain as a broad concept that is not restricted to a severe and intolerable sensation.
Example: "Pain refers to any kind of discomfort anywhere in your body. Pain also means aching and hurting. Pain can include pulling, tightness, burning, knifelike feelings, and other unpleasant sensations."
Step 4. Verify that the patient understands the broad concept of pain. Ask the patient to mention two examples of pain he or she has experienced. If the patient is already in pain that requires treatment, use the present situation as the example.
Example: "I want to be sure that I've explained this clearly, so would you give me two examples of pain you've had recently?" If the patient examples include various parts of the body and various pain characteristics, that indicates that he or she understands pain as a fairly broad concept. An example of what a patient might say is "I have a mild, sort of throbbing headache now, and yesterday my back was aching."
Step 5. Ask the patient to practice using the pain rating scale with the present pain or select one of the examples mentioned.
Example: "Using the scale, what is your pain right now? What is it at its worst?" OR "Using the pain rating scale and one of your examples of pain, what is that pain usually? What is it at its worst?"
Step 6. Set goals for comfort and function/recovery/quality of life. Ask patients what pain rating would be acceptable or satisfactory, considering the activities required for recovery or for maintaining a satisfactory quality of life.
Example for a surgical patient: "I have explained the importance of coughing and deep breathing to prevent pneumonia and other complications. Now we need to determine the pain rating that will not interfere with this so that you may recover quickly."
Example for patient with chronic pain or terminal illness: "What do you want to do that pain keeps you from doing? What pain rating would allow you to do this?"

VDS, Verbal descriptor scale.

*When a patient is obviously in pain or not focused enough to learn to use a pain rating scale, pain treatment should proceed without pain ratings. Teaching can be undertaken when pain is reduced to a level that facilitates understanding how to use a pain scale.

From Pasero, C., & McCaffery, M. (2011). *Pain assessment and pharmacologic management.* St. Louis: Mosby. Copyright 2011, McCaffery, M., & Pasero, C. Used with permission.

- Numeric Rating Scale (NRS): The NRS is usually presented as a horizontal 0-to-10 point scale, with word anchors of "no pain" at one end of the scale, "moderate pain" in the middle of the scale, and "worst possible pain" at the end of the scale (see Fig. 3-3). Some patients relate better to a vertical presentation of the scale.

FIG. 3-3 Wong-Baker FACES® pain rating scale.

- Wong-Baker FACES® Pain Rating Scale: The FACES scale consists of 6 cartoon faces with word descriptors, ranging from a smiling face on the left for "no pain (or hurt)" to a frowning, tearful face on the right for "worst pain (or hurt)." The faces are most commonly numbered 0 to 10. Patients are asked to choose the face that best describes their pain. It is important to appreciate that faces scales are self-report tools; *clinicians should not attempt to match a face shown on a scale to the patient's facial expression to determine pain intensity*. Fig. 3-3 provides the Wong-Baker FACES scale combined with the NRS.
- Faces Pain Scale-Revised (FPS-R): The FPS-R has 7 faces to make it consistent with other scales using the 0 to 10 metric. The faces range from a neutral facial expression to one of intense pain. As with the Wong-Baker FACES® scale, patients are asked to choose the face that best reflects their pain. Some research shows that the FPS-R is preferred by both cognitively intact and impaired older adults.
- Verbal Descriptor Scale (VDS): A VDS uses different words or phrases to describe the intensity of pain, such as "*no pain, mild pain, moderate pain, severe pain very severe pain*, and *worst possible pain.*" The patient is asked to select the phrase that best describes the pain intensity.

- *Quality:* Ask the patient to describe how the pain feels. He or she may use one word or a group of words to convey the sensory perception of the pain. *Avoid suggesting descriptive words for the pain; allow patients to use their own words to describe the pain.* Descriptors such as "sharp," "shooting," or "burning" may help identify the presence of neuropathic pain. Ask the patient whether the pain is superficial or deep. In general, those with pain involving superficial or cutaneous (skin) structures describe it as superficial and can often localize the pain to a specific area.

- *Onset and duration:* Ask the patient when the pain started and whether it is constant or intermittent.
- *Aggravating and relieving factors:* Ask the patient what makes the pain worse and what makes it better. Ask about strategies the patient has used before to manage pain.
- *Effect of pain on function and quality of life:* The effect of pain on the ability to perform recovery activities should be regularly evaluated. It is particularly important to ask patients with persistent pain about how it has affected their lives. Ask what they could do before the pain began that they can no longer do and what they want to do but cannot do.
- *Comfort-function (pain intensity) outcomes:* For patients with *acute pain,* identify expected short-term functional outcomes. Reinforce to the patient that adequate pain control will lead to more successful achievement of those outcomes. For example, tell surgical patients that they will be expected to ambulate or participate in physical therapy postoperatively. Ask patients to identify a level of pain that will allow accomplishment of the expected outcomes. A realistic outcome for most patients is 2 or 3 on a scale of 0 to 10. Pain intensity that is consistently above the desired level requires further evaluation and consideration of possible adjustment of the treatment plan.
- *Other information:* Consider the patient's culture, past pain experiences, and pertinent medical history such as comorbidities. Current treatments and diagnostic studies are considered when performing an assessment. For example, patients who are intubated may be awake and alert but unable to speak. Strategies to assess the presence and severity of pain in these patients include (Tate et al., 2012):

Considerations for Older Adults

Patient-Centered Care QSEN

Pain is not an inevitable consequence of aging; however, the incidence is higher in older adults. Sensitivity to pain does not diminish with age. Many older adults, even those with mild to moderate dementia, are able to use a self-report assessment tool if nurses and other caregivers take the time to administer it. Many older adults are reluctant to report pain for a variety of reasons including the belief that it is normal and that they are bothering the nurse. It is essential that attempts be made to elicit the patient's self-report and pain be assessed frequently with a focus on functional and quality-of-life indicators in this vulnerable population.

Psychosocial Assessment

Pain holds unique meaning for the person experiencing it. Patients having *acute pain* from surgery may interpret it as necessary and expected. It may be viewed with relief as a sign that some greater problem has been resolved or alleviated by the surgery. Knowing that the duration of the pain is limited may be reassuring for a patient. In contrast, acute chest pain associated with angina may mark the beginning of a life of fear and uncertainty.

Various psychosocial factors influence *chronic* pain. Some factors are similar to those found in the acute pain experience, such as anxiety or fear related to the meaning of the pain. Because chronic pain persists or is perhaps only partially relieved, the patient may feel powerless, angry, hostile, or desperate. He or she is also vulnerable to labels such as "chronic complainer" or "faker." Remember that it is unprofessional and inappropriate to label or stereotype patients. *Remain objective, and advocate for proper pain control for all patients.*

Assess the status of family and other close relationships, along with the range of social resources available to the patient with chronic pain. The existence of a pain-specific conflict with a spouse or significant other may affect or limit coping strategies. Other people may react to chronic pain with depression, social withdrawal, and preoccupation with physical symptoms. Refer the patient and family to self-help groups, such as the American Chronic Pain Association (http://theacpa.org), which provides the "10-Step Program from Patient to Person."

If the chronic pain is associated with a progressive disease such as cancer, rheumatoid arthritis, or peripheral vascular disease, the patient may have worries and concerns about the consequences of the illness. People with cancer-related pain may fear death or body mutilation. Some may think they are being punished for some wrongdoing in life. Others may attach a religious or spiritual significance to lingering pain.

Ask open-ended questions (e.g., "Tell me how your pain has affected your job or your role as a mother.") to allow the patient to describe personal attitudes about pain and its influence on life. This opportunity can help someone whose life has been changed by pain. However, some patients choose not to share their private information or fears. As a patient-centered nurse, always respect patients' preferences and values.

NCLEX Examination Challenge

Physiological Integrity

A client who had a laminectomy reports new onset of severe back pain. What responses by the nurse are most appropriate for the client at this time? **Select all that apply.**

A "How is your pain on a 0-10 scale with 10 being the worst possible pain you've had?"
B "Could you describe the pain in your back?"
C "When you had visitors, you seemed to be laughing and not in any pain."
D "I'll get you some pain medication that the surgeon ordered."
E "Can you tell me what positions make the pain feel worse and better?"

Assessment Challenges

Patients who are unable to report their pain using the customary self-report assessment tools are at higher risk for undertreated pain than those who can report. These include patients who are cognitively impaired, critically ill (intubated, unresponsive), comatose, or imminently dying. Patients who are receiving neuromuscular blocking agents or are sedated from general anesthetics and other drugs given during surgery are also among this at-risk population.

First suggested in 1999 by McCaffery and Pasero, the *Hierarchy of Pain Measures* is recommended by many professional organizations today as a framework for assessing pain in patients who cannot self-report. The key components of the Hierarchy require the nurse to (1) attempt to obtain self-report; (2) consider underlying pathology or conditions and procedures that might be painful (e.g., surgery); (3) observe behaviors; (4) evaluate physiologic indicators; and (5) conduct an analgesic trial. See Table 3-5 for detailed information on each component of the Hierarchy of Pain Measures.

TABLE 3-5

Hierarchy of Pain Measures

1. Attempt to obtain the patient's self-report, the single most reliable indicator of pain. Do not assume a patient cannot provide a report of pain; many cognitively impaired patients are able to use a self-report tool if simple actions are taken.
   - Try using a standard pain assessment tool (see Fig. 3-3).
   - Ensure eyeglasses and hearing aids are functioning.
   - Increase the size of the font and other features of the scale.
   - Present the tool in vertical format (rather than the frequently used horizontal).
   - Try using alternative words, such as "ache," "hurt," and "sore" when discussing pain.
   - Ask about pain in the present.
   - Repeat instructions and questions more than once.
   - Allow ample time to respond.
   - Remember that head nodding and eye blinking or squeezing the eyes tightly can also be used to signal presence of pain and sometimes used to rate intensity.
   - Ask awake and oriented ventilated patients to point to a number on the numeric scale if they are able.
   - Repeat instructions and show the scale each time pain is assessed.
2. Consider the patient's condition or exposure to a procedure that is thought to be painful. If appropriate, *assume pain is present* (APP) and document APP when approved by institution policy and procedure. As an example, pain should be assumed to be present in an unresponsive, mechanically ventilated, critically ill trauma patient. Nurses should assume that certain procedures are painful and premedicate based on that assumption.
3. Observe behavioral signs (e.g., facial expressions, crying, restlessness, and changes in activity). A pain behavior in one patient may not be in another. Try to identify pain behaviors that are unique to the patient ("pain signature"). Many behavioral pain assessment tools are available that will yield a pain behavior score and may help determine if pain is present. However, it is important to remember that a behavioral score is not the same as a pain intensity score. Behavioral tools are used to help identify the presence of pain and whether an intervention is effective, but the pain intensity is unknown if the patient is unable to provide it.
   - A surrogate who knows the patient well (e.g., parent, spouse, or caregiver) may be able to provide information about underlying painful pathology or behaviors that may indicate pain.
   - Although surrogates may be helpful in identifying behaviors that may indicate pain, research has shown that they commonly underestimate or overestimate the intensity of the pain. Therefore they should not be asked to rate the patient's pain intensity.
4. Evaluate physiologic indicators with the understanding that they are the *least* sensitive indicators of pain and may signal the existence of conditions other than pain or a lack of it (e.g., hypovolemia, blood loss). Patients quickly adapt physiologically despite pain and may have normal or below normal vital signs in the presence of severe pain. The overriding principle is that the absence of an elevated blood pressure or heart rate does not mean the absence of pain.
5. Conduct an analgesic trial to confirm the presence of pain and to establish a basis for developing a treatment plan if pain is thought to be present. An analgesic trial involves administering a low dose of analgesic and observing patient response. The initial low dose may not be enough to illicit a change in behavior and should be increased if the previous dose was tolerated, or another analgesic may be added. If behaviors continue despite optimal analgesic doses, other possible causes should be investigated.
   - In patients who are unresponsive, no change in behavior will be evident and the optimized analgesic dose should be continued.

From Pasero, C., & McCaffery, M. (2011). *Pain assessment and pharmacologic management.* St. Louis: Mosby.

Patients with problems of cognition are among those at highest risk for undertreated pain because they are unable or have difficulty reporting their pain. The Hierarchy of Pain Measures (Table 3-5) lists several strategies to use when obtaining self-report is a challenge. When these are ineffective, the Hierarchy suggests that a number of behaviors have been shown to be indicators of pain. Behavioral pain assessment tools are often used to systematically evaluate behaviors to help determine the presence of pain. Improvement in the behavioral pain score helps confirm suspicions that pain is present and provides a reference point for assessing the effectiveness of interventions.

It is important for nurses to remember that *a score obtained from the use of a behavioral tool is not the same as a self-reported pain intensity score*. Although it may seem logical to assume that the higher the behavioral score, the more intense the pain, this cannot be proven without the patient's report. Some patients remain nonverbal and lie completely still (which would yield a low behavioral score) despite having severe pain. The reality is that if a patient cannot report the intensity of pain, the exact intensity is unknown. Two of the most commonly used behavioral assessment tools that are used for patients with problems of cognition such

as delirium (acute confusion) or dementia (chronic confusion) are:

- Checklist of Nonverbal Pain Indicators (CNPI) has been tested in the acute care setting in patients with varying levels of cognitive impairment. The tool groups behavioral indicators of pain into six categories. Each category allows a score of 0 if the behavior is not observed and a 1 if the behavior occurred even briefly during activity or rest:
  - Facial expression (e.g., grimacing, crying)
  - Verbalizations or vocalizations (e.g., screaming)
  - Body movements (e.g., restlessness)
  - Changes in interpersonal interactions
  - Changes in activity patterns or routines
  - Mental status changes (e.g., confusion, increased confusion)
- Pain Assessment in Advanced Dementia (PAINAD) scale, which has been tested in patients with severe dementia (Herr et al., 2011). The tool groups behavioral indicators into five categories for scoring using a graduated scale of 0 (least intense behaviors) to 2 (most intense behaviors) per category for a maximum behavioral score of 10:
  - Breathing (independent of vocalization)
  - Negative vocalization
  - Facial expression
  - Body language
  - Consolability (ability to calm the patient)

NCLEX Examination Challenge

Psychosocial Integrity

An older client who has advanced Alzheimer's disease is admitted to the clinical unit after abdominal surgery and is guarding her abdomen and moaning. What action will the nurse take?

A Ask the client's family to rate the intensity of the client's pain using the 0-to-10 scale.
B Use a behavioral pain assessment tool to determine the presence of pain.
C Ask the client to rate the intensity of her pain using the 0-to-10 scale.
D Contact the primary health care provider to request an order for an antianxiety drug.

For patients who are mechanically ventilated or may not be able to use other tools for communication, you can use these interventions:

- Establishing a reliable yes-no signal (e.g., thumbs up or down, head nods, or eye blinks) may be appropriate in some patients to establish the presence of pain.
- Use of communication boards, alphabet boards, computer, or picture boards with word labels may be helpful for patients with cognition problems.

- Correctly interpreting lip reading by maintaining eye contact, encouraging the patient to speak slowly, and using dentures if required are recommended.

Pharmacologic Management of Pain

Safe and effective use of analgesics requires the development of an individualized treatment plan based on a comprehensive assessment. This plan includes clarifying the desired outcomes of treatment and discussing options and preferences with the patient and family. Desired outcomes are periodically re-evaluated and changes made depending on patient response and, in some cases, disease progression.

Multimodal Analgesia

Pain is complex, which explains why there is no single, universal treatment for it. Its complexity is also the basis for the widespread recommendation that a multimodal analgesic approach be used regardless of the type of pain (American Society of Anesthesiologists [ASA], 2012; Pasero & McCaffery, 2011; Portenoy, 2011; Turk et al., 2011; Wu & Raja, 2011). Multimodal treatment involves the use of two or more classes of analgesics to target different pain mechanisms in the PNS or CNS. It relies on the thoughtful and rational combination of analgesics to maximize relief and prevent analgesic gaps that may lead to worsening pain or unnecessary episodes of uncontrolled pain.

A multimodal approach may allow lower doses of each of the drugs in the treatment plan. Lower doses have the potential to produce fewer side effects. Further, multimodal analgesia can result in comparable or greater relief than can be achieved with any single analgesic. For postoperative pain, the use of combination therapy to prevent both inflammatory and neuropathic pain is likely to yield the best immediate results. It also offers the promise of reducing the incidence of prolonged or persistent postsurgical pain.

The multimodal strategy also has a role in the management of persistent pain. The complex nature of the many chronic conditions indicates the need for appropriate combinations of analgesics, such as anticonvulsants, antidepressants, and local anesthetics, to target differing underlying mechanisms.

Preemptive analgesia involves the administration of local anesthetics, opioids, and other drugs (multimodal analgesia) along the continuum of care, during the preoperative, intraoperative, and postoperative periods. This continuous approach is designed to decrease pain severity in the

postoperative period, reduce analgesic dose requirements, prevent morbidity, shorten hospital stay, and avoid complications after discharge. Continuous multimodal analgesia may inhibit changes in the spinal cord that can lead to changes in the peripheral and central nervous systems that initiate and sustain chronic persistent postsurgical pain (see Nociception earlier in the chapter).

Routes of Administration

The oral route is the preferred route of analgesic administration and should be used whenever feasible because it is generally the least expensive, best tolerated, and easiest to administer. Other routes of administration are used when the oral route is not possible, such as in patients who are NPO, nauseated, or unable to swallow. For example, early postoperative pain and pain that is severe and escalating is managed with the IV route of administration. Then patients are transitioned to oral analgesics when they are able to tolerate oral intake.

Around-the-Clock Dosing

Two basic principles of providing effective management are (1) preventing pain and (2) maintaining a level of pain control that allows the patient to function and have an acceptable quality of life. Accomplishment of these desired outcomes may require the mainstay analgesic to be administered on a scheduled around-the-clock (ATC) basis, rather than PRN ("as needed"), to maintain stable analgesic levels. *ATC dosing regimens are designed to control pain for patients who report it being present 12 hours or more during a 24-hour period*, such as that associated with most chronic syndromes and pain during the first 24 to 48 hours after surgery or other tissue injury. PRN dosing of analgesics is appropriate for intermittent pain, such as before painful procedures and **breakthrough pain** (additional pain that "breaks through" the pain being managed by the mainstay analgesic), for which supplemental doses of analgesic are provided.

Patient-Controlled Analgesia

Patient-controlled analgesia (PCA) is an interactive method of management that allows patients to treat their pain by self-administering doses of analgesics. It is used to manage all types of pain and given by multiple routes of administration, including IV, subcutaneous, epidural, and perineural. A PCA infusion device ("pump") is used when PCA is delivered by invasive routes of administration and is programmed so that

the patient can press a button ("pendant") to self-administer a set dose of analgesic ("PCA dose") at a set time interval ("demand" or "lockout") as needed. *Patients who use PCA must be able to understand the relationships between pain, pressing the PCA button and taking the analgesic, and pain relief. They must also be cognitively and physically able to use any equipment that is used to administer the therapy.*

PCA may be given with or without a basal rate (continuous infusion). The use of a basal rate is common when patient-controlled epidural analgesia (PCEA) is used. It is often added for opioid-tolerant patients and occasionally for opioid-naïve patients receiving IV PCA to allow them to achieve pain control. Remember that the patient has no control over the delivery of a continuous infusion. Essential to the safe use of a basal rate is prompt discontinuation of the basal rate if increased sedation or respiratory depression occurs.

Nursing Safety Priority QSEN

Action Alert

Teach patients how to use the PCA device and to report side effects, such as dizziness, nausea and vomiting, and excessive sedation. As with all opioids, monitor the patient's sedation level and respiratory status at least every 2 hours. Promptly decrease the opioid dose (i.e., discontinue basal rate) if increased sedation is detected.

The primary benefit of PCA is that it recognizes that only the patient can feel the pain and only the patient knows how much analgesic will relieve it. This fact reinforces that *PCA is for patient use only and that unauthorized activation of the PCA button (called "PCA by proxy") can be very dangerous*. Instruct staff, family, and other visitors to contact the nurse if they have concerns about pain control rather than pressing the PCA button for the patient.

The Three Analgesic Groups

Analgesics are categorized into three main groups: (1) non-opioid analgesics, which include acetaminophen and the NSAIDs; (2) opioid analgesics, such as morphine, hydromorphone, fentanyl, and oxycodone; and (3) adjuvant analgesics (sometimes referred to as *co-analgesics*), which make up the largest group and include a variety of agents with unique and widely differing mechanisms of action. Examples are local anesthetics and some anticonvulsants and antidepressants. Table 3-6 lists

the three analgesic groups and examples of drugs in each group.

TABLE 3-6
The Three Analgesic Groups

Non-Opioid Analgesics

Advantages

- Versatile with multiple agents, formulations, and routes of administration available
- Flexible and useful for a wide variety of mild to moderate nociceptive-type pain conditions
- Identified as the foundation of a multimodal approach for nociceptive-type pain
- Can produce opioid dose-sparing effects
- Available in combination with opioids

Disadvantages

- Wide inter-individual differences in response
- Ineffective for neuropathic pain
- Acetaminophen adverse effects require careful consideration of patient's hepatic status before administration and care not to exceed recommended daily dose
- NSAID adverse effects prohibit use or suggest cautionary use in some patient populations, including older adults, patients with high CV and/or GI risk factors, and those with bleeding disorders
- All of the non-opioids and combination non-opioid/opioid formulations have a maximum daily dose that should not be exceeded

Examples

- Acetaminophen (Tylenol)
- Nonselective NSAIDs:
  - Aspirin
  - Diclofenac (Voltaren; Voltaren gel; Flector patch)
  - Ibuprofen (Motrin)
  - Ketoprofen (Orudis)
  - Ketorolac (Toradol)
  - Meloxicam (Mobic)
  - Naproxen (Naprosyn)
- COX-2-selective NSAIDs:
  - Celecoxib (Celebrex)

Opioid Analgesics

Advantages

- Cornerstone of moderate to severe nociceptive-type pain
- Mu agonists have no ceiling on analgesia
- Opioid rotation can be initiated for development of tolerance
- With the exception of constipation, tolerance develops to side effects with regular daily doses over several days

Disadvantages

- Constipation is an almost universal opioid side effect and the number-one reason people stop taking pain medication
- Although most side effects are manageable, undetected excessive sedation and respiratory depression are life threatening
- Close monitoring of sedation and respiratory status is indicated during at least the first 24 hours of opioid therapy
- Screening for appropriateness and ongoing monitoring via a therapeutic relationship between the patient and prescriber are required for safe and effective long-term opioid therapy
- Some opioids produce metabolites that can accumulate and produce toxicity, for example, morphine (morphine 3-glucuronide [M3G])

Examples of Mu Opioid Agonists

- Morphine (MS Contin; Kadian; Avinza; Roxanol; Duramorph; Astramorph)
- Fentanyl (Sublimaze; Duragesic; Actiq; Fentora; Onsolis)
- Hydromorphone (Dilaudid; Hydromorph; Exalgo)
- Hydrocodone (Zogenix ER; Lortab; Vicodin [also contain acetaminophen]; Vicoprofen [also contains ibuprofen])
- Oxycodone (OxyIR; OxyContin; Percocet [also contains acetaminophen]; Percodan [also contains aspirin])
- Oxymorphone (Opana; Opana ER)
- Methadone (Dolophine; Methadose)

Adjuvant Analgesics

Advantages

- Largest and most diverse analgesic group; wide variety of agents, formulations, and routes of administration available depending on agent
- Side effects often are responsive to dose reduction
- Tolerance develops to most of the adverse effects

Disadvantages

- Contain the agents that are recommended for treatment of neuropathic pain
- Considerable variability among people in their response to agents used to treat chronic neuropathic pain, including to agents within the same class; a "trial and error" strategy must be used, and multiple analgesic trials are sometimes necessary
- Most require titration of dose over several weeks to evaluate effectiveness; patients must be forewarned of delayed onset of analgesia
- Most have a maximum daily dose
- Side effects can be significant and may limit dose escalation

Examples

- Anticonvulsants:
  - Gabapentin (Neurontin)
  - Pregabalin (Lyrica)
- Antidepressants:
  - Tricyclic antidepressants:

Nortriptyline (Aventyl; Pamelor)

Desipramine (Norpramin)

  - Serotonin-norepinephrine reuptake inhibitors (SNRIs):

Duloxetine (Cymbalta)

Venlafaxine (Effexor)

- Alpha,-adrenergic agonists:
  - Clonidine (Catapres, Duraclon)
  - Tizanidine (Zanaflex)
- Local anesthetics:
  - Bupivacaine (Marcaine)
  - Ropivacaine (Naropin)
  - Lidocaine injectable
  - Lidocaine patch 5% (Lidoderm)
- Muscle relaxants/antispasmodics:
  - Baclofen (Lioresal)
  - Cyclobenzaprine (Flexeril)
- NMDA antagonists:
  - Ketamine (Ketalar)

CV, Cardiovascular; *NMDA, N*-methyl-d-aspartate.

Non-opioid Analgesics.

Acetaminophen and NSAIDs make up the non-opioid analgesic group. *Acetaminophen* is thought to relieve pain by underlying mechanisms in the CNS. It has analgesic and antipyretic properties but is not effective to treat inflammation. In contrast, *NSAIDs* have analgesic, antipyretic, and anti-inflammatory properties. These drugs produce pain relief by blocking prostaglandins through inhibition of the enzyme *cyclooxygenase (COX)* in the peripheral nervous system (see Nociception and Fig. 3-1 earlier in the chapter).

Non-opioids are available in a variety of formulations and given by multiple routes of administration. They are also flexible analgesics used for a wide range of conditions. Non-opioid drugs are appropriate alone for mild to moderate nociceptive pain (e.g., from surgery, trauma, or osteoarthritis) or are added to opioids, local anesthetics, and/or anticonvulsants as part of a multimodal analgesic regimen for more severe nociceptive pain. *However, they are not effective for neuropathic pain.*

Acetaminophen and an NSAID may be given together, and there is no need for staggered doses. Unless contraindicated, all surgical patients should routinely be given acetaminophen and an NSAID in scheduled doses as the foundation of the pain treatment plan throughout the postoperative course, preferably initiated preoperatively.

The non-opioids are often combined in a single tablet with opioids, such as oxycodone (Percocet) or hydrocodone (Vicodin, Lortab, Vicoprofen), and are very popular for the treatment of mild to moderate acute pain. Many people with persistent pain also take a combination non-opioid/opioid analgesic. However, it is important to remember that these combination drugs are not appropriate for severe pain of any type because the maximum daily dose of the non-opioid limits the escalation of the opioid dose.

Acetaminophen.

Oral acetaminophen (Tylenol, Abenol) has a long history of safety in recommended doses in all age-groups and most patient populations. It is recommended as first-line for musculoskeletal pain (e.g., osteoarthritis) in older adults but has no inflammatory properties so is less effective than NSAIDs for chronic inflammatory pain (e.g., rheumatoid arthritis). IV acetaminophen (Ofirmev) is approved for treatment of pain and fever in adults and children age 2 years and older and is given by a 15-minute

infusion in single or repeated doses. It is given alone for mild to moderate pain or in combination with opioid analgesics for more severe pain and has been shown to be well tolerated and to produce a significant opioid dose-sparing effect and superior pain relief compared with placebo (Pasero & Stannard, 2012).

The most serious complication of acetaminophen is hepatotoxicity (liver damage) as a result of overdose. Patient's hepatic risk factors must always be considered before administration of acetaminophen. In the healthy adult, a maximum daily dose below 4000 mg is rarely associated with liver toxicity (Pasero & Stannard, 2012). Many experts recommend reducing the daily dose (e.g., 2500-3000 mg daily) when used for *long-term* treatment in older adults. Acetaminophen does not increase bleeding time and has a low incidence of GI adverse effects, making it the analgesic of choice in many people with comorbidities.

Nursing Safety Priority QSEN

Drug Alert

Teach patients to tell their primary health care provider about the amounts of acetaminophen and NSAIDs they take each day. Remind patients of the importance of being alert to the adverse effects of the medications they take and to complete any prescribed laboratory tests (e.g., liver enzymes) to identify early indicators of adverse effects.

NSAIDs.

A benefit of the NSAID group is the availability of a wide variety of agents for administration via noninvasive routes. Ibuprofen (Motrin, Novo-Profen), naproxen (Naprosyn, Nu-Naprox), and celecoxib (Celebrex) are the most widely used oral NSAIDs in the United States and Canada (see Table 3-6). Diclofenac (Voltaren) is prescribed in patch and gel form for topical administration. An intranasal patient-controlled formulation of ketorolac (Sprix) has been approved for short-term treatment of acute pain. IV formulations of ketorolac (Toradol) and ibuprofen (Caldolor) are also used to manage acute pain. Both have been shown to produce excellent analgesia alone for mild to moderate nociceptive pain and significant opioid dose-sparing effects when administered as part of a multimodal analgesic plan for more severe pain (Pasero & McCaffery, 2011).

NSAIDs have more adverse effects than acetaminophen, with gastric toxicity and ulceration being the most common of the adverse effects.

Risk factors for NSAID adverse effects include being older than 60 years or having a history of peptic ulcer or cardiovascular (CV) disease. An important principle of NSAID use is to administer the lowest dose for the shortest time necessary.

All NSAIDs carry a risk for CV adverse effects through prostaglandin inhibition. The U.S. Food and Drug Administration (FDA) cautions against the use of any NSAIDs after high-risk open heart surgery because of an elevated CV risk with NSAIDs in this population. Prostaglandins also affect renal function. Be sure that the patient is adequately hydrated when administering NSAIDs to prevent acute renal failure.

Nursing Safety Priority QSEN

Drug Alert

NSAIDs can cause GI disturbances and decrease platelet aggregation (clotting), which can result in bleeding. Therefore observe the patient for gastric discomfort or vomiting and for bleeding or bruising. Tell the patient and family to stop taking these drugs and report these effects to the primary health care provider immediately if any of these problems occur. Celecoxib has no effect on bleeding time and produces less GI toxicity compared with other NSAIDs.

Health Teaching.

When taking a patient history, ask about the use of non-opioids, keeping in mind that most people do not understand the difference between the generic and brand names of over-the-counter (OTC) drugs. Patients may be taking both a generic non-opioid (e.g., acetaminophen, naproxen, or ibuprofen) and a brand name of the same non-opioid (e.g., Tylenol, Naprosyn, or Advil) at the same time and exceeding the safe maximum daily dose. They also may not realize that many OTC medications, such as sleep and cold remedies, contain non-opioids. Ask the patient or patient's family to provide the name of each drug (prescription and OTC) that the patient is taking, as well as the daily dose. Teach patients to be aware of the amount of non-opioid in combination products such as hydrocodone (e.g., Vicodin, Vicoprofen) and oxycodone (e.g., Percocet). Stress to patients that exceeding the safe maximum daily non-opioid dose places the patient at a high risk for adverse effects, such as liver toxicity (acetaminophen) and GI bleeding and CV complications (NSAIDs).

Considerations for Older Adults

Patient-Centered Care QSEN

Older adults are at increased risk for NSAID-induced GI toxicity. Acetaminophen should be used for mild pain. If an NSAID is needed for inflammatory pain or additional analgesia, the least ulcerogenic NSAID is recommended. The addition of a proton pump inhibitor (e.g., lansoprazole, omeprazole) to NSAID therapy, or opioid analgesics rather than an NSAID, is recommended for high-risk patients.

NCLEX Examination Challenge

Physiological Integrity

An older client takes acetaminophen (Tylenol) 2000 mg daily for osteoarthritis. What health teaching will the nurse provide for the client related to this medication?

A "Be sure and take your medication with food to prevent stomach ulcers."
B "Take your medication only when you need it for chronic pain."
C "Avoid any over-the-counter medications that may contain acetaminophen."
D "Take your blood pressure often because acetaminophen can cause it to go up."

Opioid Analgesics.

Opioid analgesics are the mainstay in the management of moderate to severe nociceptive types of pain, such as postoperative, surgical, trauma, and burn pain (see Table 3-6). Although it is often used, the term "narcotic" is considered obsolete and inaccurate when discussing the use of opioids for pain management. "Narcotic" is used loosely by law enforcement and the media to refer to a variety of substances of potential abuse. Legally, controlled substances classified as narcotics include opioids, cocaine, and others. *The preferred term is "opioid analgesics" when discussing these agents in the context of pain management*. Some patients prefer the term "pain medications" or "pain medicine."

Genetic/Genomic Considerations

Patient-Centered Care QSEN

It has long been known that the cytochrome (CY) *P450* enzyme system is important to the metabolism of some opioids. Interethnic variations in phenotypes of the *CYP450* enzymes are common, causing decreased metabolism of selected analgesics in a small percentage of Caucasians and Asians. These variations have clinical implications when the opioid *codeine,* which is metabolized by the *CYP450* enzyme system, is administered. Slow metabolizers may not respond well to codeine, and ultra-rapid metabolizers may have an exaggerated response (Pasero & McCaffery, 2011).

Opioids produce their effects by interacting with opioid receptor sites located throughout the body, including in the peripheral tissues, in the GI system, and in the spinal cord and brain (Yaksh & Wallace, 2011). When an opioid binds to the opioid receptor sites, it produces analgesia as well as unwanted effects, such as constipation, nausea, sedation, and respiratory depression. There are three classifications of opioids:

- Full or *mu agonists* ("morphine-like") bind primarily to the mu type opioid receptors in the CNS and, among other actions, block the release of the neurotransmitter *substance P,* which prevents the opening of calcium channels and the transmission of pain (Yaksh & Wallace, 2011). A major benefit of the mu opioid agonists is that they have no ceiling on analgesia. This means that increases in dose produce increases in pain relief and that there is no maximum dose (see Physical Tolerance later in the chapter). This property makes the mu opioid agonists the first-line opioid analgesics for moderate to severe nociceptive pain. Examples are morphine, fentanyl, hydromorphone, oxycodone, and hydrocodone.
- *Mixed agonists antagonists* bind to more than one type of opioid receptor. They bind as agonists to the kappa opioid receptors to produce analgesia and other effects and to the mu opioid receptors as antagonists. This antagonistic property explains why these drugs can trigger severe pain and opioid withdrawal syndrome characterized by rhinitis, abdominal cramping, nausea, agitation, and restlessness in patients who have been taking regular daily doses of a mu agonist opioid for several days. Another undesirable effect of these drugs is that they produce a dose-ceiling effect, which means further increases in dose will not produce further relief. This latter property limits their usefulness in pain management. Occasionally, these drugs are used in very low doses to antagonize (in hopes of relieving) opioid-induced side effects, such as pruritus. However, this approach risks reversing analgesia, so patients must be assessed frequently to ensure adequate

pain control is maintained. Examples are butorphanol (Stadol) and nalbuphine (Nubain).

- *Partial agonists* have some kappa and mu opioid receptor activity but produce an analgesia plateau and are not easily reversed by opioid antagonists, such as naloxone (Narcan). These properties limit their role in pain management. Buprenorphine is a partial agonist opioid, available in a transdermal patch (Butrans) for stable pain management. The drug has been formulated alone (Subutex) and with naloxone (Suboxone) for the treatment of the disease of addiction.

Opioid antagonists (e.g., naloxone [Narcan], naltrexone [Revia]) are drugs that also bind to opioid receptors but produce no analgesia (Yaksh & Wallace, 2011). If an antagonist is present, it competes with opioid molecules for binding sites on the opioid receptors and has the potential to block analgesia and other effects. They are used most often to reverse opioid effects, such as excessive sedation and respiratory depression.

Key Principles of Opioid Administration.

Many factors are considered when determining the appropriate opioid analgesic for the patient with pain. These include the unique characteristics of the various opioids and patient factors, such as type of pain, pain intensity, age, gender, coexisting disease, current drug regimen and potential drug interactions, prior treatment outcomes, and patient preference.

Gender Health Considerations

Patient-Centered Care QSEN

Research has identified differences between females and males in a number of factors that influence the pharmacokinetics (absorption, distribution, metabolism, and excretion) and pharmacodynamics (effects on the body) of drugs. Some of these factors are organ physiology, body composition, gastric emptying time, enzyme activity, and drug clearance (Snidvongs, 2008). Abundant research shows that women are at substantially greater risk for more pain conditions than men and that they may experience more postoperative and procedural pain than men (Fillingim et al., 2009). In the immediate postoperative period, women seem to have a higher opioid requirement but men demonstrate higher opioid consumption after the initial recovery period. This difference may be partly explained by the faster recovery after general anesthesia in women. Side effects and complications associated with opioid and non-opioid analgesics appear to be more prevalent in women than in men.

Creatinine clearance (drug excretion) is generally higher in men than in women due to increased muscle mass, and clearance varies with the menstrual cycle in women.

Titration (dose increases or decreases) of the opioid dose is usually required at the start and throughout the course of treatment when opioids are administered. Whereas patients with cancer pain most often are titrated upward over time for progressive pain, patients with acute pain, particularly postoperative pain, are eventually titrated downward as pain resolves. Although the dose and analgesic effect of mu agonist opioids have no ceiling, the dose may be limited by side effects. The absolute dose administered is unimportant as long as a balance between pain relief and side effects is favorable. *The desired outcome of titration is to use the smallest dose that provides satisfactory pain relief with the fewest side effects.*

When an increase in the opioid dose is necessary and safe, the increase can be titrated by percentages. When a slight improvement in analgesia is needed, a 25% increase in the opioid dose may be sufficient; a 50% increase for moderate improvement; and a 100% increase may be indicated for strong improvement, such as when treating severe, escalating pain (Pasero & McCaffery, 2011). The time at which the dose can be increased is determined by the onset and peak effects of the opioid and its formulation. For example, the frequency of IV opioid doses during initial titration may be as often as every 5 to 15 minutes (see later discussion of specific opioids). In contrast, at least 24 hours should elapse before the dose of transdermal fentanyl is increased after the first patch application.

Considerations for Older Adults

Patient-Centered Care QSEN

Although the patient's weight is not a good indicator of analgesic requirement, *age is considered an important factor to consider when selecting an opioid dose.* For older adults, the guideline is to "start low and go slow" with all drug dosing. For example, the starting opioid dose should be reduced by 25% to 50% in older adults because they are more sensitive to opioid side effects than are younger adults. The amount of subsequent doses is based on patient response, which should be evaluated frequently. Monitor sedation level and respiratory status, and promptly reduce the drug dose if sedation occurs or the respiratory rate is markedly decreased, depending on agency policy. Chart 3-1 describes

best practices for pain assessment and management in the older adult.

Chart 3-1 Nursing Focus on the Older Adult

Pain

Prevalence of Pain

- Recognize that older adults are at high risk for undertreated pain and those with cognitive impairment are at even higher risk.
- Common caregiver and health care team misconceptions, such as that pain sensitivity decreases with aging and older adults cannot tolerate analgesics without significant adverse effects, contribute to the undertreatment of pain in older adults.

Beliefs About Pain

- Older adults tend to report pain less often than younger adults, which frequently results in members of the health care team administering suboptimal analgesics and doses. The failure of older adults to report pain may be related to common beliefs and concerns they have about pain and the reporting of pain, such as:
  - Pain is an inevitable consequence of aging and little can be done to relieve it.
  - Expressing pain is unacceptable or is a sign of weakness.
  - Reporting pain will result in being labeled as a "bad" patient or a "complainer."
  - Nurses and physicians are too busy to listen to reports of pain.
  - Pain signifies a serious illness or impending death.
- Be aware of the common beliefs of older patients regarding pain and its management and correct misconceptions to help prevent barriers to achieving optimal pain relief.
- Nurses and other caregivers can overcome their reluctance to administer prescribed analgesics in adequate doses by following the principles of pain management in older persons (see *Management of Pain section*).

Assessment of Pain

- Ask the patient to provide his or her own report of pain; even mild to some moderate cognitively impaired older adults are able to provide self-report if nurses and caregivers take the time to obtain it.
  - Offer various self-report pain tools.
  - Always show tools in hard copy with large lettering, adequate space

between lines, non-glossy paper, and color for increased visualization.
- Be sure the patient is wearing glasses and hearing aids if needed and available.
- Provide adequate lighting and privacy to avoid distracting background noise.
- Repeat questions more than once, and allow adequate time for response.
- Use verbal descriptions such as "ache," "sore," and "hurt" if the patient seems to have difficulty relating to the word "pain."
- Ask about present pain only.
- If the patient is able to use a self-report tool, use the same tool and reteach the tool each time pain is assessed.

Considerations for Cognitively Impaired Patients (also see Table 3-5)

- Remember to "assume pain is present" in patients with diseases and conditions or procedures commonly associated with pain (see discussion below on *analgesic trial*).
- If the patient is unable to provide self-report, look for behaviors that may indicate the presence of pain.
  - Someone who knows the patient well, such as a family member or caregiver, may be helpful in identifying behaviors that might indicate pain. Do not ask others to rate pain intensity, and do not attempt to rate it yourself. Only the patient knows how severe the pain is, and if he or she cannot rate or describe the intensity, the exact intensity is unknown.
- Assess using a reliable and valid behavioral pain assessment tool.
  - Remember that behavioral tools tell us that pain might be present and provide a reference point to help determine the effectiveness of interventions, but the scores on behavioral tools have not been correlated with the ratings on pain intensity scales. A behavioral score is not a pain intensity rating.
  - Use the same behavioral assessment tool each time pain is assessed.
- Consider an analgesic trial to help determine the presence of pain and to establish an ongoing treatment plan in patients who are thought to have pain. This involves the administration of a low-dose analgesic; changes or decreases in the intensity of behaviors indicate that pain may be the cause of the behaviors. Doses should be increased or additional analgesics added as appropriate.

Management of Pain

- Use a multimodal approach that combines analgesics with different underlying mechanisms with the desired outcome of achieving optimal pain relief with lower doses than would be possible with a single analgesic; lower doses result in fewer side effects.
- Consider the type of pain, and begin therapy with the first-line analgesics that are recommended for that type of pain.
  - Non-opioids (acetaminophen, NSAIDs), opioids, and local anesthetics are first-line analgesics for nociceptive-type pain (e.g., postoperative pain, osteoarthritis pain, cancer pain).
  - Antidepressants, anticonvulsants, and local anesthetics are first-line analgesics for neuropathic-type pain (e.g., postherpetic neuralgia, diabetic neuropathy, phantom limb pain, post-stroke pain).
- Do not give meperidine to older adults because most have decreased renal function and are unable to efficiently eliminate its CNS-toxic metabolite *normeperidine*.
- Use around-the-clock (ATC) dosing of analgesics for pain that is of a continuous nature (e.g., chronic osteoarthritis or cancer pain; chronic neuropathic pain, first 24 to 48 hours after surgery).
- Use as needed (PRN) dosing for intermittent pain and before painful activities, such as before ambulation and physical therapy.
- Be aware of the main side effects of the analgesics that are administered and that they may be more likely to occur or be more severe in older than in younger adults.
- *Start low and go slow* with drug dosing; increase doses to achieve adequate analgesia based on patient's response to the previous dose.
- Teach the patient and family or other caregiver about the pain management plan (analgesics and nonpharmacologic strategies) and when to notify the primary health care provider for unrelieved pain or unmanageable or intolerable drug side effects.
- To promote adherence to the pain management plan in the home setting, suggest using a pillbox to organize each day's medications and keeping a diary to identify times of the day or activities that increase pain. The diary can be presented to the primary health care provider who can use it to make necessary adjustments in the treatment plan.

Physical Dependence, Tolerance, and Addiction.

The terms *physical dependence* and *tolerance* often are confused with *addiction,* so clarification of definitions is important. The most widely accepted definitions of these terms are:

- *Physical dependence is a normal response* that occurs with repeated administration of an opioid for several days. It is manifested by the occurrence of withdrawal symptoms when the opioid is suddenly stopped or rapidly reduced or an antagonist such as naloxone is given. Withdrawal symptoms may be suppressed by the natural, gradual reduction of the opioid as pain decreases or by gradual, systematic reduction, referred to as *tapering. Physical dependence is not the same as addictive disease.*
- *Tolerance is also a normal response* that occurs with regular administration of an opioid and consists of a decrease in one or more effects of the opioid (e.g., decreased analgesia, sedation, or respiratory depression). Like physical dependence, *tolerance is not the same as addictive disease.* Tolerance to analgesia usually occurs in the first days to 2 weeks of opioid therapy but is uncommon after that. It may be treated with increases in dose or rotation to a different opioid. However, disease progression, not tolerance to analgesia, appears to be the reason for most dose escalations. Stable pain usually results in stable opioid doses. With the exception of constipation, tolerance to the opioid side effects develops with regular daily dosing of opioids over several days.
- *Opioid addiction is a chronic neurologic and biologic disease.* The development and characteristics of addiction are influenced by genetic, psychosocial, and environmental factors. No single cause of addiction, such as taking an opioid for pain relief, has been found. It is characterized by one or more of these behaviors: impaired control over drug use, compulsive use, continued use despite harm, and craving. *The disease of addiction is a treatable disease; as for any other suspected disease, refer the patient to an expert for diagnosis and treatment.*
- *Pseudoaddiction* is a mistaken diagnosis of addictive disease. When a patient's pain is not well controlled, the patient may begin to manifest symptoms suggestive of addictive disease. For example, in an effort to obtain adequate pain relief, the patient may respond with demanding behavior, escalating demands for more or different medications, and repeated requests for opioids on time or before the prescribed interval between doses has elapsed. Pain relief typically eliminates these behaviors and is often accomplished by increasing opioid doses or decreasing intervals between doses.

Opioid Naïve versus Opioid Tolerant.

Patients are often characterized as being either opioid naïve or opioid tolerant. An *opioid-naïve* person has not recently taken enough opioid on

a regular basis to become tolerant to the effects of an opioid. An *opioid-tolerant* person has taken an opioid long enough at doses high enough to develop tolerance to many of the effects, including analgesia and the undesirable effects, such as nausea and sedation. There is no set time for the development of tolerance with wide individual variation among people. Some patients do not develop tolerance at all. Patients who have taken opioids regularly for about 7 days or longer are considered to be opioid tolerant.

Equianalgesia.

The term *equianalgesia* means approximately "equal analgesia." An equianalgesic chart provides a list of analgesic doses, both oral and parenteral (IV, subcutaneous, and IM), that are approximately equal to each other in ability to provide pain relief (Table 3-7). Equianalgesic conversion of doses is used to help ensure patients receive approximately the same pain relief when they are switched from one opioid or route of administration to another. It requires a series of calculations based on the daily dose of the current opioid to determine the equianalgesic dose of the opioid to which the patient is to be switched. Consult and collaborate with the pharmacist whenever equianalgesic conversion is indicated.

TABLE 3-7

Equianalgesic Dose Chart for Common MU Opioid Analgesics

- *Equianalgesic* means approximately the same pain relief.
- The equianalgesic chart is a guideline for selecting doses for opioid-naïve patients. Doses and intervals between doses are titrated according to each person's responses.
- The equianalgesic chart is helpful when switching from one drug or route of administration to another.

OPIOID	ORAL	PARENTERAL	COMMENTS
Morphine	30 mg	10 mg	Standard for comparison; first-line opioid via multiple routes of administration; once-daily and twice-daily oral formulations; clinically significant metabolites.
Fentanyl	No formulation	100 mcg IV 100 mcg/hr of transdermal fentanyl is approximately equal to 4 mg/hr of IV morphine; 1 mcg/hr of transdermal fentanyl is approximately equal to 2 mg/24 hr of oral morphine	First-line opioid via IV, transdermal, and intraspinal routes; available in oral transmucosal and buccal formulations for breakthrough pain in opioid-tolerant patients; no clinically relevant metabolites.
Hydrocodone	30 mg (NR)	No formulation	Available only in combination with non-opioid and as such is appropriate only for mild to some moderate pain.
Hydromorphone (Dilaudid)	7.5 mg	1.5 mg	First-line opioid via multiple routes of administration; once-daily oral formulation; clinically significant metabolites noted with long-term, high-dose infusion.
Oxycodone	20 mg	No formulation in the United States	Short-acting and twice-daily oral formulations.
Oxymorphone	10 mg	1 mg	Parenteral and short-acting and twice-daily oral formulations.

NR, Not recommended.

Data from Pasero, C., & McCaffery, M. (2011). *Pain assessment and pharmacologic management*. St. Louis: Mosby.

Relative potency is the ratio of drug doses required to produce the same effect. For example, note in Table 3-7 that a single dose of 1.5 mg of

parenteral hydromorphone produces approximately the same analgesia as 10 mg of parenteral morphine. This means that hydromorphone is more potent than morphine, but increased potency does not mean the drug is therapeutically superior or that it provides any advantage. Safe and effective pain management requires nurses to appreciate the differences in the potencies of the various opioids and apply the principles of equianalgesia when administering opioids.

Drug Formulation Terminology.

The terms *short acting, fast acting, immediate release (IR)*, and *normal release* have been used interchangeably to describe oral opioids that have an onset of action of about 30 minutes and a relatively short duration of 3 to 4 hours. The term *immediate release* is misleading because none of the oral analgesics have an immediate or even a fast onset of analgesia. The term *short acting* is preferred to reflect the short duration of oral opioids. Oral transmucosal and intranasal formulations are appropriately referred to as *ultra fast acting* because they have a peak effect of 5 to 15 minutes, depending on formulation.

The terms *modified-release, extended release (ER), sustained release (SR),* and *controlled release* are used to describe opioids that are formulated to release over a prolonged period of time. For the purposes of this chapter, the term *modified-release* will be used when discussing these opioid formulations. *Long-acting* is applied to drugs with a long *half-life*, such as methadone. A drug's half-life provides an estimate of how fast the drug leaves the body. By definition, **half-life** is the time it takes for the amount of drug in the body to be reduced by 50%.

Nursing Safety Priority QSEN

Drug Alert

Modified-release opioids should never be crushed, broken, or chewed because doing so alters the formulation of the drug and can result in adverse events, including death from respiratory depression if consumed. Teach the patient to swallow the drug whole and allow the "time release" function of the drug to take effect. Intact modified-release tablets may be administered rectally in some patients who cannot swallow.

Selected Opioid Analgesics.

Morphine is the standard against which all other opioid drugs are compared. It is the most widely used opioid throughout the world,

particularly for cancer pain, and its use is established by extensive research and clinical experience. Morphine is a *hydrophilic* drug (readily absorbed in aqueous solution), which accounts for its slow onset and long duration of action when compared with other opioid analgesics (Table 3-8). It is available in a wide variety of short-acting and modified-release oral formulations and is given by multiple other routes of administration, including rectal, subcutaneous, and IV.

TABLE 3-8

Characteristics of Selected First-Line Opioid Analgesics*

OPIOID	ONSET (MINUTES)	PEAK (MINUTES)	DURATION (HOURS)
Morphine	30-45 (oral)	60-90 (oral)	3-4 (oral)
	5-10 (IV)	15-30 (IV)	3-4 (IV)
Fentanyl	5 (OT)	15 (OT)	2 (OT)
	3-5 (IV)	10-20 (IV)	2 (IV)
Hydromorphone	15-30 (oral)	30-90 (oral)	3-4 (oral)
	5 (IV)	10-30 (IV)	3-4 (IV)

IV, Intravenous; *OT,* oral transmucosal.

*Characteristics do not apply to modified-release formulations.

Data from Pasero, C., & McCaffery, M. (2011). *Pain assessment and pharmacologic management*. St. Louis: Mosby.

Fentanyl (Sublimaze) differs from morphine significantly in characteristics. It is a *lipophilic* (readily absorbed in fatty tissue) opioid and, as such, has a fast onset and short duration of action (see Table 3-8). These characteristics make it the most commonly used IV opioid when rapid analgesia is desired, such as for the treatment of severe, escalating acute pain and for procedural pain when a short duration of action is desirable. Fentanyl is the recommended opioid for patients with end-organ failure because it has no clinically relevant metabolites (Pasero & McCaffery, 2011). It also produces fewer hemodynamic adverse effects than other opioids so is often preferred in patients who are hemodynamically unstable, such as the critically ill.

Its lipophilicity makes fentanyl ideal for drug delivery by transdermal patch (Duragesic) for long-term opioid therapy and by the oral transmucosal (Actiq) and buccal (Fentora) routes for breakthrough pain treatment in opioid-tolerant patients. After application of the transdermal patch, a subcutaneous depot of fentanyl is established in the skin near the patch. After absorption from the depot into the systemic circulation, the drug distributes to fat and muscle. When the first patch

is applied, 12 to 18 hours are required for clinically significant analgesia to be obtained. Be aware that the patient may need adequate supplemental analgesia during that time. Change the patch every 48 to 72 hours depending on patient response.

Nursing Safety Priority QSEN

Drug Alert

Teach patients taking transdermal fentanyl not to apply heat (e.g., hot packs, heating pads) directly over the patch because heat increases absorption of the drug and can result in adverse events, including death from fentanyl-induced respiratory depression. Ask patients about the presence of patches on admission, and document and communicate this information to other members of the interdisciplinary health care team.

Hydromorphone (Dilaudid) is less hydrophilic than morphine but less lipophilic than fentanyl, which contributes to an onset and duration of action that is intermediate between morphine and fentanyl (see Table 3-8). The drug is often used as an alternative to morphine, especially for acute pain, most likely because the two drugs produce similar analgesia and have comparable side effects. It is a first- or second-choice opioid (after morphine) for postoperative management via IV PCA and is available in a once-daily modified-release oral formulation for long-term opioid treatment.

NCLEX Examination Challenge

Physiological Integrity

A client has a one-time order for morphine 2 mg IV push. The drug is available as 5 mg/mL. The nurse administers _____ mL of morphine for one dose.

Oxycodone is available in the United States for administration by the oral route only and is used to treat all types of pain. In combination with acetaminophen or ibuprofen, it is appropriate for mild to some moderate pain. Single-entity, short-acting (OxyIR) and modified-release (OxyContin) oxycodone formulations are used most often for moderate to severe cancer pain and in some patients with moderate to severe non-cancer pain. It has been used successfully as part of a multimodal treatment plan for postoperative pain as well. Like morphine, it is

available in liquid form for patients who are unable to swallow tablets.

Hydrocodone in combination with non-opioids limits its use to the treatment of mild to some moderate pain. It is one of the most commonly prescribed analgesics in the United States, but its prescription for treatment of persistent pain (except for breakthrough dosing) should be carefully evaluated because of its ceiling on efficacy and safety related to the non-opioid constituent (ingredient).

Methadone (Dolophine) is a unique opioid analgesic that may have advantages over other opioids in carefully selected patients. In addition to being a mu opioid, it is an antagonist at the NMDA (*N*-methyl-d-aspartate) receptor site and thus has the potential to produce analgesic effects as a second- or third-line option for some neuropathic pain states (Dworkin et al., 2010). It may be given as an alternative when it is necessary to switch a patient to a new opioid because of inadequate analgesia or unacceptable side effects during long-term opioid therapy.

Although it has no active metabolites, methadone has a very long and highly variable half-life (5 to 100+ hours; average is 20 hours). Watch patients closely for excessive sedation—a sign of drug accumulation during the titration period. Other limitations are its tendency to interact with a large number of medications and prolong QTc interval.

Dual Mechanism Analgesics.

The dual mechanism analgesics, *tramadol* (Ultram) and *tapentadol* (Nucynta), are relatively new to the pain management arena. These drugs bind weakly to the mu opioid receptor site and block the reuptake (resorption) of the inhibitory neurotransmitters *serotonin* and/or *norepinephrine* in the spinal cord and brainstem of the modulatory descending pain pathway (see Nociception earlier in this chapter). This makes these neurotransmitters more available to fight pain. Because they have the opioid receptor binding property, they are discussed in the Opioid Analgesics section of this chapter. However, they are usually referred to as dual mechanism rather than opioid analgesics.

Tramadol is used for both acute and chronic pain and is available in oral short-acting (Ultram) and modified-release (Ultram ER) formulations, including a short-acting tablet in combination with acetaminophen (Ultracet). It is appropriate for acute pain and has been designated as a second-line analgesic for the treatment of neuropathic pain (Dworkin et al., 2010). Side effects are similar to those of opioids. The drug can lower seizure threshold and interact with other drugs that block the reuptake of serotonin, such as the selective serotonin reuptake inhibitor (SSRI) antidepressants. Although rare, this combination can have an

additive effect and result in serotonin syndrome, characterized by agitation, diarrhea, heart and blood pressure changes, and loss of coordination.

The newer dual mechanism analgesic *tapentadol* is also available in short-acting (Nucynta) and modified-release (Nucynta ER) formulations and is appropriate for both acute and chronic pain. Major benefits of tapentadol are that it has no active metabolites and a significantly more favorable side effect profile (particularly GI effects) compared with opioid analgesics.

Opioids to Avoid.

Meperidine (Demerol) was once the most widely used opioid analgesic in the inpatient setting. In recent years, it has either been removed from or severely restricted on U.S. hospital formularies for the treatment of pain in an effort to improve patient safety. A major drawback to the use of meperidine is its active metabolite, *normeperidine*, a CNS stimulant that can cause delirium, irritability, tremors, myoclonus, and generalized seizures. It is a particularly poor choice in older adults because they have decreased renal function, which prevents the elimination of the toxic metabolite. Meperidine has no advantages over any other opioid, and it has no place in the treatment of persistent pain or in delivery systems, such as PCA. If prescribed, meperidine should not be used for more than 48 hours or at doses exceeding 600 mg/24 hours (Pasero & McCaffery, 2011).

Codeine in combination with non-opioids (e.g., with acetaminophen in Tylenol #3) has been used for many years for the management of mild to moderate pain; however, it has largely been replaced by analgesics that are more efficacious and better tolerated (e.g., Percocet, Vicodin). Research has shown that codeine/acetaminophen is less effective and associated with more adverse effects than NSAIDs, such as ibuprofen and naproxen, for acute pain.

Intraspinal Analgesia.

Intraspinal analgesia involves the administration of analgesics via a needle or catheter placed in the epidural space or the intrathecal (subarachnoid) space by an anesthesia provider. The intraspinal routes of administration are used to manage both acute pain, such as postoperative pain, and some chronic cancer and non-cancer pain.

Epidural analgesia can be delivered by intermittent bolus technique, continuous infusion, or patient-controlled epidural analgesia (PCEA) with or without continuous infusion. The most commonly administered

analgesics by the epidural route are the opioids *morphine, hydromorphone,* and *fentanyl* in combination with a long-acting local anesthetic, such as bupivacaine (Marcaine) or ropivacaine (Naropin). This multimodal approach allows lower doses of both the opioid and local anesthetic and produces fewer side effects. A single epidural injection of preservative-free morphine (Duramorph) is effective for about 24 hours. An extended-release formulation of preservative-free epidural morphine (DepoDur) is effective for 48 hours.

Intrathecal (spinal) analgesia is usually delivered via single bolus technique for patients with acute pain (e.g., hysterectomy) or continuous infusion via an implanted device for the treatment of chronic pain. Because the drug is delivered directly into the aqueous cerebral spinal fluid (CSF), morphine with its hydrophilic nature is used most often for intrathecal analgesia. Extremely small amounts of drug are administered by the intrathecal route (about 10 times less than by the epidural route) because the drug is so close to the spinal action site.

The side effects of intraspinal analgesia depend on the type of drug administered. In other words, if opioids are administered, the same opioid-induced side effects that occur with other routes of administration can occur with intraspinal administration. If local anesthetics are administered, common side effects are urinary retention, hypotension, and numbness and weakness of lower extremities. The latter can occur on a continuum (mild and localized) to a complete block (undesirable and requires prompt anesthesia evaluation). In most cases, the side effects that occur during continuous infusion or PCEA can be managed by decreasing the dose.

Complications of intraspinal analgesia are rare but can be life threatening. Perform frequent neurologic assessments and promptly report abnormal findings to the anesthesiologist or nurse anesthetist.

Nursing Safety Priority QSEN

Drug Alert

Assess patients receiving epidural local anesthetic for their ability to bend their knees and lift their buttocks off the mattress (if not prohibited by surgical procedure). Ask them to point to any areas of numbness and tingling. Mild, transient lower extremity motor weakness and orthostatic hypotension may be present, necessitating assistance with ambulation. Most undesirable effects can be managed with a reduction in local anesthetic dose. Promptly report areas of numbness

outside of the surgical site, inability to bear weight, and severe hypotension to the anesthesia provider. *Do not delegate assessment of local anesthetic effects to unlicensed assistive personnel!*

Sensory perception manifestations (e.g., increasing numbness and tingling of extremities), decreasing ability to bear weight, and/or changes in bowel or bladder function can indicate the development of an epidural hematoma or abscess. If not detected, a hematoma or abscess can cause spinal cord compression and paralysis.

Nurses have an extensive role in the management and monitoring of intraspinal techniques, including infusion device operation, replacing empty drug reservoirs, checking and protecting infusion sites and systems, treating side effects, preventing complications, discontinuing therapy, and removing catheters.

Adverse Effects of Opioid Analgesics.

The most common side effects of opioid analgesics are constipation, nausea, vomiting, pruritus, and sedation (Pasero & McCaffery, 2011). Respiratory depression is less common but the most feared of the opioid side effects. *Most of the opioid side effects are dose-related, so simply decreasing the opioid dose is sufficient to eliminate or make most of the side effects tolerable for most patients.* Table 3-9 lists interventions to prevent and manage opioid-induced side effects.

TABLE 3-9

Nursing Interventions to Prevent and Treat Selected Opioid Side Effects*

Constipation
• Assess previous bowel habits. • Keep a record of bowel movements. • Remind patients that tolerance to this side effect does not develop, so *a preventive approach must be used;* administer a stool softener plus mild stimulant laxative for duration of opioid therapy; do not give bulk laxatives because these can result in obstruction in some patients. • Provide privacy, encourage adequate fluids and activity, and give foods high in roughage. • If ineffective, try suppository or Fleet's enema.
Nausea and Vomiting (N/V)
• Use a multimodal antiemetic preventive approach (e.g., dexamethasone plus ondansetron in moderate- to high-risk patients). • Assess cause of nausea and eliminate contributing factors if possible. • Reduce opioid dose if possible. • Reassure patients taking long-term opioid therapy that tolerance to this side effect develops with regular daily opioid doses. • Treat with antiemetic drug as prescribed. • Consider switching to another opioid for unresolved N/V.
Sedation
• Remember that sedation precedes opioid-induced respiratory depression; identify patient and iatrogenic risk factors and monitor sedation level and respiratory status frequently during the first 24 hours of opioid therapy. • Use a simple sedation scale to monitor for unwanted sedation (see Table 3-10). • If excessive sedation is detected, reduce opioid dose to prevent respiratory depression. • Eliminate unnecessary sedating drugs such as antihistamines, anxiolytics, muscle relaxants, and hypnotics. If it is necessary to administer these drugs during opioid therapy, monitor sedation and respiratory status closely. • Reassure patients taking long-term opioid therapy that tolerance to this side effect develops with regular daily opioid doses. • Be aware that stimulants such as caffeine may counteract opioid-induced sedation. • Consider switching to another opioid for unresolved excessive sedation during long-term opioid therapy.
Respiratory Depression
• Be aware that counting respiratory rate alone does not constitute a comprehensive respiratory assessment. Proper assessment of respiratory status includes observation of the rise and fall of the patient's chest to determine depth and quality in addition to counting respiratory rate for 60 seconds. • Recognize that *snoring is respiratory obstruction* and an ominous sign (see text). • Remember that sedation precedes opioid-induced respiratory depression; identify patient and iatrogenic risk factors and monitor sedation level and respiratory status frequently during the first 24 hours of opioid therapy (see Sedation section). • Stop opioid administration immediately for clinically significant respiratory depression, stay with patient, continue attempts to arouse patient, support respirations, call for help (consider Rapid Response Team or Code Blue), and consider giving naloxone. • Reassure patients taking long-term opioid therapy that tolerance to this side effect develops with regular daily opioid doses.

*With the exception of constipation, opioid side effects are dose-related. This means that a multimodal analgesic approach that incorporates non-opioid analgesics as its foundation and administers the lowest effective opioid dose should be used. The simplest and most effective method for managing opioid side effects when they occur is to reduce the opioid dose.

Opioids can result in delayed gastric emptying, slowed bowel motility, and decreased peristalsis, all of which can result in slow-moving, hard stool that is difficult to pass. Risk for *constipation* is elevated with opioid use, advanced age, and immobility, but it is an almost universal opioid side effect in all populations (i.e., tolerance rarely develops). Constipation is a primary reason people stop taking their pain medication. Therefore teach the importance of taking a preventive approach and aggressive management if symptoms occur. To prevent constipation, remind patients to take a daily stool softener plus a mild peristaltic stimulant, such as senna, for as long as they are taking an opioid.

Postoperative nausea and vomiting (PONV) are among the most unpleasant of the side effects associated with surgery. It is less common in older than younger adults. Evaluate patients for PONV risk, reduce risk factors if possible, and provide multimodal analgesia so that the lowest effective opioid dose can be given.

Pruritus (itching) is a side effect, not an allergic reaction to opioids. Although antihistamines such as diphenhydramine (Benadryl) are

commonly used, there is no strong evidence that they relieve opioid-induced pruritus. Patients may report being less bothered by itching after taking an antihistamine, but this is likely the result of sedating effects. Sedation can be problematic in those already at risk for excessive sedation, such as postoperative patients. This problem can lead to life-threatening respiratory depression (Jarzyna et al., 2011; Pasero & McCaffery, 2011). *Remember that the single most effective, safest, and least expensive treatment for pruritus is opioid dose reduction.*

As patients become opioid tolerant, *tolerance to the opioid side effects (with the exception of constipation) develops.* It is reassuring for patients receiving long-term opioid therapy to know that most of the side effects will subside with regular daily doses of opioids over several days.

Most patients experience sedation at the beginning of opioid therapy and whenever the opioid dose is increased significantly. *If undetected or left untreated, excessive sedation can progress to clinically significant respiratory depression.* Like most of the other opioid side effects, sedation and respiratory depression are dose-related. Prevention of clinically significant opioid-induced respiratory depression begins with administration of the lowest effective opioid dose (multimodal analgesia with a non-opioid foundation), careful titration, and close monitoring of sedation and respiratory status throughout therapy. *Unless the patient is at the end of life, promptly reduce opioid dose or stop titration whenever increased sedation is detected to prevent respiratory depression.* In some patients (e.g., those with obstructive sleep apnea, pulmonary dysfunction, multiple comorbidities), mechanical monitoring, such as capnography (to measure exhaled carbon dioxide) and pulse oximetry (to measure oxygen saturation), is needed (Jarzyna et al., 2011; Pasero & McCaffery, 2011).

Occasionally, drugs that produce significant sedation are used to treat side effects and other conditions that accompany the pain experience. For example, *antianxiety agents* (anxiolytics), such as alprazolam (Xanax) and lorazepam (Ativan), are prescribed to reduce anxiety. Many of the drugs used to treat opioid side effects are sedating, such as the antihistamines (diphenhydramine) for pruritus and the antiemetics *promethazine (Phenergan)* and *hydroxyzine (Vistaril)* for nausea. It is important to recognize that administration of these drugs together has an additive sedating effect. If administered, closely monitor for sedation and assess respiratory status frequently.

To assess sedation, use a simple, easy-to-understand sedation scale developed for assessment of *unwanted* sedation that includes what should be done at each level of sedation (Jarzyna et al., 2011; Pasero &

McCaffery, 2011). Table 3-10 presents a widely used sedation scale. The key to assessing sedation is to determine how easy it is to arouse the patient. Assess each person's response to the first dose of an opioid. If opioids are administered by bolus technique, assess sedation level and respiratory status at the opioid's peak time after each bolus. *If a patient is difficult to arouse, always stop the opioid, stay with the patient, continue vigorous attempts to arouse, and call for help!*

TABLE 3-10

Pasero Opioid-Induced Sedation Scale (POSS) with Interventions*

S = Sleep, easy to arouse
Acceptable; no action necessary; may increase opioid dose if needed.
1 = Awake and alert
Acceptable; no action necessary; may increase opioid dose if needed.
2 = Slightly drowsy, easily aroused
Acceptable; no action necessary; may increase opioid dose if needed.
3 = Frequently drowsy, arousable, drifts off to sleep during conversation
Unacceptable; monitor respiratory status and sedation level closely until sedation level is stable at less than 3 and respiratory status is satisfactory; decrease opioid dose 25% to 50%[1] or notify primary[2] or anesthesia provider for orders; consider administering a non-sedating, opioid-sparing non-opioid, such as acetaminophen or a NSAID, if not contraindicated; ask patient to take deep breaths every 15-30 minutes.
4 = Somnolent, minimal or no response to verbal and physical stimulation
Unacceptable; stop opioid; consider administering naloxone[3,4]; call Rapid Response Team (Code Blue); stay with patient, stimulate, and support respiration as indicated by patient status; notify primary[2] or anesthesia provider; monitor respiratory status and sedation level closely until sedation level is stable at less than 3 and respiratory status is satisfactory.

*Appropriate action is given in italics at each level of sedation.

[1]Opioid analgesic orders or a hospital protocol should include the expectation that a nurse will decrease the opioid dose if a patient is excessively sedated.

[2]For example, the physician, nurse practitioner, advanced practice nurse, or physician assistant responsible for the pain management prescription.

[3]For adults experiencing respiratory depression, administer dilute solution (0.4 mg of naloxone in 10 mL of normal saline) very slowly (0.5 mL over 2 minutes) while observing the patient's response (titrate to effect).

[4]Hospital protocols should include the expectation that a nurse will administer naloxone to any patient suspected of having life-threatening opioid-induced sedation and respiratory depression.

From Pasero, C., & McCaffery, M. (2011). *Pain assessment and pharmacologic management.* St. Louis: Mosby. Copyright 1994. Used with permission.

Respiratory depression is assessed on the basis of what is normal for a particular person and is usually described as clinically significant when there is a decrease in the rate, depth, and regularity of respirations from baseline, rather than just by a specific number of respirations per minute. Risk factors for opioid-induced respiratory depression include age 55 years or older, obesity, obstructive sleep apnea, and pre-existing pulmonary dysfunction or other comorbidities.

Nursing Safety Priority QSEN

Critical Rescue

An accurate respiratory assessment requires watching the rise and fall of the patient's chest to determine depth and regularity of respirations in addition to counting the respiratory rate for 60 seconds. Listening to the sound of the patient's respiration is critical as well—*snoring indicates airway obstruction and must be attended to promptly* with repositioning and, depending on severity, a request for respiratory therapy consultation and further evaluation (Pasero & McCaffery, 2011). For accuracy, respiratory assessment is done before arousing the sleeping patient.

Considerations for Older Adults

Patient-Centered Care QSEN

The incidence of opioid side effects in the older adult population varies depending on the side effect. Older adults are sensitive to the sedating effects of opioids, making them higher risk for respiratory depression than younger adults.

NCLEX Examination Challenge

Physiological Integrity

A nursing technician reports that a postoperative client who is receiving IV PCA morphine is very drowsy, unable to complete a sentence without falling asleep, and has a respiratory rate of 12 breaths per minute. What is the nurse's first action at this time?

A Arouse the client and raise the head of the bed to a 90-degree angle.
B Promptly call the primary health care provider to request an order to reduce the opioid dose.
C Take away the client's PCA button and tell the family to notify staff when pain returns.
D Reduce environmental stimuli by darkening the room so that the client can sleep.

Nursing Safety Priority QSEN

Drug Alert

Unless the patient is at the end of life, promptly administer the opioid antagonist *naloxone (Narcan)* IV to reverse clinically significant opioid-induced respiratory depression. When giving the opioid antagonist

naloxone, administer it slowly until the patient is more arousable and respirations increase to an acceptable rate. The desired outcome is to reverse just the sedative and respiratory depressant effects of the opioid but not the analgesic effects. Giving too much naloxone too fast not only can cause severe pain but also can lead to ventricular dysrhythmias, pulmonary edema, and even death. Continue to closely monitor the patient after giving naloxone because the duration of naloxone is shorter than the duration of most opioids and respiratory depression can recur. Sometimes more than one dose of naloxone is needed.

Adjuvant Analgesics.

Adjuvant analgesics (sometimes called *co-analgesics*) are drugs that have a primary indication other than pain but are analgesic for some painful conditions (see Table 3-6). For example, the primary indication for antidepressants is depression, but some antidepressants help relieve some types of pain. The adjuvant analgesics are the largest and most diverse of the three analgesic groups. Drug selection and dosing are based on both experience and evidence-based practice guidelines (Dworkin et al., 2010).

Anticonvulsants and Antidepressants.

Anticonvulsants (also called *antiepileptic drugs [AEDs]* when used for seizure management) produce analgesia by blocking sodium and calcium channels in the CNS, thereby diminishing the transmission of pain. The gabapentinoids *gabapentin (Neurontin)* and *pregabalin (Lyrica)* are recommended as first-line analgesics for persistent neuropathic pain (Dworkin et al., 2010). They are increasingly being added to postoperative treatment plans to address the neuropathic component of surgical pain. Primary side effects are sedation and dizziness, which are usually transient and most notable during the titration phase of treatment.

Antidepressants relieve pain on the descending modulatory pathway by blocking the body's reuptake of the inhibitory neurochemicals *norepinephrine* and *serotonin.* Antidepressant adjuvant analgesics are divided into two major groups: the *tricyclic antidepressants* (TCAs) and the newer *serotonin and norepinephrine reuptake inhibitors* (SNRIs). Evidence-based guidelines recommend the TCAs *desipramine (Norpramin)* and *nortriptyline (Aventyl, Pamelor)* and the SNRIs *duloxetine (Cymbalta)* and *venlafaxine (Effexor)* as first-line options for neuropathic pain treatment (Dworkin et al., 2010).

The most common side effects of the TCAs are dry mouth, sedation,

dizziness, mental clouding, weight gain, and constipation. Orthostatic hypotension is a potentially serious TCA side effect making TCAs a poor choice for older adults. The most serious adverse effect is cardiotoxicity, especially for patients with existing significant heart disease. The SNRIs have a more favorable side effect profile and are better tolerated than the TCAs. The most common SNRI side effects are nausea, headache, sedation, insomnia, weight gain, impaired memory, sweating, and tremors.

Considerations for Older Adults

Patient-Centered Care QSEN

Older adults are often sensitive to the effects of the adjuvant analgesics that produce sedation and other CNS effects, such as anticonvulsants and antidepressants. Therapy should be initiated with low doses, and titration should proceed slowly with systematic assessment of patient response. Caregivers in the home setting must be taught to take preventive measures to reduce the likelihood of falls and other accidents. A home safety assessment is highly recommended and can be arranged by social services before discharge.

Local Anesthetics.

Local anesthetics relieve pain by blocking the generation and conduction of the nerve impulses necessary to transmit pain (Catterall & Mackie, 2011). The local anesthetic effect is dose-related. A high enough dose of local anesthetic can produce complete anesthesia, and a low enough dose (subanesthetic) can produce analgesia.

Local anesthetics have a long history of safe and effective use for the treatment of all types of pain. Allergy to local anesthetics is rare, and side effects are dose-related. CNS signs of systemic toxicity include ringing in the ears, metallic taste, irritability, and seizures. Signs of cardiotoxicity include circumoral tingling and numbness, bradycardia, cardiac dysrhythmias, and CV collapse.

The *lidocaine patch 5%* (Lidoderm) is 10 cm by 14 cm and contains 700 mg of lidocaine. The patch is placed directly over or adjacent to the painful area for absorption into the tissues directly below. A major benefit of the drug is that it produces minimal systemic absorption and side effects. The patch is left in place for 12 hours and then removed for 12 hours (12-hours-on, 12-hours-off regimen). This application process is repeated as needed for continuous analgesia.

Topical local anesthetic creams for superficial procedures, such as IV insertion, include *EMLA* (eutectic mixture of local anesthetics*) and LMX-4*. *EMLA* contains a combination of lidocaine 2.5% and prilocaine 2.5% and is applied to intact skin for 60 to 120 minutes before the procedure. *LMX-4* contains 4% lidocaine and is applied 30 minutes before the procedure. EMLA has a longer duration of action (2 hours) than LMX-4 (30 minutes) after cream removal. Topical local anesthetic side effects are rare and usually transient, with local skin reactions being the most common.

For many years, *regional anesthesia* has been administered by single-injection peripheral nerve blocks using a long-acting local anesthetic, such as bupivacaine or ropivacaine, to target a specific nerve or nerve plexus. This technique is highly effective in producing pain relief, but the effect is temporary (4-12 hours). *Continuous peripheral nerve block* (also called *perineural regional analgesia*) offers an alternative with longer lasting analgesia. A continuous peripheral nerve block involves establishment by an anesthesia provider of an initial block followed by placement of a catheter through which an infusion of local anesthetic is administered continuously, with or without PCA capability. When PCA capability is added, this is referred to as *PCRA* (patient-controlled regional analgesia). Just as with epidural and intrathecal analgesia, nurses are responsible for monitoring and managing the therapy (Pasero & McCaffery, 2011).

Use of Placebos

A placebo is defined as any medication or procedure, including surgery, which produces an effect in a patient because of its implicit or explicit intent, not because of its specific physical or chemical properties. A saline injection is one example of a placebo. Administration of a medication at a known subtherapeutic dose (e.g., 0.05 mg of morphine in an adult) is also considered a placebo.

Placebos are appropriately used as controls in research evaluating the effects of a new medication. Patients or volunteers who participate in placebo-controlled research must be able to give informed consent or have a guardian who can provide informed consent. Unfortunately, occasionally placebos are used clinically in a deceitful manner and without informed consent. This is often done when the clinician does not accept the patient's report of pain. Pain relief resulting from a placebo, should it occur, is mistakenly believed to invalidate a patient's report of pain. This typically results in the patient being deprived of pain-relief

measures despite research showing that many patients who have obvious physical stimuli for pain (e.g., abdominal surgery) report pain relief after placebo administration. The use of placebos has both ethical and legal implications, violates the nurse-patient relationship, and deprives patients of more appropriate methods of assessment or treatment.

Nursing Safety Priority QSEN

Drug Alert

Deceitful administration of a placebo violates informed consent law and jeopardizes the nurse-patient therapeutic relationship. Never administer a placebo to a patient. Promptly contact your nursing supervisor if you are given an order to do so.

Nonpharmacologic Management of Pain

Most people use self-management and nonpharmacologic strategies to deal with their health issues and promote well-being (Bruckenthal, 2010). Nonpharmacologic methods are appropriate alone for mild- and some moderate-intensity pain and should be used to complement, not replace, pharmacologic therapies for more severe pain. The effectiveness of nonpharmacologic methods can be unpredictable. Although not all have been shown to relieve pain, they offer many benefits to some patients of all ages (see Evidence-Based Practice box). For example, research has shown that nonpharmacologic methods can facilitate relaxation and reduce anxiety, stress, and depression, which often accompany the pain experience (Bruckenthal, 2010). Many patients find the use of nonpharmacologic methods helps them cope better and feel greater control over the pain experience. Nurses play an important role in providing and teaching their patients about nonpharmacologic strategies. Many of the methods are relatively easy for nurses to incorporate into daily clinical practice and may be used individually or in combination with other nonpharmacologic therapies.

Evidence-Based Practice QSEN

Does Education About the Use of Nonpharmacologic Methods Improve Pain Management in Rural Community-Dwelling Older Adults?

Fouladbakhsh, J.M., Szczesny, S., Jenuwine, E.S., & Vallerand, A.H.

(2011). Nondrug therapies for pain management among rural older adults. *Pain Management Nursing, 12*(2), 70-81.

Researchers used a quasi-experimental two-group (experimental and control) design to test an educational intervention aimed at educating older adults in a rural community about the appropriate use of nonpharmacologic treatments for pain relief. The interventions were (1) the application of a moist hot pack and/or (2) cold pack to a part of the body for a specified period of time, and/or (3) the use of relaxation breathing exercises while experiencing pain. The sample consisted of 55 adult volunteers who were 60 years of age or older, English-speaking, and had experienced pain in the past 2 weeks. The subjects enrolled in an educational session by date and location that were convenient to them. Surveys to establish baseline pain, pain-related distress, and perception of control over pain were conducted before intervention to establish baseline levels. Participants were randomized to receive either a 30-minute (control) or 60-minute (experimental) education program and a follow-up evaluation session 2 weeks later. Both groups received an additional 30-minute session focused on safe use of over-the-counter (OTC) analgesics. The experimental group received an additional 30-minute session on the safe and appropriate use of the three nonpharmacologic treatments, and each participant in the experimental group was given one hot pack and one cold pack to take home after the education sessions.

At follow-up, there was a significant increase in the use of all three of the nonpharmacologic interventions in the experimental group with two to three times more participants reporting their use than those in the control group. The most frequently used nonpharmacologic therapy was topical application of heat and cold in both groups.

Level of Evidence: 3

The researchers used a quasi-experimental two-group (experimental and control) design to test the interventions.

Commentary: Implications for Practice and Research

This study suggests that older adults with pain may benefit from the use of simple nonpharmacologic interventions and that a structured educational program is helpful in increasing their use of these methods. However, further research and a larger sample size are needed to detect statistically significant changes over time.

Nonpharmacologic interventions are categorized as being body-based

(physical) modalities; mind-body (cognitive-behavioral) methods; biologically based therapies; and energy therapies (Bruckenthal, 2010). Biologically based and energy therapies are used most often in the ambulatory care setting and are beyond the scope of this chapter.

Physical Modalities

The physical modalities have the best evidence for reducing pain. In the acute care setting, the physical modalities are used most often because of their ease in implementation and their role in postoperative recovery. In the ambulatory care setting, sustained physical regimens, such as regular low-impact exercise, in combination with analgesics improve outcomes for people with chronic pain. Many of the physical modalities require a prescription for use and reimbursement. Some require a trained expert to administer the technique (e.g., acupuncture). Among the most effective physical modalities used to manage or prevent pain are:

- Physical therapy
- Occupational therapy
- Aquatherapy
- Functional restoration (also has cognitive-behavioral components)
- Acupuncture
- Low-impact exercise programs, such as slow walking and yoga

The physical modalities are often administered using an interdisciplinary approach. The assistance of physical and occupational therapists to help design and implement an individualized plan with realistic goal setting promotes effectiveness of these methods. Coordinate with the therapist to implement strategies to decrease pain before therapy sessions with the purpose of increasing function and preventing further deterioration. Teach patients to adhere to their drug regimen to maximize effectiveness of the treatment plan. Expected patient outcomes include an increase in the range of motion, strength, and function of the affected area and an improved quality of life. The occupational therapist may also help decrease pain by making one or more splints to rest severely inflamed joints.

A number of *cutaneous (skin) stimulation* strategies, which apply mild stimulation to the skin and subcutaneous tissues, have been used for many years to relieve pain. Examples of cutaneous stimulation include:

- Application of heat, cold, or pressure
- Therapeutic massage
- Vibration
- Transcutaneous electrical nerve stimulation (TENS)

Cold applications are especially helpful for inflamed areas, such as for patients with rheumatoid arthritis and those who have knee surgery. Heat is appropriate when an increased blood flow is desired, such as for patients with osteoarthritis pain. Paraffin dips for the hands can be helpful to increase movement for those patients as well. Warm showers and compresses that can be done at home are useful in reducing stiffness and promoting movement in patients with arthritis, especially after awakening. Local short-acting gels and creams may provide *cryotherapy (cold treatment)* to relieve muscle aches and pains. These products can often be bought over the counter (OTC) (e.g., Bengay, Icy Hot). The effects of this type of application can last up to 2 hours. Discuss this information with the patient before the use of a cutaneous method:

- The benefits of these techniques are highly unpredictable and may vary from application to application.
- pain relief is generally sustained only as long as the stimulation continues.
- Multiple trials may be necessary to establish the desired effects.
- Stimulation itself may aggravate pre-existing pain or may produce new pain.

Despite these potential drawbacks, cutaneous stimulation can be effective in the management of both acute and chronic pain in selected patients. A major benefit of these methods is that many are easy for patients to self-administer.

TENS is used occasionally as an adjunctive treatment for pain. Although there are several types of TENS units, each involves the use of a battery-operated device capable of delivering small electrical currents through electrodes applied to the painful area. The voltage or current is regulated by adjusting a dial to the point at which the patient perceives a prickly "pins-and-needles" sensory perception rather than the pain. The current is adjusted based on the degree of desired relief. TENS requires the person to be skilled in the use of the necessary equipment and to be able to apply leads to the correct areas of the body. These factors are cited by patients as drawbacks and can be barriers to older adults who live alone and who may have difficulty with lead application.

Spinal cord stimulation is an *invasive* stimulation technique that provides pain control by applying an electrical field over the spinal cord. A trial with a percutaneous epidural stimulator is conducted to determine whether permanent placement of the device is appropriate. If the trial is successful, electrodes are surgically placed in the epidural space and connected to an external or implanted programmable generator. The patient is taught to program and adjust the device to maximize comfort.

Spinal cord stimulation can be extremely effective in selected patients but is reserved for intractable neuropathic pain syndromes that have been unresponsive to less invasive methods.

Cognitive-Behavioral Strategies

Cognitive-behavioral strategies are less effective in relieving pain than physical modalities. However, they help patients feel more in control and cope better with pain and the conditions that often accompany it, such as depression, anxiety, and stress. Cognitive-behavioral strategies are useful in reducing the patient's focus on pain but do not physiologically block pain transmission. They are most appropriate as an adjunct to pharmacologic therapy for more severe pain. In addition to potential benefits, the limitations of cognitive-behavioral methods should be explained to patients to prevent unrealistic expectations.

Cognitive-behavioral methods range from simple (e.g., prayer, relaxation breathing, artwork, reading, and watching television) to more complex (e.g., meditation, guided imagery, hypnosis, biofeedback, and virtual reality). It is important to recognize that many of the methods require patient teaching and subsequent patient participation. Therefore it is inappropriate to attempt to teach the more complex cognitive-behavioral methods to patients who are unfamiliar with them and are experiencing severe pain, anxiety, or agitation. Not all patients are receptive to the use of these methods. To respect their wishes, values, and preferences as part of patient-centered care, do not insist that patients use any method.

Distraction is probably the most commonly used cognitive-behavioral method. All of us use simple distraction measures in our daily life when we watch television or read a book. Nurses often observe that patients request less pain medication when family members are present and when talking on the phone. After visiting hours, it is not unusual for patients to request pain medication because they are no longer distracted.

Visual distracters (e.g., looking at a picture, watching television, playing a video game) can divert the attention to something pleasant or interesting. Auditory distracters (e.g., listening to music or relaxation tapes) can have a calming effect. Changing the environment involves removing or reducing unpleasant stressors that can interfere with the patient's ability to cope with pain, such as loud noise and bright lights. Ask patients if they use any cognitive-behavioral techniques in their daily life. Encourage them to apply those methods to their current pain experience.

Imagery is a more complex form of distraction in which the patient is encouraged to visualize or think about a pleasant or desirable feeling, sensation, or event. The person is encouraged to sustain a sequence of thoughts aimed at diverting attention away from the pain. Patients who practice this technique can mentally and vividly experience sights, sounds, smells, events, or other sensations. Intense concentration is required to visualize images; therefore patients must have fairly well-controlled pain to participate.

Before suggesting imagery, assess the patient's level of concentration to determine whether he or she can sustain a particular thought or thoughts for a desired time. The time interval for mental imagery can vary from 5 to 60 minutes. Behaviors that may be helpful in assessing whether a patient is a candidate for teaching guided imagery include that the patient is able to:

- Read and comprehend a newspaper or magazine article
- Tap to a rhythm or sing while listening to music
- Follow the logic and participate in sustained conversation
- Have an interest in environmental surroundings

When the patient has demonstrated ability to concentrate, assist him or her in identifying a pleasant or favorable thought. Encourage the patient to focus on this thought to divert attention away from painful stimuli. CDs or other audio recordings, either commercial or created by the patient and family, may help form and maintain images. This is an example of guided imagery instructions:

> *Imagine being on the beach of a deserted island. You can hear the sound of waves rushing onto the shore, the cry of seagulls flying high above, and the rustling of trees as they are brushed gently by the wind. You can feel the warmth of the sun over your body and the cooling breeze.*

Patients may also use *relaxation techniques* to reduce anxiety, tension, and emotional stress, all of which can exacerbate pain. For example, before and during a painful procedure, patients can be reminded to breathe slowly, deeply, and rhythmically to divert attention and promote relaxation. Relaxation techniques can be both physical and psychological. Physical relaxation techniques include:

- Relaxation breathing
- Receiving a body massage, back rub, or warm bath
- Modifying the environment to reduce distractions
- Moving into a comfortable position

Psychological relaxation techniques include:

- Pleasant conversation
- Laughter and humor
- Music (provide a range of choices)
- Relaxation tapes

Clinical Judgment Challenge

Patient-Centered Care; Evidence-Based Practice QSEN

An older woman visits the neurologist for low back pain that she has had for several months. She has been taking high doses of ibuprofen and acetaminophen every day with some pain relief. After a thorough physical examination, the neurologist starts her on pregabalin (Lyrica) 75 mg twice daily for pain. As her office nurse, you are preparing for health teaching.

1. What questions will you ask the patient at this time in preparation for teaching?
2. How might you find the best evidence to help prepare her teaching plan?
3. What are the concerns about her current pain management regimen?
4. What nonpharmacologic methods might benefit her? How will you determine if they are appropriate for her values and beliefs?

Community-Based Care

Before patients are discharged from an acute care setting, collaborate with members of the health care team to optimize pain control. Before discharge or transfer from a hospital, ensure that the patient, especially one who will receive opioid analgesia, has appropriate prescriptions and enough doses to last at least until the first follow-up visit with the primary health care provider.

Home Care Management

Fatigue exacerbates pain. If physical modifications in the home (e.g., installing a downstairs bathroom) are unrealistic, suggest changes in schedules, role responsibilities, and daily routines to help prevent or reduce fatigue.

At home, patients may require a referral for physical therapy, especially to start or continue exercise regimens or treatment with cutaneous stimulation or heat or cold techniques. Patients may need a social worker to assist them develop coping strategies or maintain

adequate family dynamics. A hospice or palliative care referral (hospital- or community-based) can help maintain continuity of care in the management of terminally ill patients and those who require treatment of some chronic conditions.

Home infusion therapy programs provide a wide variety of services to patients who require technology-supported pain care at home. Many of these services depend on approval by the insurance carrier, usually before analgesic options are considered and therapy is started. Case managers can be helpful in answering insurance and other payment questions. Well-defined home agency practices and professional support at home are required if patients leave the hospital with infusion therapy for pain management. Often, family members are taught to assume the responsibilities of home infusion therapy.

Self-Management Education

Teach the patient and family about analgesic regimens, including any technical skills needed to administer the analgesic; the purpose and action of various drugs, their side effects, and complications; and the importance of correct dosing and dosing intervals. Explain how to prevent or treat the constipation commonly associated with taking opioid analgesics and other medications. Inform the patient about what to do and who to contact if the prescribed management regimen is not controlling pain well or when side effects are intolerable or unmanageable.

Help the patient establish an analgesic regimen that does not interfere with sleep, rest, appetite, and level of physical mobility. Ensure that patients are aware of any dangers associated with driving or operating mechanical equipment. Tell patients to ask their primary health care provider when these activities are safe to perform. Older patients and others at risk for falls or accidents in the home setting may benefit from a home safety assessment.

In patients with pain from advanced cancer, all efforts are directed toward maximizing relief and symptom control at home and eliminating unnecessary hospital re-admissions. This may mean that the primary health care provider prescribes a flexible analgesic schedule that allows the patient to adjust analgesics according to the amount of pain. Teach the patient and family how to safely treat breakthrough pain and increase drug doses within the prescribed dosing guidelines. If painful ambulatory care treatments or procedures are expected, tell the patient how important it is to talk with his or her primary health care provider to

determine available options for preventing procedural pain (e.g., premedicating).

Evaluate family support systems to assist the patient in adhering to and continuing the proposed medical treatment and nursing plan of care. Inform and include family members in activities during and after hospitalization. To achieve a reasonable level of involvement in life activities for the patient, suggest ways to continue participation in household, social, sexual, and work-oriented activities after discharge. Help the patient identify important activities and plan to do them with adequate rest periods.

The patient with chronic pain needs continued support to cope with the anxiety, fear, and powerlessness that often accompany this type of pain. Help the patient and family or significant others identify coping strategies that have worked in the past. Outside support systems are often extremely helpful, such as organizations like the *American Chronic Pain Association* (http://theacpa.org). This organization has the "10-Step Program from Patient to Person" and provides numerous educational materials and facilitates the establishment of local support groups for people with chronic pain.

Health Care Resources

Ask the prescriber for a home health care or hospice referral, as appropriate, for patients who require assistance or supervision with the pain management regimen at home. Important information to provide to the home health care nurse includes the patient's condition, level of sedation, weakness or fatigue, possible constipation or nutritional problem, sleep patterns, and functional status. Detailed information about the patient's current pain management regimen and how well it has been tolerated is essential. Use a structured procedure such as SBAR (**s**ituation, **b**ackground, **a**ssessment, **r**ecommendations) to communicate this information.

In addition to explaining the patient's physical status to the home health care nurse, describe the patient's level of anxiety and general expectations about pain after discharge. Close relationships and available support networks are important factors in providing ongoing support for effective pain intervention strategies.

Referral to an advanced practice nurse pain specialist, social worker, or psychologist may be necessary for some patients and families to provide continued support, reinforce instructions for complex pharmacologic or nonpharmacologic strategies, or evaluate overall physical and emotional

adaptation after discharge. When severe chronic or intractable pain exists, health care professionals should direct the patient and family to appropriate resources such as pain centers or health care providers who specialize in long-term pain management.

Get Ready for the NCLEX® Examination!

Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- The nurse is legally and ethically responsible for acting as an advocate for patients experiencing pain.
- Coordinate the patient's plan of care as he or she transfers between health care agencies; be sure to clearly communicate the plan of care to the new agency. **Teamwork and Collaboration** QSEN

Health Promotion and Maintenance

- Provide information to the patient and family about nonpharmacologic therapies such as ice and heat; these modalities are additions to, not replacements for, the established plan of care.
- Consider the special needs of older adults when assessing and managing their pain (see Chart 3-1). **Patient-Centered Care** QSEN
- Assess and meet the patient's need for pain management promptly to promote relief; be sensitive to the cultural preferences and values of the patient and family. **Patient-Centered Care** QSEN

Psychosocial Integrity

- Be aware that some nurses and physicians may have biases about pain assessment and management; be objective when caring for patients with pain.
- Assess and document the patient's and family's expectations for management of pain. **Patient-Centered Care** QSEN
- Provide accurate information to patients who have misconceptions and misunderstandings about pain and pain management to prevent these from becoming barriers to effective pain management.

Physiological Integrity

- Remember that pain is what the patient says it is; self-report is always the most reliable indicator of pain. **Patient-Centered Care** QSEN
- Perform and document a complete pain assessment, including duration, location, intensity, and quality of pain. **Informatics** QSEN
- Never use placebos to assess the presence of pain; their deceitful use is prohibited by state boards of nursing and numerous professional

organizations.

- Factors that affect pain and its management include age, gender, race, genetics, and culture. **Patient-Centered Care** QSEN
- The two major types of pain are nociceptive pain and neuropathic pain. Pain is also classified by its duration as acute or chronic. Chronic pain is further classified as cancer or non-cancer chronic pain.
- Examples of causes for acute pain include surgery and trauma; arthritis and cancer are common causes of chronic pain.
- Multimodal analgesia is the recommended approach for the management of all types of pain (see Table 3-6). Multimodal analgesia combines different drugs with different underlying mechanisms of action with the goal of producing better pain relief at lower analgesic doses than would be possible with any single analgesic alone. Lower doses result in fewer side effects. Non-opioid analgesics (acetaminophen, NSAIDs) are the first-line therapy for mild to moderate nociceptive pain and the foundation for a multimodal treatment plan for more severe nociceptive pain. **Evidence-Based Practice** QSEN
- Assess patients on acetaminophen for clinical manifestations of hepatotoxicity and nephrotoxicity; these adverse drug effects may occur when the medication is taken in higher than recommended daily doses. **Safety** QSEN
- Recall that NSAIDs should be used with caution in older adults because of adverse effects, such as GI toxicity, bleeding, and fluid retention, for which they are at higher risk than younger adults. **Safety** QSEN
- The mu opioid agonists are first-line therapy for moderate to severe nociceptive pain. Morphine, fentanyl, hydromorphone, and oxycodone are the most commonly used mu opioid agonists and are available in a wide variety of formulations for administration by a variety of routes of administration for both acute and chronic pain. **Evidence-Based Practice** QSEN
- Meperidine is not recommended for the treatment of any type of pain. Its toxic metabolite (normeperidine) can accumulate and cause confusion, seizures, and even death. It is a particularly poor choice in older adults and those with decreased renal clearance. **Evidence-Based Practice** QSEN
- Physical dependence is a normal response that occurs with repeated administration of an opioid for several days. It is manifested by the occurrence of withdrawal symptoms when the opioid is suddenly

stopped or rapidly reduced or an antagonist such as naloxone is given. It cannot be equated with addictive disease.

- Tolerance is a normal response that occurs with regular administration of an opioid and consists of a decrease in one or more effects of the opioid (e.g., decreased analgesia, sedation, or respiratory depression). It cannot be equated with addictive disease. With the exception of constipation, tolerance to the opioid side effects develops with regular daily dosing of opioids over several days.
- Opioid addiction is a chronic neurologic and biologic disease. The development and characteristics of addiction are influenced by genetic, psychosocial, and environmental factors. No single cause of addiction, such as taking an opioid for pain relief, has been found. It is characterized by one or more of these behaviors: impaired control over drug use, compulsive use, continued use despite harm, and craving.
- Use an equianalgesic chart (see Table 3-7 when changing from one opioid or route of administration to another to help ensure the patient receives about the same relief with the new opioid or route as with the previous. **Evidence-Based Practice** QSEN
- Be aware of the advantages and disadvantages of the various routes of analgesic administration.
- Observe for and prevent common side effects of analgesics (see Table 3-9). Remember that the single most effective treatment of most side effects is to decrease the dose of the drug causing the side effect.
- Remember that sedation precedes opioid-induced respiratory depression; assess sedation using a sedation scale, and decrease the opioid dose if excessive sedation is detected (see Table 3-10). **Safety** QSEN
- The intraspinal routes include the intrathecal (also called *spinal*) and epidural routes of administration. Intrathecal analgesia is given by single injection of opioid (most often) into the subarachnoid space for acute pain or implanted device for chronic pain; epidural analgesia is given by single injection or continuous infusion with or without PCA capability for all types of pain and usually combines an opioid with a local anesthetic.
- Adjuvant analgesics are drugs that have a primary indication other than pain but are analgesic for some painful conditions. The most commonly used are antidepressants, anticonvulsants, and local anesthetics. Examples are listed in Table 3-6.
- Nonpharmacologic therapies may be effective alone for mild pain and are used to complement, not replace, pharmacologic interventions for moderate to severe pain. **Evidence-Based Practice** QSEN

- Pain can be managed in any setting, including the home. All patients require teaching with regard to their pain management regimen to ensure continuity of care. Patients or family members will require specialized training when infusion therapy is used in the home setting.
- Request referral or consultation with pain specialists and/or pain centers for patients with pain that cannot be managed with customary methods. **Teamwork and Collaboration** QSEN

CHAPTER 4

Genetic and Genomic Concepts for Medical-Surgical Nursing

M. Linda Workman

PRIORITY CONCEPTS

- Ethics
- Collaboration

Learning Outcomes

Safe and Effective Care Environment

1. Ensure collaboration with health care team members and genetics professionals when providing genetic testing information to patients and families.

Health Promotion and Maintenance

2. Teach the patient and family who are at increased genetic risk for a disease or disorder to implement environmental modifications to reduce the risk when possible.

Psychosocial Integrity

3. Reduce the psychological impact for the patient and family regarding genetic assessment and genetic testing.

Physiological Integrity

4. Incorporate genetic and genomic principles into patient and family assessment techniques.
5. Ensure the use of professional ethics when integrating genomic health into medical-surgical nursing practice.

http://evolve.elsevier.com/Iggy/

Genomic health is a growing part of today's comprehensive health care. Although the terms *genetics* and *genomics* often are used interchangeably, there are some differences. **Genetics** is concerned with the general mechanisms of heredity and the variation of inherited traits. Thus how genetic traits are transmitted from one generation to the next is part of genetics. The definition of **genomics** is both broader and more specific, focusing on the function of all of the human DNA, including genes and noncoding DNA regions. Thus how a gene is expressed within a person or family constitutes genomics. **Genomic health care** is the application of known genetic variation to enhance health care to individuals and their families.

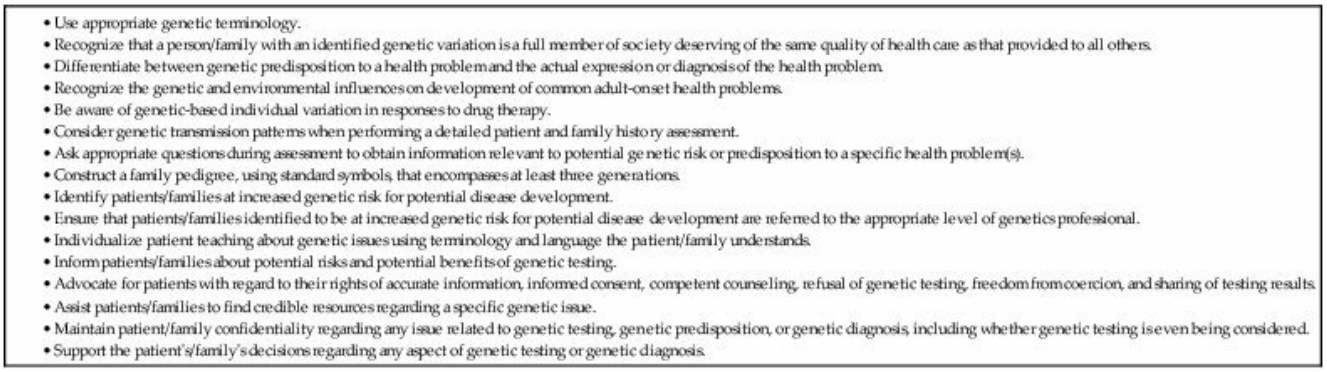
Many adult-onset health problems have a genetic basis, meaning that variation of gene sequences and expression contributes to a person's risk for disease development. Some of these health problems also demonstrate **heritability,** meaning that the risk for developing the disorder can be transmitted to one's children in a recognizable pattern. Some adult-onset disorders, such as Huntington disease, are unavoidable when a person inherits a specific genetic mutation that causes the disorder. For other health problems, the risk is increased but is not absolute, indicating a *predisposition* or *susceptibility* toward the problem when a specific genetic mutation is inherited, but such a disorder may never occur. For example, certain gene variations increase the risk for type 2 diabetes; however, the disease is more likely to develop only when the person with the genetic variations has a sedentary lifestyle and is overweight. One outcome of genomic health care is to identify personal risk for disease development and assist the person to reduce the risk by modifying his or her environment (Manuck & McCaffery, 2014).

Specific discoveries regarding each person's genetic differences are being used to assess disease risk, enhance disease prevention strategies, and personalize disease management approaches (Bielinski et al., 2014). As a result, all health care professionals, including registered nurses, are expected to have at least a minimum knowledge of basic genetics to provide the best possible care for patients and families (Calzone et al., 2013). Table 4-1 lists selected genetic competencies important in medical-surgical nursing. Nurses are expected to know enough about basic genetics to recognize when a patient or family has a possible genetic risk for a health problem and to coordinate the attention of health care team

members to ensure appropriate care.

TABLE 4-1

Selected Essential Genetic Competencies for Medical-Surgical Nursing Practice



- Use appropriate genetic terminology.
- Recognize that a person/family with an identified genetic variation is a full member of society deserving of the same quality of health care as that provided to all others.
- Differentiate between genetic predisposition to a health problem and the actual expression or diagnosis of the health problem.
- Recognize the genetic and environmental influences on development of common adult-onset health problems.
- Be aware of genetic-based individual variation in responses to drug therapy.
- Consider genetic transmission patterns when performing a detailed patient and family history assessment.
- Ask appropriate questions during assessment to obtain information relevant to potential genetic risk or predisposition to a specific health problem(s).
- Construct a family pedigree, using standard symbols, that encompasses at least three generations.
- Identify patients/families at increased genetic risk for potential disease development.
- Ensure that patients/families identified to be at increased genetic risk for potential disease development are referred to the appropriate level of genetics professional.
- Individualize patient teaching about genetic issues using terminology and language the patient/family understands.
- Inform patients/families about potential risks and potential benefits of genetic testing.
- Advocate for patients with regard to their rights of accurate information, informed consent, competent counseling, refusal of genetic testing, freedom from coercion, and sharing of testing results.
- Assist patients/families to find credible resources regarding a specific genetic issue.
- Maintain patient/family confidentiality regarding any issue related to genetic testing, genetic predisposition, or genetic diagnosis, including whether genetic testing is even being considered.
- Support the patient's/family's decisions regarding any aspect of genetic testing or genetic diagnosis.

Genetic Biology Review

Genes are the coded instructions for the making of all the different proteins the human body produces. For every hormone, enzyme, and other proteins the human body makes, it is the specific genes that tell each cell what protein to make, how to make it, when to make it, and how much to make. Think of each gene as a specific "recipe" for making a protein.

Every human somatic cell with a nucleus contains the entire set of human genes, known as the **genome.** The human genome contains between 20,000 and 25,000 genes. For example, all cells have the gene for insulin. However, the only cell type that allows the insulin gene to be **expressed** (turned on, activated) and make insulin is the beta cell of the pancreas. So, although the insulin gene is present in skin cells, heart cells, brain cells, and other cells, only in the beta cells is this gene selectively expressed when insulin is needed.

Genes are composed of DNA, which is present as 46 separate large chunks within the nucleus (Fig. 4-1). During cell division, each large chunk of DNA replicates and then organizes into a chromosome form to ensure precise delivery of the genetic information to each of the two new daughter cells. Thus DNA, chromosomes, and genes are all the same basic thing; only the structures differ.

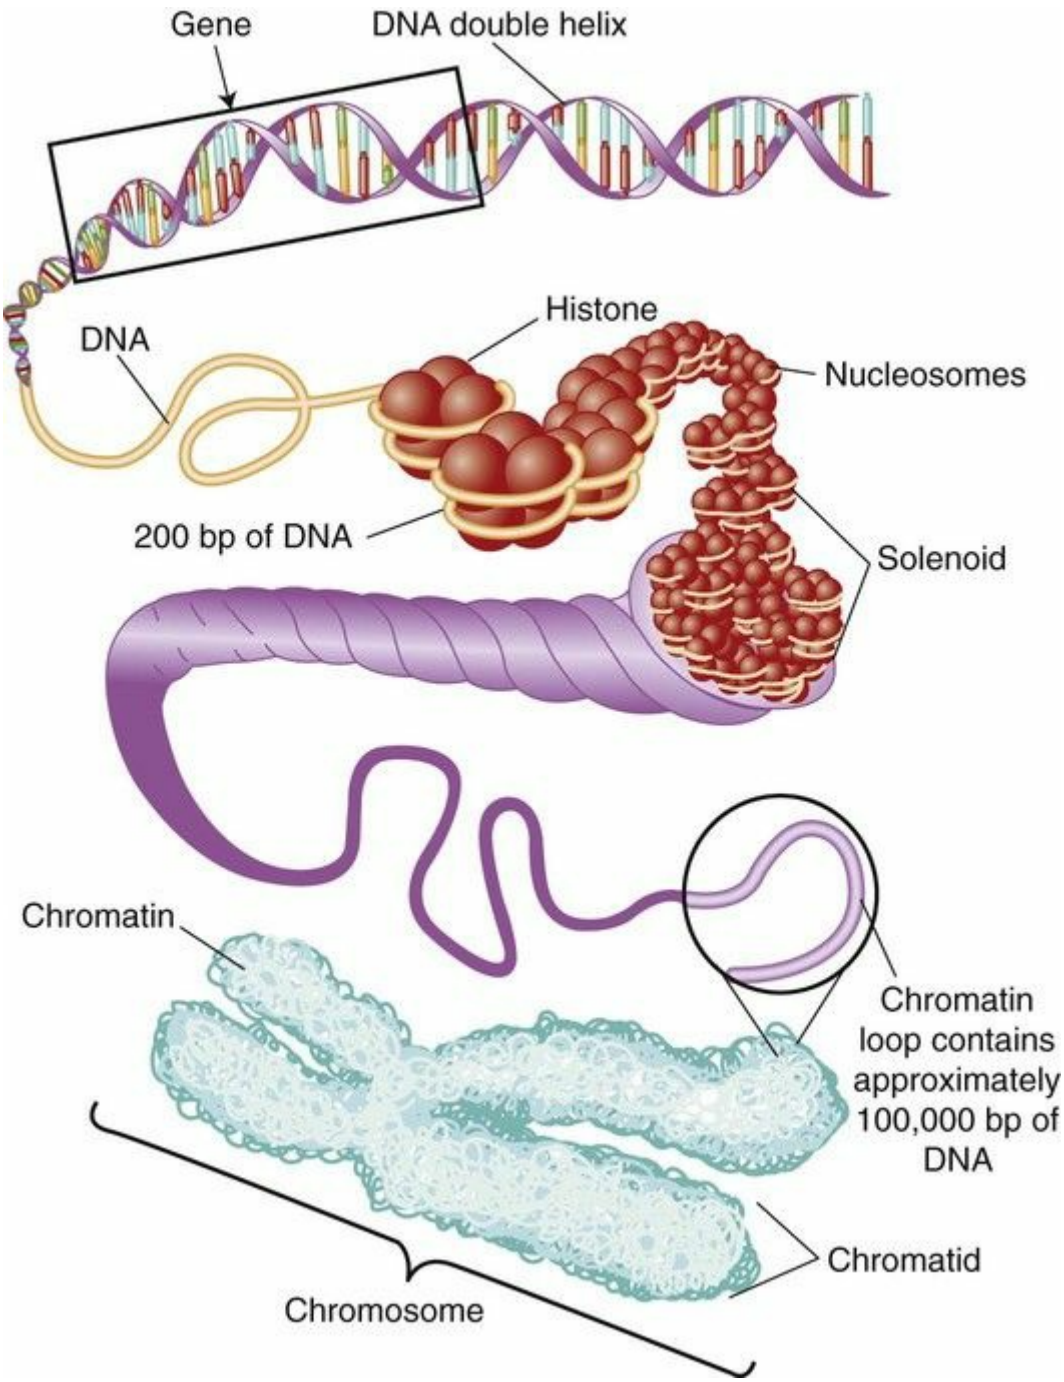

FIG. 4-1 The various forms of DNA from a loose double helix to coiled tightly into a chromosome. *bp*, Base pair.

Each chromosome has many genes within it. Humans have 23 pairs of chromosomes—46 individual chromosomes. The Y chromosome is small and has fewer than 100 genes. Larger chromosomes, such as the number 1 chromosome, contain thousands of genes.

One way to think of it is to consider all the DNA in any cell's nucleus (genome) to be a giant "cookbook" containing all the recipes needed to make all the proteins, hormones, enzymes, and other substances your body needs. The chromosome pairs are the different book chapters (so the human genome cookbook has 23 chapters), and the genes are the

individual recipes contained within the chapters.

There is a specific chromosome location **(locus)** for every gene. For example, the locus of the gene for blood type is on chromosome 9. The location and the exact DNA sequence for many, but not all, genes is now known.

DNA

DNA Structure

In humans, DNA is a linear, double-stranded structure composed of multiple units of four different nitrogenous bases, each attached to a sugar molecule. The bases in each strand are linked together by phosphate groups. These two individual strands are held together loosely. This double-stranded DNA is arranged like a long set of railroad tracks. The "backbones" of the track are the two long steel rails. For DNA, these backbones are the phosphate groups that hold the bases in place. The bases are the individual railroad ties. Think of each tie as having two pieces—one piece attached to the right-hand rail and one piece attached to the left-hand rail.

Fig. 4-2 shows a very small piece of double-stranded DNA on the left (containing only four base pairs) taken from the larger piece of DNA on the right. The phosphate groups that hold the nucleotides together as a strand are in the red box. The green box in the lower left-hand section shows a whole nucleotide (a base with the sugar and the phosphate group) in place in the left-hand DNA strand. The blue box in the middle of the two strands shows how the base from the left strand lines up with and pairs to a complementary base in the right strand.

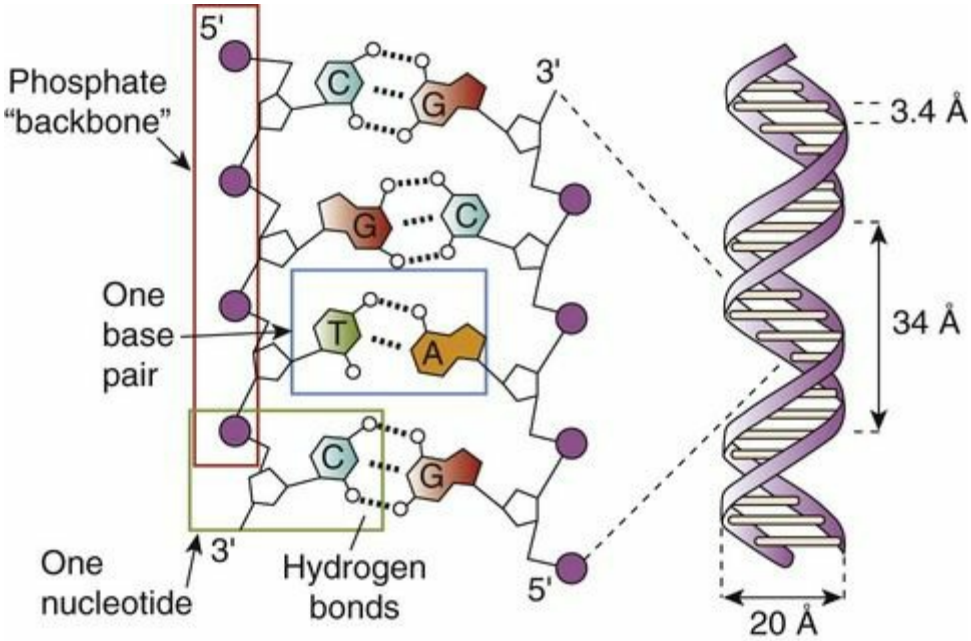

FIG. 4-2 The structure of DNA.

Bases are the essential parts of DNA. Many trillions of bases in the DNA are found in the nucleus of just one cell. The four bases in DNA are adenine (A), guanine (G), cytosine (C), and thymine (T). Each base becomes a complete **nucleotide** when a five-sided sugar (known as a *deoxyribose sugar*) and a phosphate group are attached (see Fig. 4-2). Nucleotides form the DNA strands with the phosphate groups holding the bases in place.

Base pairs are the linked bases in the two opposite strands of DNA. The bases always link together across from each other in a very specific way. Thymine always forms a pair with adenine, and cytosine always forms a pair with guanine. Thus the bases of each pair are *complementary* to each other. Because these complementary base pairs in DNA are specific, if the base sequence of one strand of DNA is known, the opposite strand's sequence could be accurately predicted. For example, if the left-hand section of DNA (strand 1 in Fig. 4-3) had the sequence C-T-C-A-A-C-C-T-G, the corresponding (complementary) right-hand section (strand 2 in Fig. 4-3) of DNA would have the sequence G-A-G-T-T-G-G-A-C.

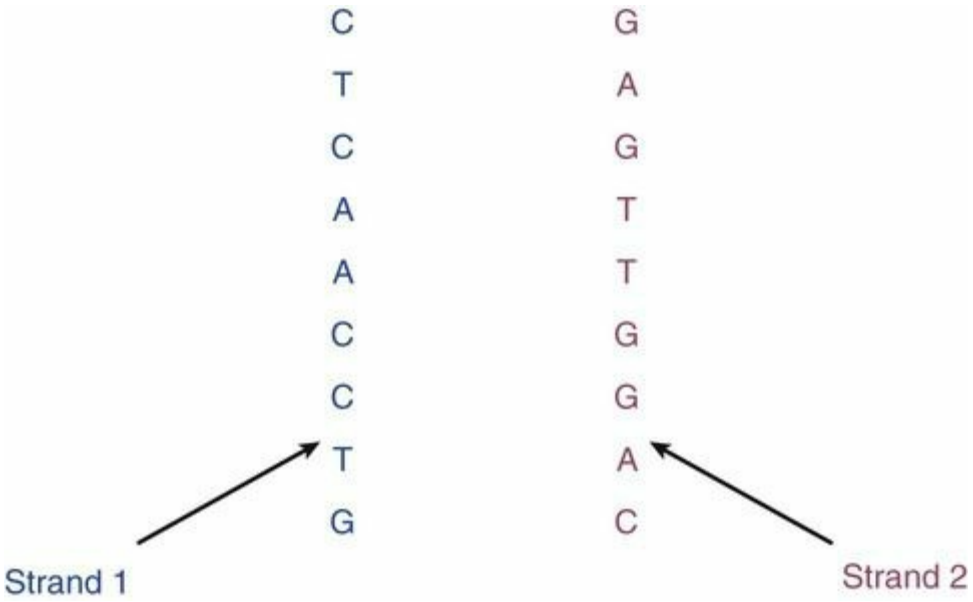

FIG. 4-3 Complementary strands of DNA.

When the two strands of DNA are lined up properly, they twist into a loose helical shape (see Fig. 4-1). In this shape, the DNA is so fine that it can be seen only with electron microscopes. Only when a cell undergoes mitosis does the DNA super-coil tightly into dense pieces called *chromosomes* (Fig. 4-1), which can be seen with standard microscopes.

DNA Replication

DNA must reproduce itself **(replicate)** every time a cell divides (undergoes mitosis). The purpose of mitosis is for one cell to reproduce into two new daughter cells, each of which is identical to the parent cell that started mitosis. For each new cell to have exactly the right amount of DNA and genes, the DNA in the dividing cell must exactly replicate. This process involves having the double strands of DNA separate and then build two new strands that are perfectly complementary to the original strands (Fig. 4-4). The result is two sets of double-stranded DNA. At the time of actual cell division with the separation into two new cells, one set of DNA will move into one of the two new cells made during mitosis and the second set will move into the other new cell. In this way, every new cell ends up with exactly the right amount of DNA with all the genes.

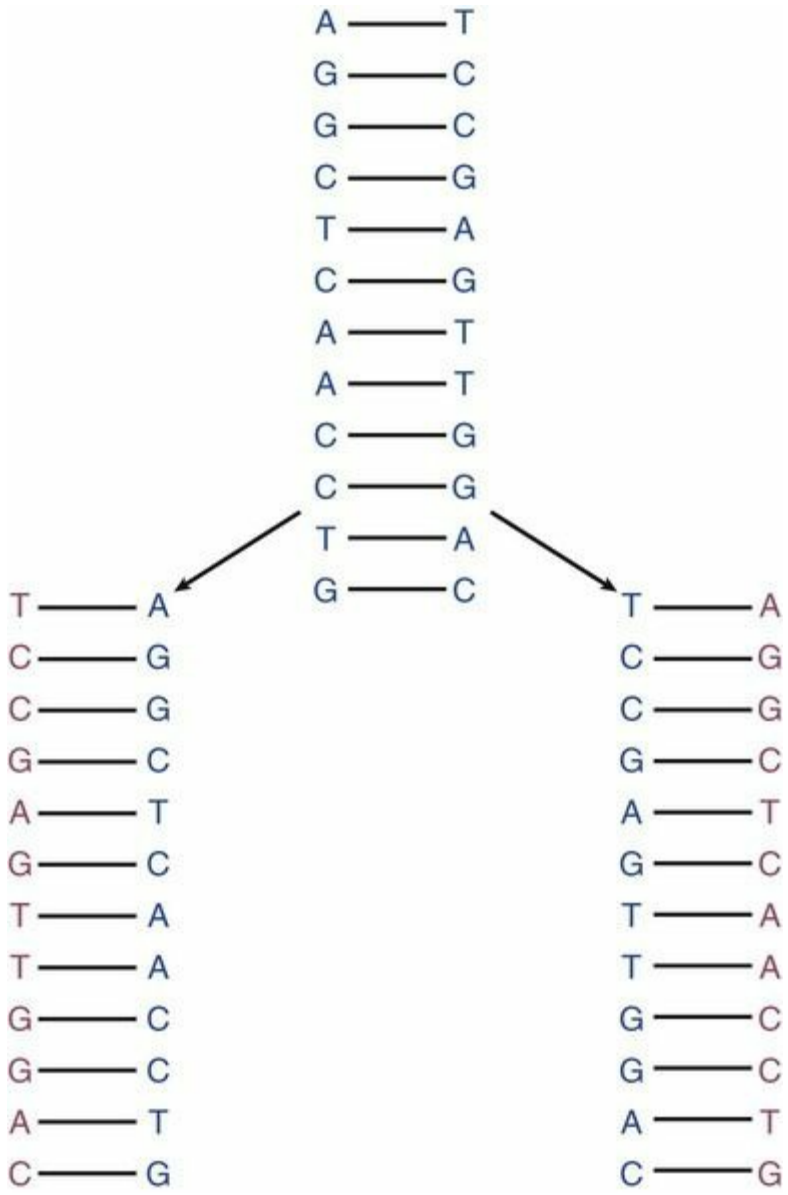

FIG. 4-4 DNA replication. *Blue type*, Original DNA; *red type*, newly replicated DNA.

Chromosomes

As shown in Fig. 4-1, a chromosome is a specific large chunk of highly condensed double-stranded DNA, with each chunk containing billions of bases and hundreds (and sometimes thousands) of genes. Each chromosome forms and moves to the center of the cell that is about to divide. Just before the cell splits into two cells, each chromosome is pulled apart so that half of each chromosome goes into one new cell and the other half goes into the other new cell. Thus chromosomes are temporary structures to ensure the precise delivery of DNA to the two new cells. Humans have 46 chromosomes divided into 23 pairs.

Some things about a person can be known by examining his or her chromosomes, but limited information can be obtained by chromosomal

analysis because each chromosome is composed of a large chunk of DNA. Only very large deletions, additions, or rearrangements of DNA show up at the level of the chromosome. Losses or gains of even tens of thousands of bases cannot be detected by chromosome analysis.

A **karyotype** is an organized arrangement of all of the chromosomes present in a cell during the metaphase section of mitosis (Fig. 4-5). A picture of the chromosomes is made. Chromosomes are first paired up and then arranged according to size (largest first) and centromere position. This gross organization of DNA can be used to determine missing or extra whole chromosomes and some large structural rearrangements. *A missing gene or a mutated gene would not show up at this level of analysis.* What can be learned about the person from whom the karyotype in Fig. 4-5 was made is that the person is human, female, and **euploid** (has the correct number of chromosome pairs for the species). This person is chromosomally "normal," although she probably has some genes that are different from (variant from or mutated from) the same genes in other people. If the karyotype is abnormal in any way (has more or less than the normal number or has broken chromosomes), the karyotype would be called **aneuploid.**

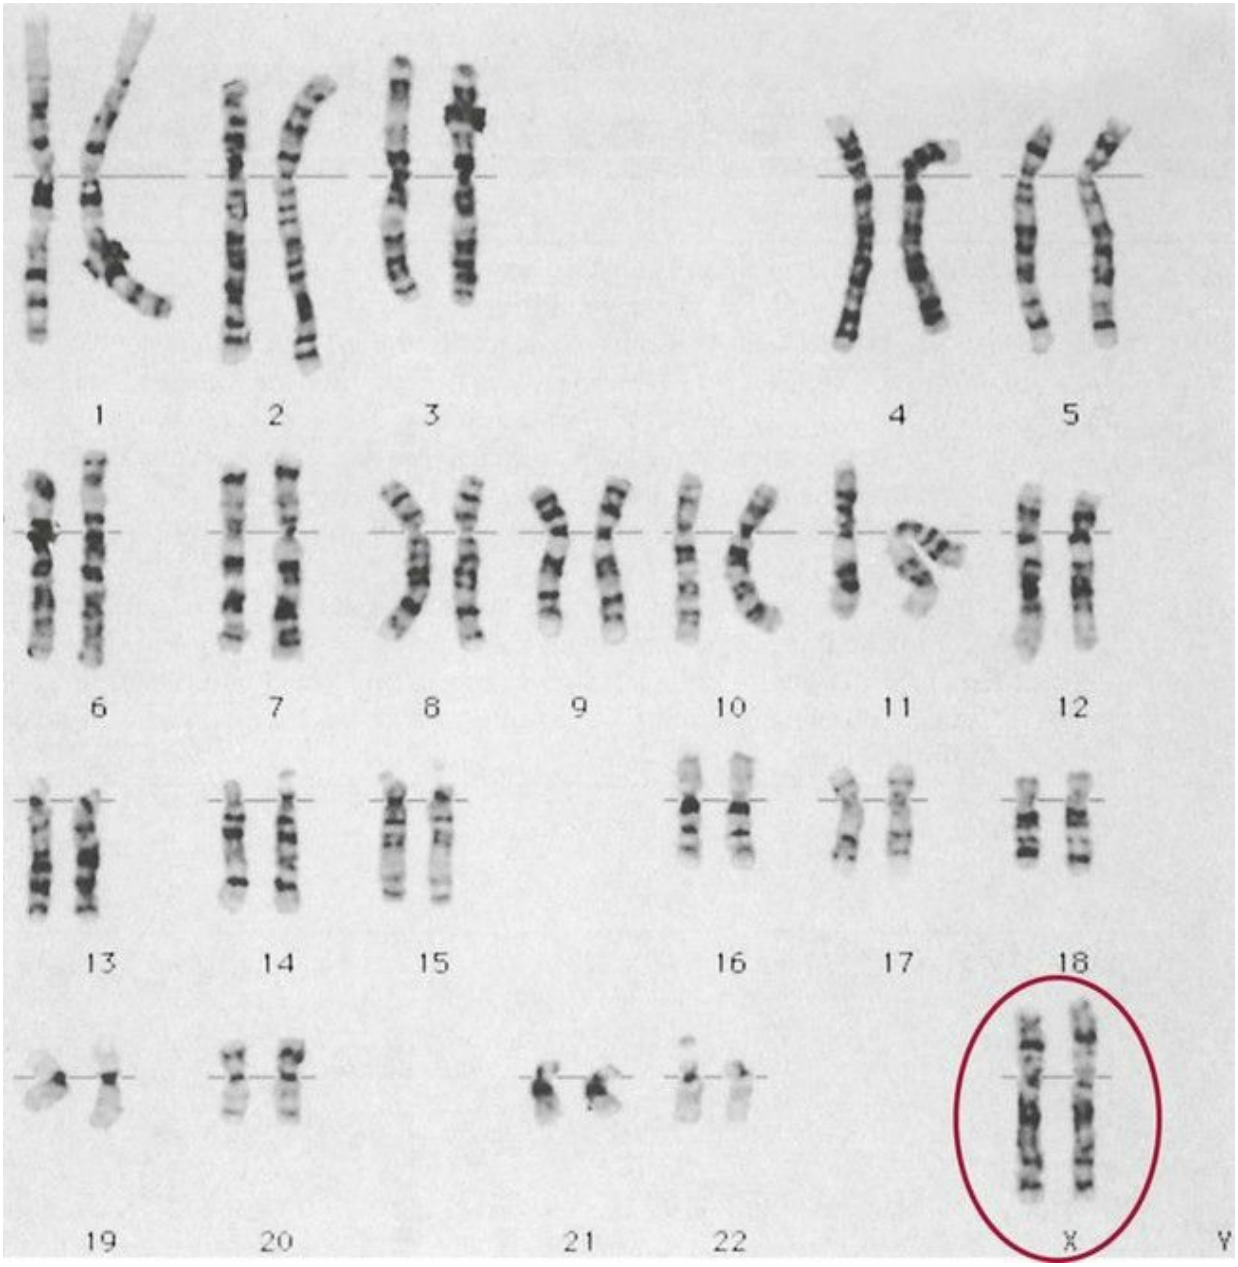

FIG. 4-5 A karyotype of a chromosomally normal female. (The sex chromosomes are *circled in red*.)

Autosomes are the 22 pairs of human chromosomes (numbered 1 through 22) that do not code for the sexual differentiation of a person. **Sex chromosomes** are the pair of chromosomes that include the genes for the sexual differentiation of the person. Chromosomally normal males have an X and a Y as the sex chromosomes. Chromosomally normal females have two Xs (XX) as the sex chromosomes (see Fig. 4-5).

Gene Structure and Function

A **gene** is a specific segment(s) of DNA that contains the code (recipe) for a specific protein (see Fig. 4-1). Thus genes are the smallest functional unit of the DNA. Each chromosome is a large segment of DNA that

contains hundreds of genes.

For many human traits, one gene controls the expression of that trait in any person. Such traits are known as "single gene traits" *(monogenic traits).* For each single gene, we have two alleles. An **allele** (pronounced "ah-**lee**-el") is an alternate form (or variation) of a gene. For example, there is one gene for blood type but there are three possible gene alleles (A, B, and O). Each person has only two of the three specific gene alleles for blood type. One of these alleles is on one chromosome 9 of the pair; the other allele is located on the other number 9 chromosome. Because each person only has two number 9 chromosomes, he or she can have only two of the three possible alleles for blood type. One gene allele was inherited from the person's mother, and the other gene allele was inherited from the person's father. *Some traits have even more than three possible alleles, but each person has only two.* Which blood type gene alleles are inherited from a person's parents determines which blood type he or she expresses.

If a person has inherited a blood type A allele from his or her mother and a blood type B allele from his or her father, he or she has the A and B alleles; the blood type expressed when the blood bank determines type is type AB. Fig. 4-6 shows this concept. In Fig. 4-6, two people are about to become pregnant. What are the possibilities for this baby to have a specific type of ear shape (pointy, rounded, square, triangular)? The gene for ear shape is trait 1, and it (for the purposes of this explanation) is on chromosome number 6.

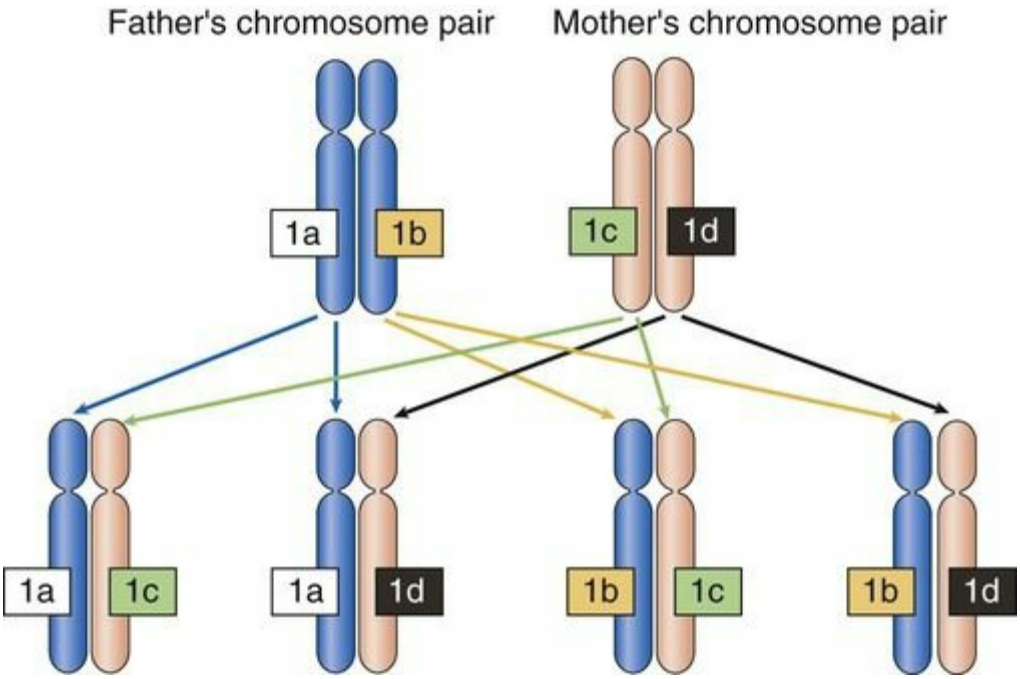

FIG. 4-6 Inheritance of four possible alleles for the single gene trait 1. (Any one person can have only two alleles for a single gene trait.)

Each of the father's sperm contains only one number 6 chromosome and each of the mother's eggs contains only one number 6 chromosome (so that when the sperm fertilizes the egg, the resulting person conceived will have only one pair of chromosome number 6 instead of two pairs of chromosome number 6).

Half the father's sperm have the 1a allele for ear shape, and the other half have allele 1b for ear shape. Half the mother's eggs have 1c for ear shape, and the other half have 1d. The resulting baby can inherit only either a 1a or a 1b from the father, not both; and this same baby can inherit only a 1c or a 1d from the mother—again, not both. The lower portion of Fig. 4-6 shows all the combinations possible for each ear shape gene alleles for any child these two people have.

If a person has two identical alleles for a single gene trait, that person is said to be *homozygous* for that trait. So if a person has an A blood-type gene allele on one number 9 chromosome and an A blood-type gene allele on the other number 9 chromosome, he or she is homozygous for that trait and will express the A blood type.

If a person has two different alleles for a single gene trait, he or she is *heterozygous* for that trait. So if a person has an A blood-type gene allele on one number 9 chromosome and a B blood-type gene allele on the other number 9 chromosome, that person is heterozygous for that trait and will express the AB blood type. Because the A and B alleles are equally dominant *(co-dominant)*, they will both be expressed in the actual

blood type.

There are differences in expression of the alleles for a trait depending on whether an allele is dominant or is recessive. If a person has an A blood-type gene allele on one number 9 chromosome and an O blood-type gene allele on the other number 9 chromosome, that person is heterozygous for that trait and expresses only the A blood type. Because the A allele is dominant and the O allele is recessive, they will not both be expressed in the actual blood type. Only the dominant allele is expressed, and the recessive allele is "silent." More information about dominant, recessive, and co-dominant expression is presented later in the Patterns of Inheritance section on p. 56.

Phenotype

The **phenotype** of any gene for a person is what characteristic can actually be observed or, in some cases, determined by a laboratory test. For example, the person who has the AO gene alleles for blood type has the phenotype of type A blood. A person with curly hair has a curly hair phenotype regardless of whether he or she has two alleles for curly hair or one allele for curly hair and one allele for straight hair.

Genotype

The **genotype** for a person's single gene trait is what the actual alleles are for that trait—not just what can be observed. A person with a phenotype of type A blood could have either an AA genotype or an AO genotype. The person who has type O blood would have an OO genotype. When a person has homozygous alleles for a trait, we would expect the genotype and phenotype to be the same. When a person has heterozygous alleles for a trait, the phenotype and the genotype are not always the same. *Recessive traits are expressed only when the person is homozygous for the alleles.* Thus for expressed recessive traits, phenotype and genotype are the same. Dominant traits are expressed whether the person is homozygous for the gene alleles or heterozygous for the gene alleles. Thus for dominant traits, phenotype and genotype can be the same but do not have to be the same.

Gene Expression

The purpose of a gene is to code for the making of a specific protein. For example, the hormone *insulin* is a protein. When a person's blood glucose level starts to rise, the beta cells of the pancreas rapidly make insulin to maintain the person's blood glucose homeostasis.

To continue the cookbook analogy, each gene is the recipe needed to make a specific protein. All the "stuff" that a human body makes—every hormone, every enzyme, every growth factor, every chemical needed to keep the person functioning—is a protein. These proteins are *gene products* because they are produced when the right gene is *expressed*. Just a few examples of gene products are insulin, hemoglobin, erythropoietin, angiotensin, and estrogen.

Protein Synthesis

Protein synthesis is the process by which genes are used to make the proteins needed for physiologic function. Proteins are made up of individual amino acids hooked together like beads on a string. There are 22 different amino acids. Every protein has a specific number of each of the amino acids and a specific order in which they are placed. *If even one amino acid is out of order or completely deleted from the sequence, the protein may be less functional or, perhaps, nonfunctional and unable to perform its job in the body.*

For example, the hormone *insulin* is a protein that contains 51 amino acids in a specific sequence. If some of the amino acids are missing or are in the wrong position, the protein made would be different from real insulin and could not reduce blood glucose levels. *Thus the actual order of the amino acids is critical for the final function of any protein.*

Within the DNA there is a three-nucleotide (base) code for each amino acid. A gene for a specific protein contains all the amino acid codes in exactly the right order for that protein. For example, the final active form of the protein *insulin* has 51 amino acids. Thus the minimum number of bases needed in the gene for insulin would be 153 (3 bases per amino acid × 51 amino acids). Fig. 4-7 shows an example of a short protein made up of only 7 amino acids.

FIG. 4-7 A sample protein composed of seven amino acids.

The key for making a functional protein is accurate placement of all the amino acids in the order specified by the gene. When problems exist in the base sequence of a gene, its expression may not result in a functional protein. In addition, the process of protein synthesis involves many complex steps and a problem at any step could result in the failure to

produce a functional protein.

Mutations

Many human genes have been sequenced, meaning that their base sequence is known and so is the sequence of their amino acids in the expressed proteins. Most people have the same base sequence for a specific gene, like the gene for insulin. When this sequence is the most common one found in a large population of humans, it is referred to as the *wild-type* gene sequence. Think of the term *wild-type* as meaning "normal" or "expected." When a person has a different sequence for a gene compared with the known wild-type sequence, the gene has a variation or mutation. Mutations as small variations in gene sequences occur more often in very large genes, and the significance of some of these changes is not known. It is these differences or variations in the sequences of some genes from the wild-type that are now being examined more closely in health care. Some of these variations can reduce the function of the protein produced, some can eliminate the function of the protein produced, and a few variations have been found that enhance the function of the produced protein compared with the function of the wild-type protein.

Mutations are DNA changes that are passed from one generation to another and thus are *inherited.* An inherited mutation does not have to mean that the mutation is passed from one human generation to another. It can mean that the mutation is passed from one *cell* generation to another and may affect only certain tissues within a person rather than be a problem within a family. These mutations occur in general body cells (somatic cells) and are known as *somatic mutations.* Because these mutations occur in a person's cells after conception, the person cannot pass a somatic mutation on to his or her children. One possible outcome of somatic mutations is an increased risk for cancer in cells with such mutations.

When mutations occur in sex cells, they are called *germline mutations.* A germline mutation *can* be passed on to a person's children, and each of that child's cells, including his or her somatic cells and sex cells, will contain the mutated DNA.

When mutations resulting in sequence variation occur in a gene area of the DNA, the change can alter the expression of that gene and an incorrect gene product (protein) might result. Mutations can have serious results, although some mutations may be beneficial. Gene mutations that increase the risk for a disorder are known as *susceptibility* genes. Gene

mutations that decrease the risk for a disorder are known as *protective* or *resistance* genes (Beery & Workman, 2012).

As stated earlier, the gene sequences for most proteins are generally the same in all people. Sometimes a base in one person's gene for a specific protein is not the same as that in the wild-type. Either this difference can be a variation known as a *single nucleotide polymorphism,* or *SNP* ("snip"), or it can be a mutation. When a base difference allows the protein to be made but there are differences in how well the protein works, the difference is called a *gene variation* or a **polymorphism.** When a base difference causes a loss of protein function, it is called a **mutation.**

Clinically, many SNPs exist within different people in the genes of a large family of enzymes involved in drug metabolism. These enzymes are the cytochrome P-450 family, coded for by at least ten separate extremely large genes, with as many as 100 subsets of genes. Cytochrome p is abbreviated as CYP (pronounced "sip"). SNPs in these genes can make the resulting enzyme less active than normal or more active than normal. Either way, a change in activity of any one of these enzymes can affect a person's response to drug therapy. For example, the drug *warfarin* (Coumadin) is metabolized for elimination primarily by two enzymes from this system, CYP2CP and CYP2C19. About 17% to 37% of white people have a SNP variation in CYP2CP that slows the metabolism of warfarin. This means that warfarin remains in the person's system longer, greatly increasing the risk for bleeding and other side effects. For people who have this gene mutation, warfarin doses need to be much lower than those for the general population (Cheek, 2013).

Cultural Considerations

Patient-Centered Care QSEN

Most people of Asian heritage have a SNP in the *CYP2C19* gene that results in low activity of the enzyme produced. This mutation greatly reduces the metabolism of warfarin, leading to a longer warfarin half-life and increased bleeding risks along with other serious side effects. Any person of Asian heritage who needs anticoagulation therapy should be started on very low dosages of warfarin and have his or her international normalized ratio (INR) monitored more frequently than people who do not have a variation of the *CYP2C19* gene.

The most devastating gene mutations are the ones that change the amino acid codes so that a proper protein is not made. Other changes

may alter how often or how well a group of cells divides. Gene mutations or variations may cause one person to have a greater-than-normal risk for developing a disease. A different variation in the same gene may cause another person to have a smaller-than-normal risk for developing the same disease.

Patterns of Inheritance

For every single gene trait, a person inherits one allele for that gene from his or her mother and one allele from his or her father. How these traits are expressed depends on whether one or both alleles are "dominant" or "recessive." Expression also depends on whether the gene for the trait is located on an autosome or on a sex chromosome.

It is possible to determine how the gene for a specific trait is passed from one human generation to the next *(transmitted)*. By looking at how that trait is expressed through several generations of a family, patterns emerge that indicate whether the gene for the trait is dominant or recessive and whether it is located on an autosomal chromosome or on one of the sex chromosomes. This information can be determined through *pedigree analysis*. Determining inheritance patterns for a specific trait makes it possible to predict the relative risk for any one person to have a trait or transmit that trait to his or her children.

Pedigree

A **pedigree** is a graph of a family history for a specific trait or health problem over several generations. Fig. 4-8 shows common symbols used when creating a pedigree. Fig. 4-9 shows a typical three-generation pedigree. Although the term *pedigree* is the correct genetic term, it can offend some patients. Use the term *family tree* in place of pedigree when talking with patients. Construct a pedigree that includes at least three generations when taking the family history. When analyzing a pedigree, note the answers to these:

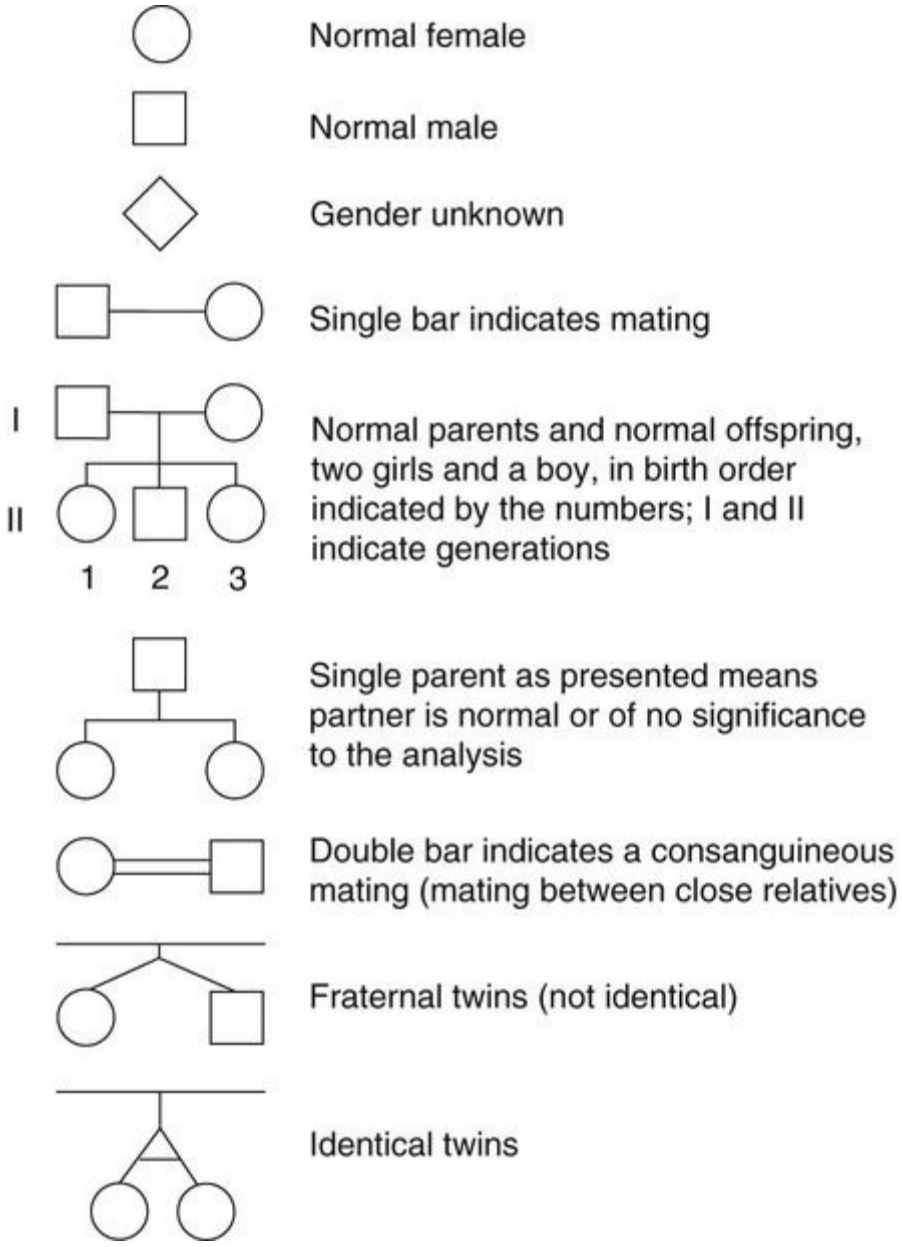

FIG. 4-8 Standard pedigree symbols.

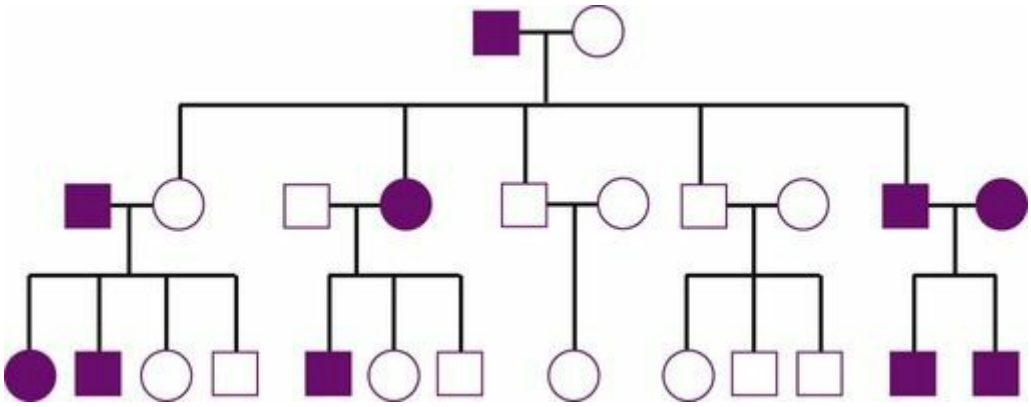

FIG. 4-9 A three-generation pedigree showing an autosomal dominant pattern of inheritance.

- Is any pattern of inheritance recognized, or does the trait appear sporadic?
- Is the trait expressed equally among male and female family members or unequally?
- Is the trait present in every generation, or does it skip one or more generations?
- Do only affected people have children who are affected with the trait, or do unaffected people also have children who express the trait?

The four types of inheritance patterns associated with single gene–controlled traits are autosomal dominant, autosomal recessive, sex-linked dominant, and sex-linked recessive. Each inheritance pattern has specific defining criteria. Table 4-2 lists the patterns of inheritance for some disorders that occur in adults or may be identified in children who live to adulthood.

TABLE 4-2

Patterns of Inheritance for Genetic Disorders Among Adults

PATTERN OF INHERITANCE	DISORDER
Autosomal dominant	Breast cancer* (mutation of *BRCA1* or *BRCA2* genes)
	Diabetes mellitus type 2*
	Familial adenomatous polyposis
	Familial melanoma
	Familial hypercholesterolemia
	Hereditary nonpolyposis colon cancer (HNPCC)
	Huntington disease
	Long QT syndrome and sudden cardiac death
	Malignant hyperthermia (MH)
	Marfan syndrome
	Myotonic dystrophy
	Neurofibromatosis (types 1 and 2)
	Ovarian cancer* (mutation of *BRCA1* genes)
	Polycystic kidney disease† (types 1 and 2)
	Retinitis pigmentosa†
	von Willebrand's disease
Autosomal recessive	Albinism
	Alpha$_1$-antitrypsin deficiency
	Beta thalassemia
	Bloom syndrome
	Cystic fibrosis
	Hereditary hemochromatosis
	Sickle cell disease
	Xeroderma pigmentosum
Sex-linked recessive	Glucose-6-phosphate dehydrogenase deficiency
	Hemophilia
	Red-green color blindness
Complex disorders/Familial clustering	Alzheimer's disease
	Autoimmune disorders
	Bipolar disorder
	Parkinson disease
	Schizophrenia
	Hypertension
	Rheumatoid arthritis

*Some disorders have both a genetic and nongenetic form.

†Some disorders have more than one genetic form and can also be autosomal recessive.

Autosomal Dominant Pattern of Inheritance

Autosomal dominant (AD) single gene traits require that the gene alleles controlling the trait be located on an autosomal chromosome. A dominant gene allele is usually expressed even when only one allele of the pair is dominant. Other criteria for AD inheritance include:

- The trait appears in every generation with no skipping.
- The risk for an affected person to pass the trait to a child is 50% with each pregnancy.
- Unaffected people do not have affected children; therefore their risk is essentially 0%.
- The trait is found about equally in males and females.

An example of an AD trait is blood type A. If a person is homozygous for the blood type A allele, he or she will express type A blood (with genotype being identical to the phenotype). If a person is heterozygous for the blood type A allele with the other allele being type O (which is a recessive trait), he or she will also express type A blood. In this case, however, the phenotype is not identical to the genotype. *When a dominant allele is paired with a recessive allele, only the dominant allele is expressed.* The blood type B allele is a dominant allele. When a B allele is paired with an O allele, B blood type is expressed. When a person has one blood type A allele and a blood type B allele, however, both alleles are expressed because they are equally dominant (co-dominant) and the person has type AB blood.

Some health problems inherited as autosomal dominant (AD) single gene traits are not apparent at birth but develop as the person ages (see Table 4-2). Two factors that affect the expression of some AD single gene traits are penetrance and expressivity.

Penetrance

Penetrance is how often or how well, within a population, a gene is expressed when it is present. Some genes are more penetrant than others. For example, the gene for Huntington disease (HD) has an autosomal dominant pattern of transmission. This gene is "highly penetrant" (sometimes called "fully penetrant"). This means that if a person has the HD gene allele, his or her risk for expressing the gene and developing the disease is about 99.99%. Therefore a person who has one HD allele is at high risk for developing HD.

Some dominant gene alleles have "reduced" penetrance. So a person who has the gene mutation has a lower risk for this gene being expressed and actually developing the disorder.

Penetrance has been calculated by examining a population of people known to have the gene mutation and assessing the percentage that go on to express the gene by developing the disorder. For example, the *BRCA2* gene mutation increases a person's risk for breast cancer. This gene is not fully penetrant, so some women (and men) who have the gene do not develop breast cancer. The penetrance rate for this gene mutation is calculated to be between 60% and 80%, meaning that a person who has the gene mutation has a 60% to 80% risk for developing breast cancer. Although this risk is far higher than among people who do not have the mutated gene, the risk is not 100%. Having the gene mutation does not absolutely predict that the person will develop breast cancer—just that the risk is high. However, the person with the mutation can pass on this genetic mutation to his or her children, who will then have an increased risk for breast cancer development.

Expressivity

Expressivity is the degree of expression a person has when a dominant gene is present. So it is a personal issue, not a population issue. The gene is *always* expressed, but some people have more severe problems than do other people. For example, the gene mutation for one form of neurofibromatosis *(NF1)* is dominant. Some people with this gene mutation have only a few light brown skin tone areas known as *café au lait spots*. Other people with the same gene mutation develop hundreds of tumors (neurofibromas) that protrude through the skin. Expressivity accounts for some variation in genetic disease severity.

Autosomal Recessive Pattern of Inheritance

Autosomal recessive (AR) single gene traits require that the gene controlling the trait be located on an autosomal chromosome. Normally, the trait can be expressed *only* when both alleles are present. Table 4-2 lists some AR adult disorders. Fig. 4-10 shows a typical pedigree for an AR disorder. Criteria for AR patterns of inheritance include:

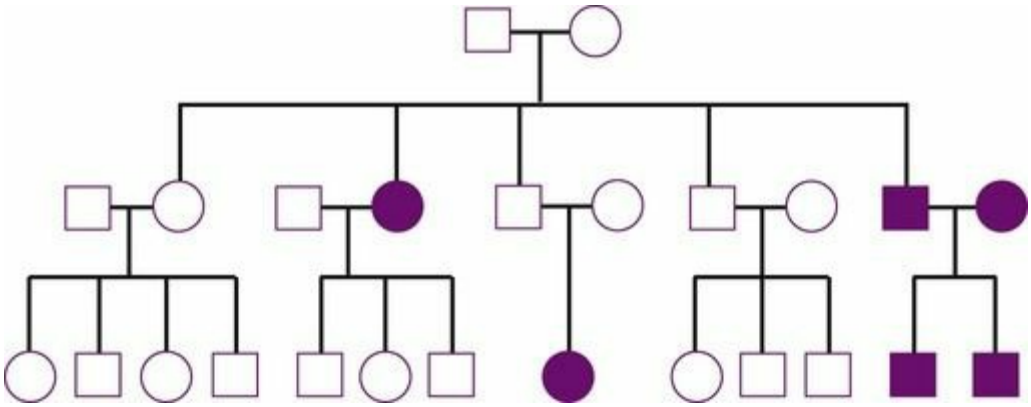

FIG. 4-10 A typical pedigree showing an autosomal recessive pattern of inheritance.

- The trait may not appear in all generations of any one branch of a family.
- The trait often first appears only in siblings rather than in parents and children.
- About 25% of a family will be affected and express the trait.
- The children of two affected parents will *always* be affected (risk is 100%).
- Unaffected people who are carriers (heterozygous for the trait) and do not express the trait themselves *can* transmit the trait to their children if their partner either is also a carrier or is affected.
- The trait is found about equally in male and female members of the same family.

An example of an AR trait is type O blood. The blood-type O allele is recessive, and both alleles must be type O (homozygous) for the person to express type O blood. If only one allele is a type O allele and the other allele is either type A or type B, the dominant allele will be expressed and the O allele, although present, is not expressed. For AR single gene traits, phenotype and genotype are always the same.

A person who has one mutated allele for a recessive genetic disorder is a **carrier.** A carrier, even though he or she may have one mutated allele, may not have any manifestations of the disorder but can pass this mutated allele on to his or her children. For some autosomal recessive disorders, a carrier may have mild manifestations. One example is sickle cell trait. A person with two sickle cell alleles has the disease and has many associated health problems. A carrier with one sickle cell allele (has "sickle cell trait") may be healthy most of the time and have manifestations only under conditions of severe hypoxia.

Sex-Linked Recessive Pattern of Inheritance

Some genes are present only on the sex chromosomes. The Y chromosome has only a few genes that are not also present on the X chromosome. These genes are important for male sexual development. The X chromosome has many single genes that are not present on the Y or elsewhere in the genome. Some of these genes are specific for female sexual development, but there are also several hundred genes on the X chromosome that code for other functions. Few disorders have X-linked dominant expression and are not discussed in this chapter.

Because the number of X chromosomes in males and females is not the same (1 : 2), the number of X-linked chromosome genes in the two genders is also unequal. Males have only one X chromosome. As a result, X-linked recessive genes have dominant expression in males and recessive expression in females. This difference in expression is because males do not have a second X chromosome to balance the presence of a recessive gene on the first X chromosome.

Sex-linked (X-linked) recessive single gene traits require that the gene allele be present on both of the X chromosomes for the trait to be expressed in females (homozygous) and on only one X chromosome for the trait to be expressed in males. Fig. 4-11 shows a typical pedigree for a sex-linked recessive disorder. Features of a sex-linked recessive pattern of inheritance are:

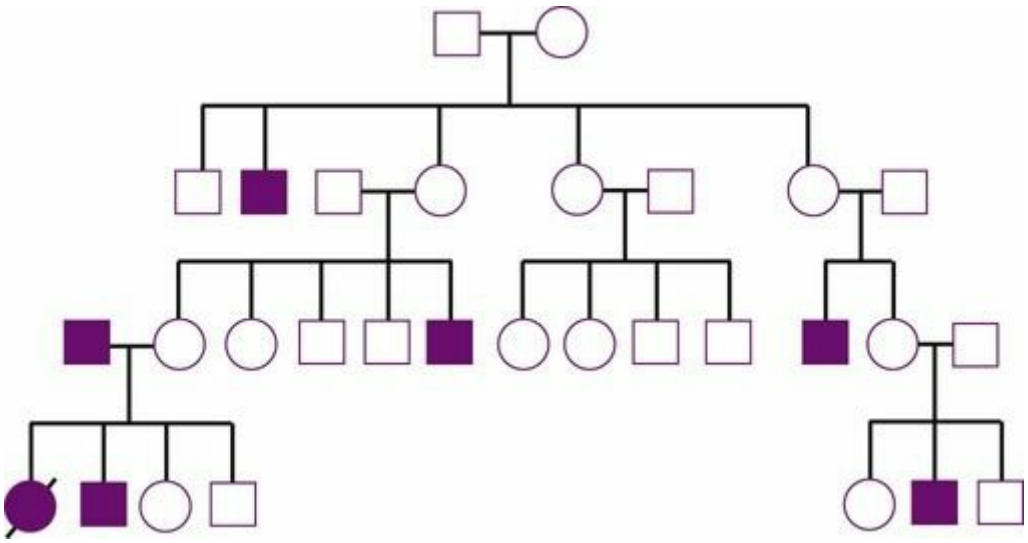

FIG. 4-11 A typical pedigree showing a sex-linked (X-linked) recessive pattern of inheritance.

- The incidence of the trait is much higher among males in a family than among females.
- The trait cannot be passed down (transmitted) from father to son.
- Transmission of the trait is from father to all daughters (who will be

carriers).
- Female carriers have a 50% risk (with each pregnancy) of passing the gene to their children.

Complex Inheritance and Familial Clustering

Some health problems appear in families at a rate higher than normal and greater than can be accounted for by chance alone; however, no specific pattern occurs within a family. Although clusters suggest a genetic influence, it is likely that additional factors, such as gender and the environment, also influence disease development or disease severity. Such disorders include Alzheimer's disease, type 1 diabetes, and many others. These disorders are often called *complex* and *multifactorial*, because although an increased genetic risk may be present, the risk is changed by diet, lifestyle, exposure to toxins, infectious agents, and other factors.

Genetic Testing

Purpose of Genetic Testing

Many people are eager to have genetic testing but also are fearful of genetic testing. The lay public often believe that a single genetic test can "tell everything about a person." Although genetic testing has the potential to be that informative, this is not currently the case. *It is important to remember that no single person is genetically perfect.*

Genetic testing can be performed with many different techniques. Some genetic tests are specific for a disorder. Others may show a gene variation but the significance of the variation may not be known. Unexpected information can be found during genetic testing. Some ordinary tests, such as blood typing and tissue typing, provide genetic information. Tests that measure the amount of an enzyme or protein also provide genetic information.

Testing for the purpose of assessing genetic information can be performed at many levels. Cellular or biochemical tests provide information about gene products made by a cell, tissue, or organ. Chromosomes and chromosome segments can be assessed for missing, extra, broken, or rearranged chromosomes. The sequence of a gene can be examined to determine variation or mutation. At present, not all genes can be analyzed and the analysis of even one gene is limited by expense and availability. Specific base pairs can be evaluated for mutations (Conley et al., 2013). Many tests are expensive, and the results may not be conclusive. Table 4-3 lists purposes of genetic testing for adults.

TABLE 4-3

Purposes of Genetic Testing for Adults

PURPOSE/TYPE	DEFINITION
Carrier testing	Determining whether a patient without symptoms has an allele for a recessive disorder that could be transmitted to his or her children. Disorders for which carrier testing is common include sickle cell disease, hemophilia, hereditary hemochromatosis, cystic fibrosis, beta thalassemia, and Tay-Sachs disease.
Diagnostic testing	Determining whether a patient has or does not have a mutation that increases the risk for a specific disorder.
Symptomatic	Patient has clinical manifestations; test results confirm a diagnosis.
Presymptomatic	Patient has no clinical manifestations but is at high risk for inheriting a specific genetic disorder for which there is no known prevention or treatment. A disorder for which presymptomatic testing is commonly performed is Huntington disease.
Predisposition	Family history or genetic testing indicates risk is high for a known genetic disorder. The patient does not have any manifestations but wants to know whether he or she has the specific mutation and what the chances are that it will be expressed. Disorders for which predisposition testing is often performed include hereditary breast/ovarian cancer and hereditary colorectal cancers. The advantage of predisposition testing is that the patient can then engage in heightened screening activities or medical and surgical interventions that reduce risk.

Benefits and Risks of Genetic Testing

Genetic testing is different from any other type of testing. Informed consent is required before genetic testing is performed. The person tested is the one who gives consent, even though genetic testing *always* gives information about family members—not just the patient (Badzek et al., 2013).

Benefits of genetic testing include the ability to confirm a diagnosis or to test people who are at risk for a health problem but do not as yet have any manifestations (presymptomatic testing). The information can help a person, family, and their health care provider develop a specific plan of care or early detection. For example, in the case of a strong genetic predisposition for colon cancer, identifying a patient before symptoms appear allows interventions to prevent the disease or to diagnosis it earlier, when cure is more likely.

Risks are associated with genetic testing that are not associated with other types of tests. Genetic testing results do not change. Thus a positive test result cannot be "taken back." Other risks may include psychological or social risks, as well as a risk for family disruption. Often genetic tests are expensive and may not be covered by insurance. Some

genetic tests have limited value for predicting future risk. Testing may identify a patient at great risk for the future development of a serious health problem that cannot be prevented or managed. Such a disorder is Huntington disease (HD), which currently has no treatment. Knowing positive test results in this case can lead to depression, blame, and guilt.

Another risk of genetic testing is that positive results may be used to discriminate against a person or a family. Some protection is in place to prevent health insurance companies from failing to insure a person or dropping the coverage of a person who is at high risk for developing a serious illness (e.g., breast or ovarian cancer). However, there are no protections against rate hikes or exclusions of specific treatments. Patients often fear workplace discrimination and personal discrimination if positive test results become known.

Genetic Counseling

Genetic testing is not a standard test that any person should have performed without knowing the benefits and risks. Counseling patients before, during, and after testing is critical and is required by the professional ethics governing genetic medicine. Entire families may be a part of the genetic evaluation and follow-up. For example, a 45-year-old woman has breast cancer. In her family, her mother, grandmother, brother, and one sister have all had breast cancer. Genetic testing indicates that she has a *BRCA1* gene mutation. This woman's older daughter wonders whether she has a gene mutation for breast cancer and asks to be tested. When she and her younger sister are tested, the older daughter does not have the mutation but the younger sister does.

Genetic counseling is a process—not a single session or a single recommendation. This process should begin when the patient or family is first identified as potentially having a genetic problem. The process continues through actual testing if the decision to test is made, and it continues through interpretation of results and follow-up. Chart 4-1 lists the steps in the process.

Chart 4-1

Best Practice for Patient Safety & Quality Care QSEN

Steps for Genetic Testing and Counseling

Pretesting Assessment and Patient Education (May Take Multiple Sessions)

- Determining patient understanding and why testing or counseling is being sought
- Determining whether testing is reasonable (considering cost of the test, specificity, probable risk, accuracy of testing)
- Establishing a trusting professional relationship
- Ensuring privacy and confidentiality
- Reviewing informed consent procedures
- Assessing the patient's ability to communicate accurately (including language issues, cognitive function, sensory perception)
- Assessing the patient's psychosocial status and availability of social support
- Taking a detailed patient health history (including drugs, diet, exercise, hormonal history, lifestyle issues)
- Obtaining physical assessment data relevant to the at-risk disorder
- Taking a detailed family history and constructing a three-generation pedigree (minimum)
- Obtaining and verifying information obtained from:
  - Patient
  - Family members
  - Medical records
  - Pathology reports
  - Death certificates
- Interpreting the family history
- Discussing the consequences of testing
- Discussing patient rights and obligations regarding disclosure of information
- Discussing testing options
- Assessing to determine whether coercion is occurring
- Obtaining material to be tested (usually blood)

Test Result Presentation

- Re-assessing the patient's wish to know or not know the test results
- Respecting the patient's decision to not know the test results
- Ensuring privacy and confidentiality
- Presenting the test results
- Interpreting the test results
- Assessing the patient's perception of the test results

Follow-Up

- Supporting the patient's decision to disclose or not disclose the information to other family members

- Discussing the potential risks for other family members
- Ensuring privacy and confidentiality
- Addressing the patient's concerns
- Discussing prevention, early detection, and treatment options
- Discussing family concerns
- Addressing psychosocial issues
- Discussing available resources for information, support, and further counseling
- Providing summary of results and consultation to the patient

Adapted from Beery, T., & Workman, M.L. (2012). *Genetics and genomics in nursing and health care.* Philadelphia: F.A. Davis.

As a nurse and patient advocate, it is your professional duty to determine whether the patient understands the consequences of testing. Often a patient may request genetic testing even when there is no indication of an increased risk for a genetic disorder. Counseling and evaluation can help patients understand whether any useful information could be obtained from testing.

Counseling should be a collaboration performed by a professional or a team who have defined expertise in interpretation of genetic testing results. Such professionals include advanced practice nurses with specialization in genetics, certified genetic counselors, clinical geneticists, and medical geneticists. Each profession has a different level of preparation in genetics and different skills or roles in the counseling process. For example, an advanced practice nurse may counsel a patient about the Huntington disease gene mutation because this test is not ambiguous and the gene is highly penetrant. When a genetic test shows a variation or mutation in an unusual gene region or when penetrance is reduced, the patient may best be served by counseling from a certified genetic counselor or a clinical or medical geneticist.

No matter which professional is involved in genetic counseling, a key feature of this counseling is to be "nondirective." When using a nondirective approach, the counselor provides as much information as possible about the risks and benefits but does not influence the patient's decision to test or not to test. Once the patient has made the decision, the counselor supports the patient and the decision.

Ethical Issues

Ethics and ethical issues are involved at every level of genetic testing. Some of the most important issues focus on the patient's right to know

versus the right not to know his or her gene status, confidentiality, coercion, and sharing of information.

The right to know genetic risk versus the right to not know is the individual patient's choice. Sometimes a patient's right to know has an impact on the right of another family member to not know.

Confidentiality is crucial to the genetic counseling process. *The results of a genetic test must remain confidential to the patient. The results cannot be given to a family member, other health care provider, or insurance carrier without the patient's permission.*

Coercion is possible by other family members and by health care professionals. *The final decision to have genetic testing or to not have testing rests with the patient.* Other people may believe it is important for the patient to have the test; however, the patient must make the decision without such pressures. As a patient advocate, professional ethics require you to assess whether the patient is freely making the decision to have genetic testing or whether someone else is urging the patient to test. This important issue can be difficult to assess. Ask the patient who else in his or her family wants to know the results of testing.

Sharing of test result information, negative or positive, can be stressful. The patient makes the final decision whether to share the information with family members. Some patients choose not to share this information even when other family members may also be at risk. This can be difficult for the health care provider who knows the patient has a positive test result for a serious inherited condition and the patient chooses not to tell other family members who may be at risk (Berkman & Hull, 2014). For example, hereditary nonpolyposis colon cancer (HNPCC) has an autosomal dominant inheritance pattern and each child of the patient has a 50% risk for having the gene. If the patient chooses not to tell his or her grown children, they then do not have the opportunity for increased screening to find the cancer at an early stage when cure is possible. An ethical dilemma arises when the health care provider wants to inform the children of their risk.

Clinical Judgment Challenge

Ethical/Legal

A 22-year-old man has a maternal grandfather with Huntington disease (HD). His father, mother, and paternal grandfather are all healthy and free of HD manifestations. He wants to know whether he also has the HD gene and arranges to be tested. His mother does not

want to know whether she has the gene mutation. The man is tested and is found to be positive for the gene mutation that causes HD.

1. Why could a positive test affect this man's mother?
2. Does the mother's right to not know her HD status override the son's right to know his status? Explain your reasoning.
3. Review the ethical principles in Chapter 1. Which principle(s) would be violated if the son informs his mother of his positive test results?

The Role of the Medical-Surgical Nurse in Genetic Counseling

Medical-surgical nurses help patients during the assessing, testing, and counseling processes, although they do not provide in-depth genetic counseling. Patients often feel most comfortable sharing information with nurses and asking nurses to clarify information.

Nurses may be the first health care professionals to identify a patient at specific genetic risk. Some of the "red flags" that a patient may have a genetic risk for a disease or disorder are:

- The disease or disorder occurs at a higher incidence within the family compared with the general population.
- The patient or close family members have another identified genetic problem.
- The incidence of a specific disease or disorder occurs in the patient or in family members at an unusually early age.
- A rare disease is present in two or more family members.
- More than one type of cancer is present in any one person.
- The specific manifestation is associated with one or more genetic disorders (e.g., unusual freckling or skin pigmentation, bicuspid aortic valve, deafness).

The nurse may be the health care professional who first verifies information to bring a genetic problem to light. For example, during an assessment, a patient reveals that her mother died of bone cancer when she was 40 years old. Bone cancer is quite rare among adults; thus the nurse might then ask, "Did your mother ever have any other type of cancer?" Often the patient may then reveal that her mother had breast cancer some years before ("bone cancer" was actually breast cancer that had spread to the bones). Breast cancer at an early age can indicate a genetic predisposition.

Patients may ask questions that indicate they have an interest in genetic testing. These are examples of questions that may be cues that the patient has genetic concerns:

- Will my children get this disease?
- Because my sister has this problem, what are the chances I might also develop it?
- Is there a way to test and see whether my chances of getting this disease or problem are high or low?

Areas of responsibility for any medical-surgical nurse in working with a patient who is considering or having genetic testing include communication, privacy and confidentiality, information accuracy, patient

advocacy, and support.

Communication

In congruence with professional ethics, act as a patient advocate by ensuring that communication between the patient and whoever is providing the genetic information is clear. First, assess the patient's ability to receive and process information. Can the patient see and hear clearly, or are assistive devices needed? Does the patient understand English, or will an interpreter be needed? Does the patient have adequate cognition at the time of meeting with the genetics professional, or is it impaired by medication, disease, anxiety, or fear?

If the patient appears not to understand terms or jargon during a discussion between him or her and a genetics professional, ask the professional to use common terms and examples for the patient. Verify with the patient that he or she understands or does not understand.

After any discussion about genetic risk or genetic testing, assess the patient's understanding of what was said. Ask the patient to explain, in his or her own words, what the issue means and what his or her expectations are.

Privacy and Confidentiality

Professional ethics require that all conversations regarding potential diagnoses or genetic testing need to occur in a private environment. The patient has the right to determine who may be a part of the discussion and can decide to exclude the primary physician and any family member from the discussion with a genetics professional. It is important that health care professionals who may be present during such discussion do not disclose information, formally or informally, without the patient's permission. It is the nurse's ethical duty and responsibility to protect this information from improper disclosure to family members, other health care professionals, other patients, insurance providers, or anyone not specified by the patient.

Information Accuracy

Correct myths about genetic disorders, and teach patients about the nature of genetic testing. In addition, help patients find accurate and helpful resource materials or websites. Medical-surgical nurses are not genetics experts and would not be expected to be the final source of definitive information; however, with collaboration they can help ensure that

the patient is referred to the correct level of genetic counseling. If you are present during the patient's discussions with a genetics professional, assess whether the patient understands the issues regarding the health problem.

Patient Advocacy and Support

Ensure that the patient's rights are not neglected or ignored. Ask the patient privately what his or her wishes are regarding genetic testing. Ask whether another person or agency is insisting on the testing. Remind the patient that he or she does not have to agree to be tested. Verify that he or she has signed an informed consent statement for the test.

Considering or having genetic testing is a stressful experience. The patient and family require support and may need help with coping. Ethically, genetic testing should be performed only after genetic counseling has occurred and should be followed with more counseling.

Patients may feel anger, depression, guilt, or hopelessness. Patients who have positive results (results that indicate a specific mutation is present) from genetic testing may have issues of risk for early death or disability and the possibility of having passed the risk for a health problem on to their children. Patients who have an ambiguous test result or one of unknown significance may feel that they have agonized over a decision, spent money, and still have no clear answer. Even patients who have negative genetic test results (results that indicate a specific mutation is not present) need counseling and support. Some patients may have an unrealistic view of what a negative result means for their general health. Others may feel guilty that they were “spared” when other family members were not.

Assess the patient's response to genetic test results. Determine what coping methods were used successfully in the past. If the patient has disclosed information to family members, assess whether they can help provide support or need support themselves. Assess whether the information about positive test results has strained family relationships. Refer the patient to appropriate support groups and general counseling services.

For some positive genetic test results, such as having a *BRCA1* gene mutation, the risk for developing breast cancer is high but is not a certainty. With high risk, the patient needs a plan for prevention and risk reduction. One form of prevention is early detection. Thus a patient who tests positive for a *BRCA1* mutation should have at least yearly

mammograms and ovarian ultrasounds to detect cancer at an early stage when it is more easily cured. Teach the patient who has positive test results that indicate an increased risk for a specific health problem about the types of screening procedures that are available and how often screening should occur. For example, some patients at known high genetic risk for breast cancer and ovarian cancer choose the primary prevention methods of bilateral prophylactic mastectomies (surgical removal of the breasts) and oophorectomies (surgical removal of the ovaries). Although these strategies are severe, they are effective and the patient should be informed about their availability.

Teach patients at known high risk for a specific disorder how to modify the environment to reduce risk. For example, a patient who has a specific mutation in the *a1AT* (alpha$_1$-antitrypsin) gene is at increased risk for early-onset emphysema. The onset of emphysema is even earlier when the patient smokes or is chronically exposed to inhalation irritants. By modifying his or her environment, the disease can be delayed or the manifestations reduced.

NCLEX Examination Challenge

Psychosocial Integrity

The client who has been found to have a mutation in a gene allele that greatly increases her risk for chronic obstructive lung disease asks the staff nurse to be present when she discloses the test results to her family. What is the nurse's role in this situation?

A Primary health care provider
B Genetic counselor
C Patient advocate
D Patient support

Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Ensure that a person or family with indications of an increased genetic risk for a disease or disorder is referred to an appropriate genetics professional. **Teamwork and Collaboration** QSEN
- Advocate for the patient with regard to whether or not to have genetic testing, informed consent before testing, and sharing of test results. **Patient-Centered Care** QSEN
- Ensure that confidentiality of genetic test results is maintained by all health care team members. **Safety** QSEN
- Determine whether an informed consent statement was obtained before any genetic test is performed.
- Keep all patient and family information regarding genetic testing confidential.

Health Promotion and Maintenance

- Identify patients and families at increased genetic risk for disease or disorder.
- Teach patients and families at known increased genetic risk for disease or disorder what types of screening procedures and schedules are most appropriate (check specific disorder chapters for the appropriate screening guidelines). **Evidence-Based Practice** QSEN
- Teach patients and families at known increased genetic risk for disease or disorder what types of environmental modifications can reduce risk, delay disease onset, or reduce symptom severity (check specific disorder chapters for appropriate modifications). **Evidence-Based Practice** QSEN

Psychosocial Integrity

- Assess patients who have received results of genetic testing for responses such as anger, guilt, or depression.
- Allow the patient and family who have been identified as being at increased genetic risk for serious health problems to express concerns and feelings.
- Ensure that the patient who undergoes genetic testing is appropriately

counseled before testing, while waiting for test results, and after test results are obtained. **Teamwork and Collaboration** QSEN

- Support the decision of the patient and family to have or not to have genetic counseling or testing.

Physiological Integrity

- Be aware that mutations or variations in gene sequences can change the activity of a protein and have adverse effects on health.
- Keep in mind that many common adult diseases or disorders have a genetic basis (hypertension, diabetes, cancer) although some of these diseases also may occur among people with no genetic risk.
- Remind the patient that having a gene variation that increases the risk for a disorder does not necessarily mean that the disorder will ever develop.
- Ensure that patients understand that genetic testing reveals information about their family members, as well as about themselves.
- Construct a three-generation pedigree from data obtained during the family history section of patient assessment.
- Remind patients that the results of genetic testing cannot be "taken back."
- Be prepared to assume the accepted roles of the medical-surgical nurse in genetic counseling, which include examining assessment data for indications of genetic risk, acting as a patient advocate, correcting myths about genetic disorders and genetic testing, protecting the patient's privacy and rights, and helping to ensure that the patient and/or family at increased genetic risk are referred to a genetics professional.

CHAPTER 5

Evidence-Based Practice in Medical-Surgical Nursing

Rona F. Levin and Fay Wright

PRIORITY CONCEPTS

- Evidence-Based Practice
- Teamwork and Collaboration
- Safety
- Quality Improvement

Learning Outcomes

Safe and Effective Care Environment

1. Describe evidence-based practice (EBP) to include the components of research evidence, clinical expertise, and patient/family values.
2. Explain the role of evidence in making clinical decisions and determining best clinical practice.
3. Explain how to use an EBP approach to identifying a clinical problem, issue, or challenge.
4. Differentiate clinical opinion from research and evidence summaries.
5. Formulate a focused clinical question about clinical practice.
6. List the steps of how to perform a systematic literature review to answer clinical questions.
7. Briefly describe two models of EBP for changing processes of care.
8. Explain the steps of the evidence-based practice improvement (EBPI) model.
9. Discuss how the EBPI model can be used to guide a clinical practice improvement project.

 http://evolve.elsevier.com/Iggy/

Overview

All health care professionals need to understand and use an evidence-based practice (EBP) approach to practice. In 2003, the Institute of Medicine (IOM) published a report entitled *Health Professions Education: A Bridge to Quality*. That report contained this mandate: "All health professionals should be educated to deliver patient-centered care as members of an interdisciplinary team, emphasizing evidence-based practice, quality improvement approaches and informatics" (IOM, 2003, p. 3). Since that report was published, EBP to improve the quality of patient care has been a consistent theme in the IOM's publications, with more than 24 reports found on their website to guide implementation of EBP (http://www.iom.edu/Reports.aspx).

In 2010, the IOM in partnership with the Robert Wood Johnson Foundation published *The Future of Nursing: Leading Change, Advancing Health* (IOM, 2010). Key among the four major recommendations is: "Nurses should be full partners, with physicians and other health care professionals, in redesigning health care in the United States" (p. 3). The specifics of this recommendation include the need for nurses to be prepared to be collaborators in health care improvement efforts and sometimes lead those projects. Aspects of this role include "taking responsibility for identifying problems and areas of system waste, devising and developing improvement plans, [and] tracking improvement over time …" (p. 3). Thus all nurses need to be equipped with the knowledge and skill that are required to be a full partner in making positive change in health care. This chapter provides the foundation to begin that preparation.

Definitions of Evidence-Based Practice

According to several nursing experts and the Quality and Safety Education for Nurses (QSEN) movement, EBP incorporates the best current evidence with the expertise of the clinician and the patient's values and preferences to make a decision about health care (Cronenwett et al., 2007; Levin et al., 2013; Melnyk & Fineout-Overholt, 2011). This definition was based on the work of Sackett et al. (2000), who had proposed three components of EBP—best evidence, clinical expertise, and patient values and preferences—as part of the definition of evidence-based medicine.

Ervin (2002) proposed this definition of EBP for nursing: "Evidence-based nursing practice is practice in which nurses make clinical decisions using the best available research and other evidence that is reflected in

approved policies, procedures, and clinical guidelines in a particular healthcare agency" (Ervin, 2002, p. 12). DiCenso et al. (2005) further extended this definition to include information about the patient's clinical state and the setting or circumstances in which health care is being provided.

The EBP process is collaborative and involves all members of the health care team, including the patient and family. This model is shared by many health care professions and is not unique to nursing. Therefore, although other professions might refer to the model as evidence-based medicine (EBM) or evidence-based social work similar to how DiCenso et al. (2005) specified the practice of nursing, the authors of this text refer to the model as EBP.

Steps of the Evidence-Based Practice Process

The process of EBP is systematic and includes several steps as presented by Sackett et al. (2000) in the context of practicing and teaching medicine.

1. Asking "burning" clinical questions
2. Finding the very best evidence to try to answer those questions
3. Critically appraising and synthesizing the relevant evidence
4. Making recommendations for practice improvement
5. Implementing accepted recommendations
6. Evaluating outcomes

Important to note is that the original approach to EBP developed in the medical community was intended to be used by physicians to solve individual patient problems for which physicians did not have ready answers. The adoption of EBP by nursing and other health care disciplines, however, required a different perspective that incorporated organizational data, goals, and priorities. Most nurses work within a health care agency, not in an independent practice setting. Nurses must collaborate with those in other disciplines who are involved in practice changes within a health care agency. An example of how EBP works within a hospital system is provided later in this chapter.

Asking "Burning" Clinical Questions

Clinical questions are derived when clinicians do not have all the information they need to make the best possible decisions about patient care. A "burning" clinical question is one that usually arises in daily practice or when attending a class or reading a professional journal on a specific topic. The question may arise in relation to an individual patient, a group or population of patients, or a patient care unit or larger

organizational area. An example of an *individual* patient question that a nurse might ask is: "My older hospitalized patient who has been placed on fall precautions fell in the bathroom. What else could I have done to prevent this patient from falling, and what can I do to prevent her from falling in the future?" At a *group or population* level, the nurse might ask: "What are current best practices for assessing hospital patients' risk for falls, and/or what are best practices for fall prevention in patients who are at risk for falls? At a *unit or organizational* level, the question might be: "Is the current policy and procedure for assessing patients' risk for falls and for implementing preventive practices based on the best available evidence?"

Once you critically think about and pose a question about clinical practice, you will need to find out at what level the question needs to be answered (i.e., at the individual patient level, patient population level, or organizational level). If the latter two levels are where the problem exists, then begin to gather background information from the literature and internal evidence from your organization to describe the problem more fully (Levin et al., 2010).

One way you can begin to use EBP in your practice is to review the policy and procedure for a specific nursing practice in your clinical setting and determine what type of evidence was used as the basis for that policy and procedure. Does the protocol list references? What types of references are cited?

Once you have described the clinical practice problem and can focus on exactly what concerns you have, ask yourself whether the question is a *background* or a *foreground* question. A *background* question usually asks for a fact, a statement on which most authorities or experts would agree. For example: What is the etiology of congestive heart failure? What are the most frequently prescribed analgesics for the management of postoperative pain? The answers to these types of questions can usually be found in a textbook and are not controversial. A *foreground* question, on the other hand, usually asks a question of relationship and may be controversial. An example of this type of question is: What are the most effective interventions for treating venous leg ulcers?

Qualitative Versus Quantitative Questions.

If you are asking a foreground question, develop a more specific, detailed clinical question to guide your search for evidence. Clinical questions may be qualitative or quantitative. A **qualitative question** focuses on the meanings and interpretations of human phenomena or experiences of people and usually analyzes the content of what a person says during an

interview or what a researcher observes. Examples of qualitative questions are:

- What is the experience of having cancer like for young adults?
- How do older women respond to a residential move to assisted-living facilities?
- What are the differences in nurses' work culture between acute care and home care agencies?

A **quantitative question** asks about the relationship between or among defined, measurable phenomena and includes a more objective approach to both data collection and data analysis. Answers to quantitative questions necessitate statistical analysis of information that is collected to answer a question. Examples of quantitative questions are:

- What is the effect of using a new assessment tool to predict the likelihood of falling to frequency and severity of falls in patients undergoing hip replacement?
- What is the effect of hydrocolloid dressings compared with silver-impregnated dressings on the rate of wound healing in patients with postsurgical incision wounds?

PICO(T) Format.

Nursing authors suggest framing clinical questions in a PICO (Fleming, 2008; Levin, 2013) or PICO(T) format (Fineout-Overholt & Stillwell, 2011). The PICO(T) format is outlined in Table 5-1. The major components of a focused clinical question are the **p**opulation, **i**ntervention, **c**omparison, and **o**utcome, with an added **t**ime component when appropriate.

TABLE 5-1

Examples of Components of PICO(T) Questions in Relation to Type of Question

	THERAPY	ETIOLOGY	DIAGNOSIS	PREVENTION	PROGNOSIS	MEANING
Population						
Intervention						
Comparison						
Outcome						
Time						

The *population* indicates the specific group of patients to whom the question applies. This component is important because evidence that may support an intervention with one group of patients may not apply to another group of patients. For example, a fall prevention program for

older adults who live at home may be very different from a fall prevention program for patients who attend a rehabilitation program. Be sure to think about the age, gender, ethnicity/race, and specific health problems to narrow your population of interest.

The *intervention* component may pertain to (1) a new therapy that has been supported by best evidence, (2) exposure to disease or harm, (3) a prognostic factor, or (4) a risk behavior or factor—for example, the need for toileting to help prevent falls (Melnyk & Fineout-Overholt, 2011). In terms of a new therapy, one might compare the use of guided imagery to decrease nausea and vomiting among patients receiving chemotherapy with similar patients who receive the current drug therapy for nausea and vomiting, and then evaluate patient outcomes.

The *comparison* component of the clinical question may be either the standard or current treatment as in the above example or may be another intervention with which the innovative practice is compared. In the case of prognostic questions, the comparison may consider another factor or potential influence that could affect the outcome of the patient's health. A preventive question might examine the absence of the risk factor as the comparison—for example, the need for toileting compared with no need for toileting to prevent falls.

The *outcome* component specifies the measurable and desired outcomes of your practice innovation, which may be focused on improving how you assess patients to make a nursing diagnosis or on a prevention or therapeutic intervention. Outcomes must include measures of the results of introducing an innovation to determine whether it was successful. For example, for an intervention outcome, measures might include patients' perception of pain, number of days spent in a hospital, or need for rehabilitative services. Or when testing a way to improve diagnostic accuracy, your outcome might focus on the sensitivity and specificity of a diagnostic test or nursing assessment tool (e.g., What is the best tool for assessing the risk for patient falls on an orthopedic unit?).

Fineout-Overholt and Stillwell (2011) advocated adding a *time* component or time frame to the focused clinical question. The question may include specifying within what time period one would expect the outcome(s) to occur. An example of a completed PICO(T) question is: What is the effect of adding hourly rounding to the standard falls protocol for the geriatric unit (patients 65 years or older) in hospital Y on the process of care provision (to be more specifically defined) and the outcomes of rate of falls, fall morbidity, and clinician satisfaction within a 3-month period?

Arriving at the focused clinical question is not an easy task, even for seasoned clinicians. Clearly identifying each component of the PICO(T) question focuses the clinical question for the next step in the EBP process: finding the best evidence to improve the practice problem.

Finding the Best Evidence

Finding the best available evidence to answer a focused clinical question has been a challenge for clinicians and health care agencies. The major barrier that prevents nurses from engaging in evidence-based practice is lack of time (Pravikoff et al., 2005). Other barriers include:

- Lack of value for research in practice
- Lack of understanding of organization or structure of electronic databases
- Difficulty accessing research materials
- Lack of computer skills
- Difficulty understanding research articles

The health care system is addressing these challenges in many settings to improve the safety and quality of patient care. Many hospitals and community health care agencies are involved in promoting evidence-based practices and projects to reach national safety goals. An example of how staff nurses are essential contributors and collaborators on such projects is presented at the end of this chapter in the Application of the EBPI Model to Clinical Practice section.

Level of evidence (LOE) refers to the status or rank of evidence. Most evidence hierarchies are pyramids with the highest level of evidence at the top (Fig. 5-1). The type of evidence needed depends on the nature of the clinical question—is the question quantitative or qualitative? For example, if you are asking about the effectiveness of different types of compression bandages on healing of venous leg ulcers, you would want to *measure* the change in size of the ulcer as one indication of healing *(quantitative)*. On the other hand, you might be interested in what the experience of having a chronic venous ulcer is like for women *(qualitative)*. Each type of question requires different types and sources of evidence to find an answer. Table 5-2 provides an internationally accepted hierarchy for qualitative levels of evidence. The Evidence-Based Practice boxes in this text identify each study's LOE.

TABLE 5-2

JBI Levels of Qualitative Evidence for Meaningfulness*

LEVEL OF EVIDENCE	MEANINGFULNESS M (1-4)
1	Meta-synthesis of research with unequivocal synthesized findings
2	Meta-synthesis of research with credible synthesized findings
3	a. Meta-synthesis of text/opinion with credible synthesized findings b. One or more single research studies of high quality
4	Expert opinion

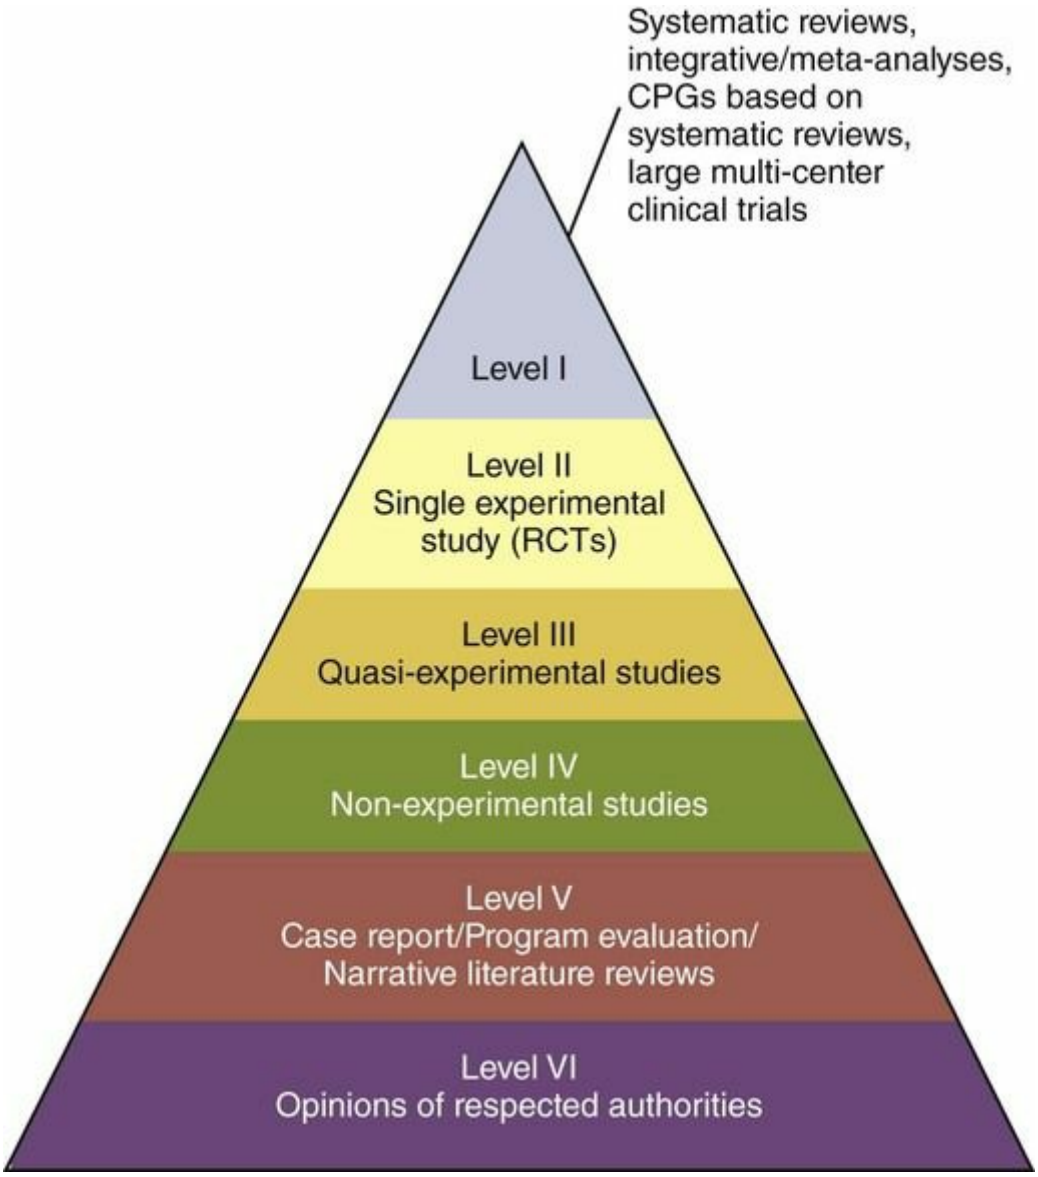

FIG. 5-1 Pyramid of evidence for questions of therapy. *CPGs,* Clinical practice guidelines; *RCTs,* randomized controlled trials.

A preliminary evidence search entails identifying whether quality clinical practice guidelines (CPGs) exist to answer the clinical question. A **clinical practice guideline** is an "official recommendation" based on evidence to diagnose and/or manage a health problem (e.g., pain management). If these guidelines are of high quality and they contain the answer to your question, the search may be complete (Levin & Jacobs, 2012). The importance of CPGs is reinforced with the IOM's consensus report on the use and effectiveness of quality clinical practice guidelines for the implementation of EBP (IOM, 2011).

If the guidelines do not provide a sufficient answer to your question and/or they are not based on high-quality evidence, you need to search the "Fantastic Four" databases:

- Cochrane Library of Systematic Reviews
- Joanna Briggs Institute (JBI) systematic reviews
- Medline (or PubMed)
- Cumulative Index to Nursing and Allied Health Literature (CINAHL)

Other databases may also contain a wealth of information depending on the nature of the question. For example, if you are asking a psychological question about the best way to help patients deal with anxiety, then PsycINFO would be a good source. The instructional or health sciences librarian at the local college/university or clinical agency can assist in finding the best current evidence to answer your question. In some cases, you may need to revise the search if the original terms used did not access relevant citations. Table 5-3 provides a template that you can use for any evidence search that you undertake.

TABLE 5-3

Example of a Search Strategy Table with Hypothetical Data

DATABASE	KEY WORDS	DATE RANGE	PEER REVIEWED	# OF CITATIONS	# RETRIEVED	# USED
Medline (PubMed)	Pain Postoperative Behavioral Assessment Scale	2002-2010	All	5	3	0
CINAHL	Pain Postoperative Behavioral Pain Scales	2000-2010	All	25	5	2

CINAHL, Cumulative Index to Nursing and Allied Health Literature.

If a continued literature search is needed for *quantitative* clinical questions, start with looking for the top level of evidence (i.e., systematic reviews, which are meta-analyses, clinical practice guidelines based on top level evidence, and/or multi-site randomized clinical trials) (see Fig. 5-1). If searching for answers to *qualitative* questions, look first for meta-syntheses. The major purpose of providing systematic reviews of evidence on a topic for both qualitative and quantitative questions is so that busy clinicians will not have to spend many hours finding original

single studies and then reviewing, critiquing, and synthesizing each study's evidence. In some cases, evidence summaries are available (Table 5-4). Fig. 5-2 provides a guide for conducting a systematic evidence search.

Critically Appraising and Synthesizing Evidence

The key to this step is a collaborative team effort. One effective strategy is to have each member of an EBP team take responsibility for summarizing and critically appraising a select number of articles (depending, of course, on the number of relevant articles your search

revealed) and then presenting a written summary and review to all team members. This allows collegial critique of the evidence, helps clarify areas of uncertainty, and facilitates team consensus on what the best evidence is to answer the clinical question. In addition, summarizing and critically appraising each piece of relevant evidence and entering the results of this activity into a table of evidence makes it easier to synthesize all the relevant evidence succinctly. This evidence synthesis will tell you if there is sufficient evidence to guide practice related to your clinical question.

Making Recommendations to Improve Practice

Once you have reviewed, critically appraised, and synthesized all the relevant evidence, you are ready to make practice recommendations in a written report to whoever needs to review them for potential approval. The clinical application at the end of the chapter illustrates this process.

Implementing Recommendations

This step is perhaps the most exciting and energizing component of an EBP project. After all the hard work of focusing the practice problem, developing a PICO question, retrieving and critically appraising the evidence, and getting practice recommendations approved, the protocol and implementation plan can be developed. This plan should improve practice, patient outcomes, and the desired outcomes of the system (e.g., cost savings). Approaches to implementation are varied. Examples of models to guide EBP projects from the beginning to the end are presented in the next section of this chapter.

Keep in mind that the process of implementation needs to be systematic, shared, and consistent. That is, the implementation protocol has to be followed strictly so that any outcomes that are achieved are actually based on the new EBP innovation being implemented. Therefore complete buy-in from the people who will be involved in implementing the new practice is essential.

Evaluating Outcomes

Evaluating outcomes requires valid and reliable measurement tools. For example, if the clinical question is evaluating the effect of music therapy on reducing postoperative abdominal pain, then a tool to measure pain intensity and quality would be used. Many of these tools are cited in the literature and can be used without permission. Others require that permission be obtained in writing. Be sure to determine whether

permission is needed before you use any measurement tool.

Clinical Judgment Challenge

Evidence-Based Practice; Quality Improvement; Safety QSEN

An 82-year-old alert and oriented woman was admitted with a diagnosis of congestive heart failure. She also has urinary frequency. You notice on her chart that she is a "high falls risk." Over 70% of patients on your unit are also at high risk for falls. The written policy and procedure for fall prevention at your hospital states that patients at risk for falling should have:

- Their health care record flagged with a yellow flower
- A yellow flower placed on their room or bed
- A bed alarm installed
- Their siderails up at all times, except when a visitor, nurse, or nursing assistant is present

The patient felt the urge to urinate and pressed her call light. Someone on the intercom told her that she would assist her shortly. After 15 minutes, the patient had to make a decision to either urinate in bed or climb over the siderails to go to the bathroom. She decided to climb over the siderails and fell. The bed alarm went off after she left the bed.

1. Considering that over 70% of patients admitted to your unit are flagged as "at risk for falls," how do you think the nurses decide that a patient is at risk for falling? Are they using valid, reliable, sensitive, and specific assessment tools to make this determination?
2. In a population of inpatient older adults, what factors can predict patient falls with a high degree of accuracy?
3. Does the best available evidence support the use of bed alarms as an intervention that prevents falls in inpatient adults of any age?
4. In a population of adult inpatients, what are the factors that have been shown by research to be the most predictive of falls?
5. What interventions have been shown to decrease the fall rates in acute care institutions with this population? (Also see Chapter 3.)

Models and Frameworks for Implementing Evidence-Based Practice

Several authors have attempted to develop models or conceptual frameworks to facilitate an understanding of the complex process of introducing evidence-based improvement efforts (Rycroft-Malone & Bucknall, 2010). Each model highlights factors or processes that need to be considered when attempting to implement practice change.

Iowa Model

The major purpose of the Iowa model of EBP is to help health care professionals use evidence to improve patient outcomes. Originally developed as a model for research utilization, Titler revised and enhanced the model in 2010 to incorporate the elements of EBP. Important aspects of the current model include the (Titler, 2010):

- Triggers that lead to clinical questions
- Assessment of whether these questions are priorities for the health care organization
- Focus on forming a team to develop an EBP initiative
- General overview or steps for deciding about whether to implement and then adopt a change in practice

Reavy and Tavernier Model

Reavy and Tavernier (2008) developed a model and process to implement EBP that uses concepts from previously developed models (e.g., Stetler model, Iowa model) and builds upon them. The emphasis of the Reavy and Tavernier model is on the crucial role of the direct caregiver (e.g., the staff nurse) in making changes to enhance clinical practice. The authors of the model view the staff nurse as the clinical expert. Given that the staff nurse may not have expertise in research and/or practice improvement, they believe that the expertise of a nurse researcher is needed to facilitate the EBP process. The nurse researcher serves as a role model and supports nursing staff in identifying areas for improvement, assists staff with literature reviews and synthesis of evidence, and helps with the implementation and evaluation of EBP projects. Reavy and Tavernier suggest that if a nurse researcher is not available in the practice setting, then a clinical nurse specialist, advanced practice nurse, or nurse manager might provide the needed support to staff nurses. Also included in this model is an emphasis on patient and family preferences and values; however, there is little explanation of the crucial role of

patient as stakeholder in any practice improvement efforts. See Table 5-5 for a more detailed description of this model.

TABLE 5-5

Processes Used for Implementation of the Reavy and Tavernier Evidence-Based Practice Model for Staff Nurses

	PATIENT VALUES AND PREFERENCES	STAFF NURSE/CLINICAL EXPERT	NURSE RESEARCHER/BEST AVAILABLE EVIDENCE
Assessment	Give verbal and nonverbal communication	Receive verbal and nonverbal messages (collect data)	
Identification and evaluation of problem		1. Identify problem(s) 2. Discuss potential interventions and outcome 3. Conduct literature search	Assist with literature search as needed
Analysis and synthesis of best available evidence		1. Analyze and critique best available evidence 2. Synthesize evidence	Assist with analysis, and critique as needed
Planning		1. Assess feasibility of change 2. Define proposed change 3. Identify resources 4. Define desired outcome	
Implementation and evaluation	Receive nursing care based on best evidence	1. Design and implement peer teaching strategies 2. Implement change 3. Conduct pilot study 4. Evaluate findings 5. Decide to adopt or reject change 6. Communicate findings	1. Provide assistance with pilot study 2. Receive communication related to ideas for research
Integration and maintenance	Receive nursing care based on best evidence	1. Integrate into policies 2. Monitor process 3. Monitor outcomes 4. Communicate updates	Receive communication related to ideas for research

ARCC Model

The Advancing Research and Clinical Practice through Close Collaboration (ARCC) model of evidence-based practice was originally developed by Bernadette Melnyk in 1999 and was enhanced by Melnyk and Fineout-Overholt over a 10-year period (Melnyk & Fineout-Overholt, 2010). The current version of the model consists of several components and how they relate to each other. The major components of the model are:

- Organizational assessment and readiness to implement EBP
- Identification of strengths and barriers to EBP implementation
- Development and use of EBP mentors
- Implementation of EBP
- Measurement of nurse, system, and patient outcomes

Key to this model is the development and use of EBP mentors who

teach, guide, and facilitate agency staff in the implementation and evaluation of evidence-based practices (Melnyk & Fineout-Overholt, 2010).

Evidence-Based Practice Improvement (EBPI) Model

The EBPI model developed by Levin et al. under the auspices of the Visiting Nurse Service of New York (Levin et al., 2010) combines the best of the EBP and PI/QI (process/quality improvement) systems into one approach for implementing practice improvement.

Steps of the EBPI Model

The model is prescriptive and easy for guiding health care practitioners from any discipline and setting to achieve positive change. As depicted in Fig. 5-3, the model includes:

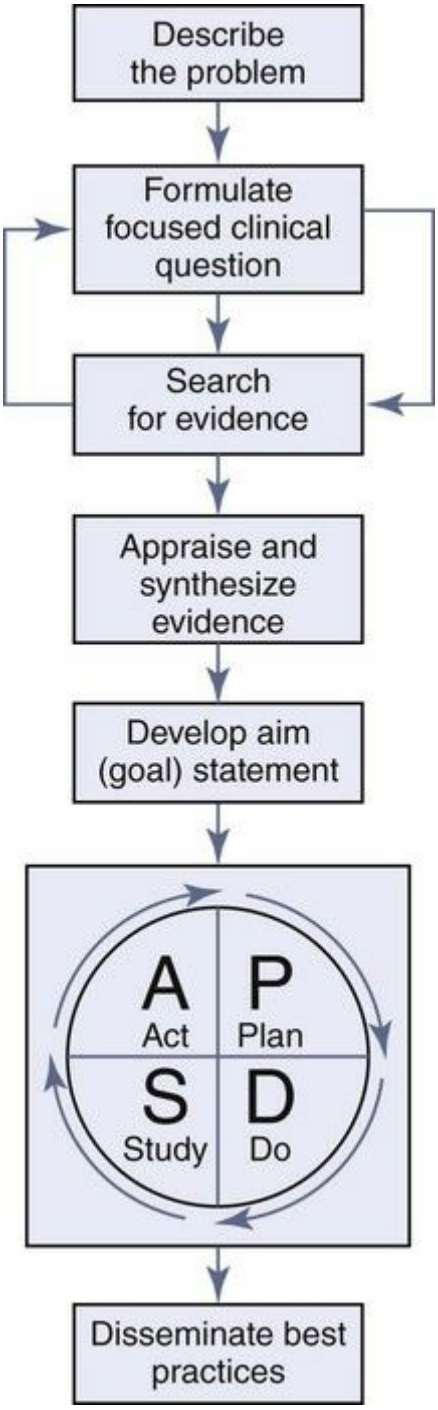

FIG. 5-3 The Evidence-Based Practice Improvement (EBPI) model.

- Describing the practice problem
- Formulating a focused clinical question (in PICO format)
- Searching for evidence to answer the question
- Appraising and synthesizing relevant evidence
- Developing an aim statement or project goal
- Developing, implementing, and evaluating the protocol for practice improvement
- Using small tests of change or **p**lan, **d**o, **s**tudy, **a**ct (PDSA) cycles to test methods

• Disseminating best practices

Adopted from the process improvement approach is the idea of PDSA cycles or small tests of change (Langley et al., 2009). Many professionals in health care, business, and other fields implement what they believe is a good idea for an improvement on too-large a scale before they have perfected the new practice or even assessed how successful it may or may not be in their setting with their populations (patients or consumers). One of the most important benefits of small tests of change is that you have a chance to perfect the process or practice that you want to implement before disseminating and using the practice on a wide scale. Small tests of change for EBPI projects in health care are conducted with a small group of people (e.g., patients or staff) for a short period and may be repeated several times until the implementation protocol is perfected (Levin, 2009).

During small tests of change, it is helpful to use the concept of **PDSA** cycles to guide the activities.

- "**P**" stands for "plan" and is the first step in introducing a practice change. During this phase, a project team develops a protocol for implementation, which includes not only the protocol or procedure for the practice innovation but also a total plan for the exact process that will be followed for implementing the project. It includes who will be administering the new practice, how it will be implemented, the time frame for implementation, and how the particular processes implemented for each small test of change will be evaluated.
- "**D**" stands for "do" and is the action-oriented phase of the process. The new innovation or a portion of it is tested according to the plan.
- "**S**" stands for "study" and refers to the review and analysis of data collected during the "do" phase of the cycle.
- "**A**" stands for "act" and is the evaluation of results from the small test to guide decisions about how to proceed with the EBP project.

Decisions then need to be made about how to revise or refine the practice protocol and institute another small test of change to try out the refined protocol and then decide whether the plan is worth continuing.

Application of the EBPI Model to Clinical Practice: A Case Study

Describe the Practice Problem

On an adult general surgical unit in a community hospital, the nursing staff identified that assessing patients' postoperative pain with the current practice of using a numeric 10-point rating scale did not seem to

be an effective assessment tool when the patient was lying quietly or appeared to be asleep. The nurses thought that to ask the restful patient to scale his or her pain refocused the patient on the pain and was not supportive of patient relaxation and pain relief. When this type of clinical observational pain assessment was performed, the nurse often did not chart the assessment in the medical record—how could the nurse label the level of pain on the scale when patient behaviors were used to assess pain? To document pain assessment and management in the patient's health record, the nurse would make up a pain rating score. A nurse's note could have been added to the medical record to describe pain behaviors the nurse identified as indicators that pain appeared to be decreasing and pain medication was working. However, the nurses on the unit did not write notes until the end of the shift. Thus the health record appeared as if no re-assessment had taken place and that the nurses were not following hospital policy. Pain assessment and management is a key quality measure for hospital accreditation making EBP quality improvement not only a clinical priority but also an important hospital initiative (The Joint Commission, 2010).

The nurses on the unit identified that pain assessment needed to be improved for quality patient care. A small team of staff nurses who understand the EBP process was formed to lead the project to address the clinical concerns. The staff identified that the main focus of the problem was assessment of patients who were asleep or appeared asleep. Was there a reliable and valid method to assess pain by observing behaviors without disturbing the patient? The nurses identified that the numeric rating scale worked for most postoperative patients after the second postoperative day. The clinical concern was assessing and re-evaluating pain management within the first 24 hours after surgery when patients were tired and often asleep because of the remnants of anesthetic and being heavily medicated for pain.

A chart audit confirmed that the nursing staff consistently assessed and re-evaluated pain with the numeric rating scale on the second postoperative day. Pain was assessed according to standards 95% of the time. On the first day after surgery, the pain scale was documented only 12% of the time. Nurses' notes to describe the patients' pain were written only 60% of the time during the first postoperative day. Clearly, there was a problem documenting pain assessment on the first postoperative day.

No one doubted that the nurses assessed pain frequently and provided pain relief; however, only the administration of pain medication was documented. Pain assessments were not consistently charted and, from a legal standpoint, the pain assessment was not done. When the numeric

pain scale was used, the nurses consistently met hospital standards for pain assessment and evaluation of pain relief. The chart audit showed that a new, easy-to-use tool that assessed pain behaviors was needed to improve the documentation of pain assessment.

Formulate a Focused Clinical Question

After conducting the chart audit, the EBP team defined the clinical problem and framed a PICO question to focus the literature search for evidence-based strategies to improve pain assessment. The PICO question developed was: In the adult hospitalized patient (**P**), does the implementation of a behavioral pain scale (**I)** compared with the use of a visual analog scale (**C**) improve the assessment and management of pain in patients on the first postoperative day (**O**)?

Search for Evidence

To start their search, the EBP team began at the Cochrane Library to try to find the highest level of evidence, a clinical practice guideline to answer their question. The Cochrane Library search revealed eight clinical practice guidelines related to pain assessment but none discussed nonverbal/behavioral assessment tools (www.thecochranelibrary.com). The EBP team then went to the hospital library and accessed the CINAHL database. The initial search term used was "Pain Assessment." This search provided 11,501 article results for the years 1966 to 2013 (www.EBSCOHOST.com). No matter how many nurses worked on the project, it would be impossible to read and evaluate over 11,000 articles. The team then remembered to use the PICO template as a guide to focus the search. Limits to narrow the search were added to the request, and only articles for pain assessment or measurement in adults ages 19 years and older were accessed. Just limiting the articles by the age of the patient reduced the number of articles to 4,836 (www.EBSCOHOST.com). This was a more manageable number of articles but still a huge number to review from a practical standpoint. So the search was further limited to the last 10 years, yielding, 3379 articles, still an insurmountable number of articles to read (www.EBSCOHOST.com). Further limiting the search using the term "inpatient" reduced the number of articles to 237—a much more manageable number, yet still overwhelming (www.EBSCOHOST.com)! Articles from 2013 appeared on the first page of the search screen. The titles revealed many interesting yet varied article topics. The search retrieved articles that addressed pain assessment with culture and pain

assessment methods for specific medical diagnoses. Articles that specifically addressed behavioral pain assessment tools in the acute care setting were not immediately apparent in a list of articles.

The team realized that using the PICO question keywords might help narrow the search to the specific topic of interest and to a manageable number of articles to review. Using the search options of "postoperative pain" and "clinical assessment tools," the search engine revealed 89 articles for review (www.EBSCOHOST.com). The nurses then saved the complete search so that they could refer to the list and read other articles as they explored solutions to the PICO question.

The EBP team reviewed the search results and identified five articles that appeared to address the clinical question specifically. One article discussed the use of three evidence-based practices for postoperative pain assessment (Carlson, 2009). The nurses were intrigued by the title of this article—is it possible that the authors have already evaluated three different methods that address their specific clinical question and that it can be read in one article? Another article examined abdominal surgery patients' pain management from the postanesthesia care unit (PACU) to the surgical unit (Wilding et al., 2009). Because PACU-to-unit transition takes place during the early postoperative period, the time that pain assessment using current practice is a concern, this article seemed to address the PICO question. Two articles complemented each other with one reporting the feasibility of using a nonverbal pain assessment tool in the critical care unit (Gélinas, 2010) and another reporting the same tool's reliability (Keane, 2012).

The fifth article also focused on pain assessment tools in the critical care unit (Hall, 2007). This article evaluated three pain assessment tools. Thus the nurses chose to review these three articles in postoperative critical care patients to see if any of the tools discussed could be used on the general surgical floor.

Appraise and Synthesize the Evidence

The team read the articles and completed tables of evidence (TOEs) so the information from the articles could be organized and discussed. The TOEs also helped the nurses systematically organize what they read in a consistent format for group discussion and analysis (Table 5-6). These tables were used as the group discussed their individual review of the articles, which included a summary of the evidence contained in the article, the strengths and limitations of the evidence, and potential application to their specific PICO question. As the nurses critically

appraised the evidence, the group referred to the quantitative evidence pyramid in Fig. 5-1 to identify the level of evidence of each article. The colorful pyramid was posted during the discussion for ease of reference. Through dialog about each article, the authors' methods, outcomes, and the limitations of the different tools to measure pain, the group rated the quality of the articles. This process was used to make an informed decision about the strength of the evidence before any practice recommendations could be made. The staff wanted to use the highest level of evidence possible to inform the practice change. One of the critical care articles was identified as a level III quasi-experimental study and presented a description of a tool that was reported as "easy to use" and reliable for nonverbal patients (Keane, 2012). The staff returned to the literature search to find more information on one of the behavioral pain tools discussed in the same article.

TABLE 5-6

Sample Entry for a Table of Evidence

NURSING SERVICES TABLE OF EVIDENCE					
PROJECT TITLE: PAIN ASSESSMENT DATE OF REVIEW: February 2013				REVIEWER: F. WRIGHT	
ARTICLE INFORMATION: AUTHORS, TITLE, DATE PUBLISHED, JOURNAL	SAMPLE CHARACTERISTICS AND SIZE	STUDY DESIGN, PATIENT SELECTION, EVIDENCE LEVEL/QUALITY RATING	INTERVENTION	AUTHORS' CONCLUSIONS	REVIEWER'S COMMENTS (STRENGTHS, LIMITATIONS, POTENTIAL PRACTICE CHANGE?)
Keane, K.M. (2012). Validity and reliability of the critical care pain observation tool: a replication study. *Pain Management Nursing, 14*(4), e216-225.	21 postoperative patients assessed for pain at rest, and after repositioning 3 times on postoperative day 1. Mean age of 64 yrs. 67% male patients.	Prospective comparison to determine if there were differences in observed pain behaviors between 2 separate nurse observers and videotaped behaviors to test the reliability and validity of the CPOT instrument. **Level III: quasi-experimental design**	Patients' pain assessed using the CPOT. The CPOT was used to assess pain and compare the results with observations and self-reports of pain when the patient could report pain levels verbally.	Initial CPOT instrument testing: strong discriminant validity (t = 5.75, p >0.001). Good face validity; 93% inter-rater reliability; Kappa statistic was 0.36 to 0.72 (p = 05). The cognitively and non–cognitively impaired groups' CNPI scores did not differ significantly in total scores. The cognitively impaired group had more pain behaviors identified at rest than the non–cognitively impaired group.	This was a replication of the initial testing (Gélinas, 2010) of the CPOT to assess pain in nonverbal critically ill patients. It seems to be reliable and simple to use. The CPOT seems to be most effective in patients when not intubated and so may be useful on the acute care floor during immediate postoperative assessments.

CNPI, Checklist of nonverbal pain indicators; *CPOT,* Critical-Care Pain Observation Tool.

Develop the Aim Statement

After reviewing the evidence to answer the focused clinical question, the nurses developed this aim statement: Improve the frequency of nurses' assessment of first-day postoperative pain from 12% to 70% after 2 weeks

of introducing a new behavioral pain assessment tool.

Implement the PDSA Cycles

After the second search for evidence to answer the clinical question and additional review of the new evidence, the team of nurses planned to make a practice change **(Plan)**. A small test of the utility of the tool needed to be performed to see if the nurses could accurately assess pain using the behavioral assessment tool and to determine its practicality for use. To evaluate the inter-rater reliability of the tool to determine if the nurses could consistently assess a patient's pain in the same way with the same tool, three of the nurses used the tool simultaneously to assess pain in 10 postoperative patients **(Do)**. The assessment results were compared and evaluated to identify whether the nurses were using the tool consistently **(Study)**. This small test of change resulted in positive feedback from nurses as to the practicality of the tool, and inter-rater reliability was high (i.e., different nurses observing patients and assessing their pain at the same time using the new tool came up with consistently similar ratings of these patients' pain).

The next step was to perform another small test of change **(Act)** to evaluate if nurses on the EBP team could use the pain assessment tool effectively in the clinical unit to improve patient pain assessment. The team used the tool for 1 week on all first-day postoperative patients. Patient records were monitored daily by the nurse educator and unit manager to evaluate the frequency of pain assessment. Because the team had the initial chart audit data, collecting the same data with the new tool in use would help identify if the behavioral scale for assessment of pain was completed and documented more consistently than before the new scale was introduced. In addition, the EBP nurse team was able to develop a step-by-step process for use of the tool.

The next step in the EBPI implementation process was for the project team to educate the rest of the unit staff on all shifts about the evidence-based intervention—the behavioral pain assessment tool and the process for its use. The TOEs were summarized and discussed to provide the staff with concrete information about the new tool. The EBP nurse team demonstrated how the tool was used. A member of the project team pretended to be asleep in a bed as a patient so that the nurses could role-play how to perform the pain assessment with the proposed tool. Informational posters were placed on the unit and multiple copies were made of the tool for use during the small test of change. The unit secretaries were involved in the education since they were responsible

for providing the tools and collecting them when they were completed.

For 2 weeks, the nursing staff used the new tool to assess the pain of first-day postoperative patients. The team reviewed patient charts daily and answered questions about the use of the tool and the documentation of the pain assessment. At the completion of this third small test of change, the team reviewed the chart audits and found that the unit nurses had appropriately documented pain assessment on the first postoperative day 85% of the time—a huge improvement! A short questionnaire was distributed to the nursing staff to determine their feedback about the use and effectiveness of the tool. All unit staff found the new tool easy to use and expressed positive beliefs in its value. They also were very proud to have achieved an outcome that exceeded their outcome in the aim statement.

Disseminate Best Practices

Given the success the nurses achieved on this one postoperative unit with their small tests of change using PDSA cycles, they recommended the introduction of the new behavioral pain assessment tool to the Hospital Standards of Practice Committee. The Committee, consisting of an interdisciplinary team of nurses, physicians, pharmacists, and other health care professionals, was excited about the evidence-based practice improvement effort. They decided to pilot the new tool on all surgical units for 1 month to see if the same results could be achieved with wider dissemination. If the initial benchmark of 70% was achieved in the pilot, then the new protocol for assessment of pain on the first postoperative day would be instituted hospital-wide as the standard of practice. At completion of the pilot, the benchmark of 70% was achieved and the Committee voted to incorporate the new policy and procedure as standard practice.

All nurses who worked on surgical units, the operating suites, and PACU were educated about the new hospital standards for pain assessment. The plan for evaluation of the new practice was to conduct random patient record audits each month for 6 months to determine whether the improvement effort continued after initial implementation. The nurse educator and the EBP mentor worked with the initial EBP nurse team (three staff nurses) to submit an abstract for presentation at an EBP conference. The Vice President of Patient Care Services agreed to pay all expenses for the five nurses who led the project to attend the conference if the abstract was accepted for presentation.

Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Describe evidence-based practice (EBP) to include the components of research evidence, clinical expertise, and patient/family values: EBP is a strategy for making clinical decisions about how we practice nursing and other health care professions.
- Describe EBP to include the components of research evidence, clinical expertise, and patient/family values: EBP incorporates the expertise of the clinician and the patient's values and preferences to make decisions about health care. **Evidence-Based Practice** QSEN
- Explain how to use an EBP approach to identifying a clinical problem, issue, or challenge, and formulate a focused clinical question about clinical practice: The first step of the EBP process is to ask a clinical "burning" question using the PICO(T) format (see Table 5-1).
- Recall that quantitative questions focus on the relationship among measurable phenomena and include statistical analysis of information.
- Remember that qualitative questions focus on the meanings and interpretations of human phenomena or experiences of people using interview or observation.
- Explain the roles of levels of evidence by reviewing Fig. 5-1 and Table 5-2, which refer to the status or rank of evidence.
- Briefly describe two models of EBP for changing processes of care: Examples of models of EBP include the Iowa model, the Reavy and Tavernier model (see Table 5-5), and the evidence-based practice improvement (EBPI) model. **Evidence-Based Practice** QSEN
- Differentiate clinical opinion from research and evidence summaries: When performing a literature search on current evidence to answer the clinical question, organize the data into a table of evidence like the one shown in Table 5-6.
- Discuss how the EBPI model can be used to guide a clinical practice quality improvement project: When making changes based on findings from the literature, use PDSA cycles to test the changes on a small scale.
- Discuss how the EBPI model can be used to guide a clinical practice improvement project: Recall that PDSA stands for "Plan," "Do," "Study," and "Act." **Quality Improvement** QSEN
- List the steps of how to perform a systematic literature review to

answer clinical questions using the steps in Table 5-5. Recall these steps include searching for clinical practice guidelines, summarizing and appraising research, making recommendations for change, implementing the change, and evaluating the outcomes.

CHAPTER 6

Rehabilitation Concepts for Chronic and Disabling Health Problems

Donna D. Ignatavicius

PRIORITY CONCEPTS

- Nutrition
- Mobility
- Elimination
- Cognition
- Tissue Integrity

Learning Outcomes

Safe and Effective Care Environment

1. Identify the roles of each member of the interdisciplinary rehabilitation team.
2. Identify health care settings where rehabilitation care is provided.
3. Delegate and supervise selected nursing tasks as part of care for the rehabilitation patient.
4. Coordinate recommendations for home modifications with the patient, family, occupational therapist, and case manager.
5. Use safe patient handling practices based on current evidence to prevent self-injury.

Health Promotion and Maintenance

6. Develop a teaching plan to prevent complications for the rehabilitation patient who has impaired physical mobility.

Psychosocial Integrity

7. Assess the patient's response to chronic or disabling health problems.
8. Identify special considerations for older adults undergoing rehabilitative care, including assessment of cognition.

Physiological Integrity

9. Interpret health assessment findings to plan appropriate collaborative care for the rehabilitation patient in the acute or long-term care setting.
10. Assess the ability of patients to use assistive/adaptive devices to promote mobility.
11. Identify the role of nutrition in the care of the patient in a rehabilitation setting.
12. Plan interventions to prevent skin breakdown and impaired tissue integrity for rehabilitation patients.
13. Differentiate retraining methods for a patient with a spastic versus flaccid bladder and bowel to promote elimination.
14. Explain the primary concerns for patients being discharged to home after rehabilitation.

 http://evolve.elsevier.com/Iggy/

A **chronic health problem** is one that has existed for at least 3 months. A **disabling health problem** is any physical or mental health/behavioral health problem that can cause disability. This text focuses primarily on physical health problems; mental health/behavioral health problems are discussed in more detail in textbooks on mental health/behavioral health nursing.

Patients with chronic and disabling health problems often participate in rehabilitation programs to prevent further disability, maintain functional ability, and restore as much function as possible. The rehabilitation nurse collaborates with the nursing and health care team and coordinates the patient's interdisciplinary care.

Overview

Chronic and Disabling Health Problems

Chronic and disabling illnesses are a major health problem in the United States, with almost half of the population having one or more chronic health problems. Complications of chronic disease account for the majority of all deaths, and associated medical costs account for over two thirds of the nation's health care cost. The rate of chronic and disabling conditions is expected to increase as more “baby boomers” approach late adulthood. Some people with chronic and disabling problems are in inpatient settings like rehabilitation centers and skilled nursing facilities, whereas others are managed at home.

Stroke, coronary artery disease, cancer, chronic obstructive pulmonary disease (COPD), asthma, and arthritis are common chronic diseases that can result in varying degrees of disability. Most occur in people older than 65 years. Younger adults are also living longer with potentially disabling genetic disorders that, in the past, would have shortened life expectancy. These specific health problems are discussed throughout this text.

Chronic and disabling conditions are not always illnesses (e.g., heart disease); they may also result from accidents. Accidents are a leading cause of trauma and death among young and middle-aged adults. Increasing numbers of people survive accidents with severe injuries because of advances in medical technology and safety equipment such as motor vehicle airbags. As a result, they are often faced with chronic, disabling neurologic conditions, such as traumatic brain injuries (TBIs) and spinal cord injuries (SCIs).

These health problems are also common among military men and women survivors who served in Iraq and Afghanistan. The most common complications of these wars are TBI and single or multiple limb amputations. These disabilities require months to years of follow-up health care after returning to the community. Because of people living longer with chronic and disabling health problems, the need for rehabilitation is on the rise.

Rehabilitation Settings

Rehabilitation is the continuous process of learning to live with and manage chronic and disabling conditions. The desired outcome of rehabilitation is that the patient will return to the best possible physical, mental, social, vocational, and economic capacity. Rehabilitation is not

limited to the return of function in post-traumatic situations. It also includes education and therapy for any chronic illness characterized by a change in a body system function or body structure. Rehabilitation programs related to respiratory, cardiac, and musculoskeletal health problems are common examples that do not involve trauma.

Rehabilitation ("rehab") can occur in a number of settings. This process starts in the acute care hospital (sometimes called *acute* or *short-term rehabilitation*) and continues after discharge from the hospital. The nurse coordinates care from acute care through community-based care to ensure successful rehabilitation.

For continuing rehabilitation services, the most common **inpatient rehabilitation facilities (IRFs)** are freestanding rehabilitation hospitals, rehabilitation or skilled units within hospitals (e.g., transitional care units [TCUs]), and skilled nursing facilities to which the patient is typically admitted for 1 to 3 weeks or longer. **Skilled nursing facilities (SNFs)** are part of either a hospital or long-term care (nursing home) setting (Fig. 6-1). Skilled rehabilitation and nursing services for older residents admitted to SNFs are reimbursed through Medicare A for the first 21 days after admission. After that time, reimbursement is a combination of Medicare and other payer sources for a specified number of days.

FIG. 6-1 Patient (resident) in a skilled nursing facility rehabilitation unit.

Patients in nursing homes or skilled nursing units in hospitals are called *residents*. The term **resident** implies that the person lives in the inpatient facility and has all the rights of anyone living in his or her home. Residents wear street clothes rather than hospital gowns and have choices in what they eat and how they plan each day.

Ambulatory care rehabilitation departments and home rehabilitation programs may be needed for continuing less-intensive services. Eighty percent (80%) of rehabilitation services are paid for by Medicare B for older adults for a specified period of time if they have this benefit. Some agencies have specialized clinics focused on rehabilitation of patients with specific health problems, such as those that care for patients with strokes; amputations; and large, chronic, and/or nonhealing wounds. After disabled patients become more confident and independent, they may choose to live at home or in a group home. Group homes are facilities in which patients live independently together with other disabled adults. Each patient or group of patients has a care provider, such as a personal care aide, to assist with ADLs and daily decisions requiring accurate judgments. The patients may or may not be actively

employed. In some cases, the care home offers employment opportunities to the residents. The purpose of these homes is to provide independent living arrangements outside an institution, especially for younger patients with TBI or SCI.

The Rehabilitation Team

Successful rehabilitation depends on the coordinated effort of a group of the patient, family, and health care professionals in planning, implementing, and evaluating patient-centered care. The focus of the rehabilitation team is to restore and maintain the patient's function to the greatest extent possible.

In addition to the patient, family, and/or significant others, members of the interdisciplinary health care team in the rehabilitation setting may include:

- Physicians, nurse practitioners, and clinical nurse specialists
- Nurses and nursing assistants
- Physical therapists and assistants
- Occupational therapists and assistants
- Speech-language pathologists and assistants
- Rehabilitation assistants/restorative aides
- Recreational or activity therapists
- Cognitive therapists or neuropsychologists
- Social workers or case managers
- Clinical psychologists
- Vocational counselors
- Spiritual care counselors
- Registered dietitians (RDs)
- Pharmacists
- Biomedical technicians

Not all settings that offer rehabilitation services have all of these members on their team. Not all patients require the services of all health care team members.

A physician who specializes in rehabilitative medicine is called a **physiatrist.** Most inpatient rehabilitation settings employ physiatrists. A primary care physician or nurse practitioner may also oversee care for the patient's medical problems.

Rehabilitation nurses in the inpatient setting coordinate the efforts of health care team members and therefore function as the patient's case manager. Nurses also create a rehabilitation milieu, which includes (Pryor, 2010):

• Allowing time for patients to practice self-management skills
• Encouraging patients and providing emotional support
• Protecting patients from embarrassment (e.g., bowel training)
• Making the inpatient unit a more homelike environment

Table 6-1 summarizes the nurse's role as part of the rehabilitation team. Because of an increase in the need for older adult rehabilitation, some nurses specialize in gerontologic rehabilitation (Association of Rehabilitation Nurses [ARN], 2008b). Nurses and other health care professionals may be designated as **rehabilitation case managers** in the home or in acute care settings.

TABLE 6-1

Nurse's Role in the Rehabilitation Team

• Advocates for the patient and family
• Creates a therapeutic rehabilitation milieu
• Provides and coordinates holistic patient care in a variety of health care settings, including the home
• Collaborates with the rehabilitation team to establish expected patient outcomes to develop a plan of care
• Coordinates rehabilitation team activities to ensure implementation of the plan of care
• Acts as a resource to the rehabilitation team having specialized knowledge and clinical skills needed to care for patient with chronic and disabling health problems
• Communicates effectively with all members of the rehabilitation team, including the patient and family
• Plans continuity of care when the patient is discharged from the health care facility
• Evaluates the effectiveness of the interdisciplinary plan of care for the patient and family

Adapted from Association of Rehabilitation Nurses. (2008). *Standards and scope of rehabilitation nursing practice*, Glenview, IL: Author.

As their name implies, **nursing assistants** or **nursing technicians** assist in the care of patients. These members of the rehabilitation team are under the direct supervision of the registered nurse (RN) or licensed practical or vocational nurse (LPN or LVN).

Physical therapists (PTs), also called **physiotherapists,** intervene to help the patient achieve self-management by focusing on gross mobility skills (e.g., by facilitating ambulation and teaching the patient to use a walker) (Fig. 6-2). They may also teach techniques for performing certain ADLs, such as transferring (e.g., moving into and out of bed), ambulating, and toileting, and can assist with cognitive retraining (often for patients with TBI). In some settings, PTs play a major role in providing wound care. Physical therapy assistants (PTAs) may be employed to help the PT.

FIG. 6-2 A physical therapist helping a patient ambulate with a walker.

Occupational therapists (OTs) work to develop the patient's fine motor skills used for ADL self-management, such as those required for eating, hygiene, and dressing. OTs also teach patients how to perform independent living skills, such as cooking and shopping. Many inpatient rehabilitation facilities have fully furnished and equipped apartments where patients can practice independent living skills in a mock setting under supervision. To accomplish these outcomes, OTs teach skills related to coordination (e.g., hand movements) and cognitive retraining (Fig. 6-3). Occupational therapy assistants (OTAs) may be available to help the OT.

FIG. 6-3 A registered occupational therapist working with a patient on improving hand strength.

Speech-language pathologists (SLPs) evaluate and retrain patients with speech, language, or swallowing problems. *Speech* is the ability to say words, and *language* is the ability to understand and put words together in a meaningful way. Some patients, especially those who have experienced a head injury or stroke, have difficulty with both speech and language. Those who have had a stroke also may have dysphagia (difficulty with swallowing). SLPs provide screening and testing for dysphagia. If the patient has this problem, the SLP recommends appropriate foods and feeding techniques. Speech-language pathology assistants (SLPAs) may be employed to help the SLP.

PTs, OTs, and SLPs are collectively referred to as *rehabilitation therapists*. Assistants to PTs, OTs, and SLPs are called *rehabilitation assistants*. **Restorative aides,** usually in the nursing department, continue the rehabilitation therapy plan of care when therapists are not available. This model of care is common in long-term care settings, such as nursing homes.

Recreational or **activity therapists** work to help patients continue or develop hobbies or interests. These therapists often coordinate their efforts with those of the OT.

Cognitive therapists, usually neuropsychologists, work primarily with patients who have experienced head injuries with cognitive impairments.

These therapists often use computers to assist with cognitive retraining.

Various counselors are helpful in promoting community reintegration of the patient and acceptance of the disability or chronic illness. **Social workers** help patients identify support services and resources, including financial assistance, and coordinate transfers to or discharges from the rehabilitation setting. **Clinical psychologists** also counsel patients and families on their psychological problems and on strategies to cope with disability. They may also perform a battery of assessments for cognition. **Spiritual counselors,** usually members of the clergy, specialize in spiritual assessments and care.

Vocational counselors assist with job placement, training, or further education. Work-related skills are taught if the patient needs to change careers because of the disability. If the patient has not yet completed high school, tutors may help with completion of the requirements for graduation.

Registered dietitians (RDs) may be needed to ensure that patients meet their needs for nutrition. For example, for patients who need weight reduction, a restricted calorie diet can be planned. For patients who need additional calories or other nutrients, including vitamins, dietitians can plan a patient-specific diet.

Pharmacists collaborate with the other members of the health care team to ensure that the patient receives the most appropriate drug therapy to meet the patient's needs. They oversee the prescription and preparation of medications and provide the health care team with essential information regarding drug safety.

Biomedical technicians maintain the safety of adaptive and electronic devices by monitoring their function and making repairs as needed.

Depending on the patient's health care needs, additional team members may be included in the rehabilitation program, such as the geriatrician, respiratory therapist, and prosthetist. Interdisciplinary team conferences for planning care and evaluating the patient's progress are held regularly with the patient, family members and significant others, and health care providers. The interdisciplinary patient record is shared and read by all team members.

❖ Patient-Centered Collaborative Care

◆ Assessment

History.

Collect the history of the patient's present condition, any current drug

therapy, and any treatment programs in progress. Begin by obtaining general background data about the patient and family. This information includes cultural practices and the patient's home situation. In collaboration with the occupational therapist, the nurse or case manager addresses the layout of the home. Together they discuss whether the physical layout at home, such as stairs or the width of doorways, will present a problem to the patient after discharge.

Assess the patient's usual daily schedule and habits of everyday living. These include hygiene practices, nutrition, elimination, sexual activity, and sleep. Ask about the patient's preferred method and time of bathing and hygiene activity. In assessing dietary patterns, note food likes and dislikes. Also, obtain information about bowel and bladder function and the normal pattern of elimination.

In assessing sexuality patterns, ask about changes in sexual function since the onset of the disability. The patient's current and previous sleep habits, patterns, usual number of hours of sleep, and use of hypnotics are also assessed. Question whether the patient feels well rested after sleep. Sleep patterns have a significant impact on activity patterns. The assessment of activity patterns focuses on work, exercise, and recreational activities.

Considerations for Older Adults

Patient-Centered Care QSEN

Older adults who need rehabilitation often have other chronic diseases that need to be managed, including diabetes mellitus, coronary artery disease, osteoporosis, and arthritis. These health problems added to the normal physiologic changes associated with aging predispose the older adult to falls, pressure ulcers, and pneumonia. When discharged from a hospital setting, some older patients are undernourished, which causes weakness and fatigue. The longer the hospital stay, the more debilitated the older adult can become.

Health teaching may be challenging because some older patients may have beginning changes in cognition, including short-term memory loss. Sensory losses, like vision and hearing, may also affect their ability to give an accurate history or grasp new information.

Physical Assessment/Clinical Manifestations.

Upon admission for baseline and at least daily (depending on agency policy and type of setting), collect physical assessment data

systematically according to major body systems (Table 6-2). The primary focus of the assessment related to rehabilitation and chronic disease is the *functional* abilities of the patient.

TABLE 6-2

Assessment of Patients in Rehabilitation Settings

BODY SYSTEM	RELEVANT DATA
Cardiovascular system	Chest pain Fatigue Fear of heart failure
Respiratory system	Shortness of breath or dyspnea Activity tolerance Fear of inability to breathe
Gastrointestinal system and nutrition	Oral intake, eating pattern Anorexia, nausea, and vomiting Dysphagia Laboratory data (e.g., serum prealbumin level) Weight loss or gain Bowel elimination pattern or habits Change in stool (constipation or diarrhea) Ability to get to toilet
Renal-urinary system	Urinary pattern Fluid intake Urinary incontinence or retention Urine culture and urinalysis
Neurologic system	Motor function Sensation Perceptual ability Cognitive abilities
Musculoskeletal system	Functional ability Range of motion Endurance Muscle strength
Integumentary system	Risk for skin breakdown Presence of skin lesions

Cardiovascular and Respiratory Assessment.

An alteration in cardiac status may affect the patient's cardiac output or cause activity intolerance. Assess associated signs and symptoms of decreased cardiac output (e.g., chest pain, fatigue). If present, determine when the patient experiences these symptoms and what relieves them. The health care provider may prescribe a change in drug therapy or may prescribe a prophylactic dose of nitroglycerin to be taken before the patient resumes activities. Collaborate with the health care provider and appropriate therapists to determine whether activities need to be modified.

For the patient showing fatigue, the nurse and patient plan methods for using limited energy resources. For instance, frequent rest periods can be taken throughout the day, especially before performing activities. Major tasks could be performed in the morning because most people have the most energy at that time.

A hindrance to rehabilitation for patients with cardiac disorders is fear, particularly for older adults. These patients may have survived a life-threatening experience (e.g., myocardial infarction) and may be so afraid of recurrence or death that they are unable or unwilling to resume any activity. They usually benefit from participation in a structured cardiac rehabilitation program. (See Chapter 38 for a complete description of cardiac rehabilitation.)

Ask the patient whether he or she has shortness of breath, chest pain, or severe weakness and fatigue during or after activity. *Determine the level of activity that can be accomplished without these symptoms*. For example, can the patient climb one flight of stairs without shortness of breath or does shortness of breath occur after climbing only two steps?

Gastrointestinal and Nutritional Assessment.

Monitor the patient's oral intake and pattern of eating. Also, assess for the presence of anorexia, **dysphagia,** nausea, vomiting, or discomfort that may interfere with oral intake. Determine whether the patient wears dentures and, if so, whether they fit. Review the patient's height, weight, hemoglobin and hematocrit levels, serum prealbumin, and blood glucose levels. (See Chapter 60 for discussion of how to perform a screening for nutrition status.) Weight loss or weight gain is particularly significant and may be related to an associated disease or to the illness that caused the disability.

Bowel elimination habits vary from person to person. They are often related to daily job or activity schedules, dietary patterns, age, and family or cultural background. Elimination habits may be difficult to assess, because many nurses are hesitant to request (and many patients are afraid to volunteer) information pertaining to elimination. Ask about usual bowel patterns before the injury or the illness.

Note any changes in the patient's bowel routine or stool consistency. The most common problem for rehabilitation patients is constipation. In their classic best practice guidelines, the Association of Rehabilitation Nurses (ARN) (2002) defines **constipation** as the passage of hard, dry stool fewer than 3 times a week or significant change in the patient's usual habits for more than 3 months. Examples of significant changes include abdominal fullness and bloating and straining when having a

bowel movement.

If the patient reports any alteration in elimination pattern, try to determine whether it is due to a change in diet, activity pattern, or medication use. Always assess bowel habits on what is normal for that person.

Ask whether the patient can manage bowel function independently. Independence in bowel elimination requires cognition, manual dexterity, sensation, muscle control, and mobility. If the patient requires help, determine whether someone is available at home to provide the assistance. Also assess the patient's and family's ability to cope with any dependency in bowel elimination.

Renal and Urinary Assessment.

Ask about the patient's baseline urinary elimination patterns, including the number of times he or she usually voids. Determine whether he or she routinely awakens during the night to empty the bladder **(nocturia)** or sleeps through the night. Record fluid intake patterns and volume, including the type of fluids ingested and the time they were consumed.

Question whether the patient has ever had any problems with urinary incontinence or retention. Also, monitor laboratory reports, especially the results of the urinalysis and culture and sensitivity, if needed. *Urinary tract infections (UTIs) among older adults are often missed because acute confusion may be the only indicator of the infection.* Many health care professionals expect older patients to be confused and may not detect this problem. If untreated, UTIs can lead to kidney infection and possible failure.

Neurologic and Musculoskeletal Assessment.

The neurologic assessment includes motor function (mobility), sensation, and cognition. Assess the patient's pre-existing problems, general physical condition, and communication abilities. Patients may have **dysphasia** (slurred speech) because of facial muscle weakness or may have **aphasia** (inability to speak or comprehend), usually the result of a cerebral stroke or traumatic brain injury (TBI). These communication problems are discussed in detail in the chapters on problems of the nervous system.

Determine if the patient has **paresis** (weakness) or **paralysis** (absence of movement). Observe the patient's gait. Identify sensory-perceptual changes, such as visual acuity, that could contribute to the patient's risk for injury. Assess his or her response to light touch, hot or cold temperature, and position change in each extremity and on the trunk. Identify levels of decreased sensation. For a perceptual assessment, the

nurse evaluates the patient's ability to receive and understand what is heard and seen and the ability to express appropriate motor and verbal responses. During this portion of the assessment, begin to assess short-term and long-term memory.

Assess the patient's cognitive abilities, especially if there is a head injury or stroke. Several tools are available to evaluate cognition. One of the most commonly used tools in rehabilitation and long-term care settings is the Brief Interview for Mental Status (BIMS), which is described in detail in Chapter 41. The Confusion Assessment Method (CAM) is used to determine if the patient had delirium, an acute confusional state. (See Table 2-3 in Chapter 2 for description of the CAM tool.)

As with other body systems, nursing assessment of the musculoskeletal system focuses on function. Assess the patient's musculoskeletal status, response to the impairment, and demands of the home, work, or school environment. Determine the patient's endurance level, and measure active and passive joint range of motion (ROM). Review the results of manual muscle testing by physical therapy, which identifies the patient's ROM and resistance against gravity. In this procedure, the therapist determines the degree of muscle strength present in each body segment.

Skin Assessment.

Identify actual or potential interruptions in skin and tissue integrity. To maintain healthy skin, the body must have adequate food, water, and oxygen intake; intact waste-removal mechanisms; sensation; and functional mobility. Changes in any of these variables can lead to rapid and extensive skin breakdown. If the patient cannot protect or maintain the skin, assess and plan for his or her needs.

Nursing Safety Priority QSEN

Action Alert

Be sure to remind unlicensed assistive personnel to report changes in the patient's skin promptly, including any new onset of redness. Assess the patient frequently to determine the risk for skin breakdown before it occurs! Older adults are at a very high risk for heel and sacral pressure ulcers, which can occur within 24 hours after admission.

Most rehabilitation settings use special skin assessment tools to identify patients at risk for skin breakdown. For example, the classic

Braden Scale for Predicting Pressure Ulcer Risk (see Chapter 25) assesses several areas: sensory perception, skin moisture, activity level, nutritional status, and potential for friction and shear.

Other skin risk assessment tools are available. Some tools also include additional indicators of nutritional status, such as the serum prealbumin. When these levels are low, the patient is at high risk for pressure ulcers. Some tools include incontinence and altered mental state as risk factors.

If a pressure ulcer or other change in skin integrity develops, accurately assess the problem and its possible causes. Inspect the skin every 2 hours until the patient learns to inspect his or her own skin several times a day. Measure the depth and diameter of any open skin areas in inches or centimeters, depending on the policy of the facility. Assess the area around the open lesion to determine the presence of cellulitis or other tissue damage. Chapter 25 includes several widely used classification systems for assessing skin breakdown. Determine the patient's knowledge about the cause and treatment of skin breakdown, as well as his or her ability to inspect the skin and participate in maintaining tissue integrity.

In most health care agencies, the skin assessment is documented on a special form or part of the electronic health record to keep track of each area of skin breakdown. A baseline assessment is conducted on admission to the agency and updated periodically depending on the agency's policy and the nurse's judgment. In most long-term care, acute care, and rehabilitation settings and with the patient's (or family's if the patient cannot communicate) permission, photographs of the skin are taken on admission and at various intervals for documentation.

NCLEX Examination Challenge

Physiological Integrity

An older adult is admitted for rehabilitation after a total hip replacement. Which statement by the nursing assistant will require follow-up by the nurse?

A "The client has an abduction pillow between her legs."
B "The client reports being tired after her physical therapy session."
C "The client is resting in bed after she had her pain pill."
D "The client's sacrum is reddened and uncomfortable."

Functional Assessment.

Functional ability refers to the ability to perform **activities of daily living**

(ADLs), such as bathing, dressing, feeding, and ambulating, and **independent living skills,** including using the telephone, shopping, preparing food, and housekeeping. These latter skills are sometimes referred to as **instrumental activities of daily living (IADLs).** Functional assessment tools are used to assess a patient's abilities. Rehabilitation nurses, physiatrists, or rehabilitation therapists complete one or more of these assessment tools based on the patient's abilities and the policy of the health care setting.

One classic uniform data system still used for outcome data collection across the United States is the Functional Independence Measure (FIM) developed by Granger and Gresham (1984). As a basic indicator of the severity of a disability, the FIM attempts to quantify what the person actually does, whatever the diagnosis or impairment. It does not measure what a person should do or how the person would perform under a different set of circumstances. To eliminate the bias of a particular discipline, the assessment may be performed by trained clinicians. The entire assessment may be performed by one person, or certain categories may be completed by various professionals.

Categories for assessment are self-care, sphincter control, mobility and locomotion, communication, and cognition. Scoring is done with numbers that use predetermined criteria for measurement. The patient is evaluated when he or she is admitted to and discharged from a rehabilitation institution and at other specified times to determine progress. The FIM system has also been adapted for use in other health care settings, including acute care and home care, and is available in multiple languages.

In U.S. long-term care settings, the interdisciplinary **Minimum Data Set (MDS) 3.0** is required by the U.S. Centers for Medicare and Medicaid (CMS) to assess patients (residents) in nursing homes. The resident's mobility, sensation, and cognition are evaluated, as well as the overall health status. A list of assessment components for the MDS 3.0 is presented in Table 6-3. Similar to the FIM, all health care team members involved in the resident's care record their assessments on the MDS and the RN coordinates the comprehensive assessment.

TABLE 6-3

Assessment Components of the Minimum Data Set (MDS) 3.0

• Hearing, Speech and Vision • Cognitive Patterns • Mood • Behavior • Preferences for Customary Routines and Activities • Functional Status • Bowel and Bladder • Active Disease Diagnoses • Health Conditions (e.g., pain, fall history)	• Swallowing and Nutritional Status • Oral/Dental Status • Skin Condition • Medications • Special Treatments and Procedures • Restraints • Participation in Assessment and Goal Setting • Supplemental Therapies

Data from Centers for Medicare and Medicaid Services (CMS). MDS 3.0 for nursing homes and swing bed providers, 2013. Retrieved September 2014 from http://www.cms.gov/Medicare/Quality-Initiatives-Patient-Assessment-Instruments/NursingHomeQualityInits/NHQIMDS30.html.

Psychosocial Assessment.

In addition to determining cognitive function, assess the patient's body image and self-esteem through verbal indicators and descriptions of self-care. Encourage the family to allow the patient to perform as many functions as possible independently to build feelings of self-worth.

Assess the patient's use of defense mechanisms and manifestations of anxiety. To assess the patient's response to loss, ask him or her to describe feelings concerning the loss of a body part or function. Assess for the presence of any stress-related physical problem. Some patients have symptoms of depression, such as fatigue, a change in appetite, or feelings of powerlessness. See Chapter 7 for a thorough discussion of loss and grieving and Chapter 2 for a brief description of depression among the older adult population.

Determine the availability of support systems for the patient. The major support system is typically the family or significant others. Patients who do not have these support systems are more likely to develop depression. Identify the patient's spiritual and/or religious needs, and refer to an appropriate health care team member as needed. Assess sexuality and intimacy needs, and document findings in the electronic health record (EHR).

Vocational Assessment.

To assist patients in maximizing functional status, encourage them to resume usual activities. Vocational counselors can help patients find meaningful training, education, or employment after discharge from the rehabilitation setting, if needed.

Patients in the United States should be informed about the Americans with Disabilities Act, which was passed by Congress in 1991 to prevent

employer discrimination against disabled people. The employer must offer *reasonable* assistance to a disabled employee to allow him or her to perform the job. For example, if an employee has a severe hearing loss, the employer may need to hire an interpreter for sign language. Workers have a right to ask for special adaptations based on their disabilities.

The rehabilitation team assesses the cognitive and physical demands of the patient's job to determine whether he or she can return to the former job or whether retraining in another field is necessary. The physical demands of jobs range from light in sedentary occupations (0 to 10 lbs often lifted) to heavy (more than 100 lbs often lifted). The nurse must also consider other aspects of the job, such as mobility or senses required (e.g., hearing).

Job analysis also involves assessing the work environment of the patient's former job. Collaborate with the vocational counselor to determine whether the environment is conducive to the patient's return. Job modifications may be needed to accommodate the patient at work. If an injured worker requires vocational rehabilitation, refer him or her to vocational rehabilitation personnel to evaluate present skills and learn new skills for employment if needed. In most states, Workers' Compensation insurance helps support vocational rehabilitation.

Analysis

Regardless of age or specific disability, these priority patient problems are common. Additional problems depend on the patient's specific chronic illness or disability. The priority NANDA-I nursing diagnoses and collaborative problems for patients with chronic and disabling health problems include:

1. Impaired Physical Mobility related to neuromuscular impairment, sensory-perceptual impairment, and/or chronic pain (NANDA-I)
2. Decreased functional ability related to neuromuscular impairment and/or impairment in perception or cognition
3. Risk for Impaired Skin Integrity related to altered sensation and/or altered nutritional state (NANDA-I)
4. Urinary incontinence or Urinary Retention related to neurologic dysfunction and/or trauma or disease affecting spinal cord nerves (NANDA-I)
5. Constipation related to neurologic impairment, inadequate nutrition, or decreased mobility (NANDA-I)

Planning and Implementation

Improving Physical Mobility

Planning: Expected Outcomes.

The patient with chronic illness or disability is expected to reach a level of physical mobility that allows him or her to function independently with or without assistive devices. In addition, the patient is expected to be free of complications of immobility.

Interventions.

Most problems requiring rehabilitation relate to decreased physical mobility. For example, patients with neurologic disease or injury, amputations, arthritis, and cardiopulmonary disease usually experience some degree of immobility. Coordinate care with physical and occupational therapists as the key rehabilitation team members in helping patients meet their mobility outcomes. Patients initially spend 5 to 6 hours a day for at least 5 days a week in rehabilitation therapy departments to regain mobility and self-management skills.

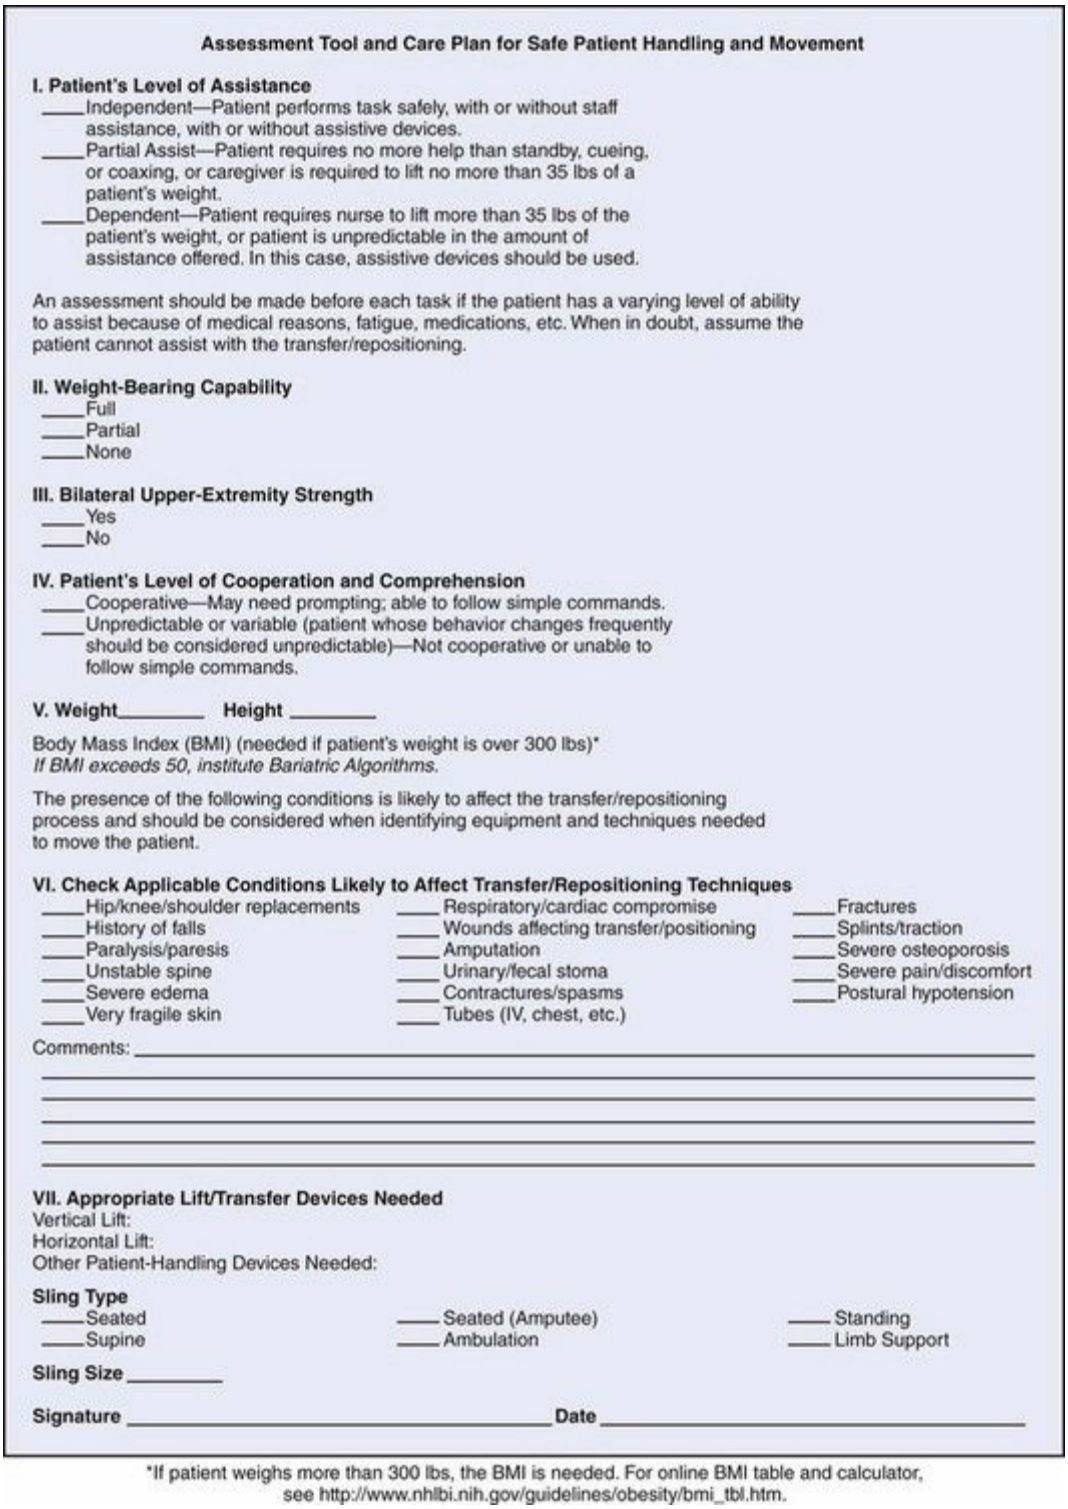
Safe Patient Handling Practices.

Before they learn to become independent, patients with decreased mobility in any health care setting or at home often need assistance with positioning in bed and transfers, such as from a bed to a chair, commode, or wheelchair. Patients may not be able to bear full weight, may have inadequate balance, and/or may be very obese. For many years, nurses relied on "body mechanics" to prevent staff injury when moving patients or assisting them to move. This traditional, but outdated, approach was based on the belief that correct body positioning by staff members would protect them from the force of lifting and moving. For example, if the patient could not bear weight or did not have sufficient balance (e.g., quadriplegic spinal cord injury), nurses and therapists used a "bear hug" technique to lift the patient from bed to chair or back again. Obese patients were also lifted with multiple staff assistance.

Heavy lifting and dependent transfers by staff members have resulted in a very high incidence of **work-related musculoskeletal disorders (MSDs),** most often chronic back injuries, which can be prevented. As a response to this costly problem, the National Institute for Occupational Safety and Health (NIOSH) established evidence-based guidelines for safe patient handling. Based on this document, the American Nurses Association, in partnership with NIOSH and the Veterans Health Administration, developed a curriculum for all nursing students and practicing nurses on how to safely handle and move patients in any

health care setting or home environment (American Nurses Association, 2012). In collaboration with other health care team members, nurses assess patient mobility and use best practices for safe patient handling (SPH).

Because each patient has unique needs and characteristics, assess the patient's mobility level using a standardized tool to plan interventions for SPH. An example of an appropriate assessment tool for this purpose is shown in Fig. 6-4. Before moving the patient, assess his or her environment for potential hazards that could cause injury, such as a slippery or uneven floor.



Assessment Tool and Care Plan for Safe Patient Handling and Movement

I. Patient's Level of Assistance

____Independent—Patient performs task safely, with or without staff assistance, with or without assistive devices.
____Partial Assist—Patient requires no more help than standby, cueing, or coaxing, or caregiver is required to lift no more than 35 lbs of a patient's weight.
____Dependent—Patient requires nurse to lift more than 35 lbs of the patient's weight, or patient is unpredictable in the amount of assistance offered. In this case, assistive devices should be used.

An assessment should be made before each task if the patient has a varying level of ability to assist because of medical reasons, fatigue, medications, etc. When in doubt, assume the patient cannot assist with the transfer/repositioning.

II. Weight-Bearing Capability

____Full
____Partial
____None

III. Bilateral Upper-Extremity Strength

____Yes
____No

IV. Patient's Level of Cooperation and Comprehension

____Cooperative—May need prompting; able to follow simple commands.
____Unpredictable or variable (patient whose behavior changes frequently should be considered unpredictable)—Not cooperative or unable to follow simple commands.

V. Weight_____ **Height** _____

Body Mass Index (BMI) (needed if patient's weight is over 300 lbs)*
If BMI exceeds 50, institute Bariatric Algorithms.

The presence of the following conditions is likely to affect the transfer/repositioning process and should be considered when identifying equipment and techniques needed to move the patient.

VI. Check Applicable Conditions Likely to Affect Transfer/Repositioning Techniques

____Hip/knee/shoulder replacements	____Respiratory/cardiac compromise	____Fractures
____History of falls	____Wounds affecting transfer/positioning	____Splints/traction
____Paralysis/paresis	____Amputation	____Severe osteoporosis
____Unstable spine	____Urinary/fecal stoma	____Severe pain/discomfort
____Severe edema	____Contractures/spasms	____Postural hypotension
____Very fragile skin	____Tubes (IV, chest, etc.)	

Comments: _____

VII. Appropriate Lift/Transfer Devices Needed

Vertical Lift:
Horizontal Lift:
Other Patient-Handling Devices Needed:

Sling Type

____Seated	____Seated (Amputee)	____Standing
____Supine	____Ambulation	____Limb Support

Sling Size _____

Signature _____ **Date** _____

*If patient weighs more than 300 lbs, the BMI is needed. For online BMI table and calculator, see http://www.nhlbi.nih.gov/guidelines/obesity/bmi_tbl.htm.

FIG. 6-4 Example of a tool to assess physical mobility.

Use these general SPH practices, and teach to staff members:

- Maintain a wide, stable base with your feet.
- Put the bed at the correct height—waist level while providing direct care and hip level when moving patients.
- Try to keep the patient or work directly in front of you to prevent your spine from rotating.
- Keep the patient as close to your body as possible to prevent reaching.

The Veterans Health Administration and many other health care

systems follow a no-lift or limited-lift policy for all of their facilities due in large part to technology. That means that nurses and therapists either rely on the patient to independently move and transfer or use a powered, mechanical full-body lift that is either ceiling- or wall-mounted or portable (mobile) (Fig. 6-5). Most lifts use slings that are comfortable, safe, and easy to apply. Electric-powered, portable sit-to-stand devices are also available.

FIG. 6-5 Example of powered, mechanical full-body lift.

Instead of a no-lift policy, though, some long-term care facilities limit lifting to 35 pounds (15.9 kg). These changes involve intensive staff training and compliance to prevent staff injury. Mechanical lifts are also available for home use.

For patients who are learning to become independent in transfer or bed mobility skills, the physical or occupational therapist usually specifies the procedure for these maneuvers. For example, a quadriplegic patient may use a sliding board for transfer, whereas a paraplegic patient may need a wheelchair with removable arms. A patient still in bed may be taught to turn independently using the siderails. In any case, for safety, always plan or teach the patient to plan the transfer technique before initiating it. The desired outcome is that the patient will eventually be able to transfer independently *and* safely.

Nursing Safety Priority QSEN

Critical Rescue

Before any transfer, carefully observe for potential problems. Orthostatic, or postural, hypotension is a common problem in rehabilitation settings and contributes to falls, which are common for any patient with impaired mobility. If the patient moves from a lying to a sitting or standing position too quickly, his or her blood pressure drops; as a result, he or she becomes dizzy or faints. This problem is worsened by antihypertensive drugs, especially in older adults. To prevent this situation, help the patient change positions slowly, with frequent rest periods to allow the blood pressure to stabilize. If needed, measure blood pressure with the patient in the lying, sitting, and standing positions to examine the differences. **Orthostatic hypotension** is indicated by a drop of more than 20 mm Hg in systolic pressure or 10 mm Hg in diastolic pressure between positions. Notify the health care provider and the therapists about this change.

If the patient has problems maintaining blood pressure while out of bed, the physical therapist may start him or her on a tilt table to gradually increase tolerance. A low blood pressure is a particularly common problem for patients who are quadriplegic because they have a delayed blood flow to the brain and upper part of the body.

Weight gain is another potential problem when rehabilitation patients have impaired mobility. Excessive weight hinders transfers both for the nurse or the therapist who is assisting and for the patient who is learning to transfer independently. Weight is usually checked every week to monitor gains or losses. If needed, collaborate with the dietitian to plan a weight-reduction diet for the patient.

Gait Training.

The physical therapist works with patients for gait training if they are able to ambulate. While regaining the ability to ambulate, patients may need to use assistive devices, such as a variety of canes or walkers (Fig. 6-6). The specific device selected for each patient depends on the amount of weight bearing that is allowed or tolerated. For example, a stroke patient who has problems with maintaining balance or a steady gait when walking might need a walker. Some patients use walkers with rollers made of tennis ball materials; others who fatigue easily may need a walker with a built-in seat to rest at intervals. A patient who had a total hip replacement 6 weeks ago may be able to use a straight (also called *single-point*) cane.

FIG. 6-6 Assistive devices for ambulation. Assistive devices vary in the amount of support they provide. A straight (single-point) cane provides less support than a walker **(A)** or quadripod cane **(B)**.

When working with patients who are using these devices, also known as **ambulatory aids,** the physical therapist ensures that there is a level surface on which to walk. The patient wears a transfer (gait) belt for safety so that the therapist or nurse can guide him or her during ambulation to help prevent falls. Use of transfer belts is recommended as one of the best practices for safe patient handling (Waters & Rockefeller, 2010).

Reinforce the physical therapist's instructions and encourage practice, with the outcome being to walk independently with or without an assistive device. Older patients typically use a walker, with or without rollers, for a broader base of support. Younger or minimally impaired patients often progress to the use of a hemi-cane or straight cane. Chart 6-1 outlines best practices for patient safety when teaching patients how to use ambulatory aids.

Chart 6-1 Best Practice for Patient Safety & Quality Care QSEN

Gait Training with Selected Ambulatory Aids

Walker Assisted

- Apply a transfer belt around the patient's waist.
- Guide the patient to a standing position.
- Remind the patient to place both hands on the walker.
- Ensure that the patient is well balanced.
- Teach the patient repeatedly to perform this sequence:
  - Lift the walker.
  - Move the walker about 2 feet forward, and set it down on all legs.
  - While resting on the walker, take small steps.
  - Check balance.
  - Repeat the sequence.

Cane Assisted

- Apply a transfer belt around the patient's waist.
- Guide the patient to a standing position.
- Be sure the cane is at the height of the patient's wrist when the arm is placed at his or her side. (Many canes can be adjusted to the required height.)
- Remind the patient to place his or her strong hand on the cane.
- Ensure that the patient is well balanced.
- Teach the patient to perform this sequence repeatedly:
  - Move the cane and weaker leg forward at the same time.
  - Move the stronger leg one step forward.
  - Check balance and repeat the sequence.

Some patients never regain the ability to walk because of their impairment, such as advanced multiple sclerosis or complete high spinal cord injury. They may become wheelchair dependent and need to learn wheelchair or motorized scooter mobility skills. With the help of physical and occupational therapy, most patients can learn to move anywhere in a wheelchair or scooter. For example, quadriplegic patients often use motorized wheelchairs that can be directed and propelled by moving their head or blowing into a device. Patients with multiple sclerosis often use scooters to get around.

During the rehabilitation phase, patients are at risk for complications of immobility. Table 6-4 lists some of the common complications and strategies the nurse can use to help prevent each complication. Implementing range-of-motion (ROM) routines, adhering to schedules for turning and repositioning, and maintaining skin care are constant components of rehabilitation nursing care to prevent complications of immobility.

TABLE 6-4

Prevention of the Common Complications of Immobility

BODY SYSTEM	COMPLICATIONS	PREVENTION
Musculoskeletal	Contractures Footdrop Osteoporosis Susceptibility to fractures Muscular atrophy	Foot support while in bed, range-of-motion exercises, high-top tennis shoes Ambulation if possible (walking) Other weight-bearing exercises
Gastrointestinal	Constipation	Sitting in an upright position Increased activity level Increased fluid and fiber intake
Cardiovascular	Decreased cardiac output Increased venous stasis Thrombus formation Embolism	Range-of-motion exercises Exercise Antiembolism stockings Avoidance of leg massage Low–molecular-weight heparin or other anticoagulant
Neurologic	Disorientation	Sleep-wake schedule in accord with light-dark pattern Reorientation (to person, place, time) Control of sensory stimulation
Renal/urinary	Calculi	Decreased dietary calcium level, if needed Increased fluid intake Ensuring low post-void residuals
	Infection	Intermittent catheterization instead of indwelling if possible
Respiratory	Pneumonia	Frequent oral hygiene Frequent repositioning in wheelchair or bed Breathing exercises
Integumentary (Skin)	Pressure ulcers	Frequent repositioning in wheelchair or bed Pressure reduction or relief devices (in bed and wheelchair) Meticulous skin care Adequate nutrition Frequent skin assessments

One way to increase mobility, even with patients who are bedridden, is through ROM exercises. ROM techniques are beneficial for any patient with decreased mobility. Although simple ROM techniques are presented in basic nursing textbooks, a few key principles are pertinent to rehabilitation nursing care:

- The human body contains more joints than simply the knees, hips, elbows, and shoulders. For ROM techniques to be effective in preventing musculoskeletal contractures, the patient must exercise all joints, including each joint of the fingers, hands, toes, and so forth.
- In performing ROM activities, the nurse or patient performs full-range movement of each joint at least five times and completes the entire process at least three times daily.
- The nurse or PT does not move the joints beyond the point at which the patient expresses pain or beyond the point at which resistance occurs. Patients with decreased mobility who are able to follow directions are

taught by the nurse and the physical therapist to perform active or active-assisted ROM exercises.

Increasing Functional Ability

Planning: Expected Outcomes.

The patient with chronic illness or disability is expected to increase functional ability in self-care and other self-management skills with or without assistive/adaptive devices.

Interventions.

ADLs, or self-care activities, include eating, bathing, dressing, grooming, and toileting. Encourage the patient to perform as much self-care as possible. Be patient because he or she often takes more time to complete a task than healthy adults do. Collaborate with the occupational therapist (OT) to identify ways in which self-care activities can be modified so the patient can perform them independently and with minimal frustration if possible. For example, the OT teaches a hemiplegic patient to put on a shirt by first placing the affected arm in the sleeve and then putting the unaffected arm in the appropriate sleeve. Slip-on shoes or shoes with Velcro straps may be recommended for some patients. Encourage patients to practice, and allow them time to try to be independent in ADLs.

In long-term care (LTC) settings, federal regulations require that residents not lose their functional skills while they are in the facility. Therefore most facilities have developed *restorative nursing* programs and have coordinated these programs with rehabilitation therapy and activity therapy. The focus of this coordinated effort includes:

- Bed mobility
- Walking
- Transfers
- Dressing
- Grooming
- Active range of motion
- Communication

A variety of devices are available for patients with chronic illness and disability for *assisting with self-care*. An **assistive/adaptive device,** or self-care support device, is any item that enables the patient to perform all or part of an activity independently and safely. Examples include long-handled shoehorns and reachers to prevent bending and losing one's balance. Table 6-5 identifies common devices and describes their use.

TABLE 6-5

Examples and Uses of Common Assistive/Adaptive Devices

DEVICE	USE
Buttonhook	Threaded through the buttonhole to enable patients with weak finger mobility to button shirts Alternative uses include serving as pencil holder or cigarette holder
Extended shoehorn	Assists in the application of shoes for patients with decreased mobility Alternative uses include turning light switches off or on while patient is in a wheelchair
Plate guard and spork (spoon and fork in one utensil)	Applied to a plate to assist patients with weak hand and arm mobility to feed themselves; spork allows one utensil to serve two purposes
Gel pad	Placed under a plate or a glass to prevent dishes from slipping and moving Alternative uses include placement under bathing and grooming items to prevent them from moving
Foam buildups	Applied to eating utensils to assist patients with weak hand grasps to feed themselves Alternative uses include application to pens and pencils to assist with writing or over a buttonhook to assist with grasping the device
Hook and loop fastener (Velcro) straps	Applied to utensils, a buttonhook, or a pencil to slip over the hand and provide a method of stabilizing the device when the patient's hand grasp is weak
Long-handled reacher	Assists in obtaining items located on high shelves or at ground level for patients who are unable to change positions easily
Elastic shoelaces or Velcro shoe closure	Eliminates the need for tying shoes

Many medical equipment stores and large pharmacies carry clothing and assistive/adaptive devices designed for patients with disabilities. The occupational therapist determines specific patient needs for this equipment. Collaborate with the occupational therapist to look for creative and inexpensive alternatives to meeting these needs. For example, barbecue tongs may be used as "reachers" for pulling up pants or obtaining items on high shelves. A foam curler with the plastic insert removed may be placed over a pencil or eating utensil to make a built-up device. The patient might use an extended shoehorn to operate light switches from wheelchair height. Hook-and-loop fasteners (Velcro) sewn on clothes can prevent the frustrations caused by buttons and zippers.

Assistive technology has further increased the ability for disabled patients to care for themselves using electronic equipment. For example, telephones and computer keyboards can be operated by voice-activation devices. **Robotic technology** provides mechanical parts for the extremities when they are not functional or have been amputated. The cost of these aids has prevented their widespread use (Stein, 2012).

Fatigue often occurs with chronic and disabling conditions. Therefore collaborate with the OT to assess the patient's self-care abilities and to determine possible ways of *conserving energy*. Coordinate with the therapist to develop strategies for energy conservation after evaluating the patient's self-care routines. Preparation for ADLs can help reduce effort and energy expenditure (e.g., gathering all necessary equipment before starting grooming routines). If a patient has high energy levels in the morning, he or she can be taught to schedule energy-intensive activities in the morning rather than later in the day or evening. Spacing activities is also helpful for conserving energy. In addition, allowing time

to rest before and after eating and toileting decreases the strain on energy level.

Clinical Judgment Challenge

Evidence-Based Practice; Safety QSEN

A 61-year-old widower is admitted to an inpatient facility for rehabilitation after a right knee replacement for severe osteoarthritis that resulted from his carpentry job. He lives alone in a one-story house and has two daughters nearby who visit every week. After his wife died 10 years ago, the patient was diagnosed with diabetes mellitus type 2 and hypertension. His serum cholesterol is elevated, and he is overweight. His favorite foods are fried chicken, mashed potatoes and gravy, and homemade buttermilk biscuits, which his daughters frequently prepare for him. As his nurse, you complete his admission assessment.

1. What are this patient's priority problems?
2. With what health care team members will you need to collaborate?
3. What safe patient handling practices would you need to use?
4. What type of ambulatory assistive device would be most appropriate for him at this time?
5. What health teaching does the patient need regarding his mobility and nutrition?

Maintaining Skin Integrity

Planning: Expected Outcomes.

The patient with chronic illness or disability is expected to have intact skin and tissue integrity.

Interventions.

The best intervention to prevent skin breakdown and maintain tissue integrity is frequent position changes in combination with adequate skin care and sufficient nutritional intake. Teach staff to *turn and reposition all patients at least every 2 hours* if they are unable to perform this activity. This time frame may not be sufficient for people who are frail and have thin skin, especially older adults. To determine the best turning schedule, assess the patient's skin condition during each turning and repositioning. For example, if the patient has been sleeping for 2 hours and the nursing assistant decides to postpone turning for 1 hour, reddened areas over the

bony prominences may be present. If reddened areas do not fade within 30 minutes after pressure relief or do not blanch, they may be classified as pre-ulcer areas, or stage I pressure areas (see Chapter 25).

Patients who sit for prolonged periods in a wheelchair need to be repositioned at least every 1 to 2 hours. Each patient is evaluated by the physical or occupational therapist for the best seating pad or cushion that is comfortable yet reduces pressure on bony prominences. Patients who are able are taught to perform "wheelchair push-ups" by using their arms to lift their buttocks off the wheelchair seat for 10 seconds or longer every hour, or more often if needed. The PT helps them strengthen their arm muscles in preparation for performing wheelchair push-ups.

If the patient wears high-top tennis shoes for foot positioning to prevent footdrop, remove the shoes and assess for pressure areas every 2 hours. Many patients with neurologic problems have decreased or absent sensation and may not be able to feel the discomfort of increased pressure. Also, check patients who are sitting in wheelchairs for signs of pressure, especially on the lower legs where the leg of the wheelchair could rub against the skin.

Adequate skin care is an essential component of prevention. Perform or assist patients in completing skin care each time they are turned, repositioned, or bathed. Delegate and supervise skin care to unlicensed assistive personnel (UAP), including cleaning soiled areas, drying carefully, and applying a moisturizer. If a patient is incontinent, use topical barrier creams or ointments to help protect the skin from moisture, which can contribute to skin breakdown. *To prevent damage to the already fragile capillary system, teach UAP to avoid rubbing reddened areas.* Instead, carefully observe the areas for further breakdown and relieve pressure on the areas as much as possible. Bed pillows are often good pressure-relieving devices. (See Chapter 25 for a complete discussion of skin care interventions.)

Sufficient nutrition is needed both to repair wounds and to prevent pressure ulcers. Collaborate with the dietitian to assess the patient's food selection and ensure that it contains adequate protein and carbohydrates. Both the nurse and the dietitian closely monitor the patient's weight and serum prealbumin levels. If either of these indices decreases significantly, the patient may need high-protein, high-carbohydrate food supplements (e.g., milkshakes) or commercial preparations. Chapter 60 describes nutritional supplementation in detail.

Pressure-relieving or pressure-reducing devices include waterbeds, gel mattresses or pads, air mattresses, low–air loss overlays or beds, and air-fluidized beds. Mattress overlays, such as air and gel types, and

replacement mattresses are often effective in reducing pressure. *The use of any mechanical device (except air-fluidized beds) does not eliminate the need for turning and repositioning.*

Specialty beds are categorized as either "low air loss" or "air fluidized." Air-fluidized therapy (e.g., Clinitron Rite Hite® bed) provides the most effective pressure relief by distributing the patient's weight to prevent pressure in any one area. These beds are not often used to *prevent* skin breakdown because insurers may not reimburse the agency for the use of the bed. Therefore these special beds are reserved for *severe skin problems* that have not healed with the use of a conventional bed or other mechanical device. The primary disadvantage of this therapy is its expense, which may exceed several hundred dollars for each day of use. Patients also report discomfort from the heat generated by the bed. Although air-fluidized beds are heavy to move, lighter and more portable versions are available for home use. The cost of air-fluidized therapy is reimbursed by some health insurance providers if the bed is deemed medically necessary to treat the patient's skin problem.

Establishing Urinary Continence

Planning: Expected Outcomes.

Most patients with chronic illness or disability are expected to have normal patterns of urinary elimination without retention, infection, or incontinence.

Interventions.

Neurologic disabilities often interfere with successful bladder control in a patient undergoing rehabilitation. These disabilities result in two basic functional types of neurogenic bladder: overactive (e.g., reflex or spastic bladder) and underactive (e.g., hypotonic or flaccid bladder).

An overactive **spastic** (upper motor neuron) **bladder** causes incontinence with sudden, gushing voids. The bladder does not usually empty completely, and the patient is at risk for urinary tract infection. Neurologic problems affecting the upper motor neuron typically occur in patients with strokes or with high-level spinal cord injuries (cervical) or those above the mid-thoracic region. These injuries result in a failure of impulse transmission from the lower spinal cord areas to the cortex of the brain. Therefore when the bladder fills and transmits impulses to the spinal cord, the patient cannot perceive the sensation. Because there is no injury to the *lower* spinal cord and the voiding reflex arc is intact, the efferent (motor) impulse from a distended bladder is relayed and the

bladder contracts.

Experimental technology using sacral neuromodulation is being tested with complete spinal cord–injury patients. The results have been positive in preventing urinary incontinence in patients with spastic bladders (Sievert et al., 2010).

Nonpharmacologic Management.

An underactive **flaccid** or **areflexic** (lower motor neuron) **bladder** results in urinary retention and overflow (dribbling). Injuries that damage the lower motor neuron at the spinal cord level of S2-4 (e.g., multiple sclerosis, spinal cord injury or tumor below T12) may directly interfere with the reflex arc or may result in inaccurate interpretation of impulses to the brain. The bladder fills, and afferent (sensory) impulses conduct the message via the spinal cord to the brain cortex. Because of the injury, the impulse is not interpreted correctly by the brain's bladder center and there is a failure to respond with a message for the bladder to contract.

Patients who cannot completely empty their bladder are at risk for post-void residual urine and subsequent possible urinary tract infection. **Post-void residual (PVR)** is the amount of urine remaining in the bladder within 20 minutes after voiding. PVR assessments using a noninvasive ultrasound device called the *BladderScan* are performed by nurses at the bedside. The residual amount measured is accurate if the device is used correctly. It is not accurate when used for morbidly obese patients. The outcome of bladder ultrasonography is to prevent the use of an indwelling urinary catheter. Long-term urinary catheters cause urinary tract infections that are often chronic. A picture of the BladderScan device is in Chapter 65 (see Fig. 65-10).

The nurse can teach a variety of techniques to assist the patient in retraining or repatterning voiding, including (Table 6-6):

TABLE 6-6

Management of Neurogenic Bladder

FUNCTIONAL TYPE	NEUROLOGIC DISABILITY	DYSFUNCTION	RE-ESTABLISHING VOIDING PATTERNS
Reflex (spastic)	Upper motor neuron spinal cord injury above T12	Urinary frequency, incontinence but may not empty completely	Triggering or facilitating techniques Drug therapy, as appropriate Bedside bladder ultrasound Intermittent catheterization Consistent toileting schedule Indwelling urinary catheter (as last resort) Increased fluids
Flaccid	Lower motor neuron spinal cord injury below T12 (affects S2-4 reflex arc)	Urinary retention, overflow	Valsalva and Credé maneuvers Increased fluids Intermittent or indwelling urinary catheterization

- Facilitating, or triggering, techniques
- Intermittent catheterization
- Consistent scheduling of toileting routines; "timed void"

These techniques may not be as effective in patients with physiologic changes associated with aging, including stress incontinence in women with weak pelvic floor muscles and overflow incontinence in men with enlarged prostate glands.

Facilitating (triggering) techniques are used to stimulate voiding. If there is an upper motor neuron problem but the reflex arc is intact (reflex bladder pattern), the voiding response can be initiated by any stimulus that sends the message to the spinal cord level S2-4 that the bladder might be full. Such techniques include stroking the medial aspect of the thigh, pinching the area above the groin, massaging the penoscrotal area, pinching the posterior aspect of the glans penis, and providing digital anal stimulation.

When the patient has a lower motor neuron problem, the voiding reflex arc is not intact (flaccid bladder pattern) and additional stimulation may be needed to initiate voiding. Two techniques used to facilitate voiding are the Valsalva maneuver and the Credé maneuver. For the Valsalva maneuver, teach the patient to hold his or her breath and bear down as if trying to defecate. This technique should not be used by spinal cord–injured patients who are at risk for bradycardia due to loss of vagus nerve control. Assist the patient in performing the **Credé maneuver** by placing the patient's hand in a cupped position directly over the bladder area and instructing him or her to push inward and downward gently as if massaging the bladder to empty.

Intermittent catheterization may be needed for a flaccid or spastic bladder. Initially, a urinary catheter is inserted to drain urine every few hours—after the patient has attempted voiding and has used the Valsalva

and Credé maneuvers. If less than 100 to 150 mL of post-void residual is obtained, the nurse typically increases the interval between catheterizations. *The patient should not go beyond 8 hours between catheterizations*. If intermittent self-catheterization is needed at home after discharge from the rehabilitation facility, the patient may use a specialized appliance to help perform the procedure, especially if he or she has problems with manual dexterity. For patients who cannot catheterize themselves, a family member or significant other may need to be taught how to perform the procedure.

Most patients who need intermittent catheterization have chronic bacteriuria (bacteria in the urine with a positive culture), especially those with spinal cord injury (SCI). Unless the patient has symptoms of a urinary tract infection (UTI), such as fever or burning when voiding, the infection is not treated.

Nursing Safety Priority QSEN

Action Alert

To *prevent* UTI, teach patients and their caregivers to wash their hands thoroughly before and after catheterization and clean the genital area well. Remind the patient to drink at least 8 to 10 glasses of fluid (two quarts) every day by dinnertime and avoid carbonated beverages. If patients have indwelling urinary catheters, remind them to drink 15 glasses of fluid (three quarts) each day before dinner and avoid carbonated beverages.

The Natural Medicines Comprehensive Database states that cranberry juice or extract may be effective to help *prevent* UTI (U.S. National Library of Medicine [NIH], 2011). It is not effective for *treating* urinary infection.

Consistent toileting routines may be the best way to re-establish voiding continence when the patient has an overactive bladder. Assess the patient's previous voiding pattern, and determine his or her daily routine. At a minimum, the nurse or nursing staff assists the patient with voiding after awakening in the morning, before and after meals, before and after physical activity, and at bedtime. *Remind the staff to toilet the patient every 2 hours during the day and every 3 to 4 hours at night.*

Consider the patient's bladder capacity, which may range from 100 to 500 mL, as well as mobility limitations and restrictive clothing. Bladder capacity is determined by measuring urine output. Ensure that the

patient is aware of nearby bathrooms at all times or has a call system to contact the nurse or unlicensed assistive personnel for assistance. Chapter 66 also describes methods of achieving bladder control.

Drug Therapy.

Drugs are not commonly used for urinary elimination problems. Mild overactive bladder problems may be treated with antispasmodics, such as oxybutynin (Ditropan XL, Apo-Oxybutynin), solifenacin (VESIcare), or tolterodine (Detrol LA), to prevent incontinence on a short-term basis.

Considerations for Older Adults

Patient-Centered Care QSEN

When urinary antispasmodic drugs are used in older adults, observe for, document, and report hallucinations, delirium, or other acute cognitive changes due to the anticholinergic effects of the drugs.

Patients with symptomatic UTIs are managed with short-term antibiotics, such as trimethoprim (Trimpex) or trimethoprim/sulfamethoxazole (Septra, Bactrim). Patients who have frequent UTIs may be placed on pulse antibiotic therapy in which they alternate one week of antibiotic therapy with 3 weeks without antibiotics. Report the patient's progress in bladder training to the rehabilitation team so that the best decision regarding drug therapy can be made.

Establishing Bowel Continence

Planning: Expected Outcomes.

The patient with chronic illness or disability is expected to have regular evacuation of stool without constipation. If possible, patients will control their bowel elimination schedule.

Interventions.

Neurologic problems often affect the patient's bowel pattern by causing a reflex (spastic) bowel, a flaccid bowel, or an uninhibited bowel. Bowel retraining programs are designed for each patient to best meet the expected outcomes (Table 6-7). Pardee et al. (2012) found that establishing a successful bowel program can also enhance the quality of life for patients, especially those who have a spinal cord injury (SCI).

TABLE 6-7

Management of Neurogenic Bowel

FUNCTIONAL TYPE	NEUROLOGIC DISABILITY	DYSFUNCTION	RE-ESTABLISHING DEFECATION PATTERNS
Reflex (spastic)	Upper motor neuron spinal cord injury above T12	Defecation without warning, but may not empty completely	Triggering mechanisms Facilitation techniques High-fiber diet Increased fluids Laxative use (for some patients) Consistent toileting schedule Manual disimpaction
Flaccid	Lower motor neuron spinal cord injury below T12 (affects S2-4 reflex arc)	Usually absent stools for patients with complete lesions	Triggering or facilitating techniques Increased fluids High-fiber diet Suppository use Consistent toileting schedule Manual disimpaction

Upper motor neuron diseases and injuries, such as a cervical or mid-level spinal cord injury, may result in a reflex (spastic) bowel pattern, with defecation occurring suddenly and without warning. With a reflex pattern, any facilitating or triggering mechanism may lead to defecation if the lower colon contains stool. An example of facilitating or triggering techniques is digital stimulation. For this technique, use a lubricated glove or finger cot and massage the anus in a circular motion for no less than 1 full minute.

Nursing Safety Priority QSEN

Critical Rescue

Do not use digital stimulation for patients with cardiac disease because of the risk for inducing a vagal nerve response. This response causes a rapid decrease in heart rate (bradycardia).

Lower motor neuron diseases and injuries interfere with transmission of the nervous impulse across the reflex arc and may result in a flaccid bowel pattern, with defecation occurring infrequently and in small amounts. The use of manual disimpaction may get the best results. Some patients also need oral laxatives and/or stool softeners (Coggrave & Norton, 2010) (see the Evidence-Based Practice box).

Evidence-Based Practice QSEN

Manual Bowel Disimpaction in Patients with Spinal Cord Injury

Coggrave, M.J., & Norton, C. (2010). The need for manual evacuation

and oral laxatives in the management of neurogenic bowel dysfunction after spinal cord injury: A randomized controlled trial of a stepwise protocol. *Spinal Cord, 48*(6), 504-510.

The researchers used a randomized controlled design to test interventions needed to maintain bowel continence among patients who had spinal cord injuries for many years. The 68 volunteers were randomized into an intervention group of 35 and a control group of 33. The control group used their usual bowel management program. The intervention group used oral laxatives and manual disimpaction in a stepwise protocol and in combination. All study participants kept bowel diaries for 6 weeks.

Findings from the study showed that manual disimpaction significantly improved bowel continence more than oral laxatives or other bowel management programs. Some patients needed both laxatives and disimpaction to maintain bowel continence.

Level of Evidence: 1

This study used a randomized controlled design to compare bowel management interventions between a control group and an experimental group that used two specific bowel management interventions—manual disimpaction and oral laxatives.

Commentary: Implications for Practice and Research

This research added to the evidence for planning the best bowel management protocol for spinal cord–injured patients. Nurses can use this information to teach patients how to maintain bowel continence. Bowel control is a sensitive and embarrassing patient problem, and nurses can be instrumental in teaching patients about which methods achieve the best outcome.

Neurologic injuries that affect the brain may cause an uninhibited bowel pattern, with frequent defecation, urgency, and reports of hard stool. Patients may manage uninhibited bowel patterns through a consistent toileting schedule, a high-fiber diet, and the use of stool softeners.

In some cases, patients are not able to regain their previous level of control over their bowel function. The rehabilitation team assists in designing a bowel elimination program that accommodates the disability.

Collaborate with patients to schedule bowel elimination as close as possible to their previous routine. For example, a patient who had stools at noon every other day before the illness or injury should have the

bowel program scheduled in the same way. An exception is the patient who prefers another time that best fits into his or her daily routine. If the patient is employed during the day, a time-consuming bowel elimination program in the morning may not work. The bowel protocol can then be changed to the evening when there is more time.

Bowel retraining programs for patients with neurologic problems are often designed to include a combination of methods. Although drug therapy should not be a first choice when formulating a bowel training program, consider the need for a suppository if the patient does not re-establish defecation habits through a consistent toileting schedule, dietary modification, anal stimulation, and disimpaction.

Bisacodyl (Dulcolax), a commonly used laxative, may be prescribed either rectally or orally as part of a bowel training program. Suppositories must be placed against the bowel wall to stimulate the sacral reflex arc and promote rectal emptying. Results occur in 15 to 30 minutes. Administer the suppository when the patient expects to defecate, for example, after a meal to coincide with the gastrocolic reflex. Using the suppository every second or third day is usually effective in re-establishing defecation patterns.

Many rehabilitation patients are at high risk for constipation, especially older adults. Encourage fluids (at least 8 glasses a day) and 20 to 35 g of fiber in the diet. Teach patients to eat 2 to 3 daily servings of whole grains, legumes, and bran cereals and 5 daily servings of fruits and vegetables. Do not offer a bedpan when toileting. Instead, be sure that the patient sits upright on a bedside commode or bathroom toilet to facilitate defecation.

NCLEX Examination Challenge

Physiological Integrity

Which statement by a quadriplegic client indicates a need for the nurse to provide further teaching about bowel retraining?
A "I'll eat low-fiber foods each day to prevent diarrhea."
B "I'll drink at least a quart of water or other liquids every day."
C "I'll do my daily bowel training routine after I eat breakfast."
D "I'll use a suppository to help empty my rectum."

Community-Based Care

Discharge planning begins at the time of the patient's admission. If the patient is transferred from a hospital to a rehabilitation unit or long-term

care facility, orient him or her to the change in routine and emphasize the importance of self-care. When the patient is admitted, a nurse, case manager, and/or OT assess his or her current living situation at home. Together with the patient and family members or significant others, they determine the adequacy of the current situation and the potential needs after discharge to home. The patient with chronic illness and disability may require home care, assistance with ADLs, nursing care, or physical or occupational therapy after discharge.

Other health care professionals may be necessary to meet the unique needs of special populations. For example, patients with brain injury may benefit from life planning—a process that examines and plans to meet lifelong needs. External case managers specializing in life planning may be part of the interdisciplinary rehabilitation team.

Home Care Management.

Before the patient returns home, the nurse assesses his or her readiness for discharge from the rehabilitation facility or hospital. The home may be assessed in multiple ways and points in time.

Predischarge Assessment.

Before discharge, the case manager or OT may visit the home to assess its layout and accessibility. These professionals may be employed by the health care agency or by a third-party payer, such as a health maintenance organization. Because of the stress of hospitalization, a patient with a fractured hip who is ambulating well with a walker may neglect to explain to the nurse that the bathroom in the home is accessible by stairway only. The patient may not consider it important to mention that throw rugs, which can cause falls, are scattered throughout the apartment. Fall prevention strategies in the home environment for older adults are discussed in Chapter 2.

During a predischarge visit to the home, the accessibility of bathrooms, bedrooms, and kitchen is assessed. If the patient will be wheelchair dependent after discharge from the facility, home modifications may be needed, such as ramps to replace steps. Doorways should be checked for adequate width. A doorway width of 36 to 38 inches (slightly less than 1 meter [m]) is usually sufficient for a standard-size wheelchair. Obese patients require bariatric wheelchairs and furniture and therefore need a wider door opening. Any room that the patient needs to use is assessed. The bedroom should have sufficient space for the patient to maneuver transfers to and from the wheelchair and the bed, if needed. The bathroom may need a raised toilet seat to at

least 17 inches (43 cm).

Space requirements depend on the patient's need to use a wheelchair, walker, or cane. In the bathroom, grab bars may need to be installed before the patient comes home. Bathtub benches can provide support for the patient who has difficulty with mobility and, when used in combination with a handheld showerhead, can provide easily accessible bathing facilities. Assessment of the kitchen may or may not be critical, depending on whether the patient has help with cooking and preparing meals. If the patient will be cooking after discharge, the kitchen may need to be assessed for wheelchair or walker accessibility, appliance accessibility, and the need for adaptive equipment.

Leave-of-Absence Visit.

A second method of assessing the patient's home is through a brief home visit, also called a *leave-of-absence (LOA) visit*, before discharge. Explain the need for the trial home visit, and assess the patient's comfort level with this idea. The patient who has been hospitalized for a lengthy period may feel intense anxiety about returning home. The nurse may allay such anxieties with careful preparation. Before the visit, the rehabilitation nurse meets with the patient and family members or significant others to set goals for the visit and to identify specific tasks to be attempted while at home. After the home visit, interview the patient to determine the success of the visit and to assess additional education or training needs before final discharge.

Going home may not be an option for everyone. Some patients may not have a support network of family members or significant others. For example, many older adults have no spouse or close friends living nearby. Children may live far away, which can make home care difficult. If no caregiver is available, the family must decide whether care can be provided in the home by an outside resource. The patient may need to be admitted to a 24-hour supervised health care setting, such as a nursing home. Continued rehabilitation services are available in most long-term care settings (skilled nursing facilities) at least 5 days a week if it is medically necessary.

Self-Management Education.

The OT and PT teach the patient to perform ADLs and IADLs independently. The patient's learning potential and cognitive capacity are assessed. The patient is asked to perform or direct each skill or technique independently to verify understanding. Written material explaining the steps in the procedure is provided to the patient and family members to

reinforce learning and to provide support with the technique after discharge. Before distributing written material, the rehabilitation team assesses the reading level of the material and determines whether it is appropriate for the patient's reading ability and language skills.

Any chronic illness or disability necessitates changes in lifestyle and body image. Assist the patient in dealing with such changes by encouraging verbalization of feelings and emotions. A focus on existing capabilities instead of disabilities is emphasized.

The patient may fail to relate psychologically to the disability during hospitalization. For example, he or she may display anger or frustration in attempting to perform self-care routines before discharge from the rehabilitation facility. Encourage the patient to be open about such feelings and to talk about ways to prevent worries from becoming realities after discharge. If needed, refer the patient to a mental health care professional to help with adjustment and coping strategies.

The LOA home visit assists the patient and family members or significant others in psychosocial preparation for discharge. It allows the experience of the home situation while being able to return to the hospital environment after a few hours. Often the patient finds new problems in the home that must be addressed before discharge. Review this information with the patient in preparation for discharge to the home.

Health Care Resources.

After discharge to the home, various health care resources (e.g., physical therapy, home care nursing, vocational counseling) are available to the patient with chronic illness and disability. Assess the need for additional care and support throughout the hospitalization, and coordinate with the case manager and physician in arranging for home services. A newer process using technology called *tele-health*, or *tele-rehabilitation* allows for care coordination in the home setting. Through the use of various electronic devices, phone, or computer software, a health care team member can monitor the patient's vital signs, weight, and other assessment data. Other programs, such as Rehab@Home, allow patients to perform therapeutic exercises at home using Wii, a webcam, and a computer.

Evaluation: Outcomes

The patient and rehabilitation team evaluate the effectiveness of interdisciplinary interventions based on the common patient problems.

Expected outcomes may include that the patient will:

- Reach a level of physical mobility that allows him or her to function independently with or without assistive devices
- Prevent complications of decreased physical mobility
- Perform self-care and other self-management skills independently or with minimal assistance, possibly using assistive/adaptive devices
- Have intact skin and underlying tissues
- Establish urinary continence without infection or retention
- Have regular evacuation of stool without constipation

Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Recall that rehabilitation is the process of learning to live with chronic and disabling conditions; the role of the rehabilitation nurse is outlined in Table 6-1.
- Collaborate with members of the interdisciplinary rehabilitation team, including physicians, nurse practitioners, physiotherapists, occupational therapists, dietitians, and speech/language pathologists; the patient and family are also members of the team. **Teamwork and Collaboration** QSEN
- Know that acute (short-term) rehabilitation care occurs in a variety of settings, including inpatient rehabilitation facilities (IRFs) and skilled nursing facilities (SNFs) in either a nursing home or hospital.
- Delegate and supervise selected nursing tasks, such as reporting reddened skin areas, as part of quality care for the rehabilitation patient.
- After assessing the home environment, the case manager, OT, and/or rehabilitation nurse make recommendations to the patient and family about home modifications.
- Use evidence-based safe patient handling practices, such as using mechanical lifts and working with other team members, when assessing and moving patients to prevent injury and improve mobility. **Evidence-Based Practice** QSEN
- Recall that the rehabilitation therapists teach patients transfer, bed mobility, and gait training techniques (see Chart 6-1).
- Encourage the patient to be as independent as possible when performing ADLs and safe mobility skills.

Health Promotion and Maintenance

- In coordination with the PT and OT, assess the patient's ability to perform ADLs and mobility skills using a functional assessment process. **Teamwork and Collaboration** QSEN
- Prevent complications of immobility for patients, and teach them how to prevent complications by using interventions listed in Table 6-4. Examples include pressure ulcers, urinary calculi, constipation, and venous thromboembolism. **Evidence-Based Practice** QSEN

Psychosocial Integrity

- Assess the patient's self-esteem and changes in body image caused by chronic or disabling health problems.
- Assess the patient's cognition to screen for depression, delirium, and dementia using tools such as the Confusion Assessment Method (CAM), especially for older adults.
- Assess the patient's and family's response to chronic and disabling conditions, including feelings of loss and grief.
- Assist patients in coping with their loss, and assess the availability of patient support systems, especially for older adults. **Patient-Centered Care** QSEN

Physiological Integrity

- Assess rehabilitation patients as outlined in Table 6-2 to help plan appropriate collaborative care.
- Review the Functional Independence Measure (FIM) system as one assessment tool used to assess functional ability of the patient in rehabilitation, including the need for assistive/adaptive devices.
- Recognize that the Minimum Data Set (MDS) 3.0 is the comprehensive assessment tool required by the Centers for Medicare and Medicaid Services that is used in long-term care/nursing home settings (see Table 6-3).
- Assess patients in rehabilitation for risk factors that make them likely to develop skin breakdown; interventions to prevent skin problems include repositioning and adequate nutrition. **Quality Improvement** QSEN
- Patients with neurogenic bladder and bowel problems are managed by training programs; overactive (spastic or reflex) and underactive (hypotonic or flaccid) elimination problems are managed differently (see Tables 6-6 and 6-7).
- In collaboration with the rehabilitation therapists, evaluate the ability of patients to use assistive/adaptive devices to promote independence. **Teamwork and Collaboration** QSEN
- Determine patient and family needs regarding discharge to home or other community-based setting.

CHAPTER 7

End-of-Life Care

Mary K. Kazanowski

PRIORTY CONCEPTS

- Palliation
- Pain
- Cognition
- Perfusion

Learning Outcomes

Safe and Effective Care Environment

1. Describe the importance of collaborating with members of the interdisciplinary team when caring for the dying patient and family or other caregivers.
2. Discuss the ethical and legal obligations of the nurse with regard to end-of-life care.

Health Promotion and Maintenance

3. Explain to patients and their families the purpose and procedure for advance directives.

Psychosocial Integrity

4. Assess the patient's and family's ability to cope with the dying process.
5. Assess and plan interventions to meet the dying patient's spiritual needs.
6. Incorporate the patient's cultural practices and beliefs when providing care during the dying process and death.
7. Identify the need for providing psychosocial support to the family or

other caregivers during the patient's dying process.

Physiological Integrity

8. Describe the pathophysiology of death.
9. Compare the concepts of hospice and palliation.
10. Assess patients for signs and symptoms related to the end of life.
11. Explain how to provide evidence-based end-of-life care to the dying patient, including symptom management.
12. Explain best practice guidelines for performing postmortem care.

Overview of Death and Dying

Although dying is part of the normal life cycle, it is often feared as a time of pain and suffering. For the family, death of a member is a life-altering loss that can cause significant and prolonged suffering. As sad and difficult as the death may be, the experience of dying need not be physically painful for the patient or emotionally agonizing for the family. The dying process is an opportunity to change a potentially difficult situation into one that is tolerable, peaceful, and meaningful for the patient and the family left behind.

Because nurses spend more time with patients than do any other health care providers, it is the nurse who often has the greatest impact on a person's experience with death. A nurse can affect the dying process to prevent death without dignity (bad death) from occurring while striving to promote a peaceful and meaningful death (good death). To accomplish this desired outcome, nurses need to have knowledge of end-of-life care, compassion, advocacy, and therapeutic communication skills (Clabots, 2012).

A **good death** is one that is free from avoidable distress and suffering for patients, families, and caregivers; in agreement with patients' and families' wishes; and consistent with clinical practice standards. Persistent pain, not having one's wishes followed at the end of one's life, isolation, abandonment, and agonizing about losses associated with death are characteristics of a **bad death.**

Death in the United States

Table 7-1 lists the most common causes of death in the United States. Of all people who die, only a small percentage of them die suddenly and unexpectedly. Most people die after a long period of illness (e.g., cardiac, renal, respiratory disease), with gradual deterioration until an active dying phase before the death. Most people who die are older than 65 years.

TABLE 7-1

Leading Causes of Death in the United States

1. Diseases of the heart
2. Malignant neoplasms (cancer)
3. Chronic lower respiratory diseases (e.g., chronic obstructive pulmonary disease [COPD])
4. Cerebrovascular diseases
5. Accidents (unintentional injuries)
6. Alzheimer's disease
7. Diabetes mellitus
8. Influenza and pneumonia
9. Nephritis, nephritic syndrome, and nephrosis
10. Intentional self-harm (suicide)
11. Septicemia
12. Chronic liver disease and cirrhosis
13. Essential hypertension and hypertensive renal disease
14. Parkinson disease
15. Pneumonitis caused by aspiration of solids and liquids

Data from Hoyert, D.L., & Xu, J. (2011). Deaths: Preliminary data for 2011. *National Vital Statistics Reports, 61*(6), 1-52. National Center for Health Statistics. Retrieved December 2013 from www.cdc.gov/nchs/data/nvsr/nvsr61/nvsr61_06.pdf.

Considerations for Older Adults

Patient-Centered Care QSEN

Older adults in the United States are estimated to account for 75% of deaths each year. Older adults are also more likely than younger adults to think about their needs and preferences related to end of life (EOL). Data suggest that older adults want early discussions with their health care provider in preparation for death (Gillick, 2010). Despite this desire, understanding of preferences and needs related to end of life is lacking.

The U.S. health care system is based on the acute care model, which is focused on prevention, early detection, and cure of disease. This focus and the advances in survival rates for once deadly diseases have made it difficult for many patients and health care providers to accept death as an outcome of disease. Many view death as a failure.

These negative views have led to a major deficiency in the quality of care provided to many people at the end of life. In 1995, a landmark study highlighted the poor quality of dying experienced by hospitalized patients. The Study to Understand Prognoses and Preferences for Outcomes and Risks of Treatment (SUPPORT) showed that more than 50% of a sample of 9105 hospitalized patients with a life-threatening disease had moderate to severe pain during the last days of their lives. In addition, they did not have their wishes met, even when their wishes

were known.

Pathophysiology of Dying

Death is defined as the cessation of integrated tissue and organ function, manifested by lack of heartbeat, absence of spontaneous respirations, or irreversible brain dysfunction. It generally occurs as a result of an illness or trauma that overwhelms the compensatory mechanisms of the body, eventually leading to cardiopulmonary failure/arrest. Direct causes of death include:

- Heart failure secondary to cardiac dysrhythmias, myocardial infarction, or cardiogenic shock
- Respiratory failure secondary to pulmonary embolism, heart failure, pneumonia, lung disease, or respiratory arrest caused by increased intracranial pressure
- Shock secondary to infection, blood loss, or organ dysfunction, which leads to lack of blood flow (i.e., perfusion) to vital organs

Inadequate perfusion to body tissues deprives cells of their source of oxygen, which leads to anaerobic metabolism with acidosis, hyperkalemia, and tissue ischemia. Dramatic changes in vital organs lead to the release of toxic metabolites and destructive enzymes, referred to as *multiple organ dysfunction syndrome (MODS).* As illness or organ damage progresses, the syndrome occurs with renal and liver failure. Renal or liver failure can also *start* the dying process.

When the body is hypoxic and acidotic, a lethal dysrhythmia such as ventricular fibrillation or asystole can occur, which ultimately leads to the lack of cardiac output and perfusion. Shortly after cardiac arrest, respiratory arrest occurs. When respiratory arrest occurs first, cardiac arrest follows within minutes.

Planning for End-of-Life and Advance Directives

In 1991, the U.S. Congress passed the Patient Self-determination Act (PSDA), which granted people the right to determine the medical care they wanted provided (or not provided) if they became incapacitated. Documentation of this self-determination is accomplished by completing an **advance directive (AD).** The PSDA requires that a representative in every health care agency ask patients when admitted if they have written advance directives. Patients who do not have ADs should be provided with information on the value of having an AD in place and given the opportunity to complete the state-required forms. Ideally, advance directives should be completed long before a medical crisis.

Advance directives vary from state to state but are readily available through Caring Connections, an online program of the National Hospice and Palliative Care Organization (www.caringinfo.org). Anyone can complete the advance directive forms without legal consultation. Exact titles for each AD form vary from state to state. Generally speaking, most ADs have a section where one names a **durable power of attorney for health care (DPOAHC).** The DPOAHC is not the same as DPOA for financial affairs. Most legal representatives recommend that the person who is the durable power of attorney be different from the person who is the durable power of attorney for one's finances.

The DPOAHC is the designation for the person or persons appointed to make one's decisions related to health care in the event the person loses decision-making capacity (Fig. 7-1). The DPOAHC, often referred to as a *health care proxy, health care agent,* or *surrogate decision maker,* does not make health care decisions until a physician states that the person loses or lacks the capacity to make his or her own health care decisions because of impairment in cognition.

NEW HAMPSHIRE DURABLE POWER OF ATTORNEY FOR HEALTH CARE

I, _____ (name), hereby appoint _____ (name of agent)
of _____ (address)
as my agent to make any and all health care decisions for me, except to the extent I state otherwise in this document or as prohibited by law. This durable power of attorney for health care shall take effect in the event I become unable to make my own health care decisions.

STATEMENT OF DESIRES, SPECIAL PROVISIONS, AND LIMITATIONS REGARDING HEALTH CARE DECISIONS.

For your convenience in expressing your wishes, some general statements concerning the withholding or removal of life-sustaining treatment are set forth below. (Life-sustaining treatment is defined as procedures without which a person would die, such as but not limited to the following: cardiopulmonary resuscitation, mechanical respiration, kidney dialysis or the use of other external mechanical and technological devices, drugs to maintain blood pressure, blood transfusions, and antibiotics.) There is also a section that allows you to set forth specific directions for these or other matters. If you wish, you may indicate your agreement or disagreement with any of the following statements and give your agent power to act in those specific circumstances.

1. If I become permanently incompetent to make health care decisions, and if I am also suffering from a terminal illness, I authorize my agent to direct that life-sustaining treatment be discontinued.
   YES NO (Circle your choice and initial beneath it.)
2. Whether terminally ill or not, if I become permanently unconscious I authorize my agent to direct that life-sustaining treatment be discontinued.
   YES NO (Circle your choice and initial beneath it.)
3. I realize that situations could arise in which the only way to allow me to die would be to discontinue artificial feeding (artificial nutrition and hydration). In carrying out any instructions I have given above in #1 or #2 or any instructions I may write in #4 below, I authorize my agent to direct that (circle your choice of [a] or [b] and initial beside it):
   (a) artificial nutrition and hydration not be started or, if started, be discontinued,
   —OR—
   (b) although all other forms of life-sustaining treatment be withdrawn, artificial nutrition and hydration continue to be given to me.

If you do not complete item 3, your agent will not have the power to direct the withdrawal of artificial nutrition and hydration.

4. Here you may include any specific desires or limitations you deem appropriate, such as when or what life-sustaining treatment you would want used or withheld, or instructions about refusing any specific types of treatment that are inconsistent with your religious beliefs or unacceptable to you for any other reason. You may leave this question blank if you desire.

(attach additional pages as necessary)

In the event the person I appoint above is unable, unwilling or unavailable, or ineligible to act as my health care agent, I hereby appoint
_____ (name of alternate agent) of _____ (address of alternate agent)
as alternate agent.

I hereby acknowledge that I have been provided with a disclosure statement explaining the effect of this document. I have read and understand the information contained in the disclosure statement.

The original of this document will be kept at _____ and the following persons and institutions will have signed copies:
In witness, whereof, I have hereunto signed my name this _____ (day) day of _____ (month), 20 _____ (year).

_____ (signature)

I declare that the principal appears to be of sound mind and free from duress at the time the durable power of attorney for health care is signed and that the principal has affirmed that he or she is aware of the nature of the document and is signing it freely and voluntarily.

Witness: _____ Address: _____
Witness: _____ Address: _____

STATE OF NEW HAMPSHIRE, COUNTY OF _____
The foregoing instrument was acknowledged before me this _____ day of _____, 20 ___, by _____.

My commission expires:

FIG. 7-1 An example of a durable power of attorney for health care (DPOAHC).

To have decision-making ability, a person must be able to perform three tasks:

- Receive information (but not necessarily oriented × 4)
- Evaluate, deliberate, and mentally manipulate information
- Communicate a treatment preference

By definition, the comatose patient does not have decisional ability.

The second part of the Advance Directive is a **living will** (LW), which

identifies what one would (or would not) want if he or she were near death. Treatments that are discussed include cardiopulmonary resuscitation (CPR), artificial ventilation, and artificial nutrition or hydration. The third type of advance directive is a do-not-resuscitate (DNR) form. A **DNR** is an actual order from a physician or other authorized health care provider who instructs that CPR not be attempted in the event of cardiac or respiratory arrest. DNR directives are intended for people with known life-limiting conditions, such as terminal cancer. Depending on the state of residence, people who have made the decision not to be resuscitated may have portable DNR documents and or bracelets to identify themselves as having orders not to resuscitate. Some states also have directives referred to as *POLST* (physician orders for life-sustaining treatment), which document additional treatments in case of cardiac or pulmonary arrest. Like portable DNRs, POLST follow the patient across health care settings.

By law, all health care providers must initiate CPR for a person who is not breathing or is pulseless unless that person has a DNR order. The problem with performing CPR is that it can be a violent, likely painful intervention, which prevents a peaceful death. CPR is also likely to be unsuccessful when performed on a patient with advanced disease and comorbidities, especially when the patient is older than 65 years. Many patients and families, however, do not understand the limitations of CPR and do not realize it was never intended to be performed on patients with end-stage disease (Peberdy et al., 2008).

Hospice and Palliative Care

The concept of hospice in the United States came about from a grassroots effort in response to the unmet needs of terminally ill people. As both a philosophy and a system of care, **hospice** uses an interdisciplinary approach to assess and address the holistic needs of patients and families to facilitate quality of life and a peaceful death. This holistic approach neither hastens nor postpones death but provides relief of symptoms. Hospice systems of care are provided in a variety of settings. They are often affiliated with home care agencies, providing services to patients at home or in a long-term care or assisted-living facility. Some communities also have hospice houses, which provide care to patients in the terminal phase of their lives.

The *Medicare Hospice Benefit* serves as a guide for hospice care in the United States. This benefit pays for hospice services for Medicare recipients who have a prognosis of 6 months or less to live and who agree

to forego curative treatment for their terminal illness. Historically, those with terminal cancer made up the majority of patients receiving hospice care. The proportion of patients with terminal cancer, however, has recently decreased, with increases in numbers of patients with other terminal illnesses, (e.g., dementia, end-stage chronic obstructive pulmonary disease [COPD], cardiac disease, or neurologic disease).

Guidelines are available to assist health care providers and families in identifying who is entitled to hospice care under Medicare. Patients who do not qualify for Medicare may have benefits through private insurance or government medical assistance programs (e.g., Medicaid).

Considerations for Older Adults

Patient-Centered Care QSEN

Although twice as many older adults died in hospice care as in a hospital or nursing home compared with a decade ago, hospice is often treated as a last resort after aggressive critical care (see the Evidence-Based Practice box). Earlier referrals to hospice care by physicians in collaboration with the health care team would increase its benefit for older adults and families.

Evidence-Based Practice QSEN

When Do Medicare Patients Use Hospice Services?

Kelley, A.S., Deb, P., Du, Q., Aldridge Carlson, M.D., & Morrison, R.S. (2013). Hospice enrollment saves money for Medicare and improves care quality across a number of different lengths-of-stay. *Health Affairs, 32(3),* 552-561.

Despite the demonstrated potential to improve quality of care and lower costs, the Medicare Hospice Benefit has been found to produce savings only for patients enrolled 53 to 105 days before death. The researchers for this study reviewed data from the Health and Retirement Study data (2002-2008) for the most common hospice enrollment periods, which are: 1 to 7 days, 8 to 14 days, 15 to 30 days, and 53 to 105 days before death. Patients enrolling in these periods in hospice were compared with matched, non-hospice controls.

Within all enrollment periods, hospice patients had significantly lower rates of hospital and critical care use, hospital readmissions, and in-hospital death when compared with the matched non-hospice patients.

Level of Evidence: 1

This was a large systematic study that overcame limitations of previous research.

Commentary: Implications for Practice and Research

This study indicates that hospice is the best model of care for people near death, saves health care costs, and addresses quality of care at the end of life. Nurses should provide information to patients at end of life about the value of hospice to ensure a peaceful, dignified death.

Because benefits and care generally require a prognosis of 6 months or less, its use is limited. Many people with chronic, serious illness whose prognosis may be longer than 6 months often do not have access to the support services that work so well within the hospice model. In an effort to address this need, palliative care has evolved.

Palliative care is a philosophy of care for people with life-threatening disease that assists patients and families in identifying their goals of care, assists them with informed decision making, and facilitates quality symptom management. Unlike hospice, palliation is provided by a physician, nurse practitioner, or team of providers, as a consultation visit, with one or more follow-up visits. Palliative care consults are provided in a large number of hospitals and on an ambulatory care basis in some communities. Table 7-2 compares palliative care to hospice care.

TABLE 7-2

Comparison of Hospice and Palliative Care

HOSPICE CARE	PALLIATIVE CARE
Patients have a prognosis of six (6) months or less to live.	Patients can be in any stage of serious illness.
Care is provided when curative treatment, such as chemotherapy, has been stopped.	A consult is provided that is concurrent with curative therapies or therapies that prolong life.
Care is provided in 60- and 90-day periods with an opportunity to continue if eligibility criteria are met.	Care is not limited by specific time periods.
Ongoing care is provided by RNs, social workers, chaplains, and volunteers.	Care is in the form of a consult visit by a physician or advanced practice nurse who makes recommendations; follow-up visits may be provided.

Because of their proximity to patients, nurses are often in the position of assisting patients in exploring their wishes for end-of-life care. To elicit this information, the nurse could ask these questions (Steed, 2012):

- Do you have advance directives?
- Have you thought who you would want to speak for you about your

medical care, if you were not able to speak for yourself?
- What are your goals for end-of-life care?
- Have you discussed resuscitation with your health care provider?
- Do you want to be at home at the end of your life?
- Do you currently have any distressing symptoms that are not being controlled?
- Do you feel that your spiritual needs are being met? If not, how can we help meet them?

When developing a plan of care for people nearing the end of their lives, consideration should be given for where the person wants to die. A large percentage of Americans would like to die at home. If this is the patient's preference, work with the patient, family, and health care provider to determine if this goal is possible. Providers trained in end-of-life care are available through hospice agencies who can meet with the patient and family to evaluate their needs and assist them in the discharge plan.

Clinical Judgment Challenge

Patient-Centered Care QSEN

A 77-year-old female with stage IV heart failure has had two hospitalizations for congestive heart failure (CHF) exacerbations in the past month. The patient lives alone and has no durable power of attorney for health care or living will. She tells you she does not need an advance directive because she "can just come back to the hospital and they will take care of me."

1. How would you respond to the patient at this time?
2. What types of referral might you make for her? How would you do this?
3. Is the patient a candidate for hospice at this time? Why or why not?
4. What symptoms of distress do you anticipate?
5. How do you feel about the patient wanting re-hospitalization for heart failure?

Patient-Centered Collaborative Care

Assessment

Obtain information about the patient's diagnosis, past medical history, and recent state of health to identify the risks for symptoms of distress at end of life. People with lung cancer, heart failure, or chronic respiratory

disease are at high risk for respiratory distress and dyspnea as they decline. Those with brain tumors are at risk for seizure activity. Patients with tumors near major arteries (e.g., head and neck cancer) are at risk for hemorrhage. Those who have been experiencing pain often continue to have pain at the end of life, which may increase, decrease, or remain at the same level of intensity.

Physical Assessment/Clinical Manifestations.

As death nears, patients often have signs and symptoms of decline in physical function, manifested as weakness, anorexia, and changes in cardiovascular function, breathing patterns, and GI and genitourinary function. As death nears, peripheral circulation decreases and the patient's skin is often cold, mottled, and cyanotic because of poor tissue perfusion. Blood pressure decreases and often is only palpable. The dying person's heart rate may increase, become irregular, and gradually decrease before stopping. Changes in breathing pattern are common, with breaths becoming very shallow and rapid. Periods of apnea and **Cheyne-Stokes respirations** (apnea alternating with periods of rapid breathing) are also common. Death occurs when respirations and heartbeat stop.

Although these signs and symptoms of physical decline are often disturbing to patients and families, they generally do not cause physical discomfort to the patient. However, symptoms that cause suffering can occur in patients with cancer and non-cancer diagnoses.

Near the end of life, the patient often becomes weak and drowsy, often sleeping 23 or more hours of the day. Eventually he or she can become unresponsive. As the patient's ability to speak diminishes, it is difficult to assess his or her perception of symptoms. When caring for those who are unable to communicate their distress or needs, identify alternative ways to assess symptoms of distress. Teach family caregivers to watch closely for objective signs of discomfort (e.g., restlessness, grimacing, moaning) and identify when these symptoms occur in relation to positioning, movement, medication, or other external stimuli. Teach them how to perform interventions that can help relieve discomfort and stress as described in Chart 7-1.

Chart 7-1

Patient and Family Education: Preparing for Self-Management

Common Physical Signs and Symptoms of Approaching Death with Recommended Comfort Measures

Coolness of Extremities

Circulation to the extremities is decreased; the skin may become mottled or discolored.

- Cover the person with a blanket.
- Do not use an electric blanket, hot water bottle, electric heating pad, or hair dryer to warm the person.

Increased Sleeping

Metabolism is decreased.

- Spend time sitting quietly with the person.
- Do not force the person to stay awake.
- Talk to the person as you normally would, even if he or she does not respond.

Fluid and Food Decrease

Metabolic needs have decreased.

- Do not force the person to eat or drink.
- Offer small sips of liquids or ice chips at frequent intervals if the person is alert and able to swallow.
- Use moist swabs to keep the mouth and lips moist and comfortable.
- Coat the lips with lip balm.

Incontinence

The perineal muscles relax.

- Keep the perineal area clean and dry. Use disposable underpads (Chux) and disposable undergarments.
- If the person would be more comfortable, consider a Foley catheter.

Congestion and Gurgling

The person is unable to cough up secretions effectively.

- Position the patient on his or her side.
- Administer medications to decrease the production of secretions.

Breathing Pattern Change

Slowed circulation to the brain may cause the breathing pattern to become irregular, with brief periods of no breathing or shallow breathing.

- Elevate the person's head.

■ Position the person on his or her side.

Disorientation

Decreased metabolism and slowed circulation to the brain may occur.

■ Identify yourself whenever you communicate with the person.
■ Reorient the patient as needed.
■ Speak softly, clearly, and truthfully.

Restlessness

Decreased metabolism and slowed circulation to the brain may occur.

■ Play soothing music, and use aromatherapy.
■ Do not restrain the person.
■ Massage the person's forehead.
■ Reduce the number of people in the room.
■ Talk quietly.
■ Keep the room dimly lit.
■ Keep the noise level to a minimum.
■ Consider sedation if other methods do not work.

Adapted from the Hospice of North Central Florida, Inc.

Although the patient's point of view is the most valid indicator of comfort or distress, the family's perception of symptoms is also important. Family caregivers, health care providers, and dying patients may differ in their perceptions of symptoms in terms of intensity, significance, and meaning. Whereas health care providers are often able to identify symptoms of distress, families are often more knowledgeable about the patient's habits and preferences. Incorporate all pertinent information into the plan for symptom management, and work with patients and families toward a common outcome.

Assess any symptom of distress in terms of intensity, frequency, duration, quality, exacerbating (worsening) and relieving factors, and effect on the patient's comfort when awake or asleep. A method for rating the intensity of symptoms should be used to facilitate ongoing assessments and evaluate treatment response. A rating scale of 0 to 10 is commonly used, with 0 indicating no distress and 10 indicating the worst possible distress. The intensity of the symptom before and after an intervention (e.g., medication) is documented by the nurse or the family caregiver and is used daily to evaluate the patient's overall comfort.

Psychosocial Assessment.

People facing death may have fear and/or anxiety about their impending

death and experience difficulty coping. Assess cultural considerations, values, and religious beliefs of the patient and family for their influence on the dying experience, control of symptoms, and family bereavement.

Cultural Considerations

Patient-Centered Care QSEN

Be aware that patients differ in their needs at end of life depending on their gender and ethnicity. For example, families may not want to know about the terminal conditions of their loved ones. In some cultures, this decision is based on respect for older family members. Ask the family what they want to know and if they desire the assistance of a language interpreter (Clabots, 2012).

Families of people near death often manifest fear, anxiety, and knowledge deficits regarding the process of death and their role in providing care. Assess the patient and family for fear and anxiety and their expectations of the death experience. Ask them if they want to talk to a **bereavement** (grief) counselor or want guidance from clergy. Explain the common emotional signs of approaching death as described in Chart 7-2.

Chart 7-2

Patient and Family Education: Preparing for Self-Management

Common Emotional Signs of Approaching Death

Withdrawal

The person is preparing to "let go" from surroundings and relationships.

Vision-like Experiences

The person may talk to people you cannot see or hear and see objects and places not visible to you. These are not hallucinations or drug reactions.

- Do not deny or argue with what the person claims.
- Affirm the experience.

Letting Go

The person may become agitated or continue to perform repetitive tasks. Often this indicates that something is unresolved or is preventing the person from letting go. As difficult as it may be to do or say, the dying person takes on a more peaceful demeanor when loved ones are able to say things such as, "It's okay to go. We'll be alright."

Saying Goodbye

When the person is ready to die and you are ready to let go, saying "goodbye" is important for both of you. Touching, hugging, crying, and saying "I love you," "Thank you," "I'm sorry," or "I'll miss you so much" are all natural expressions of sadness and loss. Verbalizing these sentiments can bring comfort both to the dying person and to those left behind.

Adapted from the Hospice of North Central Florida, Inc.

Interventions

The desired outcomes for a patient near the end of life (EOL) are that the patient will have:

- Needs and preferences met
- Control of symptoms of distress
- Meaningful interactions with family
- A peaceful death

Interventions are planned to meet the physical, psychological, social, and spiritual needs of patients using an interdisciplinary approach. The coordinated, interdisciplinary care of hospice is the most successful approach to end-of-life care to date. *Although the perception of hospice is that it provides care for the dying, the major focus of hospice care is on quality of life.* Drug therapy is a major component of hospice care to provide symptom relief. Commonly used drugs are summarized in Chart 7-3.

Chart 7-3 Best Practice for Patient Safety & Quality Care QSEN

Symptom Relief Kit for Patients in Home Hospice

- For unrelieved pain: Morphine solution (20 mg/1 mL solution) 0.25 to 0.5 mL orally or sublingually every 2 to 3 hours as needed.
- For unrelieved dyspnea: Morphine solution (20 mg/1 mL solution) 0.25 to 0.5 mL orally or sublingually every 2 hours as needed.
- For nausea or vomiting: Prochlorperazine 25-mg suppository rectally or 10-mg tablet orally every 6 hours as needed.

- For severe agitation and restlessness:
  - Determine if patient is in pain; treat accordingly.
  - Determine if patient is experiencing urinary retention; insert straight or Foley catheter.
  - Haloperidol 0.5 to 1 mg orally or sublingually every 6 hours.
  - Lorazepam 0.5 to 1 mg elixir or tablet dissolved in 0.5 mL water, administered against buccal mucosa every 4 hours to keep patient comfortable. If patient becomes more agitated after lorazepam, discontinue and contact hospice.
- For oral secretions or loud, wet respirations:
  - Atropine sulfate ophthalmic drops 1%, (2 drops orally or sublingually) every 4 hours as needed; or hyoscyamine drops (Levsin) (0.125-0.25 mg orally every 6 hours).
  - Scopolamine 1 to 3 transdermal patches every 72 hours.
- For unrelieved pain, dyspnea, nausea, vomiting, agitation, or secretions, call hospice.

Interventions to relieve symptoms of distress include positioning, administration of medications, and a variety of complementary and alternative therapies. When medications are used, they are often scheduled around the clock to maintain comfort and prevent reoccurrence of the symptom. The most common end-of-life symptoms that can cause the patient distress are:

- pain
- Weakness
- Breathlessness/dyspnea
- Nausea and vomiting
- Restlessness and agitation
- Seizures

Pain Management.

Pain is the most distressing symptom that dying patients fear the most. Diseases such as cancer often cause tumor pain as a result of the infiltration of cancer cells into organs, nerves, and bones. Other causes of pain in dying patients include osteoarthritis, muscle spasms, and stiff joints secondary to immobility.

Patients who have had their pain controlled with either short-acting or long-acting opioids should continue their scheduled doses to prevent reoccurrence of the pain. As patients get closer to death, however, they often lose the ability to swallow. Long-acting oral opioids generally cannot be crushed, and rotation to rectal, transdermal, intravenous, or a

subcutaneous route may be necessary. Short-acting opioids such as morphine sulfate, oxycodone, or hydromorphone elixir can be given sublingually, via the buccal mucosa, or rectally. They are quick-acting, effective, and safe to administer, even to comatose patients.

Considerations for Older Adults

Patient-Centered Care QSEN

Pain relief is often the priority need of older adults receiving palliation. But pain is often underreported and undertreated. Do not withhold opioid drugs from older adults. Instead, reduce starting doses, make dose increases slowly, and monitor for changes in mental status or excessive sedation.

Some experts in symptom management at end of life (EOL) recommend discontinuing routine doses of opioids such as morphine when patients become oliguric or anuric. The rationale for this decision is to decrease the risk for delirium that may occur as the result of a failing kidney's inability to excrete morphine metabolites from the body. If delirium is interfering with the patient's ability to achieve a quality end of life, changing the opioid to fentanyl IV is an option. Fentanyl does not have active metabolites, and the delirium may improve. For patients with known renal failure, fentanyl should ideally be used from the start of opioid administration. In cases where it cannot be easily obtained (i.e., when not available by sublingual route or IV route), oxycodone is a better choice over morphine. Chapter 3 describes in detail the management of chronic pain.

Complementary and Alternative Therapies.

Nonpharmacologic interventions are often integrated into the pain management plan. Some common approaches are presented here, as well as in Chapter 3.

Massage may decrease pain in people with cancer and is one of the most popular complementary interventions used for patients at EOL. This technique involves manipulating the patient's muscles and soft tissue, which improves circulation and promotes relaxation. Patients who are severely weak, are arthritic, or have advanced age may not tolerate extensive massage but may benefit from a short treatment to sites of their choice. In working with patients with cancer, use light pressure and avoid deep or intense pressure. Massage should not be done over the site of tissue damage (e.g., open wounds, tissue undergoing radiation

therapy), in patients with bleeding disorders, and in those who are uncomfortable with touch.

Music therapy is another complementary therapy used by people near end of life that has been shown to decrease pain by promoting relaxation. Select music based on patient preferences and values.

Therapeutic Touch involves moving one's hands through the patient's energy field to relieve pain. Reiki therapy is another type of energy therapy being evaluated for its role in pain and symptom management. Use of Reiki requires a Reiki practitioner who is trained in the method.

Aromatherapy can be used in conjunction with other treatments to relieve pain near EOL. It is thought to decrease pain by promoting relaxation and reducing anxiety. Lavender, capsicum, bergamot, chamomile, rose, ginger, rosemary, lemongrass, sage, and camphor have been used in end-of-life care.

NCLEX Examination Challenge

Physiological Integrity

A client with metastasis to the bone is receiving IV antibiotics for pneumonia but has declined further treatment for his disease. He is experiencing severe back pain rated as a 9 on a 0-to-10 scale. What interventions are the most appropriate for the nurse to implement for this client? **Select all that apply.**

A Provide both non-opioid and opioid analgesics.
B Offer music therapy to help the client relax and decrease anxiety.
C Obtain an order for physical therapy to encourage ambulation.
D Help the client assume the best position of comfort.
E Offer Reiki therapy, if available.

Weakness Management.

Patients commonly experience weakness and fatigue as death nears. Weakness combined with decreased neurologic function may impair the ability to swallow (dysphagia). Once the patient has difficulty swallowing, oral intake should be limited to soft foods and sips of liquids, only if the patient wants. Teach families about the risk for aspiration, and reassure them that anorexia is normal at this stage. Families often have difficulty accepting that their loved ones are not being fed and may request that IV fluids be started. With great sensitivity, reinforce that stopping food and liquid intake is a natural process. Inform families that giving fluids can actually increase discomfort in a person with multisystem slowdown

(Buck, 2012). Discomfort from fluid replacement could lead to respiratory secretions (and distress), increased GI secretions, nausea, vomiting, edema, and ascites. Most experts believe that dehydration in the last hours of life (i.e., terminal dehydration) does not cause distress and may stimulate endorphin release that promotes the patient's sense of well-being. To avoid a dry mouth and lips, moisten them with soft applicators and apply an emollient to soften the lips.

Nursing Safety Priority QSEN

Action Alert

Dysphagia near death presents a problem for oral drug therapy. Although some tablets may be crushed, drugs such as sustained-release capsules should not be taken apart. Reassess the need for each medication. Collaborate with the prescriber about discontinuing drugs that are not needed to control pain, dyspnea, agitation, nausea, vomiting, cardiac workload, or seizures. In collaboration with a pharmacist experienced in palliation, identify alternative routes and/or alternative drugs to maintain control of symptoms. Choose the least invasive route such as oral, buccal mucosa (inside cheek), transdermal (via the skin), or rectal. Some oral drugs can be given rectally. Depending on the patient needs, the subcutaneous or IV routes may be used if access is available. The IM route is almost never used at the end of life because it is considered painful and drug distribution varies among patients.

Breathlessness/Dyspnea Management.

Dyspnea is a subjective experience in which the patient has an uncomfortable feeling of breathlessness, often described as terrifying. It is a common symptom of distress near the end of life, especially among older adults because of decreased oxygen reserves associated with aging. Patients, families, and health care providers often consider it the major cause of suffering at end of life. Dyspnea can be:

- Directly related to the primary diagnosis (e.g., lung cancer, breast cancer, coronary artery disease)
- Secondary to the primary diagnosis (e.g., pleural effusion)
- Related to treatment of the primary disease (e.g., heart failure caused by chemotherapy, pneumonitis or constrictive pericarditis caused by radiation therapy, anemia related to chemotherapy)
- Unrelated to the primary disease (e.g., pneumonia or congestive heart failure [CHF]).

Depending on the cause, the pathophysiology of dyspnea can involve:

- Obstructive, restrictive, or vascular disturbances in the airways with tumor or lymph node involvement
- Pulmonary congestion secondary to fluid overload and/or cardiac dysfunction
- Bronchoconstriction and bronchospasm as seen with respiratory infection, chronic obstructive pulmonary disease (COPD), or airway blockage by a tumor
- Decreased hemoglobin-carrying capacity as with anemia
- Hyperventilation secondary to neuromuscular disease with limited movement of the diaphragm

Perform a thorough assessment of the patient's dyspnea. Include onset, severity (e.g., 0-to-10 scale), and precipitating factors. Precipitating factors may include time of day, position, anxiety, pain, cough, or emotional distress.

Pharmacologic interventions should begin early in the course of dyspnea near death. Nonpharmacologic interventions can be used in conjunction with but not in place of drug therapy.

Opioids such as morphine sulfate are the standard treatment for dyspnea near death. They work by (1) altering the perception of air hunger, reducing anxiety and associated oxygen consumption and (2) reducing pulmonary congestion by dilating pulmonary blood vessels. Patients who have not been receiving opioids are given starting doses of morphine 5 to 6 mg (or less for patients of advanced age) orally every 4 hours during the day and 10 mg at bedtime. If dyspnea occurs only with activity, give morphine before the activity up to every 2 hours. Those who are taking morphine or other opioids for pain may need higher doses for breathlessness, at times up to 50% more than their usual dose.

If a patient is having severe respiratory distress and poor oxygenation, morphine by mouth may need to be repeated as often as every 30 minutes and an IV or subcutaneous route may need to be established. Subcutaneous or intravenous doses of 1 to 2 mg of morphine may be given every 5 to 10 minutes until dyspnea is relieved.

Oxygen therapy for dyspnea near death has not been established as a standard of care for all patients. However, those who do not respond promptly to morphine or other drugs should be tried on oxygen (2 to 6 L by nasal cannula) to assess its effect. Patients often feel more comfortable when the oxygen saturation is greater than 90%. If possible, provide oxygen by nasal cannula (NC) because masks can be frightening. If oxygen is not effective, discontinue it.

Nursing Safety Priority QSEN

Action Alert

Offer oxygen to any patient with dyspnea near death, regardless of his or her oxygen saturation, because comfort is the desired outcome. If the patient is feeling dyspneic even though the oxygen saturation is above 90%, be sure that he or she receives oxygen to relieve respiratory distress. In addition, offer a fan directed toward the patient's face. Some patients find the circulating air more comfortable than oxygen therapy.

Bronchodilators, such as albuterol (Proventil) or ipratropium bromide (Atrovent, Apo-Ipravent) via a metered dose inhaler (MDI) or nebulizer, may be given for symptoms of bronchospasm (heard as wheezes). *Corticosteroids*, such as prednisone (Deltasone, Winpred), may also be given for bronchospasm and inflammatory problems within and outside the lung. Superior vena cava syndrome and cancer-related lymphangitis causing dyspnea may also respond to corticosteroids (also see Chapter 22).

People who have fluid overload with dyspnea, crackles on auscultation, peripheral edema, and other signs of CHF may be given a *diuretic* such as furosemide (Lasix, Uritol) to decrease blood volume, reduce vascular congestion, and reduce the workload of the heart. Furosemide can be administered by mouth, IV, or subcutaneously. IV push administration, which is effective within minutes, may be preferred for heart failure and pulmonary edema.

Antibiotics may be indicated for dyspnea from a respiratory infection. A thorough workup for a respiratory infection is not appropriate when death is imminent. However, if signs or symptoms of a respiratory infection occur with dyspnea, a trial of an appropriate antibiotic may be considered to make the patient comfortable.

Secretions in the respiratory tract and oral cavity may also contribute to dyspnea near death. Loud, wet respirations (referred to as **death rattle**) are disturbing to family and caregivers even when they do not seem to cause dyspnea or respiratory distress. Reposition the patient onto one side to reduce gurgling, and place a small towel under his or her mouth to collect secretions. *Anticholinergics,* such as atropine (ophthalmic) solution 1% given sublingually every 4 hours as needed or hyoscyamine (Levsin) every 6 hours, are commonly given to dry up secretions. Scopolamine may also be given transdermally to reduce secretion production. Oropharyngeal suctioning is not recommended for loud

secretions in the bronchi or oropharynx because it is often not effective and may only agitate the patient.

Fear and anxiety may be components of respiratory distress at end of life. For this reason, benzodiazepines are commonly given when morphine does not fully control the person's dyspnea. Low-dose lorazepam (Ativan) is administered orally, sublingually, or IV every 4 hours as needed or around the clock.

Nonpharmacologic interventions include:

- Applying wet cloths on the patient's face
- Positioning the patient with the head of the bed up either in a hospital bed or a reclining chair to increase chest expansion
- Encouraging imagery and deep breathing

Insertion of a urinary (Foley) catheter to avoid the need for exertion with voiding may be a comfort measure if the patient or family agrees. Risk for infection should not be a consideration when a person is near death.

NCLEX Examination Challenge

Physiological Integrity

The nurse is caring for a client who has severe dyspnea because of end-stage chronic obstructive pulmonary disease. Which interventions are the most appropriate to help improve his breathing? **Select all that apply.**

A Administer morphine sulfate on an around-the-clock schedule.
B Teach the client and family to keep him in a sitting position.
C Use a large electric fan to circulate the air.
D Keep the room temperature warm to prevent respiratory infection.
E Teach the client and family that he should use bronchodilators as prescribed.

Nausea and Vomiting Management.

Although not as common a problem as pain or dyspnea, nausea and vomiting occur frequently among terminally ill patients during the last week of life. It is particularly common in patients with acquired immune deficiency syndrome (AIDS) and with breast, stomach, or gynecologic cancers.

Other causes of nausea and vomiting at the end of life include:

- Uremia (increased serum urea nitrogen)
- Hypercalcemia

- Increased intracranial pressure
- Constipation or impaction
- Bowel obstruction

If constipation is identified as the cause of nausea and vomiting, give the patient a biphosphate enema (e.g., Fleet) to remove stool quickly. If stool in the rectum cannot be evacuated, a mineral oil enema followed by gentle disimpaction may relieve the patient's distress. Nausea and vomiting related to other causes can be controlled by one or more antiemetic agents such as prochlorperazine (Compazine), ondansetron (Zofran), dexamethasone (Decadron, Deronil, Dexasone), or metoclopramide (Reglan, Maxeran). Based on a patient's response, one or more of these drugs may be combined and compounded into rectal suppositories or oral troches. In addition to providing medications, be sure to remove sources of odors and keep the room temperature at a level that the patient desires.

Complementary and Alternative Therapies.

Aromatherapy using chamomile, camphor, fennel, lavender, peppermint, and rose may reduce or relieve vomiting. Some patients, however, may have worse nausea with aroma. Ask the patient and family about their preferences, and respect culturally established practices.

Agitation and Delirium Management.

Agitation at the end of life first requires assessing for pain or urinary retention, constipation, or another reversible cause. If constipation is ruled out as the cause and if analgesia and catheterization do not relieve restlessness, delirium (acute confusion) is suspected. ***Delirium*** *is a neuropsychiatric syndrome manifested by an acute change in the level of arousal. Clinical manifestations include altered sleep/wake cycle, mumbling speech, disturbance of memory and attention, and perceptual disturbances with delusions and hallucinations.* Delirium can be hyperactive or hypoactive. *Hypoactive (quiet)* delirium is probably not uncomfortable for patients. *Agitated (noisy)* delirium with emotional and behavioral symptoms (e.g., yelling, hallucinations) can be uncomfortable, especially for family. Chapter 2 discusses delirium in more detail.

When delirium occurs in the week or two before death, it is referred to as *terminal delirium*. Possible causes include the adverse effects of opioids, benzodiazepines, anticholinergics, or steroids. If drugs are suspected causes, they may be decreased or discontinued, particularly if recently started.

Nursing Safety Priority QSEN

Drug Alert

Do not give the patient more than one antipsychotic drug at a time because of the risk for adverse drug events (ADEs). A neuroleptic such as a low dose of haloperidol (Haldol, Peridol) 0.5-2 mg orally, IV, subcutaneously, or rectally is commonly used at end of life. Although haloperidol has the potential to cause extrapyramidal symptoms or adverse cardiovascular events and death in older adults with dementia, the benefits of treating delirium usually outweigh the risks.

Benzodiazepines are not generally used as a first choice for older adults with agitation because of their risk for causing delirium. Development of increased agitation after receiving a benzodiazepine could represent a paradoxical reaction—the opposite of what is expected.

Complementary and Alternative Therapies.

Music therapy may produce relaxation by quieting the mind and promoting a restful state. Aromatherapy with chamomile may also help overcome anxiety, anger, tension, stress, and insomnia in dying patients.

Seizure Management.

Seizures are not common at end of life but may occur in patients with brain tumors, advanced AIDS, and pre-existing seizure disorders. Around-the-clock drug therapy is needed to maintain a high seizure threshold for patients who can no longer swallow antiepileptic drugs (AEDs) and are at risk for seizures. Benzodiazepines, such as diazepam (Valium) and lorazepam (Ativan), are the drugs of choice. For home use, rectal diazepam gel or sublingual lorazepam oral solution (2 mg/mL) may be preferred. As a second choice, barbiturates such as phenobarbital may be given rectally or IV.

Management of the Refractory Symptoms of Distress.

Patients receiving opioids for pain or dyspnea and other drugs such as antiemetics or antianxiety agents may experience mild sedation as a side effect to therapy. Depending on the patient and how soon death is expected, this side effect may decrease with time. What is important to understand is that drug therapy for symptoms of distress at end of life are guided by protocols, using medications believed to be safe, with the intent of alleviating suffering. *There is no evidence that administering medications for symptoms of distress using established protocols hastens*

deaths. The ethical responsibility of the nurse in caring for patients near death is to follow guidelines for drug use to manage symptoms and to facilitate prompt and effective symptom management until death (Arnstein & Robinson, 2011).

A small percentage of patients have refractory symptoms of distress that do not respond to treatment near the end of life. These patients may be candidates for **proportionate palliative sedation**—a care management approach involving the administration of drugs such as benzodiazepines (e.g., midazolam [Versed]), neuroleptics, barbiturates, or anesthetic agents (e.g., propofol [Diprivan]) for the purpose of "lowering of patient consciousness." *The intent of palliative sedation to promote comfort and not hasten death distinguishes it from euthanasia (discussed later in this chapter).* The use of palliative sedation for refractory symptoms of distress is supported by a consensus of experts in palliative care as a comfort therapy of last resort (Arnstein & Robinson, 2011).

Psychosocial Management.

The personal experience of dying or of losing a loved one through death is life altering. Unexpected deaths, particularly in young people, tend to be most traumatic. When a person has a chronic life-threatening disease, he or she and the family may have some knowledge of the expected outcome. Others, however, may have never considered their illness to be potentially terminal. It is important to first assess what patients and family understand about their illness and then help them identify the desired outcomes for care in the context of the illness.

Whereas death is the termination of life, dying is a process. People facing death may demonstrate emotional signs and symptoms of their response to the dying process through behaviors that equate to saying goodbye or through actual withdrawal. Some patients attempt to make families feel better by reassuring them that everything will be fine. Teach families that such behaviors are normal to the process of dying (see Chart 7-2).

Assisting Patients During the Grieving Process.

Grief is the emotional feeling related to the perception of the loss. Patients who are dying suffer not only from the anticipated death but also from the loss of the ability to engage with others and in the world. **Mourning** is the outward social expression of the loss. Interventions to assist patients and families in grieving and mourning are based on cultural beliefs, values, and practices. Some patients and their families express their grief openly and loudly, whereas others are quiet and

reserved. Table 7-3 lists basic beliefs regarding death, dying, and afterlife for some of the major religions.

TABLE 7-3

Basic Beliefs Regarding Care at End of Life and Death Rituals for Selected Religions

Christianity
• There are many Christian denominations, which have variations in beliefs regarding medical care near end of life. • Roman Catholic tradition encourages people to receive Sacrament of the Sick, administered by a priest at any point during an illness. This sacrament may be administered more than once. Not receiving this sacrament will NOT prohibit them from entering heaven after death. • People may be baptized as Roman Catholics in an emergency situation (e.g., person is dying) by a layperson. Otherwise, they are baptized by a priest. • Christians believe in an afterlife of heaven or hell once the soul has left the body after death.
Judaism
• The dying person is encouraged to recite the confessional or the affirmation of faith, called the *Shema*. • According to Jewish law, a person who is extremely ill and dying should not be left alone. • The body, which was the vessel and vehicle to the soul, deserves reverence and respect. • The body should not be left unattended until the funeral, which should take place as soon as possible (preferably within 24 hours). • Autopsies are not allowed by Orthodox Jews, except under special circumstances. • The body should not be embalmed, displayed, or cremated.
Islam
• Based on belief in one God Allah and his prophet Muhammad. Qur'an is the scripture of Islam, composed of Muhammad's revelations of the Word of God (Allah). • Death is seen as the beginning of a new and better life. • God has prescribed an appointed time of death for everyone. • Qur'an encourages humans to seek treatment and not to refuse treatment. Belief is that only Allah cures but that Allah cures through the work of humans. • Upon death, the eyelids are to be closed and the body should be covered. Before moving and handling the body, contact someone from the person's mosque to perform rituals of bathing and wrapping body in cloth.

Data from Giger, J.N. (2013). *Transcultural nursing: Assessment and intervention* (6th ed.). St. Louis: Mosby.

Nursing interventions are aimed at providing appropriate emotional support to allow patients and their families to verbalize their fears and concerns. Support includes keeping the patient and family involved in health care decisions and emphasizing that the goal is to keep the patient as comfortable as possible until death. Interventions for providing psychosocial support are summarized in Chart 7-4.

Chart 7-4 Best Practice for Patient Safety & Quality Care QSEN

Psychosocial Interventions for Care of the Dying Patient and the Family

- Offer physical and emotional support by "being with" the patient.
- Respect cultural preferences.
- Be realistic.
- Encourage reminiscence.
- Promote spirituality.
- Avoid explanations of the loss.
- Communicate with the patient.
- Provide referrals to bereavement specialists.
- Teach about the physical signs of death (see Chart 9-1).
- Ensure that the patient is receiving palliative care, with an emphasis on

symptom management.

Intervene with those grieving an impending death by "being with" as opposed to "being there." "Being with" implies that you are physically and psychologically with the grieving patient, empathizing to provide emotional support. Listening and acknowledging the legitimacy of the patient's and/or family's impending loss are often more therapeutic than speaking; this concept is often referred to as **presence.** Nurses facilitate the expression of grief by giving the person who is mourning permission to express himself or herself. Your manner and words show that these expressions of grief are acceptable and expected. An example of therapeutic communication might be "This must be very difficult for you" or "I'm sorry this is happening."

Do not minimize a patient's or family member's pain of loss. Avoid trite assurances such as "Things will be fine. Don't cry," "Don't be upset. She wouldn't want it that way," or "In a year you will have forgotten." Such comments can be barriers to demonstrating care and concern. Accept whatever the grieving person says about the situation. Remain present, be ready to listen attentively, and guide gently. In this way, you can help the bereaved family and significant others prepare for the necessary reminiscence and integration of the loss.

Storytelling through reminiscence and life review can be an important activity for patients who are dying. **Life review** is a structured process of reflecting on one's life, which is often facilitated by an interviewer. **Reminiscence** is the process of randomly reflecting on memories of events in one's life. The benefits of storytelling through either method provide the ability to attain perspective and enhance meaning. Suggest that the patient and family record autobiographic stories (print or video), write memories in a journal, or develop a scrapbook. Young dying parents often write letters for their children to read when they are older. If the patient does not have enough energy for these activities, familiar objects such as photographs and favorite jewelry can be used to spark ideas for stories.

Meeting Spiritual Needs.

Spirituality is whatever or whoever gives ultimate meaning and purpose in one's life that invites particular ways of being in the world in relation to others, oneself, and the universe. A person's spirituality may or may not include belief in God. **Religions** are formal belief systems that provide a framework for making sense of life, death, and suffering and responding to universal spiritual questions. Religions often have beliefs,

rituals, texts, and other practices that are shared by a community. For some patients, spirituality and religion can help them cope with the thought of death, contributing to quality of life during the dying process.

Perform a spiritual assessment to identify the patient's spiritual needs and to facilitate open expression of his or her beliefs and needs. A spiritual assessment could start with questions such as "What is important to you?" or "What gives you meaning or purpose in your life?"

Cultural Considerations

Patient-Centered Care QSEN

When assessing the spiritual needs of the dying patient, consider end-of-life preferences based on ethnic beliefs and practices. For example, the medicine wheel represents the spiritual journey to find one's own path for indigenous people in many countries, including American Indians (e.g., Cherokee, Navajo, Lakota) and Aboriginal people (e.g., Inuit, First Nations) in Canada and Alaska (also known as *Alaska Natives*). The medicine wheel helps people in these groups maintain balance and harmony within four life dimensions (Clarke & Holtslander, 2010) (Fig. 7-2). Depending on specific tribal practices and beliefs, the dimensions may be represented by colors, seasons, or directions.

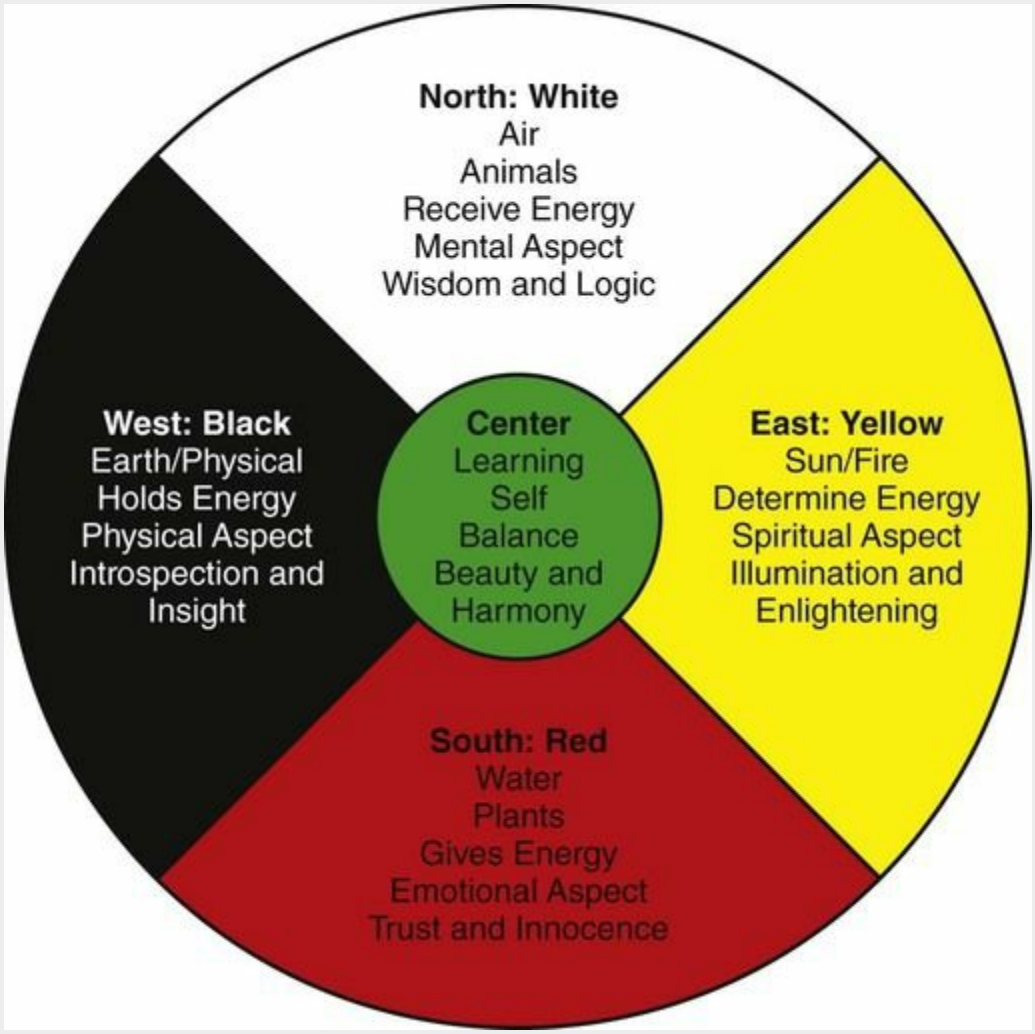

FIG. 7-2 An example of a medicine wheel used by indigenous people to provide harmony and balance in life and transition into the spirit worlds after death.

As part of the dying process, certain tribal ceremonies must take place for patients to have a peaceful transition into the Spirit World and experience a "good death." One special ceremony involves smudging: Selected tribal medicines are burned, and the smoke is passed over the patient's body to cleanse it.

Be aware that supporting patients and their families within their cultural framework is essential as part of the dying process for all patients. Respect all practices, and allow for privacy during ceremonies and ritual practices.

Regardless of whether a person has had an affiliation with a religion or a belief in God or other Supreme Being, he or she can experience what is referred to as *spiritual* or *existential distress.* Existential distress is brought about by the actual or perceived threat to one's continued existence. Terminal illness and facing death can pose a profound threat to one's personhood. The main task for a person at EOL is coming to terms with

one's losses, which may include loss of meaning and loss of relationships and facing the unknown. Acknowledge the patient's spiritual pain, and encourage verbalization. Use a family tree to discuss relationships, fears, hopes, and unfinished business. If the patient or family prefers, arrange for counseling with chaplains or others trained in end-of-life care. *Do not try to explain the loss in philosophic or religious terms.* Statements such as "Everything happens for the best" or "God sends us only as much as we can bear" are not helpful when the person has yet to express feelings of anguish or anger.

Although emotionally challenging, witnessing the death of a loved one may help facilitate the family to accept death. Witnessing how ill a person is makes the event real and enhances an understanding of how disease affects bodily function and decline. Describe the physical signs in detail—realistic enough to be unmistakable yet not so graphic as to alarm the listeners (see Chart 7-1). Booklets with this information should be provided to families to help them see what is expected and "normal" to the dying process.

Families witnessing the dying process often have difficulty distinguishing what is a normal finding of decline from signs and symptoms of distress. Instructing families on signs and symptoms of pain (e.g., grimacing, moaning, guarding behaviors) or dyspnea is essential. Emphasize that in the absence of dyspnea or pain, patients often die very peacefully with cessation of breathing. Nurses and family members know that a person has died when he or she stops breathing. Chart 7-5 lists other physical manifestations of death.

Chart 7-5 Patient and Family Education: Preparing for Self-Management

Signs That Death Has Occurred

- Breathing stops.
- Heart stops beating.
- Pupils become fixed and dilated.
- Body color becomes pale and waxen.
- Body temperature drops.
- Muscles and sphincters relax.
- Urine and stool may be released.
- Eyes may remain open, and there is no blinking.
- The jaw may fall open.
- Observers may hear trickling of fluids internally.

Postmortem Care

If the death was in the home and expected, emergency assistance should not be notified. If the person was a patient in a hospice program, the family calls hospice. If a death is unexpected or suspicious, the medical examiner is notified. Otherwise, the nurse or physician performs the pronouncement and completes a death certificate (Chart 7-6). Most states allow nurses to pronounce death in nursing homes and other long-term care facilities, but only a few states permit nurses to pronounce in acute care facilities such as hospitals. Be sure to check your health care agency's policies for who can pronounce death and the specific procedure to follow.

Chart 7-6 Best Practice for Patient Safety & Quality Care QSEN

Pronouncement of Death

- Note time of death that the family or staff reported the cessation of respirations.
- Identify the patient by the hospital identification (ID) tag; note the general appearance of the body.
- Ascertain that the patient does not rouse to verbal or tactile stimuli. Avoid overtly painful stimuli, especially if family members are present.
- Auscultate for the absence of heart sounds; palpate for the absence of carotid pulse.
- Look and listen for the absence of spontaneous respirations.
- Record the time at which your assessment was completed.
- Document the time of pronouncement and all notifications in the medical record (i.e., to attending physician). Document if the medical examiner needs to be notified (may be required for unexpected or suspicious death). Document if an autopsy is planned per the attending physician and family.
- If your state and agency policy allows an RN to pronounce death, document as indicated on the death certificate.

After the patient dies, ask the family or other caregivers if they would like to spend time with the patient to assist them in coping with what has happened and say their good-byes. Even if the death has been anticipated, no one knows how he or she will feel until it occurs. It may take hours to days to weeks or months for each person to realize the full effect of the event. Some family members may find it therapeutic to

bathe and prepare the person's body for transfer to the funeral home or the hospital morgue. Offer families this opportunity if it is culturally acceptable.

Before preparing the body for transfer, ask the physician whether an autopsy will be required. When the death is expected, an autopsy is not likely. An autopsy is generally performed only when the cause of death is not known. Some religions do not allow autopsies, such as Orthodox Jews.

After the family or significant others view the body, follow agency procedure for preparing the patient for transfer to either the morgue or a funeral home. In the hospital, a postmortem kit is generally used with a shroud and identification tags. Chart 7-7 describes best practice guidelines for postmortem care.

Chart 7-7 Best Practice for Patient Safety & Quality Care QSEN

Postmortem Care

- Provide all care with respect to communicate that the person was important and valued.
- Ask the family or significant others if they wish to help wash the patient or comb his or her hair; respect and follow their cultural practices for body preparation.
- If no autopsy is planned, remove or cut all tubes and lines according to agency policy.
- Close the patient's eyes unless the cultural/religious practice is for a family member or other person to close the eyes.
- Insert dentures if the patient wore them.
- Straighten the patient, and lower the bed to a flat position.
- Place a pillow under the patient's head.
- Wash the patient as needed, and comb and arrange the patient's hair unless the family desires to perform bathing and body preparation.
- Place waterproof pads under the patient's hips and around the perineum to absorb any excrement.
- Clean the patient's room or unit.
- Allow the family or significant others to see the patient in private and to perform any religious or cultural customs they wish (e.g., prayer).
- Assess that all who need to see the patient have done so, before transferring to the funeral home or morgue.
- Notify the hospital chaplain or appropriate religious leader if requested

by the family or significant others.
- Ensure that the nurse or physician has completed and signed the death certificate.
- Prepare the patient for transfer to either a morgue or funeral home; wrap the patient in a shroud (unless the family has a special shroud to use), and attach identification tags per agency policy.

The Concept of Euthanasia

Nurses are usually in the best and most immediate position to discuss end-of-life issues. This includes assisting in the decision-making process regarding immediate or future needs. To do this, nurses must be knowledgeable about terminology and ethical issues related to death and dying (Table 7-4).

TABLE 7-4

Definitions of Ethical Concepts Related to Issues at End of Life

Withdrawing or withholding life-sustaining therapy (formerly called *passive euthanasia*) An act of omission (e.g., withholding or withdrawing treatment) that might prolong the life of a person who cannot be cured by the treatment. In this situation, the withdrawal of the intervention does not directly cause the patient's death.
Principle of double effect Involves taking an action intended to have a good effect, which also has a known harmful effect. This is not active euthanasia.
Voluntary active euthanasia An act by which the causative agent or treatment in the death of a patient is administered directly by another.
Involuntary active euthanasia The action to end the patient's life is taken without the patient's consent.
Physician-assisted suicide A practice whereby a physician provides a means (e.g., medication) to a patient with the knowledge that the patient will use the means to commit suicide.

Much confusion exists regarding the concept of euthanasia. **Withdrawing or withholding life-sustaining therapy,** formerly called **passive euthanasia,** involves discontinuing one or more therapies that might prolong the life of a person who cannot be cured by the therapy. Another phrase sometimes used is "letting the person die naturally" or "allowing natural death (AND)," as discussed earlier in this chapter. *In this situation, the withdrawal of the intervention does not directly cause the patient's death.* The progression of the patient's disease or poor health status is the cause of death. Professional organizations (e.g., American Nurses Association, American Medical Association) and religious communities (e.g., the Catholic church) support the right of patients and their surrogate decision makers to refuse or stop treatment (e.g., mechanical ventilation, antibiotics, IV fluids) when patients are close to death and interventions are considered medically futile and/or capable of causing harm. The U.S. court system also supports withdrawal of aggressive treatment and the rights of surrogate decision makers to refuse or stop treatment.

By contrast, **active euthanasia** requires that health care providers take action (e.g., give medication or treatment) that purposefully and directly causes the patient's death. *Active euthanasia is not supported by most professional organizations, including the American Nurses Association.* In the states of Oregon, Washington, and Vermont, physician-assisted suicide is legal in certain situations. Nurses should not be involved in active euthanasia or physician-assisted euthanasia. They do, however, play a major role in end-of-life care by advocating for patients' wishes and ensuring quality symptom management and support at the end of life.

Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Hospice care uses an interdisciplinary approach to assess and address the holistic needs of patients who have a 6-month prognosis or less; examples of health care team members include the social worker, case manager, pharmacist, and physician. **Teamwork and Collaboration** QSEN
- Assess the patient and family to determine if they have written advance directives, such as a durable power of attorney for health care (DPOAHC), a living will, or portable DNR.
- The decision by DPOAHC to withdraw or withhold life-sustaining therapy is supported by the U.S. Supreme Court and other professional/religious organizations.
- Be aware that active euthanasia involves giving a patient a treatment or agent that causes death (see Table 7-4) and is legal only in Oregon, Washington State, and Vermont under certain circumstances.
- Be aware that nurses have an ethical obligation to provide timely information about expected care outcomes so that patients and families can make the best EOL decisions.

Health Promotion and Maintenance

- Stress the importance of having a DPOAHC to inform health care providers of your wishes if you lack capacity.
- Teach the patient and family that an advance directive is a written document that specifies what, if any, extraordinary actions the patient would want if he or she could no longer make decisions about care.

Psychosocial Integrity

- Assess the patient's emotional signs of impending death; assess coping ability of the patient and family or other caregiver (see Chart 7-2).
- Incorporate the patient's personal cultural practices and spiritual beliefs regarding death and dying (see Table 7-3). **Patient-Centered Care** QSEN
- Be aware that people facing death may experience fear and anxiety about their impending death and experience difficulty coping.
- Provide psychosocial interventions to support the patient and family

during the dying process, as listed in Chart 7-4.

Physiological Integrity

- Death is defined as the cessation of integrated tissue and organ function, manifested by cessation of heartbeat, absence of spontaneous respirations, or irreversible brain dysfunction.
- Hospice and palliative care are different, as described in Table 7-2.
- Assess the patient for pain, dyspnea, agitation, nausea, and vomiting, which are common problems at the end of life. **Evidence-Based Practice** QSEN
- Recognize that older adults are often undertreated for pain or other symptoms at EOL.
- Assess for the common physical signs of approaching death, as listed in Chart 7-1.
- Medications are frequently given to control dyspnea, pain, nausea, vomiting, and agitation in patients near death (see Chart 7-3).
- Because of the risk for delirium, particularly in older adults, providers may avoid use of benzodiazepines for treatment of anxiety, even at end of life. Development of increased agitation after receiving benzodiazepine could represent a paradoxical reaction. **Safety** QSEN
- Terminal delirium may occur in a week or two before death. Haloperidol given orally or IV is the drug of choice.
- Assessment of oxygen saturation for patients at end of life is not necessary. Oxygen should be provided based on comfort. **Evidence-Based Practice** QSEN
- Common complementary and alternative therapies used for symptom management at end of life include aromatherapy, music therapy, and energy therapies, such as Therapeutic Touch.
- Follow Chart 7-7 for best practice guidelines for performing postmortem care; incorporate the patient's cultural and religious beliefs in body preparation and burial (see Table 7-3). **Patient-Centered Care** QSEN

UNIT II

Concepts of Emergency Care and Disaster Preparedness

OUTLINE

CHAPTER 8

Concepts of Emergency and Trauma Nursing

Linda Laskowski-Jones and Karen L. Toulson

PRIORITY CONCEPTS

- Safety
- Teamwork and Collaboration
- Communication

Learning Outcomes

Safe and Effective Care Environment

1. Describe the emergency department (ED) environment, including vulnerable populations and interdisciplinary team members.
2. Engage in collaboration with members of the interdisciplinary health care team members in the ED.
3. Plan and implement best practices to maintain staff and patient safety in the ED.
4. Explain selected core competencies that nurses need to function in the ED.
5. Triage patients in the ED to prioritize the order of care delivery.
6. Prioritize resuscitation interventions based on the primary survey of the injured patient.

Psychosocial Integrity

7. Describe the role of the ED nurse in providing support for families after the death of a loved one.

Physiological Integrity

8. Describe the general process of admission through disposition of a

patient in the ED.

9. Prevent or reduce common risk factors in the ED that contribute to adverse events in older adults.

 http://evolve.elsevier.com/Iggy/

The demand for emergency care in the United States is growing rapidly. Emergency departments (EDs) function as safety nets for communities of all sizes by providing services to both insured and uninsured patients seeking medical care. They are also responsible for safety through public health surveillance and emergency disaster preparedness. Some hospital-based emergency departments also provide observation, procedural care, and employee or occupational health services. Other hospital-based emergency departments have interdisciplinary specialty teams who take part in collaboration to provide first-line care for patients with stroke and cardiac problems (Alberts et al., 2011). The role of the ED is so vital that the Centers for Medicare and Medicaid Services (2013) has a process for designating small rural facilities of 25 inpatient beds or fewer as **critical access hospitals** if they provide around-the-clock emergency care services 7 days a week. Critical access hospitals are considered *necessary providers of health care* to community residents that are not close to other hospitals in a given region.

Because of the multi-specialty nature of the environment, EDs play a unique role within the U.S. health care system. More than 119 million people visit the ED each year (Centers for Disease Control and Prevention [CDC], 2010). The demand for emergency care has greatly increased over the past 15 years, and the health care consumer has higher expectations. However, the capacity to provide necessary resources has not kept pace in most systems. Emergency department crowding occurs when the need for care exceeds available resources in the department, hospital, or both (Howard, 2009). The Joint Commission has established a set of metrics (Core Measure Sets) based on ED length of stay (LOS) that hospitals are required to submit. The longer the ED length of stay for admitted patients, the more overcrowded the ED becomes. That, in turn, limits access to other patients who are in need of ED beds for emergency care. A prolonged LOS also indicates problems with inpatient bed availability and poor overall hospital throughput.

Health care reform initiatives stemming from the Affordable Care Act will certainly impact emergency services; the full spectrum of that impact

is currently evolving. The widespread availability of health insurance may produce an increase in the number of patients who use the emergency department because they now have greater access to the necessary financial resources. Emergency department use may actually decrease for some types of patients as hospitals and providers partner in Accountable Care Organization models. This will better control costs by managing patient outcomes through primary care networks and disease management programs. Emergency departments may also experience a shift in focus from admitting the majority of acutely ill patients to the hospital for care to collaborating more with home care services and establishing better access to resources in the community to enable patients to be safely discharged home from the ED when possible.

The Emergency Department Environment of Care

In the emergency care environment, rapid change is the rule. The typical ED is fast paced and, at the height of activity, might even appear chaotic. Patients seek treatment for a number of physical, psychological, spiritual, and social reasons. In general, nurses work in this environment because they dislike routines and thrive in challenging, stimulating work settings. Although most EDs have treatment areas that are designated for certain populations such as patients with trauma or cardiac, psychiatric, or gynecologic problems, care can actually take place almost anywhere. In a crowded ED, patients may receive initial treatment outside of the usual treatment rooms, including the waiting room and hallways.

The ED is typically alive with activity and noise, although the pace decreases at times because arrivals are random. Emergency nurses can expect background sounds that include ringing telephones, monitor alarms, vocal patients, crying children, and radio transmissions between staff and incoming ambulance or helicopter personnel. Interruptions and distractions are the norm, and the nurse must ensure these events do not impact patient safety.

Demographic Data and Vulnerable Populations

Staff members in the ED provide care for people across the life span with a broad spectrum of issues, illnesses, and injuries—as well as various cultural and religious values. Especially vulnerable populations who visit the ED include the homeless, the poor, and older adults. During a given shift, for example, the emergency nurse may function as a cardiac nurse, a geriatric nurse, a psychiatric nurse, a pediatric nurse, and a trauma nurse. Patient acuity ranges from life-threatening emergencies to minor symptoms that could be addressed in a primary care office or community clinic. Some of the most common reasons that people seek ED care are:

- Abdominal pain
- Chest pain
- Breathing difficulties
- Injuries (especially falls in older adults)
- Headache
- Fever
- Pain (the most common symptom)

Considerations for Older Adults

Patient-Centered Care QSEN

Older adults usually visit the ED because of worsening of an existing chronic condition or because the condition affects their ability to perform ADLs. Older adults are also sometimes admitted from nursing homes or assisted-living facilities for procedures (e.g., insertion of a percutaneous endoscopic gastrostomy [PEG] tube or peripherally inserted central catheter [PICC]) or for treatments (e.g., blood transfusions). Some hospitals plan direct admission of the patient to same-day surgery or hold a bed for the procedure or treatment to bypass the ED. This arrangement decreases the patient's wait time and therefore decreases the risks for adverse events, such as pressure ulcer development or hospital-acquired infection. Incorporating family members of older adults into the ED care process can aid in overall patient evaluation, decision making, and satisfaction with the ED experience (Nikki et al., 2013).

Special Nursing Teams

Many EDs have specialized nursing teams that deal with high-risk populations of patients. One example is the forensic nurse examiner team. **Forensic nurse examiners (RN-FNEs)** are educated to obtain patient histories, collect forensic evidence, and offer counseling and follow-up care for victims of rape, child abuse, and domestic violence—also known as *intimate partner violence (IPV)* (Desy, 2010). They are trained to recognize evidence of abuse and to intervene on the patient's behalf. Forensic nurses who specialize in helping victims of sexual assault are called *sexual assault nurse examiners (SANEs)* or *sexual assault forensic examiners (SAFEs)*.

Interventions performed by forensic nurses may include providing information about developing a safety plan or how to escape a violent relationship. Forensic nurse examiners document injuries and collect physical and photographic evidence. They may also provide testimony in court as to what was observed during the examination and information about the type of care provided.

The **psychiatric crisis nurse team** is another example of an ED specialty team. Many patients who visit the ED for their acute problems also have chronic mental health disorders. The availability of mental health nurses can improve the quality of care delivered to these patients who require specialized interventions in the ED and can offer valuable expertise to the emergency health care staff. For example, the team evaluates patients with emotional behaviors or mental illness and facilitates the follow-up treatment plan, including possible admission to an appropriate

psychiatric facility. These nurses also interact with patients and families when sudden illness, serious injury, or death of a loved one may have caused a crisis. On-site interventions can help patients and families cope with these unexpected changes in their lives.

Interdisciplinary Team Collaboration

The emergency nurse is one member of the large interdisciplinary team who provides care for patients in the ED. A team approach to emergency care using collaboration is considered a standard of practice (Fig. 8-1). In this setting, the nurse coordinates care with all levels of health care team providers, from prehospital emergency medical services (EMS) personnel to physicians, hospital technicians, and professional and ancillary support staff.

FIG. 8-1 The ability to work as part of an interdisciplinary team is crucial to positive outcomes for emergency department (ED) patients.

Prehospital care providers are typically the first caregivers that

patients see before transport to the ED by an ambulance or helicopter (Fig. 8-2). Local protocols define the skill level of the EMS responders dispatched to provide assistance. **Emergency medical technicians (EMTs)** offer basic life support (BLS) interventions such as oxygen, basic wound care, splinting, spinal immobilization, and monitoring of vital signs. Some units carry automatic external defibrillators (AEDs) and may be authorized to administer selected drugs such as an EpiPen or nitroglycerin based on established medical protocols. For patients who require care that exceeds BLS resources, paramedics are usually dispatched. **Paramedics** are advanced life support (ALS) providers who can perform advanced techniques, which may include cardiac monitoring, advanced airway management and intubation, establishing IV access, and administering drugs en route to the ED (Fig. 8-3).

FIG. 8-2 Advanced life support helicopter arriving at emergency department landing zone. Helicopters are used to rapidly transport critically ill and injured patients to the hospital for emergent care.

FIG. 8-3 Prehospital providers take a patient from the ambulance to be brought into the emergency department.

The prehospital provider is a key source for valuable patient data. Emergency nurses rely on these providers to be the "eyes and ears" of the health care team in the prehospital setting and to ensure communication of this information to other staff members for continuity of care.

Another integral member of the emergency health care team is the **emergency medicine physician.** These medical professionals receive specialized education and training in emergency patient management. As emergency care has become increasingly complex and specialized, emergency medicine is a recognized physician specialty practice.

The emergency nurse interacts with a number of staff and community physicians involved in patient care but is involved in close collaboration with emergency medicine physicians. Even though other physician specialists may be involved in ED patient treatment, the emergency medicine physician typically directs the overall care in the department. Many EDs also employ nurse practitioners (NPs) and physician assistants (PAs) to assume designated roles in patient assessment and treatment. Teaching hospitals also have resident physicians who train in the ED. They act in collaboration with or under the supervision of the emergency medicine physician to assist with emergency care delivery.

The emergency nurse interacts and regularly takes part in collaboration with *professional and ancillary staff* who function in support roles. These personnel include radiology and ultrasound technicians, respiratory therapists, laboratory technicians, social workers, case managers, nursing

assistants, and clerical staff. Each support staff member is essential to the success of the emergency health care team. The ED nurse is accountable for communicating pertinent staff considerations, patient needs, and restrictions to support staff (e.g., physical limitations, Transmission-Based Precautions) to ensure that ongoing patient and staff safety issues are addressed. For example, the respiratory therapist can assist the nurse to troubleshoot mechanical ventilator issues. Laboratory technicians can offer advice regarding best practice techniques for specimen collection. During the discharge planning process, social workers or case managers can be tremendous patient advocates in locating community resources, including temporary housing, durable medical equipment (DME), drug and alcohol counseling, health insurance information, and prescription services.

The emergency nurse's interactions extend beyond the walls of the ED. Communication with nurses from the inpatient units is necessary to ensure continuity of patient care. Providing a concise but comprehensive report of the patient's ED experience is essential for the *hand-off communication* process and patient safety (Blouin, 2011). Information should include the patient's:

- Situation (reason for being in the ED)
- Brief medical history
- Assessment and diagnostic findings
- Transmission-Based Precautions if needed
- Interventions
- Response to those interventions

The Joint Commission's National Patient Safety Goals (NPSGs) (The Joint Commission [TJC], 2013) advocate that hospitals and other health care agencies use a standardized approach to hand-off communications to prevent errors caused by poor or inadequate communication. Many agencies use the SBAR method (**s**ituation, **b**ackground, **a**ssessment, **r**esponse) or some variation of that method to ensure complete and clearly understood communication. Chapter 1 discusses the SBAR technique in more detail.

Both emergency nurses and nurses on inpatient units need to understand the unique aspects of their two practice environments to prevent conflicts. For example, nurses on inpatient units may be critical of the push to move patients out of the ED setting quickly, particularly when the unit activity is high. Similarly, the emergency nurse may be critical of the inpatient unit's lack of understanding or enthusiasm for accepting admissions rapidly. Effective interpersonal communication skills and respectful negotiation can optimize teamwork and collaboration

between the emergency nurse and the inpatient unit nurse. For instance, when ED patient volume or acuity is overwhelming, the unit nurse can volunteer to assist the ED nurse by moving a monitored patient to the hospital bed. Whenever possible, the emergency nurse may decide to delay sending admitted patients to inpatient units during change of shift or crisis periods such as a cardiac arrest on the unit.

Staff and Patient Safety Considerations

In the emergency department (ED) setting, staff and patient safety are major concerns (Chart 8-1).

Chart 8-1 Best Practice for Patient Safety & Quality Care QSEN

Maintaining Patient and Staff Safety in the Emergency Department

SAFETY CONSIDERATION	INTERVENTIONS TO MINIMIZE RISK
Patient identification	Provide an identification (ID) bracelet for each patient. Use two unique identifiers (e.g., name, date of birth). If patient identity is unknown, use a special identification system.
Injury prevention for patients	Keep rails up on stretcher. Keep stretcher in lowest position. Remind the patient to use call light for assistance. Reorient confused patient frequently. If patient is confused, ask a family member or significant other to remain with him or her. Implement measures to protect skin integrity for patients at risk for skin breakdown.
Risk for errors and adverse events	Obtain a thorough patient and family history. Check the patient for a medical alert bracelet or necklace. Search the patient's belongings for weapons or other harmful devices when he or she has altered mental status.
Injury prevention for staff	Use Standard Precautions at all times. Anticipate hostile, violent patient, family, and/or visitor behavior. Plan options if violence occurs, including assistance from the security department.

Staff Safety

Staff safety concerns center on the potential for transmission of disease and on personal safety when dealing with aggressive, agitated, or violent patients and visitors. The emergency nurse uses Standard Precautions at all times when a potential for contamination by blood or other body fluids exists. Patients with tuberculosis or other airborne pathogens are preferentially placed in a negative pressure room if available. The nurse wears a powered air-purifying respirator (PAPR) or a specially fitted facemask before engaging in any close interaction with these patients (see Chapter 23).

Nursing Safety Priority QSEN

Action Alert

Hostile patient and visitor behaviors also pose injury risks to staff members. Be alert for volatile situations or people who demonstrate aggressive or violent tendencies through verbal abuse or acting out. Be

sure to follow the hospital's security plan, including looking for an escape route, attempting de-escalation strategies before harm can occur, and notifying security staff as well as supervisory staff of the situation. Emergency visits resulting from gang or domestic violence can produce particularly hazardous conditions. Report all episodes of assaultive or violent behaviors through the hospital's event documentation process so that hospital leaders and risk managers are aware of the scope of the problem and can plan safety strategies, including staff education, accordingly (Harding, 2011).

EDs employ several methods of ensuring safety. Many EDs have at least one security guard present at all times for immediate assistance with these situations. Metal detectors may be used as a screening device for patients and visitors who are suspected of having weapons. Strategically located panic buttons and remote door access controls allow staff to get help and secure major ED or hospital entrances. The triage reception area—a particularly vulnerable access point into the ED—is often designed to serve as a security barrier with bullet-proof glass and staff-controlled door entry into the treatment area. Hospitals may even employ canine units made up of specially trained officers and dogs to patrol high-risk areas and respond to handle threatening situations (Johnson & Parker, 2009).

Patient Safety

In addition to concerns about staff safety, some of the most common *patient safety* issues are:

- Patient identification
- Fall risk
- Skin breakdown in vulnerable populations
- High risk for medical errors or adverse events

Hospital emergency departments have unique factors that can affect patient safety. These factors include the provision of complex emergency care, constant interruptions, and the need to interact with the many providers involved in caring for one patient.

Correct *patient identification* is critical in any health care setting. All patients are issued an identification bracelet at their point of entry in the ED—generally at the triage registration desk or at the bedside if emergent needs exist. For patients with an unknown identity and those with emergent conditions that prevent the proper identification process (e.g., unconscious patient without identification, emergent trauma

patient), hospitals commonly use a "Jane/John Doe" or another identification system. Whatever method is used, always verify the patient's identity using two unique identifiers before each intervention and before medication administration per The Joint Commission's 2013 National Patient Safety Goals. Examples of appropriate identifiers include the patient's name, birth date, agency identification number, home telephone number or address, and/or Social Security number.

Fall prevention starts with identifying people at risk for falls and then applying appropriate fall precautions and safety measures. Patients can enter the ED without apparent fall risk factors, but because of interventions such as pain medication, sedation, or lower extremity cast application, they can develop a risk for falls. Falls can also occur in patients with medical conditions or drugs that cause syncope ("blackouts"). Many older adults also experience orthostatic (postural) hypotension as a side effect of cardiovascular drugs. In this case, patients become dizzy when changing from a lying or sitting position (see Chapter 2).

Nursing Safety Priority QSEN

Action Alert

Help patients move slowly from a supine to an upright position and when ambulating, if needed. Also, confirm that siderails are up and locked on stretchers, that the call light is within reach, and that a patient's fall risk is communicated clearly to visitors and staff members who may assume responsibility for care.

Older adults who are on beds or stretchers should *always* have all siderails up and the bed or stretcher in the lowest position. Access to a call light is especially important; instruct the patient to call for the nurse if assistance is needed rather than attempt independent ambulation. Many older adults have difficulty adjusting to the noise and pace of the ED and/or have illnesses or injuries that cause delirium, an acute confusional state. Reorient the patient frequently, and re-assess mental status. Undiagnosed delirium increases the risk for mortality for older adults who are admitted to the hospital. Assess the need for a family member, significant other, or sitter to stay with the patient to prevent falls and assist with reorientation. Additional safety strategies are listed in Chart 8-1.

Some patients spend a lengthy time on stretchers while awaiting unit

bed availability—possibly as long as 1 to 2 days in some hospitals, especially during high census periods as often occurs in flu season. During that time, basic health needs require attention, including providing nutrition, hygiene, safety, and privacy for all ED patients. Waiting in the ED can cause increased pain in patients with back pain or arthritis.

Protecting skin integrity also begins in the ED. Emergency nurses need to assess the skin frequently and implement preventive interventions into the ED plan of care, especially when caring for older adults or those of any age who are immobilized. Interventions that promote clean, dry skin for incontinent patients, mobility techniques that decrease shearing forces when moving the immobile patient, and routine turning help prevent skin breakdown. Chapter 25 describes additional nursing interventions for preventing skin breakdown.

A significant safety risk for all patients who enter the emergency care environment is the *potential for medical errors or adverse events*, especially those associated with medication administration. The episodic and often chaotic nature of emergency management in an environment with frequent interruptions can easily lead to errors.

To reduce error potential, the emergency nurse makes every attempt to obtain essential and accurate medical history information from the patient, family, or reliable significant others as necessary. When dealing with patients who arrive with an altered mental status, a quick survey to determine whether the person is wearing a medical alert bracelet or necklace is important to gain medical information. In addition, a two-person search of patient belongings may yield medication containers; the name of a physician, pharmacy, or family contact person; or a medication list. In this case, the nurse serves as a detective to find clues, which may not only promote safety but also help determine the diagnosis and influence the overall emergency treatment plan. Automated electronic tracking systems are also available in some EDs to assist staff in identifying the location of patients at any given time and in monitoring the progress of care delivery during the visit. These valuable safety measures are especially important in large or busy EDs with a high population of older adults (Laskowski-Jones, 2008).

In addition to falls and pressure ulcer development, another adverse event that can result from a prolonged stay in the ED is a *hospital-acquired infection*. Older adults, in particular, are at risk for urinary tract or respiratory infections. Patients who are immune suppressed, especially those on chronic steroid therapy or immune modulators, are also at a high risk. Nurses and other ED personnel need to wash their hands

frequently and thoroughly or use hand sanitizers to help prevent pathogen transmission.

Clinical Judgment Challenge

Safety QSEN

The emergency department manager has created a task force to decrease the rate of adverse incidents in patients who have increased safety needs during their stay in the department. At their meeting, each person discussed a specific safety need and actions that can be taken to reduce that risk.

1. What populations are at highest risk for safety compromise while in the emergency department?
2. What specific procedures can the unit implement to decrease medication errors?
3. What actions can be delegated to unlicensed personnel in these areas: medication administration, skin protection, and fall risk?
4. How can the staff reduce hazard risk for patients who are confused (either as a chronic condition or as the result of medication side effects) or who have delirium?

Scope of Emergency Nursing Practice

The scope of emergency nursing practice encompasses management of patients across the life span—from birth through death—and all health conditions that prompt a person of any age to seek emergency care.

Core Competencies

Emergency nursing practice requires that nurses be skilled in patient assessment, priority setting and clinical decision making, multitasking, and communication. A sound knowledge base is also essential. Flexibility and adaptability are vital traits because situations within the ED, as well as individual patients, can change rapidly.

Like that of any nurse in practice, the foundation of the emergency nurse's skill base is *assessment*. He or she must be able to rapidly and accurately interpret assessment findings according to acuity and age. For example, mottling of the extremities may be a normal finding in a newborn but it may indicate poor peripheral perfusion and a shock state in an adult.

Considerations for Older Adults

Patient-Centered Care QSEN

Some older adults may not be able to provide an accurate history because of memory loss or acute delirium. If possible, review their prior hospitalization records to obtain complete histories, or ask a family member or friend for pertinent information. Older adults usually have many pre-existing diseases (comorbidities) that must be considered as part of the assessment. *Knowing the history is vital because these conditions might adversely affect or complicate the cause for the ED visit.* For example, a patient who has rib fractures but has a history of chronic obstructive pulmonary disease (COPD) may not be able to maintain adequate oxygenation without endotracheal intubation and mechanical ventilatory support in the ED.

Another consideration for older adult assessment is that the presenting symptoms of older adults are often different or less specific than those of younger adults. For example, increasing weakness, fatigue, and confusion may be the only admission concerns. These vague symptoms can be caused by serious illnesses, such as an acute myocardial infarction (MI), urinary tract infection, or pneumonia. Diagnosing older adults often keeps them in the ED for extended

periods, which can lead to patient safety concerns as discussed on p. 108.

Another skill for the emergency nurse is *priority setting*, which is essential in the triage process. Priority setting depends on accurate assessment, as well as good critical thinking and clinical decision-making skills. These skills are generally gained through hands-on clinical experience in the ED. However, discussion of case studies and the use of human patient simulation and simulation software and aids can help prepare nurses to acquire this skill base in a nonthreatening environment and then apply it in the actual clinical situation (Kisner & Johnson-Anderson, 2010).

The knowledge base for emergency nurses is broad and ranges from critical care emergencies to less common problems, such as snakebites and hazardous materials contamination (see Chapters 9 and 10). ED nurses also learn to recognize and manage the legal implications of societal problems such as domestic violence, elder abuse, and sexual assault.

Although most EDs have physicians available around the clock who are physically located within the ED, the nurse often initiates collaborative interdisciplinary protocols for lifesaving interventions such as cardiac monitoring, oxygen therapy, insertion of IV catheters, and infusion of appropriate parenteral solutions. In many EDs, nurses function under clearly defined medical protocols that allow them to initiate drug therapy for emergent conditions such as anaphylactic shock and cardiac arrest. Emergency care principles extend to knowing what essential laboratory and diagnostic tests may be needed and, when necessary, obtaining them.

The emergency nurse must be proficient in performing a variety of technical skills (multitasking), sometimes in a stressful, high-pressure environment such as a cardiac or trauma resuscitation. In addition to basic skills, he or she may also need to be proficient with critical care equipment, such as invasive pressure monitoring devices and mechanical ventilators. This type of equipment is commonly found in EDs that are part of Level I and Level II trauma centers.

The nurse also collaborates with and assists the physician with a number of procedures. Knowledge and skills related to procedural setup, patient preparation, teaching, and postprocedure care are key aspects of emergency nursing practice. Common ED procedures include:

- Simple and complex suturing for wound closure
- Foreign body removal
- Central line insertion

- Endotracheal intubation and initiation of mechanical ventilation
- Transvenous pacemaker insertion
- Lumbar puncture
- Pelvic examination
- Chest tube insertion
- Paracentesis
- Fracture management

More than one nurse may be necessary to assist with some procedures. For example, if moderate sedation is used to produce amnesia and relaxation during fracture reduction, one nurse assists the physician with the actual procedure while the other nurse monitors the patient before, during, and after the moderate sedation medications are administered.

Finally, an essential aspect of the emergency nurse's skill base is *communication*. The ED environment is complex; therefore multiple barriers to effective communication are likely. One common barrier is the patient's cultural beliefs and practices, especially if they differ from those of the health care team. Assess each patient as an individual, and be careful not to stereotype anyone based on his or her ethnicity, socioeconomic status, gender identity, or religion.

Cultural Considerations

Patient-Centered Care QSEN

Be aware of the various cultural and religious values of patients that may influence care. Many people have distinct beliefs that must be respected in the health care setting. For example, some Mexican Americans are modest and do not like to have their bodies exposed. They often tend to be very family-oriented and affectionate toward each other.

Patients with language barriers can present a challenge. The population of non-English-speaking people is rapidly increasing in the United States. When a patient who is not proficient in English arrives to the ED seeking care, access available resources such as telephone language lines and dedicated interpreters contracted by the hospital to ensure an understanding of all aspects of care.

A religious belief system can also affect the delivery of care. For example, Jehovah's Witness patients do not accept blood transfusions and may not accept certain medications that are derived from human blood components.

Be aware that not all patients identify themselves as male or female.

Some patients may be in the process of changing their gender identity from male to female or female to male (transgender people). Ask the patient what pronoun (he, she, or other term) that the person prefers to be called. Demonstrate professional behaviors that promote trust. Chapter 73 discusses the special care for this population in detail.

ED crowding and insufficient nursing personnel to meet the demand for services also create difficulties with communication of pertinent patient information and quality of written documentation. The high-stress ED environment can negatively affect effective interpersonal behaviors, particularly when nurses must deal with angry, violent, or demanding patients.

Training and Certification

Two general types of certification are referred to in emergency nursing practice: the "certification" that marks successful completion of a particular course of study; and emergency nursing specialty certification (Table 8-1). As part of the orientation and employment requirements for staff nurses in most U.S. EDs, successful completion of the Basic Life Support (BLS) for Healthcare Providers and Advanced Cardiac Life Support (ACLS) and Pediatric Advanced Life Support (PALS) provider courses through the American Heart Association is necessary. These courses provide instruction in fundamental, evidence-based management theory and techniques for cardiopulmonary resuscitation (CPR). Course participants include physicians, nurses, and prehospital personnel. The ACLS course builds on the BLS content to include:

TABLE 8-1

Descriptions of Training and Certifications for Emergency Nursing

CERTIFICATION	DESCRIPTION
Basic Life Support (BLS) (required)	Noninvasive assessment and management skills for airway maintenance and cardiopulmonary resuscitation (CPR)
Advanced Cardiac Life Support (ACLS) (usually required)	Invasive airway management skills, pharmacology, and electrical therapies, special resuscitation
Pediatric Advanced Life Support (PALS) (may be required)	Neonatal and pediatric resuscitation
Certified Emergency Nurse (CEN) (optional)	Validates core emergency nursing knowledge base

- Advanced concepts in cardiac monitoring
- Invasive airway management skills

- Pharmacologic and electrical therapies
- Intravascular access techniques
- Special resuscitation situations
- Post-resuscitation management considerations

Additional certification may be required through successful completion of trauma continuing education courses.

Emergency Nursing Principles

Triage

ED **triage** is an organized system for sorting or classifying patients into priority levels depending on illness or injury severity. The organization of emergency care and the ED is structured through triage principles. The key concept is that patients who present to the ED with the highest acuity needs receive the quickest evaluation, treatment, and prioritized resource utilization such as x-rays, laboratory work, and computed tomography (CT) scans. These patients also have priority for hospital service areas, such as the operating room or cardiac catheterization laboratory. A person with a lower acuity problem may wait longer in the ED because the higher acuity patient is moved to the "head of the line." The staff may need to communicate information about this system to the patient and family who may not understand why other patients are treated first.

The triage nurse is the gatekeeper in the emergency care system. When patients present to the ED, regulatory standards dictate that a registered nurse (RN), physician, or physician assistant (PA) perform a rapid assessment to determine triage priority. However, the RN is typically the person assigned to perform the triage function in most hospitals. The triage nurse requires appropriate training and experience in both emergency nursing and triage decision-making concepts to develop an expert knowledge base, as well as ongoing mentoring and quality improvement feedback (Dateo, 2013). In some instances, the triage nurse may seek the input of an emergency physician, advanced practice nurse (e.g., nurse practitioner [NP]), or PA to help establish the acuity level if the patient's presentation is highly unusual.

Based on the triage priority, patients may be rushed into a treatment room, directed to a lower acuity area within the ED, or asked to sit in the waiting room. Variations on this theme include:

- Triage nurse–initiated protocols for laboratory work or diagnostic studies that may be performed before the patient is actually evaluated by a physician
- Initiation of care while the patient is on a stretcher in the hallway of a crowded ED

These protocols are especially beneficial for certain populations who require rapid diagnosis and collaborative treatment within a defined time frame from ED arrival to meet established standards of care. Examples are patients with chest pain or those with a clinical presentation indicative of stroke, sepsis, or pneumonia.

Emergent, Urgent, and Nonurgent Categories

Many triage systems can be used by a hospital ED. Any system must be applied consistently by triage nursing staff and endorsed by the emergency medicine physician staff. Based on the severity of the patient's condition, a well-known triage scheme used in the United States is the three-tiered model of "emergent, urgent, and nonurgent" (Table 8-2). In this system, for example, a patient experiencing crushing substernal chest pain, shortness of breath, and diaphoresis would be classified as emergent and triaged immediately to a treatment room within the ED. Similarly, a critically injured trauma patient or a person with an active hemorrhage would also be prioritized as emergent. The **emergent triage** category implies that a condition exists that poses an immediate threat to life or limb.

TABLE 8-2

Three-Tiered Triage System and Examples of Patients Triaged in Each Tier

TIER LEVEL	EXAMPLES OF PATIENTS TRIAGED IN EACH TIER
Emergent (life threatening)	Respiratory distress
	Chest pain with diaphoresis
	Stroke
	Active hemorrhage
	Unstable vital signs
Urgent (needs quick treatment, but not immediately life threatening)	Severe abdominal pain
	Renal colic
	Displaced or multiple fractures
	Complex or multiple soft tissue injuries
	New-onset respiratory infection, especially pneumonia in older adults
Nonurgent (could wait several hours if needed without fear of deterioration)	Skin rash
	Strains and sprains
	"Colds"
	Simple fracture

The **urgent triage** category indicates that the patient should be treated quickly but that an immediate threat to life does not exist at the moment. Reassessment is needed if a physician cannot evaluate the patient in a timely manner. In people with evidence of clinical deterioration, triage priority may be upgraded from urgent to emergent. Examples of patients who typically fall into the urgent category are those with a new onset of pneumonia (as long as respiratory failure does not appear imminent), renal colic, complex lacerations not associated with major hemorrhage, displaced fractures or dislocations, and temperature greater than 101° F (38.3° C). Those categorized as **nonurgent** can generally tolerate waiting

several hours for health care services without a significant risk for clinical deterioration. Conditions within this classification include patients with sprains and strains, simple fractures, "cold" symptoms, and skin rashes.

Other Multi-Tiered Models

To further sort patient conditions within an acuity classification or triage priority system, four- and five-tier triage models also exist. Such models are based either on comprehensive lists of conditions that indicate the particular triage priority to which a patient should be assigned or on the nature of resources that a patient will use in the ED setting. A patient situation may generate various triage classifications in different hospitals depending on the triage priority system used at that particular institution. Some schemes may even take into account the presence of pre-existing conditions such as a history of anticoagulant use, diabetes, heart disease, and organ transplantation.

It is surprising that there is no universally accepted triage system recognized in the United States. Thus there is no standardization of triage acuity data to compare patient acuity among hospitals. Medical providers, health insurance companies, and patients often disagree on the definition of an emergent versus a nonurgent ED visit, making it essential to use a practical triage system to maintain department efficiency and allocation of resources (Aacharya et al., 2011). The Emergency Nurses Association in collaboration with the American College of Emergency Physicians studied the available research literature on acuity scales and concluded that two standardized five-level systems, the **Emergency Severity Index (ESI)** and the **Canadian Triage Acuity Scale (CTAS),** are the most reliable (Shelton, 2010). The ESI model uses an algorithm that fosters rapid, reliable, and clinically pertinent categorization of patients into five groups, from level 1 (emergent) to level 5 (nonurgent). The CTAS model differs from ESI in that lists of descriptors are used to establish the triage level.

Whatever triage model is used, triage nurses must employ a systematic approach, apply solid clinical decision-making skills, and maintain a caring ethic. Compassion fatigue, or burn-out, can hinder objectivity in dealing with patients who present to the ED. A biased approach threatens the ED nurse's ability to triage patients accurately. Mistriage is a patient safety risk that can be the "root cause" of delayed or inadequate treatment with potentially deadly consequences.

NCLEX Examination Challenge

Safe and Effective Care Environment

The emergency department nurse is assigned to five clients waiting for orders to be implemented. Which client does the nurse assess first?

A 60-year-old waiting for transport to the operating room for an emergency appendectomy

B 25-year-old with a closed femur fracture who received pain medication 10 minutes ago

C 30-year-old with nausea and vomiting who has IV fluids infusing and is now sleeping

D 28-year-old construction worker with a laceration to the arm that is waiting to be sutured

Disposition

At the conclusion of the assessment, the physician must make a decision regarding patient disposition (i.e., where the patient should go after being discharged from the ED). Should the patient be admitted to the hospital, transferred to a specialty care center, or be discharged to home with instructions for continued care and follow-up? Usually, the answer is straightforward. A patient who has an evolving myocardial infarction, stroke, or acute surgical need is admitted.

Sometimes, though, the ED disposition decision is less clear. Often the physician discusses this decision in collaboration with the emergency nurse. The nurse may have a greater sense of how well a patient will manage in a home setting depending on whether other family members or friends are available to assist and are reliable. For example, in the event a patient with a minor head injury has suffered a loss of consciousness, someone is typically expected to remain with that person for the first 12 to 24 hours to be sure that he or she does not show any evidence of neurologic deterioration. Another common scenario involves the potential risk to the patient in cases of actual or suspected domestic violence. If discharge to home is not deemed safe, the patient may be admitted to the hospital in an observation status until resources can be organized to provide for a safe environment. Coordinate the discharge plan and continuing care with the social worker or case manager.

Considerations for Older Adults

Patient-Centered Care QSEN

If discharge from the ED to home is possible, ensure that safety issues are considered. For example, collaborate with the emergency department

physician to evaluate the patient's prescription and over-the-counter medications to determine if the drug regimen should be continued. Involve the ED-based pharmacist if one is available for consultation when necessary. If the medication regimen needs to be changed, be sure that the patient and family member or significant other has the new information in writing and that it is explained verbally. If needed, assess whether the patient has someone who can dispense medications into a "medi-set" to ensure accuracy and prevent adverse drug events. Consider a social services or case management referral for those patients in need of financial resources to obtain prescribed medications.

To prevent future ED visits, screen older adults per agency policy for functional assessment, cognitive assessment, and risk for falls. Depression screening is also important because suicide rates are two times higher among older adults when compared with younger adults. White men older than 85 years are at the highest risk (Touhy & Jett, 2012).

More than half of all older patients are admitted to the hospital directly from the ED (Nolan, 2009). If hospitalization is needed, determine if the patient has advance directives or is able to make decisions about advance directives before admission. If the patient was admitted from a nursing home, contact the facility to let them know the patient's status. If the patient was receiving home health care services, notify the agency about the hospital admission. Contact the patient's primary physician and designated family member if he or she is not present with the patient.

Case Management

Some EDs employ registered nurse case managers who screen ED patients and intervene when necessary to arrange appropriate referral and follow-up. This is an evolving role in the ED setting that can be beneficial in providing comprehensive care and as a strategy to avoid inappropriate use of resources.

ED case managers, supported by electronic information systems, can review the ED census on both a "real-time" and a retrospective basis to determine which patients have visited the ED frequently in a given period. The case manager can then determine the reasons they sought emergency services, such as lack of a primary health care provider, exacerbation ("flare-up") of a chronic condition, a lack of health education, or lack of the financial resources necessary to manage the health condition. Collaborative case management interventions include

facilitating referrals to primary care providers or to subsidized community-based health clinics for patients or families in need of routine services.

For those with needs related to chronic conditions, the case manager can arrange referral into appropriate disease management programs in the community if available. Disease management programs are specific to a particular condition such as asthma, COPD, diabetes, hypertension, heart failure, and renal failure. They help patients learn how to manage their condition on a day-to-day basis to prevent exacerbations or clinical deterioration. The desired outcome is to keep the person out of the hospital as long as possible. Health teaching is a key component of these programs. For other health teaching needs, the ED case manager directs the patient to the appropriate educational resources such as a health educator, registered dietitian, or community organization (e.g., the American Cancer Society, the American Heart Association).

Other functions of the ED case manager might include working in collaboration with staff to plan disposition for homeless people, locating a safe environment for victims of domestic violence or elder abuse, or providing information on resources for low-cost or free prescriptions. Homeless adults often have multiple chronic medical illnesses for which they visit emergency departments frequently. A large study of homeless adults with chronic medical illnesses demonstrated a decrease in ED visits and hospital admissions as a result of an organized follow-up system for housing and ongoing case management support. (See the Quality Improvement box.)

Quality Improvement QSEN

Improving the Flow of Stable Patients Through an Emergency Department

Popovich, M.A., Boyd, C., Dachenhaus, T., & Kusler, D. (2012). Improving stable patient flow through the emergency department by utilizing evidence-based practice: One hospital's journey. *Journal of Emergency Nursing, 38*(5), 474-478.

Many nonemergent patients use emergency departments (EDs) for medical care, resulting in overcrowding, lengthy wait times, patient dissatisfaction, and increasing numbers of patients who leave without being seen (LWBS). Increased length of wait has been correlated with poorer outcomes. A project was designed in the country's fifth-largest pediatric emergency department to investigate whether an evidence-

based, volume-driven protocol would increase rapid treatment of stable patients. The protocol included a volume-based driver, unlike other tools used in EDs to manage patient flow, staffing, and resource allocation, such as the Emergency Severity Index (ESI), which is a 5-level decision-making tool used in triage. The protocol was designed to determine when to open the satellite unit for stable patients.

A participating hospital contained a 68-bed Level I trauma center and a nearby 8-bed satellite unit. A benchmark of 120 minutes for total length of stay (TLOS) was established as the quality indicator. After reviewing ED statistics, a tool was developed that considered total patient census and the number of ESI 4 and 5 patients in the unit. The triggers were a total census of 55 and/or 11 to 16 ESI level 4 patients and/or 5 to 7 ESI level 5 patients in the department. Other considerations included more than two people in the triage line, more than three people in the lobby waiting to be seen, and whether the urgent care section was full. Training was conducted to ensure consistency among the nurses in categorizing level 4 and level 5 patients. Use of the tool increased the number of days the satellite was open and decreased the number of patients who LWBS by 29%. The 120-minute benchmark was not met, but only by 7.5 minutes.

Commentary: Implications for Practice and Research

This demonstrated that patient satisfaction and outcomes were diminished as waiting times for ED services increased. EDs using an evidence-based tool can eliminate personal opinions when considering whether to use additional resources to expedite the flow of stable patients through the department. Specifying triggers for activating these resources can allow for better use of ED services. Research should continue on fine-tuning the tool to meet the needs of individual EDs, correlating use of the tool and patient outcomes, and should investigate patient satisfaction with the resulting (it is hoped decreased) wait times.

Patient and Family Education

A key role of the emergency nurse is health teaching. At the most basic level, nurses review discharge instructions with the patient and family before signing them out of the department.

Cultural Considerations

Patient-Centered Care QSEN

Most discharge instructions are either preprinted or computer generated and can be customized to address the patient's needs. Consider his or her reading level, primary language, and visual acuity. Educational materials and instructions should be available at no higher than the 6th-grade reading level. For patients who have English as a second language, many hospitals have educational materials available in Spanish and other regional languages. However, interpreters may be necessary to assist the health care provider customize the information appropriately. For older adults and others with vision deficits, large-print materials may be helpful.

In addition to discharge instructions, the ED environment and community-at-large present many opportunities for health education. Emergency nurses are in an ideal position to educate the public about wellness and injury-prevention strategies. If the patient presented after a motor vehicle crash, for instance, the nurse can reinforce the need to wear seat belts or use child safety seats correctly. ED visits that result from mishaps in the home provide an excellent opportunity to discuss home safety issues (e.g., the need for smoke detectors and carbon monoxide detectors) and fall prevention tips (e.g., the need for proper lighting, removal of throw rugs). Injury is not the only topic that affords a teaching opportunity. A new onset or an exacerbation of a medical condition also allows for education, such as how to measure blood glucose and ways to control blood pressure or reduce the risk for heart disease.

Death in the Emergency Department

Not all critically ill or injured patients who come to the ED can be saved. Sometimes a patient's death is expected by family members, typically when they have dealt with a loved one's terminal condition or age-related decline. Usually, however, a death in the ED is a sudden and unexpected event that produces a state of crisis and chaos for family and significant others. Emergency department staff members need to address the needs of the family members in this overwhelming time.

If resuscitation efforts are still underway when the family arrives, one or two family members may be given the opportunity to be present during lifesaving procedures. Family presence during resuscitation is gaining wider acceptance in the health care community; however, a significant number of hospitals still have not devised clear policies or guidelines to facilitate family-witnessed resuscitation (Feagan & Fisher,

2011).

If the patient dies before family members arrive, ED staff members try to prepare the body and the room for viewing by the family. However, certain types of ED deaths may require forensic investigation or become medical examiner's cases. Therefore ED staff may not be able to remove IV lines and indwelling tubes or clean the patient's skin if these actions could potentially damage evidence. Trauma deaths, suspected homicide, or abuse cases always fall into this category. In these situations, cover the body with a sheet or blanket while leaving the patient's face exposed, and dim the lights before family viewing.

When dealing with family members in crisis, simple and concrete communication is best. Words such as *death* or *died,* although seemingly harsh, create less confusion than terms such as *expired* or *passed away.* Demonstrate caring, compassion, and empathy during all interactions, even in periods of heightened emotions. Intense grief can provoke a range of family reactions from silence to violence. If available, coordinate with crisis staff (social workers or psychiatric nurses) to assist families and maintain safety during this time. Offer the family the option of speaking with clergy or calling someone of their choice for additional support. A family member may need to be admitted to the ED to be treated for anxiety or physical manifestations of stress such as chest pain, difficulty breathing, or severe headache.

Dealing with death is often difficult for ED personnel, especially during busy periods when the ability to console family members may be limited. In response, some emergency departments have developed bereavement committees that focus on meeting the needs of grieving families. Actions such as sending sympathy cards, attending funerals, making follow-up phone calls, and creating memory boxes are common. These actions help communicate caring and compassion after the moment of crisis.

The Impact of Homelessness

Homelessness affected 636,000 people in 2011, an increase of 1% from the prior year (National Alliance to End Homelessness, 2012). The homeless population is made up of both adults and children who live from day to day in a state of fear, chaos, and confusion (Gerber, 2013). People become homeless as a result of a crisis or persistent poverty (Gerber, 2013). They have a high incidence of acute and chronic health conditions, psychiatric illnesses, physical disabilities or limitations, and problems with substance abuse (Gerber, 2013). They are vulnerable to physical trauma, weather exposure, sexually transmitted diseases, infestation, and infectious diseases such as tuberculosis and influenza.

Homeless patients often seek ED care for a variety of reasons. Because the ED is open 24 hours per day and is mandated by federal law to perform an emergency medical screening examination on all of their patients, patients who are homeless know that they will gain entry despite their inability to pay for services. The ED represents a safe place to go for shelter in poor weather and for food, medical care, pain relief, and human interaction. Some homeless patients simply seek a temporary respite from their current living conditions, which may be a park, homeless shelter, car, abandoned building, or cardboard box. Those people who have been persistently homeless may assimilate into the homeless culture, learn to take great pride in their survival skills, and fiercely protect their few belongings as well as their living space. They may develop a distrust of outsiders, including members of the health care profession, and are especially sensitive to any perceived bias or stereotyping (Gerber, 2013).

Patients who are homeless bring special challenges to their ED evaluation, treatment, and disposition. Some visit the ED frequently and do not adhere to treatment recommendations or follow-up with community referrals. Those with mental illness or substance abuse may act out or become disruptive, posing a safety risk to staff and patients.

To best care for homeless patients in the ED setting, nurses must first maintain their situational awareness and attend to their own needs for personal safety. These include not only anticipating the potential for violent behavior but also using Standard Precautions and assessing the need to isolate the patient in a negative pressure room if airborne disease such as tuberculosis (TB) is a concern. The key nursing action is to demonstrate behaviors that promote trust. These include making eye contact (if culturally appropriate), speaking calmly, avoiding any prejudicial or stereotypical remarks, being patient, showing genuine care

and concern by listening, following through on promises, and exercising caution when there is a need to enter into the patient's personal space (Gerber, 2013). Clear professional boundaries must be stated if the patient becomes disruptive, profane, or sexually inappropriate. While collaborating with the emergency care provider to ensure that the patient's emergency medical needs are identified and treated, consult a social worker or case manager to work with the patient in identifying safety needs, referral options, and community resources. It is also important to develop an individual care plan with the interdisciplinary health care team if the patient uses the ED frequently. This type of care plan is extremely beneficial in establishing a consistent approach to patient management, especially when the patient has complex conditions or exhibits drug-seeking and disruptive behavior.

Trauma Nursing Principles

The general public tends to use the term *trauma* to mean any type of crisis ranging from a heart attack to psychological stress. Among health care professionals, though, **trauma** refers to bodily injury. More than 180,000 people in the United States die each year as a result of injuries, and nearly 2 million are hospitalized, often with permanent and disabling consequences (National Center for Injury Prevention and Control [NCIPC], 2012). Injuries can be categorized as either intentional (i.e., assault, homicide, suicide) or unintentional (i.e., accidents). *Unintentional injury,* such as a motor vehicle crash, is the leading cause of death for Americans younger than 35 years and is one of today's most significant public health problems (NCIPC, 2012).

Injury management is a key component of emergency department services. About 30 million people in the United States visit the ED each year to receive treatment for injuries (NCIPC, 2012). Therefore an important part of emergency nursing practice is a core competency in general trauma care. For emergency nurses who work in accredited trauma centers, opportunities typically exist to further develop expertise in trauma nursing through ongoing clinical practice, specialty training programs, and continuing education. Trauma nursing is a field that encompasses the continuum of care from injury prevention and prehospital services to acute care, rehabilitation, and, ultimately, community reintegration.

Trauma Centers and Trauma Systems

Trauma centers have their roots in military medicine. Injured soldiers who received rapid transport from the battlefield and treatment from skilled health care personnel had a survival advantage in the mobile army surgical hospital (MASH) units first deployed in the Korean and Vietnam wars. Consequently, the MASH unit became the original model for the development of civilian trauma centers. Today's **trauma center** in the United States is a specialty care facility that provides competent and timely trauma services to patients, depending on its designated level of capability.

Trauma Centers

Not all EDs that offer around-the-clock emergency services are trauma centers. The American College of Surgeons Committee on Trauma (2006) has set forth national standards for trauma center accreditation and

categorizes the resource requirements necessary for the highest capability trauma center (Level I) to the lowest (Level IV) (Table 8-3).

TABLE 8-3

Levels and Functions of Trauma Centers

LEVELS OF TRAUMA CENTER	FUNCTIONS OF TRAUMA CENTER
Level I	Usually located in large teaching hospital systems in densely populated areas
	Provides a full continuum of trauma services for all patients
	Conducting research is a requirement for designation
Level II and Level III	Both typically located in community hospitals
	Level II Provides care to most injured patients Transports patient if needs exceed resource capabilities
	Level III Stabilizes patients with major injuries Transports patient if needs exceed resource capabilities
Level IV	Usually located in rural and remote areas
	Provides basic trauma patient stabilization and advanced life support within resource capabilities
	Arranges transport to higher trauma center levels as necessary

A *Level I trauma center* is a regional resource facility that is capable of providing leadership and total collaborative care for every aspect of injury, from prevention through rehabilitation. These centers also have a responsibility to offer professional and community education programs, conduct research, and participate in system planning. Because a significant resource and experience commitment is required to maintain strict accreditation standards, Level I trauma centers are usually located in large teaching hospitals and serve dense population areas (Fig. 8-4).

FIG. 8-4 A trauma team participates in a realistic trauma resuscitation simulation. This type of training ensures staff remain proficient in skills and able to care for any situation that might present to the emergency department (ED).

Level II trauma centers are usually located in community hospitals and are capable of providing care to the vast majority of injured patients. However, a Level II trauma center may not be able to meet the resource needs of patients who require very complex injury management, such as those in need of advanced surgical care. These people are generally transferred to a Level I trauma center for specialty care. In communities without a Level I trauma center, Level II centers play a significant leadership role in injury management, education, prevention, and emergency preparedness planning.

A *Level III trauma center* is a critical link to higher capability trauma centers in communities that do not have ready access to Level I or Level II centers. The primary focus is initial injury stabilization and patient transfer. Level III trauma centers are usually found in smaller, rural hospitals and serve areas with low population density. Because Level III trauma centers have general surgeons and orthopedic surgeons immediately available, patients with some major injuries may be admitted for care. However, if the injuries are severe or critical, transfer to a Level I or II trauma center occurs after ED assessment, resuscitation, and stabilization—sometimes after emergent, lifesaving surgery. Patients are typically transported out in either an advanced life support

ambulance or helicopter with critical care transport personnel in attendance.

The function of a *Level IV trauma center* is to offer advanced life support care in rural or remote settings that do not have ready access to a higher-level trauma center, such as a ski area. Patients are stabilized to the best degree possible before transfer, using available personnel such as advanced practice nurses, physician assistants, nurses, and paramedics. Resources, including the consistent availability of a physician, may be extremely limited. Transport time to the final care center can be prolonged because of both distance and bad weather conditions that may prevent transfer by air.

Level III and Level IV trauma centers establish close collaborative relationships with Level I and Level II trauma centers. Based on accreditation standards, care providers at Levels I and II trauma centers have a responsibility to readily accept injured patients in transfer. They provide timely feedback to trauma personnel at referring hospitals and share expertise by offering educational opportunities to advance trauma care delivery in the region. In addition, personnel from all levels of trauma centers participate in focused system improvement and patient safety initiatives that enhance quality of care and solve identified problems.

Trauma Systems

Trauma centers save lives—but a trauma center is only as good as the overall trauma system that supports it. A **trauma system** is an organized and integrated approach to trauma care designed to ensure that all critical elements of trauma care delivery are aligned to meet the injured patient's needs. These elements include (Cooper & Laskowski-Jones, 2006):

- Access to care through communication technology (e.g., an enhanced 911 service)
- Timely availability of prehospital emergency medical care
- Rapid transport to a qualified trauma center
- Early provision of rehabilitation services
- System-wide injury prevention, research, and education initiatives

The overall desired outcome of an organized trauma system is to enable an injured patient not only to recover from trauma but also to return to a productive role in society.

A well-functioning trauma system is also essential to general public health and safety. It provides the structure necessary for disaster readiness

and community emergency preparedness (see Chapter 10). Although most states now have at least some basic elements of a trauma system in place, significant gaps still exist in many regions.

Mechanism of Injury

The **mechanism of injury (MOI)** describes how the patient's traumatic event occurred, such as a high-speed motor vehicle crash, a fall from a standing height, or a gunshot wound to the torso. Knowing key details about the MOI can provide insight into the energy forces involved and may help trauma care providers predict injury types and, in some cases, patient outcomes. Prehospital care providers report the MOI as a communication standard when handing off care to ED and trauma personnel. Similarly, patients who present to the ED for medical care will often relate the MOI by describing the particular chain of events that caused their injuries.

Two of the most common injury-producing mechanisms are blunt trauma and penetrating trauma. **Blunt trauma** results from impact forces like those sustained in a motor vehicle crash, a fall, and an assault with fists, kicks, or a baseball bat. **Blast effect** from an exploding bomb also causes blunt trauma. The energy transmitted from a blunt trauma mechanism, particularly the rapid **acceleration-deceleration** forces involved in high-speed crashes or falls from a great height, produces injury by tearing, shearing, and compressing anatomic structures. Trauma to bones, blood vessels, and soft tissues occurs.

Penetrating trauma is caused by injury from sharp objects and projectiles. Examples are wounds from knives, ice picks, and other comparable implements, as well as bullets (gunshot wounds [GSWs]) or pellets. Fragments of metal, glass, or other materials that become airborne in an explosion (shrapnel) can also produce penetrating trauma. Each mechanism has the risk for specific injury patterns and severity that the trauma team considers when planning diagnostic evaluation and management strategies. Certain injury mechanisms, such as a gunshot wound to the chest or abdomen or a stab wound to the neck, are so highly associated with life-threatening consequences that they automatically require trauma team intervention for a rapid and coordinated resuscitation response.

Primary Survey and Resuscitation Interventions

A basic tenet of emergency care in any environment is scene safety. In the prehospital setting, emergency care providers must ensure that they are

aware of any hazards that might pose a threat to rescuers and take actions to decrease or eliminate the risk. This same concept applies to the hospital ED setting. Before engaging in trauma resuscitation as a nurse member of the trauma team, keep in mind that there is a high risk for contamination with blood and body fluids. For this reason, use Standard Precautions in *all* resuscitation situations and at other times when exposure to blood and body fluids is likely. Proper attire consists of an impervious cover gown, gloves, eye protection, a facemask, and surgical cap, as well as shoe covers (if *significant* blood loss is anticipated, such as during an ED procedure).

The initial assessment of the trauma patient is called the **primary survey,** which is an organized system to rapidly identify and effectively manage immediate threats to life. The primary survey is based on a standard "ABC" mnemonic plus a "D" and "E" for trauma patients: airway/cervical spine **(A)**; breathing **(B)**; circulation **(C)**; disability **(D)**; and exposure **(E)**. Resuscitation efforts occur simultaneously with each element of the primary survey (American College of Surgeons Committee on Trauma, 2008; Laskowski-Jones, 2009). Even though the resuscitation team may encounter multiple clinical problems or injuries, issues identified in the primary survey are managed before the team engages in interventions of lower priority, such as splinting fractures and dressing wounds.

A: Airway/Cervical Spine

Like for any patient, the highest priority intervention is to establish a patent airway. Even minutes without an adequate oxygen supply can lead to brain injury that can progress to anoxic brain death.

Nursing Safety Priority QSEN

Critical Rescue

Clear the airway of any secretions or debris either with a suction catheter or manually if necessary. Protect the cervical spine in any trauma patient with the potential for spinal injury by manually aligning the neck in a neutral, in-line position and using a jaw-thrust maneuver when establishing an airway. Provide supplemental oxygen for all patients who require resuscitation.

In general, a non-rebreather mask is best for the spontaneously breathing patient. Bag-valve-mask (BVM) ventilation with the appropriate

airway adjunct and a 100% oxygen source is indicated for the person who needs ventilatory assistance during resuscitation. A patient with significantly impaired consciousness requires an endotracheal tube and mechanical ventilation (American College of Surgeons Committee on Trauma, 2008).

B: Breathing

After the airway is successfully secured, breathing becomes the next priority in the primary survey. *This assessment determines whether or not ventilatory efforts are effective—not only whether or not the patient is breathing.* Listen to breath sounds and evaluate chest expansion, respiratory effort, and any evidence of chest wall trauma or physical abnormalities. Both apneic patients and those with poor ventilatory effort need BVM ventilation for support until endotracheal intubation is performed and a mechanical ventilator is used. If cardiopulmonary resuscitation (CPR) becomes necessary, the mechanical ventilator is disconnected and the patient is manually ventilated with a BVM device. Lung compliance can be assessed through sensing the degree of difficulty in ventilating the patient with the BVM.

C: Circulation

When effective ventilation is ensured, the priority shifts to circulation. The adequacy of heart rate, blood pressure, and overall perfusion becomes the focus of the assessment. Common threats to circulation include cardiac arrest, myocardial dysfunction, and hemorrhage leading to a shock state. Interventions are targeted at restoring effective circulation through cardiopulmonary resuscitation, hemorrhage control, IV vascular access with fluid and blood administration as necessary, and drug therapy. *External* hemorrhage is usually quite obvious and best controlled with firm, direct pressure on the bleeding site with thick, dry dressing material. This method is effective in decreasing blood flow for most wounds. *Tourniquets that occlude arterial blood flow distal to the injury may be considered to manage severe bleeding from extremity trauma when direct pressure fails to achieve hemorrhage control; hemostatic dressings (e.g., dressings impregnated with substances that speed the formation of a blood clot) are another essential tool to manage life-threatening hemorrhage (Strickler, 2010). Internal* hemorrhage is a more hidden complication that must be suspected in injured patients or those who present in a shock state.

In a resuscitation situation, blood pressure can be quickly and easily estimated before a manual cuff pressure can be obtained by palpating for

the presence or absence of peripheral and central pulses:
- Presence of a radial pulse: BP at least 80 mm Hg systolic
- Presence of a femoral pulse: BP at least 70 mm Hg systolic
- Presence of a carotid pulse: BP at least 60 mm Hg systolic

By the time hypotension occurs, compensatory mechanisms used by the body in an attempt to maintain vital signs in a shock state have been exhausted. Timely, effective intervention is critical to preserve life and vital organ function.

IV access is best achieved initially with insertion of large-bore (16-gauge) peripheral IV lines in the antecubital area (inside bend of the elbow). Additional access can be obtained via central veins in the femoral, subclavian, or jugular sites using large-bore (8.5 Fr) central venous catheters. Intraosseous access is an excellent initial approach for critically ill patients when veins cannot be rapidly accessed by the resuscitation team (see Chapter 13 for discussion of intraosseous infusion therapy). Ringer's lactate and 0.9% normal saline (NS) are the crystalloid solutions of choice for resuscitation; hypertonic saline may also be prescribed in some situations, particularly in the case of head trauma. Fluids and blood products should be warmed before administration to prevent hypothermia. Anticipate the need for rapid blood component administration in a hemorrhagic shock state using packed red blood cells, fresh frozen plasma, and platelets to both replace blood loss and prevent coagulopathy when significant hypotension persists after infusion of 2 L of solution (Davis et al., 2012). However, the priority intervention is to stop the bleeding.

D: Disability

The disability examination provides a rapid baseline assessment of neurologic status. A simple method to evaluate level of consciousness is the "AVPU" mnemonic:
- A: **A**lert
- V: Responsive to **v**oice
- P: Responsive to **p**ain
- U: **U**nresponsive

Another common way of determining and documenting level of consciousness is the **Glasgow Coma Scale (GCS),** an assessment that scores eye opening, verbal response, and motor response. The lowest score is 3, which indicates a totally unresponsive patient; a normal GCS score is 15. Metabolic abnormalities (e.g., severe hypoglycemia), hypoxia, neurologic injury, and illicit drugs or alcohol can impair level of

consciousness. Frequent reassessment is needed for rapid intervention in the event of neurologic compromise or deterioration.

E: Exposure

The final component of the primary survey is **exposure.**

Nursing Safety Priority QSEN

Action Alert

Remove all clothing to allow for thorough assessment. Always *cut away* clothing with scissors:

- During resuscitation when rapid access to the patient's body is critical
- When manipulating a patient's limbs to remove clothing could cause further injury
- When thermal or chemical burns have caused fabrics to melt into the patient's skin

If evidence preservation is an issue, handle items per institutional policy. Evidence may include articles of clothing, impaled objects, weapons, drugs, and bullets. Emergency nurses are often called upon to provide testimony in court regarding their recall of the presentation and treatment of patients in the ED. Examples of types of cases in which evidence collection is vital are rape, elder abuse, domestic violence, homicide, suicide, drug overdose, and assault.

Once clothing is removed, hypothermia (body temperature less than or equal to 97° F [36° C]) poses a risk to injured patients, especially those with burns and traumatic shock states (Moore, 2011). Hypothermia is discussed in detail in Chapter 9.

Table 8-4 highlights the primary survey and associated resuscitation interventions.

TABLE 8-4

The Primary Survey and Resuscitation Interventions

PRIORITIES OF THE PRIMARY SURVEY	EXAMPLES OF SPECIFIC INTERVENTIONS
A: Airway/cervical spine	Establish a patent airway by positioning, suctioning, and oxygen as needed.
	Protect the cervical spine by maintaining alignment; use a jaw-thrust maneuver if there is a risk for spinal injury.
	If the Glasgow Coma Scale (GCS) score is 8 or less or the patient is at risk for airway compromise, prepare for endotracheal intubation and mechanical ventilation.
B: Breathing	Assess breath sounds and respiratory effort.
	Observe for chest wall trauma or other physical abnormality.
	Prepare for chest decompression if needed.
	Prepare to assist ventilations if needed.
C: Circulation	Monitor vital signs, especially blood pressure and pulse.
	Maintain vascular access using a large-bore catheter.
	Use direct pressure for external bleeding; anticipate need for a tourniquet for severe, uncontrollable extremity hemorrhage and use of a hemostatic dressing.
D: Disability	Evaluate the patient's level of consciousness (LOC) using the GCS.
	Re-evaluate the patient's LOC frequently.
E: Exposure	Remove all clothing for a complete physical assessment.
	Prevent hypothermia (e.g., cover the patient with blankets, use heating devices, infuse warm solutions).

NCLEX Examination Challenge

Safe and Effective Care Environment

A trauma client has been brought to the emergency department after a motor vehicle crash. The client has severe injuries. What action does the nurse perform first?

A Start 2 large-bore IVs and run normal saline.
B Apply oxygen and an oximeter probe to the client.
C Stabilize the cervical spine and assess the airway.
D Place pressure on a large bleeding wound to the forehead.

The Secondary Survey and Resuscitation Interventions

After the ED resuscitation team addresses the immediate life threats, other activities that the emergency nurse can anticipate include insertion of a gastric tube for decompression of the GI tract to prevent vomiting and aspiration, insertion of a urinary catheter to allow careful measure of urine output, and preparation for diagnostic studies. The resuscitation team also performs a more comprehensive head-to-toe assessment, known as the **secondary survey,** to identify other injuries or medical issues that need to be managed or that might affect the course of treatment.

Disposition

The patient may be transported immediately to the operating room or interventional radiology suite directly from the ED, depending on the nature of the injury. When no immediate procedural intervention is indicated, patients are admitted to inpatient units for management and nursing care based on the nature and severity of their injuries, as well as any other pre-existing medical conditions that could complicate trauma care. However, if the facility does not have the resource capabilities to manage the injured patient, the physician arranges for transfer to a higher level of care.

Work in collaboration with the interdisciplinary team to address the trauma patient's complex health care needs, including early consultation with social services and the rehabilitation team. Coordinate with other support services as necessary, such as pastoral care, nutrition support, psychiatry, behavioral health specialists, and substance abuse counselors. Trauma centers are required to incorporate systems to identify patients with high-risk alcohol use (American College of Surgeons Committee on Trauma, 2006). An effective strategy is to implement an SBIRT (**s**creening, **b**rief **i**ntervention, and **r**eferral to **t**reatment) program in which interdisciplinary trauma team members, including emergency and trauma nurses, are educated to assess patients for problem drinking. The typical interaction involves a brief, respectful conversation that offers feedback, advice, and motivation to reduce alcohol consumption (Desy et al., 2010).

Consider the needs of family members in crisis and address them when planning nursing care. A trauma advanced practice nurse, if available, can help coordinate trauma care by offering clinical expertise, facilitating communication among caregivers, and serving as an educator for the patient, staff, and family (Mower-Wade & Pirrung, 2010). They can organize family meetings with the interdisciplinary team and arrange for necessary resources. If this resource is not available, a case manager or specially educated direct care nurse may perform these functions.

Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Understand that emergency departments (EDs) are fast-paced, often crowded environments where care occurs for patients across the life span with a variety of health problems.
- Recognize that some vulnerable populations who present to the ED include patients who are uninsured (poor), homeless, and older adults. **Patient-Centered Care** QSEN
- Anticipate that some of the most common reasons that patients seek ED care are chest pain, abdominal pain, difficulty breathing, injury, headache, fever, and pain.
- Collaborate with members of the interdisciplinary health care team in the ED, which includes prehospital providers, physicians, nurses, specialty teams, and support staff. **Teamwork and Collaboration** QSEN
- Review Chart 8-1 to plan and implement best practices to maintain staff and patient safety in the ED. **Safety** QSEN
- Explain the core competencies needed for nurses to function in the ED, including assessment, priority setting, knowledge, technical skills, and communication.
- Understand that the three-level triage model categorizes patients as emergent, urgent, and nonurgent (see Table 8-2). The Emergency Severity Index is a five-tier triage system that uses both acuity and the prediction of necessary resources to rapidly categorize the priority of patients.
- Recall that trauma centers are categorized as Levels I through IV, based on their resource capabilities as listed in Table 8-3.
- Remember that the mechanism of injury describes the manner in which the traumatic event occurred.
- Recall that the two most common injury-producing mechanisms are blunt trauma and penetrating trauma.
- Prioritize resuscitation interventions based on the primary survey of the injured patient by implementing the steps of the primary survey and trauma resuscitation as outlined in Table 8-4.
- Recall that patient education as part of the discharge plan is an important part of ED nursing practice.

Psychosocial Integrity

- Provide support by working in collaboration with the psychiatric crisis team as needed.

Physiological Integrity

- Remember the general process of admission through discharge in the ED. Patients managed in the ED are treated and stabilized before discharge. Patients may be discharged to their homes or be admitted for observation or inpatient care.
- Recall that about half of all older adults who visit the ED are admitted to the hospital. **Patient-Centered Care** QSEN
- Understand that ED nurses are accountable for preventing or reducing risks such as falls, medication errors, pressure ulcers, and hospital-acquired infections. Communication with the older adult may be challenging if he or she has memory loss or develops acute delirium while in the ED. **Safety** QSEN

CHAPTER 9

Care of Patients with Common Environmental Emergencies

Linda Laskowski-Jones

PRIORITY CONCEPTS

- Pain
- Thermoregulation
- Tissue Integrity

Learning Outcomes

Safe and Effective Care Environment

1. Collaborate with the interdisciplinary health care team when providing care for patients with common environmental emergencies.

Health Promotion and Maintenance

2. Teach people at risk how to prevent heat-related and cold-related injuries, especially older adults.
3. Teach people at risk how to prevent arthropod bites and stings and snakebites.

Physiological Integrity

4. Assess patients at high risk for environmental emergencies.
5. Prioritize first aid/prehospital interventions for patients who have thermoregulation problems.
6. Prioritize first aid/prehospital interventions for patients who have arthropod bites affecting tissue integrity.
7. Prioritize first aid/emergency care interventions for patients who have venomous snakebites.

8. Apply knowledge of pathophysiology to identify best practices for care of patients with environmental emergencies.
9. Develop an evidence-based plan of care for a patient who is allergic to bees and is stung.
10. Prioritize care for patients who have been struck by lightning.
11. Prioritize care for patients who survive a drowning incident.
12. Explain best practices for patients who are at risk for or experience altitude-related illnesses.

http://evolve.elsevier.com/Iggy/

Recreational activities, as well as home and work responsibilities, inspire people of all ages to leave their homes and go outdoors. However, seemingly harmless outside activities can have associated environmental risks, especially for older adults. Some risks, such as insect bites or stings, reptile bites, and environmental conditions, may also pose threats indoors. This chapter provides an overview of selected environmental emergencies, their initial emergency management (first aid), and acute care interventions. Illness and injury prevention strategies for nurses to incorporate into their own lifestyle and health teaching opportunities are also discussed.

Heat-Related Illnesses

High environmental temperature (above 95° F [35° C]) and high humidity (above 80%) are the most common environmental factors causing heat-related illnesses. These thermoregulation-related illnesses include heat exhaustion and heat stroke. Some of the most vulnerable, at-risk populations for these problems are:

- Older adults
- People with mental health conditions
- People who work outside, such as construction and agricultural workers (more men than women)
- Homeless people
- Illicit drug users (especially cocaine users)
- Outdoor athletes (recreational and professional)
- Members of the military who are stationed in countries with hot climates (e.g., Iraq, Afghanistan)

Older adults have less body fluid volume and can easily become dehydrated when exposed to excessive heat and humidity. Wearing heavy clothing, inadequate acclimatization to hot weather, and social disadvantage (e.g., poor housing, lack of air-conditioning) are also significant contributing factors.

A patient's health status can also increase the risk for heat-related illness, especially obesity, heart disease, fever, infection, strenuous exercise, seizures, mental health disorders, and all degrees of burns (even sunburn). In addition, the use of certain prescribed drugs such as lithium, neuroleptics, beta-adrenergic blockers, anticholinergics, angiotensin-converting enzyme (ACE) inhibitors, and diuretics increases the risk for heat-related illness (Cusack et al., 2011).

Health Promotion and Maintenance

Teach older adults before participating in any hot weather activity how to consider their risks and to take steps to eliminate or minimize them whenever possible. Ask them to have a family member, friend, or neighbor check on them several times each day to ensure that there are no signs of heat-related illness. Chart 9-1 lists other essential heat-related illness prevention strategies for older adults, many of which apply to adults of any age.

Chart 9-1 Nursing Focus on the Older Adult

Heat-Related Illness Prevention

- Avoid alcohol and caffeine.
- Prevent overexposure to the sun; use a sunscreen with an SPF of at least 30 with UVA and UVB protection.
- Rest frequently, and take breaks from being in a hot environment. Plan to limit activity at the hottest time of day.
- Wear clothing suited to the environment. Lightweight, light-colored, and loose-fitting clothing is best.
- Pay attention to your personal physical limitations; modify activities accordingly.
- Take cool baths or showers to help reduce body temperature.
- Stay indoors in air-conditioned buildings, if possible.
- Ask a neighbor, friend, or family member to check on the older adult at least twice a day during a heat wave.

SPF, Sun protection factor; *UVA,* ultraviolet A; *UVB,* ultraviolet B.

Heat Exhaustion

❖ Pathophysiology

Heat exhaustion is a syndrome resulting primarily from dehydration. It is caused by heavy perspiration, as well as inadequate fluid and electrolyte intake during heat exposure over hours to days. Patients feel ill, and their clinical manifestations resemble the flu. Profuse diaphoresis can lead to profound, even fatal, dehydration and hyponatremia caused by excessive sodium lost in perspiration. *If untreated, heat exhaustion can lead to heat stroke, which is a true emergency condition that has a very high mortality rate.*

❖ Patient-Centered Collaborative Care

In heat exhaustion, patients usually have flu-like symptoms with headache, weakness, nausea, and/or vomiting. Body temperature is not significantly elevated in this condition. The patient may continue to perspire despite dehydration.

Nursing Safety Priority QSEN

Action Alert

Assess the patient for orthostatic hypotension and tachycardia, especially the older adult who is predisposed to rapid dehydration. Older adults who are already dehydrated often experience acute

confusion and are at risk for falls.

Ask the person experiencing heat exhaustion to immediately stop physical activity; move him or her to a cool place, and use cooling measures. Effective cooling measures include placing cold packs on the neck, chest, abdomen, and groin; soaking the person in cool water; or fanning him or her while spraying water on the skin. Remove any constrictive clothing. Provide an oral rehydrating solution such as a sports drink or an oral rehydration therapy solution. Mistakenly drinking plain water can worsen the sodium deficit. *Do not give salt tablets*—they can cause stomach irritation, nausea, and vomiting. If these signs and symptoms persist, call an ambulance to transport the patient to the hospital.

In the clinical setting, monitor vital signs. Rehydrate the patient with IV 0.9% saline solution if nausea or vomiting persists. Draw blood for serum electrolyte analysis. Hospital admission is indicated only for patients who have other health problems that are worsened by the heat-related illness or for those with severe dehydration. The management of hypovolemic dehydration is discussed in more detail in Chapter 11.

Heat Stroke

Pathophysiology

Heat stroke is a *true medical emergency* in which body temperature may exceed 104° F (40° C). It has a high mortality rate if not treated in a timely manner. The victim's thermoregulation mechanisms fail and cannot adjust for a critical elevation in body temperature (Laskowski-Jones, 2010). If the condition is not treated or the patient does not respond to treatment, organ dysfunction and death can result. In their cohort study of 16 emergency departments, Hausfater et al. (2010b) found that nine factors help predict mortality in patients admitted to emergency departments with non-exertional heat stroke (see the Evidence-Based Practice box).

Evidence-Based Practice QSEN

What Factors Predict Who Will Develop Non-exertional Heat Stroke?

Hausfater, P., Megarbane, B., Dautheville, S., Patzak, A., Andronikof, M., Andre, S., et al. (2010). Prognostic factors in non-exertional heatstroke. *Intensive Care Medicine, 36,* 272-280.

Heat-related illnesses are often medical emergencies that can lead to

death. The authors presented findings of a large multi-center observational cohort study of 1456 patients who were admitted to 16 emergency departments (EDs) in teaching hospitals during heat waves. The mean age of the sample was 79 years, and 391 of them were critically ill on admission. All of the study patients had an elevated core body temperature. The survival rate for the study sample was only 57% at 1 year after diagnosis.

On retrospective review of the patients' charts, it was found that nine factors negatively influenced survival rates. They included an age older than 80 years, body temperature of over 104° F (40° C), systolic blood pressure less than 100 mm Hg, Glasgow Coma Scale score of less than 12, presence of cancer and/or cardiac disease, previous treatment with diuretics, living in an institution, and transported to the ED by ambulance.

Level of Evidence: 4

This study is a nonexperimental or descriptive cohort study, but it used a large sample size in multiple emergency departments. Random assignment or comparison of two groups was not appropriate for answering the research question.

Commentary: Implications for Practice and Research

The results of this study indicate that older, institutionalized patients with cardiac disease or cancer and heat stroke have a high risk for not surviving a year after the heat-related illness. The major nursing implication from this study is that more emphasis on preventing heat-related illnesses in institutionalized patients is needed, particularly if they are older than 80 years. Strengths of the study included the large sample size collected from multiple emergency departments. A weakness might be the level of evidence (Level 4: nonexperimental or descriptive cohort study), but this is probably outweighed by the sampling method and the fact that an experimental design was not appropriate to answer the research question. Nurses are in a key position to advocate for these patients and to implement interventions that can help prevent heat stroke. Early detection and treatment also are needed. Chart 9-1 lists best practices for decreasing the risk for heat-related illnesses in older adults.

The two major types of heat stroke are exertional and classic. **Exertional heat stroke** has a sudden onset and is often the result of strenuous physical activity in hot, humid conditions. Not being used to

hot weather and wearing clothing too heavy for the environment are common contributing factors. **Classic heat stroke,** also referred to as *non-exertional heat stroke,* occurs over a period of time as a result of chronic exposure to a hot, humid environment, such as a home without air-conditioning in the high heat of the summer. It generally affects ill and older adults and causes several hundred deaths in the United States every year. The risk factors for heat stroke are similar to those for heat exhaustion.

Patient-Centered Collaborative Care

Assessment

Victims of heat stroke have a profoundly elevated body temperature (above 104° F [40° C]). *Although the patient's skin is hot and dry, the presence of sweating does not rule out heat stroke—people with heat stroke may continue to perspire.*

Mental status changes occur as a result of thermal injury to the brain. Manifestations can include confusion, bizarre behavior, seizures, or even coma (Chart 9-2). Vital sign abnormalities may include hypotension, tachycardia, and tachypnea. Recent research demonstrates that cardiac troponin I (cTnI) is frequently elevated during non-exertional heat-related illnesses. A severe increase (>1.5 ng/mL) indicates severe myocardial damage and decreases the chance of patient survival 1 year after the event (Hausfater et al., 2010a).

Chart 9-2 Key Features

Heat Stroke

- Body temperature more than 104° F (40° C)
- Hot and dry skin; may or may not perspire
- Mental status changes, such as:
  - Acute confusion
  - Bizarre behavior
  - Anxiety
  - Loss of coordination
  - Hallucinations
  - Agitation
  - Seizures
  - Coma
- Vital sign changes, including:
  - Hypotension
  - Tachycardia
  - Tachypnea (increased respiratory rate)
- Electrolyte imbalances, especially sodium and potassium
- Decreased renal function (oliguria)
- Coagulopathy (abnormal clotting)
- Pulmonary edema (crackles)

Complications of thermoregulation failure due to classic heat stroke include multiple organ dysfunction syndrome (MODS), renal impairment, electrolyte and acid-base disturbances, coagulopathy (abnormal clotting), pulmonary edema, and cerebral edema (O'Brien et al., 2012). Any of these problems can lead to death and are described in detail elsewhere in this book.

Interventions

Coordinate care with the health care team to recognize and treat immediately and aggressively to achieve optimal patient outcomes. Chart 9-3 lists evidence-based emergency care of patients with heat stroke.

Chart 9-3 Best Practice for Patient Safety & Quality Care QSEN

Emergency Care of the Patient with Heat Stroke: Restoring Thermoregulation

At the Scene

- Ensure a patent airway.
- Remove the patient from the hot environment (into air-conditioning or into the shade).
- Remove the patient's clothing.
- Pour or spray cold water on the patient's body and scalp.
- Fan the patient (not only the person providing care, but all surrounding people should fan the patient with newspapers or whatever is available).
- If ice is available, place ice in cloth or bags and position the packs on the patient's scalp, in the groin area, behind the neck, and in the armpits.
- Contact emergency medical services to transport the patient to the emergency department.

At the Hospital

- Give oxygen by mask or nasal cannula; be prepared for endotracheal intubation.
- Start at least one IV with a large-bore needle or cannula.
- Administer normal saline (0.9% sodium chloride) as prescribed, using cooled solutions if available.
- Use a cooling blanket.
- Do not give aspirin or any other antipyretics.

- Insert a rectal probe to measure core body temperature continuously, or use a rectal thermometer and assess temperature every 15 minutes.
- Insert an indwelling urinary drainage catheter.
- Monitor vital signs frequently as clinically indicated.
- Obtain baseline laboratory tests as quickly as possible: serum electrolytes, cardiac enzymes, liver enzymes, and complete blood count (CBC).
- Assess arterial blood gases.
- Administer muscle relaxants (benzodiazepines) if the patient begins to shiver.
- Measure urine output and specific gravity to determine fluid needs.
- Stop cooling interventions when core body temperature is reduced to 102° F (39° C).
- Obtain urinalysis, and monitor urine output.

First Aid/Prehospital Care.

Do not give food or liquid by mouth because vomiting and aspiration are risks in patients with neurologic impairment. Immediate medical care using advanced life support is essential.

Nursing Safety Priority QSEN

Critical Rescue

After ensuring that the patient has a patent airway, effective breathing, and adequate circulation, use rapid cooling as the first priority for care. Methods for rapidly cooling include:

- Removing clothing
- Placing ice packs on the neck, axillae, chest, and groin
- Immersing the victim in cold water
- Wetting the patient's body with cold water and then fanning rapidly to aid in cooling by evaporation

Drenching the victim with large amounts of icy water may be the fastest, most effective means to reduce core body temperature (O'Brien et al., 2012).

Hospital Care.

The first priority for collaborative care is to monitor and support the patient's airway, breathing, and circulatory status. Provide high-concentration oxygen therapy, start several IV lines with 0.9% saline solution, and insert an indwelling urinary catheter. Continue aggressive interventions to cool

the patient until the rectal temperature is 102° F (38.9° C) (O'Brien et al., 2012). External continuous cooling methods include using cooling blankets and applying ice packs in the axillae and groin and on the neck and head. Internal cooling methods may include iced gastric and bladder lavage. Use a continuous core temperature–monitoring device (e.g., rectal or esophageal probe) or a temperature-monitoring urinary bladder catheter to prevent hypothermia.

If shivering occurs during the cooling process, give a parenteral benzodiazepine such as diazepam (Valium). Lorazepam (Ativan) is an alternative agent. Seizure activity can further elevate body temperature and is also treated with an IV benzodiazepine. Once the patient is stabilized, admission to a critical care unit is warranted to monitor for complications such as multi-system organ dysfunction syndrome and severe electrolyte imbalances; these problems increase mortality risk.

NCLEX Examination Challenge

Physiological Integrity

An older client with heat exhaustion is being cooled with cool water spray and fanning. What assessment indicates to the nurse that the client needs hospitalization?

A The client is alert and oriented.
B The client's mucous membranes are dry and sticky.
C The client reports weakness and nausea.
D The client continues to sweat while being cooled.

Snakebites

Although most snake species are nonvenomous (nonpoisonous) and harmless, there are two families of poisonous snakes in North America: pit vipers *(Crotalidae)* and coral snakes *(Elapidae).*

Pit vipers are named for the characteristic depression between each eye and nostril that serves as a heat-sensitive organ for locating warm-blooded prey. They include various species of rattlesnakes, copperheads, and cottonmouths and account for the majority of the poisonous snakebites in the United States (Figs. 9-1 and 9-2).

FIG. 9-1 Southern copperhead *(Agkistrodon contortrix)* has markings that make it almost invisible when lying in leaf litter.

FIG. 9-2 Cottonmouth water moccasin *(Agkistrodon piscivorus).* The open-mouthed threat gesture is characteristic of this semiaquatic pit viper.

Coral snakes are found from North Carolina to Florida and in the Gulf states through Texas and the southwestern United States. They have broad bands of red and black rings, separated by yellow or cream rings. These nonaggressive snakes have short, fixed fangs and inject highly neurotoxic venom into prey.

Most snakes fear humans and attempt to avoid contact with them. Sudden, unexpected confrontations at close range often lead to defensive strikes. Awareness is the key to snakebite prevention.

Health Promotion and Maintenance

Chart 9-4 provides common-sense actions to avoid being bitten by a poisonous snake. Teach people who own snakes to follow these precautions. Remind them that snakebites can be life threatening.

Chart 9-4 Patient and Family Education: Preparing for Self-Management

Snakebite Prevention

- Do not keep venomous snakes as pets.
- Be extremely careful in locations where snakes may hide, such as tall grass, rock piles, ledges and crevices, woodpiles, brush, boxes, and cabinets. Snakes are most active on warm nights.
- Don protective attire such as boots, heavy pants, and leather gloves. When walking or hiking, use a walking stick or trekking poles.
- Inspect suspicious areas before placing hands and feet in them.
- Do not harass any snakes you may encounter. Striking distance can be up to two-thirds the length of the snake. Even young snakes pose a threat; they are capable of envenomation from birth.
- Be aware that newly dead or decapitated snakes can inflict a bite for up to an hour after death because of persistence of the bite reflex.
- Do not transport the snake with the victim to the medical facility for identification purposes; instead, take a digital photo of the snake at a safe distance if possible.

North American Pit Vipers

North American pit vipers can be differentiated from harmless snakes by these key anatomic features:

- A heat-sensing "pit"
- A triangular head that indicates the presence of venom glands and

elliptical pupils
- Two retractable, curved fangs that have canals for venom flow
- Up to three sets of developing "replacement" fangs behind the primary fangs

Unlike copperheads and cottonmouths, rattlesnakes also have interlocking horny rings in their tails that vibrate and serve as a characteristic warning signal. Pit vipers can regulate the amount of venom flow through their fangs, depending, in part, on the size of the prey. The amount of venom injected in bites to humans varies. A bite might actually be "dry," meaning there is no **envenomation** (venom injection), yet there are distinctive fang marks on the patient. In contrast, "harmless" snakes do not have venom glands or fangs but can bite and leave skin marks.

Pathophysiology

When providing emergency care to a victim of snakebite, assess for evidence that venom has been injected into the body. The primary functions of venom are to immobilize, kill, and aid in digestion of prey. Therefore venom causes local and systemic toxic effects. The enzymes in venom break down human tissue proteins, alter membrane integrity, and impair blood clotting. The pathophysiologic effects of pit viper envenomation can lead to impaired tissue integrity from local tissue necrosis and massive tissue swelling, intravascular fluid shifts and hypovolemic shock, pulmonary edema, renal failure, hemorrhagic complications from disseminated intravascular coagulation (DIC), and death. These complications are discussed elsewhere in this book.

Patient-Centered Collaborative Care

Assessment

The clinical manifestations of venom release are based on the type and amount of venom injected; the bite location; and the age, size, and health status of the victim. Puncture wounds in the skin are a key local sign of pit viper envenomation. One or more puncture wounds may be present, depending on how many fangs the snake has and how many times the snake struck the patient. Severe pain, swelling, and redness or **ecchymosis** (bruising) in the area around the bite are common. Hours later, vesicles or hemorrhagic bullae may form. Systemic responses to venom must be distinguished from the effects of anxiety and panic related to being bitten by a snake. Common reports by the victim include a minty,

rubbery, or metallic taste in the mouth and tingling or paresthesias of the scalp, face, and lips. Other effects include muscle **fasciculations** (twitching) and weakness, nausea, vomiting, hypotension, seizures, and **coagulopathy** (clotting abnormalities) or DIC. If the bite site does not show evidence of local tissue swelling or redness within 8 hours, systemic effects are less likely to develop.

Interventions

First Aid/Prehospital Care.

First aid interventions for snakebite should begin in the field and can improve the victim's outcome.

Nursing Safety Priority QSEN

Critical Rescue

The first priority is to move the person to a safe area away from the snake and encourage rest to decrease venom circulation. Next, remove jewelry and constricting clothing before swelling worsens. Call for immediate emergency assistance. Do not attempt to capture or kill the snake, but do take digital photographs at a safe distance if possible to aid in snake identification.

Immobilizing the affected extremity in a position of function with a splint may help limit the spread of the venom. Maintain the extremity at the level of the heart. Keep the person warm, and provide calm reassurance. Do not offer any alcohol because it can cause the venom to spread through vasodilation (Bledsoe et al., 2009). *Do not incise or suck the wound, apply ice to it, or use a tourniquet—these actions are ineffective and can worsen the patient's outcome* (Norris et al., 2012).

Hospital Care.

Acute care in a hospital is required as soon as possible because envenomation is a medical emergency. Supportive care includes supplemental oxygen, two large-bore IV lines, and infusion of crystalloid fluids such as normal saline solution or Ringer's lactate solution. Apply continuous cardiac and blood pressure monitoring equipment to quickly detect clinical deterioration. Because venom can cause severe pain at the bite site, opioids are indicated. Provide tetanus prophylaxis and wound care as part of the collaborative plan of care.

Severe pit viper bites cause coagulopathy and promote hemorrhage and tissue destruction. Along with typical baseline laboratory studies, anticipate obtaining specimens for a coagulation profile, complete blood count (CBC), creatine kinase (CK), type and crossmatch for possible blood transfusion, and urinalysis. An electrocardiogram (ECG) is necessary to detect evidence of myocardial ischemia or other cardiac abnormalities.

Obtain pertinent patient history related to the event, including a full description of the snake's appearance, the time the bite occurred, prehospital interventions, and any past incidence of snakebite or antivenom use. To accurately assess the development of tissue edema at the bite site, measure and record the circumference of the bitten extremity every 15 to 30 minutes. Delineate the border of skin discoloration or edema with a skin marker to better track the progression of venom effects.

Venom potency varies. Not all snakebite victims need antivenom administration. The decision whether or not to give antivenom is based on the severity of the snakebite. Table 9-1 classifies **envenomation** severity. *Contact the regional poison control center so that toxicologists can provide specific advice for antivenom dosing and medical management.*

TABLE 9-1

Grades of Pit Viper Envenomation

ENVENOMATION	CHARACTERISTICS
None	Fang marks, but no local or systemic reactions
Minimal	Fang marks, local swelling and pain, but no systemic reactions
Moderate	Fang marks and swelling progressing beyond the site of the bite; systemic signs and symptoms, such as nausea, vomiting, paresthesias, and hypotension
Severe	Fang marks present with marked swelling of the extremity, subcutaneous ecchymosis, severe symptoms, including manifestations of coagulopathy

From Auerbach, P.S., Donner, H.J., & Weiss, E.A. (2013). *Field guide to wilderness medicine* (4th ed.). St. Louis: Mosby.

The newest and safest antivenom for pit viper bites is Crotalidae Polyvalent Immune Fab (CroFab), which is derived from sheep (ovine). This drug consists of specific antibody fragments of immunoglobulin G (IgG) that bind and neutralize toxins in pit viper venom to counteract its effects on the body (Norris et al., 2012). Unlike the older antivenoms that were derived from horse serum, serum sickness rarely occurs after IV CroFab administration. **Serum sickness** is a type III hypersensitivity reaction that develops within 3 to 21 days, first as a skin rash with

progression to fever, joint pain, and **pruritus** (itching). Although mild to moderate allergic reactions such as pruritus and **urticaria** (hives) can occur, anaphylaxis is rare. If the patient has a known hypersensitivity to papain or papaya, which is used during the manufacturing process, CroFab is contraindicated unless the benefits are believed to outweigh the risks (Fougera Pharmaceuticals, Inc., 2008). Give CroFab cautiously to patients who have:

- A previous allergic reaction to antivenom therapy
- A hypersensitivity to bromelain (a pineapple-derived enzyme) or sheep protein
- Prior CroFab therapy for a past envenomation (patients can become sensitized to the foreign sheep protein)
- Pregnancy
- Sensitivity to mercury-containing products (the antivenom contains mercury)

CroFab should be given to patients as soon as possible, with the optimal timing within 6 hours of the bite (Fougera Pharmaceuticals, Inc., 2008). The recommended initial IV dose is 4 to 6 vials infused over 60 minutes. During the first 10 minutes, the infusion should be slow (25-50 mL/hr). Monitor the patient closely for an allergic reaction (e.g., hives, rash, difficulty breathing). If symptoms are not effectively controlled with the first dose, an additional 4 to 6 vials are recommended. Once the symptoms are under control, 2 more vials of CroFab are administered every 6 hours for a total of 18 hours of administration (Fougera Pharmaceuticals, Inc., 2008).

Coral Snakes

❖ Pathophysiology

North American coral snakes are found in the southeastern and southwestern United States (Fig. 9-3). These snakes burrow into the ground and are nonaggressive. Coral snakes account for fewer than 1% of venomous snakebites in the United States (Norris, 2011). Their ability to inject venom is less efficient than that of the pit vipers. Their maxillary fangs are small and fixed in an upright position. Most bites occur when people attempt to handle the snake. Coral snake venom has two toxins: a nerve toxin and a muscle toxin. The amount of venom in an adult coral snake is enough to kill an adult.

FIG. 9-3 Sonoran coral snake *(Micruroides euryxanthus)* is also known as the *Arizona coral snake.* No documented fatality has followed a bite by this species.

Coral snakes can be recognized by bands of black, red, and yellow that circle around the body of the snake. Several harmless snake species closely resemble the coral snake. If a black band lies between the red and yellow bands, the snake is usually nonvenomous. If the red band touches the yellow band, the snake is venomous. A helpful memory aid for identifying coral snakes is "red on yellow can kill a fellow" and "red on black, venom lack." *Be aware that this saying applies only to coral snakes found in the United States!*

Patient-Centered Collaborative Care

Assessment

Manifestations of coral snake envenomation are the result of its neurotoxic properties. The physiologic effect is to block neurotransmission, which produces weakness, cranial nerve deficits (ptosis, diplopia, swallowing difficulty), an altered level of consciousness, and, ultimately, respiratory paralysis (Norris, 2011). Unlike the pain from pit viper bites, pain at the coral snakebite site may be only mild and transient. The venom is spread via the lymphatic system, but swelling, if present, is typically mild. Fang marks may be difficult to find because of the coral snake's small teeth. The toxic effects of coral snake venom also may be delayed up to 13 hours after a bite but then produce rapid clinical deterioration (Norris et al., 2012). Early signs and symptoms include nausea, vomiting, headache, pallor, and abdominal pain. Assess for neurologic manifestations, such as paresthesias (painful tingling),

numbness, muscle fasciculations, and mental status changes, as well as cranial nerve and peripheral nerve deficits. Total flaccid paralysis may occur later, and the patient may have difficulty speaking, swallowing, and breathing. Clotting disorders do not occur.

Respiratory problems and cardiovascular collapse can occur in severe cases (Norris, 2011). Arterial blood gas analysis reveals respiratory insufficiency. The muscle toxin in the venom can cause an elevation in creatine kinase (CK) levels from muscle breakdown and produce **myoglobinuria** (release of muscle myoglobulin into the urine). Despite these clinical effects, death is rare if the patient receives timely management.

Interventions

First Aid/Prehospital Care.

Because several varieties of harmless snakes resemble the coral snake, the first priority, if possible, is to identify the snake as a coral snake. *However, if the snake cannot be positively identified, the victim should be treated as if venom has been injected.* Because coral snake venom does not destroy tissue, the field treatment to limit the spread of venom includes the use of pressure immobilization techniques (Norris et al., 2012). The affected extremity is encircled snugly with an elastic bandage or roller gauze dressing to impede lymphatic flow; it is then splinted. *This compression bandage must not be so tight that it impairs arterial flow. It should not be removed until the victim is managed at an acute care facility* (Norris et al., 2012).

Hospital Care.

Once in an acute care setting, patients who have had an actual or potential coral snake envenomation will have continuous cardiac, blood pressure, and pulse oximetry monitoring and are admitted to a critical care unit. Prepare to provide aggressive airway management via endotracheal intubation if respiratory insufficiency or severe neurologic impairment occurs. Aspiration of secretions is a significant risk for this patient.

Coral snake antivenom is no longer manufactured in the United States. Until another drug manufacturer takes over production, supportive care is recommended as the primary patient management strategy (Norris, 2011). A patient can survive a coral snake bite without antivenom but may require prolonged mechanical ventilation; the effects of severe bites can persist for many days (Norris, 2011). *Contact the regional poison control*

center immediately for specific advice on patient management.

Nursing Safety Priority QSEN

Critical Rescue

The most significant risk to the victim is airway compromise and respiratory failure. Therefore ensure that the patient's IV lines are patent and that resuscitation equipment is immediately available.

Arthropod Bites and Stings

Arthropods include spiders, scorpions, bees, and wasps. Unlike snakes, almost all species of spiders are venomous to some degree—most are not harmful to humans either because their mouth is too small to pierce human skin or the quantity or quality of their venom is inadequate to produce major health problems. Brown recluse and black widow spiders, scorpions, bees, and wasps are examples of venomous arthropods that can cause toxic reactions in humans. Chart 9-5 lists actions that help prevent arthropod bites and stings.

Chart 9-5 Patient and Family Education: Preparing for Self-Management

Arthropod Bite/Sting Prevention

- Wear protective clothing, including gloves and shoes, when working in areas known to harbor venomous arthropods, such as spiders, scorpions, bees, and wasps.
- Cover garbage cans. Bees and wasps are attracted to uncovered garbage.
- Use screens in windows and doors to prevent flying insects from entering buildings.
- Inspect clothing, shoes, and gear for insects before putting on these items.
- Shake out clothing and gear that have been on the ground to prevent arthropod "stowaways" and inadvertent bites and stings.
- Consult an exterminator to control arthropod populations in and around the home. Eliminating insects that are part of the arthropod's food source may also limit their presence.
- Identify nesting areas such as yard debris and rock piles; remove them whenever possible.
- Do not place unprotected hands where the eyes cannot see.
- Avoid handling insects or keeping them as "pets."
- Do not swat insects, wasps, and Africanized bees because they can send chemical signals that alert others to attack.
- Carry a prescription epinephrine autoinjector and antihistamines if known to be allergic to bee and wasp stings. Ensure at least one family member is also able to use the autoinjector.

Brown Recluse Spider

Pathophysiology

Brown recluse spiders are known for producing bites that result in skin ulcers. Also known as "fiddlebacks" or "violin spiders," they are medium-size spiders that are light brown and have a dark brown, fiddle-shaped mark that extends from their eyes down their back (Fig. 9-4). Like their name implies, brown recluse spiders are shy and hide in areas that are dark and secluded, such as boxes, closets, basements, sheds, and garages. Most indoor bites occur when people are sleeping, reaching into boxes or closets, or donning clothing that contains the spider. Few people ever see the spider that bit them. The only evidence may be impaired tissue integrity from a skin lesion or a necrotic wound or, less often, systemic effects from the injected toxin, commonly referred to as **loxoscelism**. Note that it is also common for patients to mistake a skin lesion for a spider bite; the lesion may actually be due to a skin infection, an insect bite, or even the manifestation of a health condition (Suchard, 2011).

FIG. 9-4 Brown recluse spider *(Loxosceles reclusa)*.

Patient-Centered Collaborative Care

Assessment

Brown recluse spider venom causes cell damage. The bite may be described as painless or stinging to sharp and painful. Some victims are unaware that they were bitten until intense local aching and pruritus develop over minutes to hours. The central bite site may demonstrate impaired tissue integrity appearing as a bleb or vesicle surrounded by edema and erythema, which may expand over the course of hours as the toxin spreads to surrounding tissues. The center of the bite becomes bluish

purple. Some people have few or no tissue changes and therefore do not require medical attention.

For other people who are bitten, over the next 1 to 3 days the central part of the wound becomes dark and necrotic (Fig. 9-5). **Eschar** (a necrotic, leathery covering over the wound) eventually forms. The combination of these tissue changes is often referred to as the classic "red, white, and blue sign" that is associated with severe brown recluse spider bites.

FIG. 9-5 Brown recluse spider bite after 24 hours, with central ischemia and rapidly advancing cellulitis.

When the eschar sloughs, tissue integrity is impaired by an open wound or ulcer that can remain for weeks to months. In rare cases, some patients may also have manifestations of systemic toxicity to brown recluse spider bites. These can include a rash, fever, chills, nausea, vomiting, malaise, and joint pain. In the worst cases, hemolytic reactions, renal failure, pulmonary edema, cardiovascular collapse, and death can occur.

Interventions

First Aid/Prehospital Care.

The basic first aid for a brown recluse spider bite is to apply cold compresses over the site intermittently until there is no further progression of the wound (Arnold, 2012). Cold helps decrease the enzyme activity of the venom and may limit tissue swelling and necrosis. *Do not use heat because it increases the enzyme activity and potentially worsens the wound.* Recommended actions include elevation of the affected extremity, local wound care, and rest.

Hospital Care.

Supportive care and ongoing monitoring for complications meet the needs of most patients with a brown recluse spider bite. For patients with wounds that appear infected, topical antiseptic and sterile dressings are necessary. Wound cultures and antibiotics may also be indicated. Tetanus prophylaxis is recommended.

A surgeon evaluates patients whose wounds require interventions beyond conservative management. Débridement (removal of necrotic tissue) and skin grafting may be required to promote tissue integrity and healing in severe wounds. Where available, collaborate with a wound specialist nurse.

A small number of patients experience severe systemic complications (loxoscelism). Manifestations include:

- Fever and chills
- Nausea and vomiting
- Renal failure
- **Hemolytic anemia** (anemia caused by destruction of red blood cells)
- **Thrombocytopenia** (decreased platelets)
- Disseminated intravascular coagulation (DIC)
- Death

These problems are discussed elsewhere in this text. Critical care management, including aggressive hydration, blood transfusions, hemodialysis, and supportive therapies, is required to prevent further deterioration and promote recovery.

Black Widow Spider

Pathophysiology

Black widow spiders can be found in every state in the United States except Alaska. They can inflict deadly bites and are found in cool, damp environments like outdoor log piles, vegetation, and rocks. They also commonly inhabit barns, sheds, and garages. The female spider is best identified by her shiny black color and the red hourglass pattern on her abdomen. Male spiders are smaller in size and lighter in color with white and gray markings. The hourglass pattern is faint in males. Black widow spiders carry neurotoxic venom. Bites to humans are usually defensive when the spider is at risk for being crushed.

The initial bite of a black widow spider ranges from nearly painless to sharply painful. Typically, the person notices a tiny papule or small, red punctate mark. Some people have intense pain, which seems out of proportion to the lesion. In many cases, the symptoms do not progress beyond a local reaction in the area of the bite site. If systemic signs and

symptoms do occur, they generally develop within 1 hour and involve the neuromuscular system.

Patient-Centered Collaborative Care

Assessment

Black widow spider venom produces a syndrome known as **latrodectism,** in which the venom causes neurotransmitter release from nerve terminals. Severe abdominal pain, muscle rigidity and spasm, hypertension, and nausea and vomiting are common. The problem may be incorrectly diagnosed as an acute abdomen, and surgical consultation may be considered because of the clinical features similar to peritonitis (Boyer et al., 2012). Muscle spasms involve the large muscles of the abdomen, back, and limbs. Other problems include facial edema, **ptosis** (eyelid drooping), diaphoresis, weakness, increased salivation, respiratory difficulty from excessive secretions, fasciculations (twitching), and **paresthesias** (painful tingling or numbness). The effects of the bite are self-limited and generally resolve in a few days. *However, older adults with other health problems like cardiovascular disease are at much higher risk for complications.*

Interventions

First Aid/Prehospital Care

Nursing Safety Priority QSEN

Action Alert

The priority intervention for a black widow spider bite in the prehospital setting is to apply an ice pack because cold application decreases the action of the neurotoxin.

Monitor the person for evidence of systemic toxicity as described in the previous Assessment section. If this problem occurs, support the patient's airway, breathing, and circulation. Patients should be transported to a medical facility as soon as possible for advanced life support care.

Hospital Care.

In the emergency department, closely monitor vital signs, with special

attention to blood pressure and respiratory function. Supportive therapy in the hospital includes administration of opioid pain medication and muscle relaxants such as diazepam (Valium) or other benzodiazepines. Provide tetanus prophylaxis as needed. Observe the patient for seizures related to a rapidly rising blood pressure (Boyer et al., 2012). For some patients, antihypertensive agents are needed. Although relapses may occur, the patient usually recovers within a week.

Less often, pulmonary edema, uncontrollable hypertension, seizures, respiratory arrest, and shock occur. These patients require critical care management. Antivenom is available for black widow spider bites. Although it can cause anaphylaxis and serum sickness, antivenom is considered effective in treating severe reactions (Boyer et al., 2012). The drug is also given to pregnant women because they may have uterine contractions from a black widow spider bite that can lead to a premature delivery (Boyer et al., 2012). The regional poison control center provides information about antivenom dosing and management for women who are pregnant.

Scorpions

Pathophysiology

Scorpions are found in many states within the United States although not typically in the Midwest or New England. However, stings are always possible when people keep scorpions as pets or when scorpions are accidentally transported in baggage and packaging. Unlike spiders that envenom their prey by inflicting a bite, scorpions inject venom through a stinging apparatus on their tail. Most scorpion stings produce a mild reaction characterized by local pain, inflammation, and mild systemic symptoms. These effects are usually self-limiting and best treated by analgesics, supportive management, and basic wound care.

One species of scorpion found in the southwestern United States that can inflict a sting associated with a potentially fatal systemic response is the bark scorpion (Fig. 9-6). It is often found in trees and woodpiles and around debris. Humans are usually stung when the scorpion gets into clothing, shoes, blankets, and personal items left on the ground.

FIG. 9-6 The bark scorpion of Arizona *(Centruroides sculpturatus)*.

Patient-Centered Collaborative Care

Assessment

Because bark scorpion venom is neurotoxic, clinical manifestations result from cranial nerve and/or skeletal muscle involvement. The sting site may or may not show evidence of the venom release. There may be no redness or other obvious sign of inflammation. Gentle tapping at the potential sting site causing increased pain is associated with a bark scorpion sting (Suchard, 2012). The severity of the reaction varies from local pain to severe systemic manifestations, such as excessive salivation, hyperactivity, high fever, hypertension, GI disorders, tachycardia, cardiac dysfunction, pulmonary edema, and nervous system involvement. In rare cases, death can occur.

Symptoms usually begin immediately after the sting and can reach a crisis level within 12 hours. Recovery occurs gradually. pain and paresthesias can remain for up to 2 weeks (Suchard, 2012).

Interventions

Hospital Care.

The first priority of patient management is vital sign assessment and continuous monitoring for several hours in a hospital emergency department or critical care unit. As symptoms worsen, the patient may develop

respiratory failure and need intubation and mechanical ventilation.

Provide supplemental oxygen and IV fluid replacement immediately. Apply an ice pack to the sting site to control pain. Give analgesic and sedative agents with caution in the non-intubated, spontaneously breathing patient. Potent opioids, benzodiazepines, and barbiturates can cause loss of airway reflexes and precipitate respiratory failure. Fever is treated with acetaminophen (Tylenol) and application of a cooling blanket as needed. Because scorpion stings produce a puncture wound impairing tissue integrity, provide tetanus prophylaxis and basic wound care with an antiseptic agent. *Contact the poison control center as soon as possible to assist with patient management, particularly in regard to use of pharmacologic agents for scorpion stings.*

Bees and Wasps

Pathophysiology

Bees and wasps are also venomous arthropods. Stings can produce a wide range of reactions from discomfort at the sting site to severe pain, multi-system problems, and life-threatening anaphylaxis in allergic people. Bumblebees, hornets, and wasps are capable of stinging repeatedly when disturbed. They have a smooth stinger that may or may not become lodged in the victim. Only honeybees can sting just once. When a honeybee stings a person, the stinger and venom sac pull away from the bee. The bee dies, but venom injection continues because the stinger and sac remain in the victim.

"Africanized" bees, also called "killer bees," are a very aggressive species that are found in the southwestern states. They are known to attack in groups and can remain agitated for several hours. People under attack should attempt to outrun the bees, if possible, and keep their mouth and eyes protected from the swarm. A person should never go into a body of water because the bees will attack when he or she comes up for air. When a person sustains multiple stings, reactions are more severe and may be fatal because multiple venom doses have cumulative toxic effects.

Health Promotion and Maintenance

Chart 9-5 lists actions that may help prevent arthropod bites and stings.

Patient-Centered Collaborative Care

Assessment

The person who is stung by a bee or wasp first has a local reaction of immediate pain and a wheal-and-flare skin reaction. For some people, swelling can be extensive and involve an entire limb or body area. Systemic effects can then develop based on the venom load and the person's sensitivity to the venom. These effects may include generalized edema, nausea, vomiting, and diarrhea and are reactions to the toxic effects of the venom itself, not necessarily an allergic reaction. Other toxic venom effects include destruction of red and white blood cells and platelets, damage to the blood vessel walls, acute kidney injury, renal failure, liver injury, and cardiac complications; multi-system organ failure can develop (Lin et al., 2011).

If the patient has an *allergy to the venom*, then **urticaria** (hives), pruritus (itching), and swelling of the lips and tongue may occur. An allergic response can rapidly progress to an anaphylactic reaction in highly sensitive patients. **Anaphylaxis** is a life-threatening allergic response and is evidenced by respiratory distress with bronchospasm and laryngeal edema, hypotension, deterioration in mental status, and cardiac dysrhythmias. *This type of reaction constitutes a true medical emergency that is imminently life threatening and may lead to cardiac arrest.* Initially it may be impossible to distinguish an allergic reaction from a toxic venom reaction because they both can cause the same types of early signs and symptoms.

Interventions

First Aid/Prehospital Care.

Basic emergency care for bee and wasp stings includes quick removal of the stinger (if present) and application of an ice pack (Laskowski-Jones, 2010). Tweezers formerly were avoided for stinger removal because it was believed that pinching the stinger would cause additional venom to be injected. However, this concern appears to be unfounded (Auerbach, 2009). The stinger is best removed with tweezers or by gently scraping or brushing it off with the edge of a knife blade, credit card, or needle. The method used to remove the stinger is not as important as the speed of removal (Auerbach, 2009).

Advanced prehospital emergency care interventions are prioritized to ensure that airway, breathing, and circulation are maintained. First, determine whether the patient has a history of allergic reactions to bee stings. If the patient has a severe allergic reaction with wheezing, facial swelling, and respiratory distress, epinephrine must be given immediately. Allergic adult patients typically carry an epinephrine

autoinjector (e.g., EpiPen®, Auvi-Q™. This device administers a quick and simple single dose of epinephrine in an emergency with just a click of a button. The injection is given via the IM route, typically in the mid-portion of the outer thigh. (See Chapter 20 for further discussion of epinephrine administration for anaphylaxis management.)

After epinephrine administration, an antihistamine such as diphenhydramine (Benadryl, Allerdryl) or chlorpheniramine (Chlor-Trimeton, Novo-Pheniram) is also given. In the field setting, oral liquid diphenhydramine (available over the counter) may be easier for the victim to swallow than the tablet form if there is tongue or pharyngeal edema. *Call 911 to transport the patient to a medical facility as soon as possible, since epinephrine administration may need to be repeated in 15 minutes if symptoms persist.*

Hospital Care.

Once in a clinical setting, patients who sustain serious reactions to bee or wasp stings need oxygen administration and continuous cardiac and blood pressure monitoring. Establish an IV infusion with normal saline solution to support blood pressure. Advanced life support drugs and resuscitation equipment should be made immediately available. If epinephrine IM fails to relieve the life-threatening reaction, a different epinephrine formulation may be requested as a very slow IV bolus.

Nursing Safety Priority QSEN

Drug Alert

IV epinephrine administration has much greater risk for adverse cardiovascular effects than IM epinephrine. Use the IV form of epinephrine with extreme caution, especially in older adults with cardiovascular disease, because it can dramatically increase pulse rate and blood pressure. Monitor the patient's vital signs frequently—at least every 10 to 15 minutes for 1 hour after IV administration.

Bronchospasm can be treated with albuterol (Proventil, Novo-Salmol) via inhalation or a similar bronchodilating agent. Parenteral antihistamines, such as diphenhydramine (Benadryl, Allerdryl), and corticosteroids are also commonly prescribed to decrease the immune response. The toxin in the bee and wasp venom may outlast the effects of the initial doses of epinephrine and antihistamines and cause a recurrence of the allergic reaction over time. Therefore doses may need

to be repeated for hours or days. Corticosteroids in tapered doses are often given to manage or prevent delayed allergic effects, termed a *biphasic reaction,* which generally occurs within 4 to 6 hours of the sting; however, the evidence regarding the effectiveness of corticosteroid administration is unclear (Choo et al., 2013).

All patients who have sustained multiple stings (particularly more than 50) are observed in an emergency care setting for several hours to monitor for the development of toxic venom effects. A critical care admission may be needed.

Nursing Safety Priority QSEN

Action Alert

Teach anyone who develops an allergic reaction to bee or wasp stings to always carry a prescription epinephrine autoinjector and wear a medical alert tag or bracelet.

Lightning Injuries

Pathophysiology

Lightning is a year-round force of nature responsible for multiple injuries and deaths each year. It is caused by an electric charge generated within thunderclouds that may become cloud-to-ground lightning—the most dangerous form to people and structures. Young adult males account for the majority of lightning-related deaths. Most lightning-related injuries occur in the summer months during the afternoon and early evening because of increased thunderstorm activity and greater numbers of people spending time outside. Anyone without adequate shelter, including golfers, hikers, campers, beach-goers, and swimmers, is at risk.

Lightning has an enormous magnitude of energy and a different current flow than a typical high-voltage electric shock. The duration of contact is nearly instantaneous, resulting in a flashover phenomenon—an effect that may account for the relatively low overall mortality rate. Because water is a conductor of electricity and current takes the path of least resistance to the ground, any wetness on the body increases the flashover effect of a lightning strike. Lightning flashover produces an explosive force that can injure victims directly, as well as cause them to fall or to be thrown. The clothing and shoes of victims may be damaged or blown off in the process.

Lightning produces injury by directly striking a victim, by splashing off a nearby object, or by traveling through the ground. Although few people die after a lightning strike, many survivors are left with permanent disabilities.

Health Promotion and Maintenance

Injuries caused by lightning strike are highly preventable. Teach people to stay indoors during an electrical storm. Chart 9-6 lists common prevention strategies. For more information, the Wilderness Medical Society (http://wms.org) also offers evidence-based practice guidelines for the prevention and treatment of lightning injuries (Davis et al., 2012).

Chart 9-6

Patient and Family Education: Preparing for Self-Management

Lightning Strike Prevention

- Observe weather forecasts when planning to be outside.
- Seek shelter when you hear thunder. Safe choices include going inside the nearest building or an enclosed vehicle. Isolated sheds and the entrances to caves are dangerous, however. Do not stand under an isolated tall tree or structure (e.g., ski lift, flagpole, boat mast, power line) in an open area such as a field, ridge, or hilltop; lightning seeks the highest point. A stand of dense trees offers better protection.
- Leave the water immediately (including an indoor shower or bathtub), and move away from any open bodies of water.
- Avoid metal objects like chairs or bleachers; put down tools, fishing rods, garden equipment, golf clubs, and umbrellas; stand clear of fences, exposed pipes, motorcycles, bicycles, tractors, and golf carts.
- If camping in a tent, stay away from the metal tent poles and wet walls.
- Once inside a building, stay away from open doors, windows, fireplaces, metal fixtures, and plumbing.
- Turn off electrical equipment including computers, televisions, and stereos.
- Stay off the telephone. Lightning can enter through the telephone line and produce head and neck trauma, including cataracts and tympanic membrane disruption. Death can result.
- If you are caught out in the open and cannot seek shelter, attempt to move to lower ground such as a ravine or valley; stay away from any tall trees or objects that could result in a lightning strike splashing over to you; place insulating material between you and the ground (e.g., sleeping pad, rain parka, life jacket). A lightning strike is imminent if your hair stands on end, you see blue halos around objects, and hear high-pitched or crackling noises. If you cannot move away from the area immediately, crouch on the balls of your feet and tuck your head down to minimize the target size; do not lie down on the ground or have hand contact with the ground.

Data from Auerbach, P.S., Donner, H.J., & Weiss, E.A. (2013). *Field guide to wilderness medicine* (4th ed.). St. Louis: Mosby.

Patient-Centered Collaborative Care

Assessment

Both the cardiopulmonary and the central nervous systems are profoundly affected by lightning injuries. *The most lethal initial effect of massive electrical current discharge on the cardiopulmonary system is cardiac*

arrest. Because cardiac cells are autorhythmic, an effective cardiac rhythm may return spontaneously. However, prolonged respiratory arrest from impairment of the medullary respiratory center can produce hypoxia and, subsequently, a second cardiac arrest. Therefore, when attempting to manage multiple victims of a lightning strike, provide care to those who are in cardiopulmonary arrest first. Initiate resuscitation measures with immediate airway and ventilatory management, chest compressions, and other appropriate life-support interventions.

People who survive the immediate lightning strike may be treated in a less emergent fashion. However, these victims can have serious myocardial injury, which may be manifested by ECG and myocardial perfusion abnormalities, such as angina and dysrhythmias. The initial appearance of mottled skin and decreased to absent peripheral pulses usually arises from arterial vasospasm and typically resolves spontaneously in several hours.

Central nervous system (CNS) injury is common in lightning strike victims. A classic finding is an immediate but temporary paralysis that affects the lower limbs to a greater extent than the upper limbs. This condition usually resolves within hours, but the patient must be evaluated for spinal injury. Other clinical manifestations and complications resulting from lightning strikes include cataracts, tympanic membrane rupture, cerebral hemorrhage, depression, and post-traumatic stress disorder. Lightning strikes also cause skin burns. Most burns are superficial and heal without incident. Patients may have full-thickness burns, charring, and contact burns from overlying metal objects. An uncommon but characteristic skin manifestation of lightning is the appearance of branching or ferning marks on the skin called **Lichtenberg figures.**

Interventions

First Aid/Prehospital Care.

Because of lightning's powerful impact to the body, patients are at great risk for multi-system trauma. The full extent of injury may not be known until thorough monitoring and diagnostic evaluation can be performed in the hospital. Initial care includes spinal immobilization with priority attention to stabilization of airway, breathing, and circulation through standard basic and advanced life support measures. Cardiopulmonary resuscitation (CPR) is performed immediately when a person is in cardiac arrest. If cardiopulmonary or CNS injury is present, skin burns are *not* an initial priority. However, if time and resources permit, a sterile

dressing may be applied to cover the sites. *Victims of lightning strike are not electrically charged; the rescuer is in no danger from physical contact.* Nonetheless, the storm can present a continued threat to everyone in the vicinity who lacks adequate shelter. Contrary to popular belief, lightning can and does strike in the same place more than once.

Hospital Care.

Once in the acute care hospital setting, the focus of care is advanced life support management, including cardiac monitoring to detect cardiac dysrhythmias and a 12-lead ECG. The patient may require mechanical ventilation until spontaneous breathing returns. Collaborate with the health care team to perform a thorough physical and diagnostic evaluation to identify obvious and occult (hidden) traumatic injuries because the patient may have suffered a fall or blast effect during the strike. A computed tomography (CT) scan of the head may be performed to identify intracranial hemorrhage. A creatine kinase (CK) measurement may be requested to detect skeletal muscle damage resulting from the lightning strike. In severe cases, **rhabdomyolysis** (circulation of by-products of skeletal muscle destruction) can lead to renal failure. Burn wounds are assessed and treated according to standard burn care protocols. Tetanus prophylaxis is necessary for burns or any break in skin integrity. Some institutions transfer these victims to a burn center for follow-up management.

Clinical Judgment Challenge

Patient-Centered Care QSEN

A nurse is working at a day camp for church leaders when a sudden severe thunderstorm occurs. Several adults participating in outdoor activities appear to have been hit by lightning. The nurse arrives on scene and finds four injured people. One person appears to be unconscious, one has ferning marks and burns on his skin, and the other two are sitting up against the wall of a building and reporting severe weakness of their lower extremities.

1. What risk factors did these people have for lightning injury?
2. Which person should the nurse assess first and what is the priority of care of this patient?
3. What potential complication does the nurse plan to address in the immediate rescue period?
4. What direction should the nurse give the large crowd of campers and

camp staff?

Cold-Related Injuries

Two common cold-related injuries are hypothermia and frostbite. Both types of injury can be prevented by implementing protection from the cold. Teach patients at risk ways to prevent these injuries through methods to maintain thermoregulation, which can range from mild discomfort to major systemic complications.

Health Promotion and Maintenance

When participating in cold weather activities, clothing choices are critical to the prevention of hypothermia and frostbite. Teach the importance of wearing synthetic clothing because it moves moisture away from the body and dries fast. Cotton clothing, especially as an undergarment, holds moisture, becomes wet, and contributes to the development of hypothermia. Cotton clothing should be strictly avoided in a cold outdoor environment; this rule applies to gloves and socks as well. Wet socks and gloves promote frostbite in the toes and fingers. Wearing too many pairs of socks can decrease circulation and lead to frostbite.

Clothing should be layered so that it can be easily added or removed as the temperature changes. The inner layers, such as polyester fleece, provide warmth and insulation. The outer layer's purpose is to block the wind and provide moisture protection. This layer is best made of a windproof, waterproof, breathable fabric. A hat is an essential clothing item that significantly decreases body heat loss through the head. Face protection with a facemask should be used on particularly cold days when wind chill poses a risk. Sunscreen (minimum sun protection factor [SPF] 30) and sunglasses are also important to protect skin and eyes from the sun's harmful rays.

Teach people to keep water, extra clothing, and food in their car when driving in winter in case the vehicle becomes stranded. Maintaining personal fitness and conditioning is also an important consideration to prevent hypothermia and frostbite. People should not diet or restrict food or fluid intake when participating in winter outdoor activities. Malnutrition and dehydration contribute to cold-related illnesses and injuries. Finally, it is important for people to know their physical limits and to come in out of the cold when these limits have been reached.

Hypothermia

Pathophysiology

Hypothermia is a core body temperature below 95° F (35° C). Common

predisposing conditions that promote hypothermia include:

- Cold water immersion
- Acute illness (e.g., sepsis)
- Traumatic injury
- Shock states
- Immobilization
- Cold weather (especially for the homeless and people working outdoors)
- Advanced age
- Selected medications (e.g., phenothiazines, barbiturates)
- Alcohol intoxication and substance abuse
- Malnutrition
- Hypothyroidism
- Inadequate clothing or shelter (e.g., the homeless population)

An environmental temperature below 82° F (28° C) can produce impaired thermoregulation and hypothermia in any susceptible person. *Therefore people, especially older adults, are actually at risk on a year-round basis in most areas of the world*. Wind chill is a significant factor: heat loss increases as wind speed rises. Wet conditions further increase heat loss through evaporation. Weather is the most common cause of hypothermia for outdoor sports enthusiasts and for those with inadequate clothing or shelter. It is also a problem for the older adult, the homeless, and the poor who cannot afford heating.

Patient-Centered Collaborative Care

Assessment

Hypothermia is commonly divided into three categories by severity: *mild* (90° to 95° F [32° to 35° C]); *moderate* (82.4° to 90° F [28° to 32° C]); and *severe* (below 82.4° F [28° C]). Treatment decisions are based on the severity of hypothermia. Chart 9-7 summarizes by category the common key features for the patient who is hypothermic.

Chart 9-7 Key Features

Hypothermia

Mild	Severe
• Shivering • Dysarthria (slurred speech) • Decreased muscle coordination • Impaired cognition ("mental slowness") • Diuresis (caused by shunting of blood to major organs) **Moderate** • Muscle weakness • Increased loss of coordination • Acute confusion • Apathy • Incoherence • Possible stupor • Decreased clotting (caused by impaired platelet aggregation and thrombocytopenia)	• Bradycardia • Severe hypotension • Decreased respiratory rate • Cardiac dysrhythmias, including possible ventricular fibrillation or asystole • Decreased neurologic reflexes • Decreased pain responsiveness • Acid-base imbalance

Interventions

First Aid/Prehospital Care.

For treatment of *mild hypothermia,* the person needs to be sheltered from the cold environment, have all wet clothing removed, and undergo passive or active external rewarming. Passive methods involve applying warm clothing or blankets. Active methods incorporate heating blankets, warm packs, and convective air heaters or warmers to speed rewarming. If a heating blanket is used, monitor the patient's skin at least every 15 to 30 minutes to reduce the risk for burn injury.

In the case of mild, uncomplicated hypothermia as the only health problem, having the victim drink warm high-carbohydrate liquids that do not contain alcohol or caffeine can aid in rewarming. Alcohol is a peripheral vasodilator; both alcohol and caffeine are diuretics. These effects can potentially worsen dehydration and hypothermia.

Hospital Care.

General management principles apply to both *moderate* and *severe* hypothermia. Protect patients from further heat loss and handle them gently to prevent ventricular fibrillation. Positioning the patient in the supine position prevents orthostatic changes in blood pressure from cardiovascular instability. Follow standard resuscitation efforts with special attention to maintenance of airway, breathing, and circulation as recommended by the American Heart Association (2011):

- Administer drugs with caution and/or spaced at longer intervals because metabolism is unpredictable in hypothermic conditions.
- Remember that drugs can accumulate without obvious therapeutic effect while the patient is cold but may become active and potentially lead to drug toxicity as effective rewarming is underway.
- Consider withholding IV drugs, except vasopressors, until the core temperature is above 86° F (30° C).
- Initiate CPR for patients without spontaneous circulation.

- For a hypothermic patient in ventricular fibrillation or pulseless ventricular tachycardia, one defibrillation attempt is appropriate. Be aware that defibrillation attempts may be ineffective until the core temperature is above 86° F (30° C).

Treatment of *moderate* hypothermia may involve both active external and core (internal) rewarming methods. Applying external heat with heating blankets can promote core temperature "after-drop" by producing peripheral vasodilation. **"After-drop"** is the continued decrease in core body temperature after the victim is removed from the cold environment; it is caused by the return of cold blood from the periphery to the central circulation. Therefore the patient's trunk should be actively rewarmed before the extremities. Core rewarming methods for moderate hypothermia include administration of warm IV fluids, heated oxygen or inspired gas to prevent further heat loss via the respiratory tract, and heated peritoneal, pleural, gastric, or bladder lavage.

Nursing Safety Priority QSEN

Critical Rescue

Patients who are *severely* hypothermic are at high risk for cardiac arrest. Avoid using active *external* rewarming with heating devices because it is dangerous and contraindicated in this population due to rapid vasodilation.

The treatment of choice for *severe* hypothermia is to use *extracorporeal* rewarming methods such as cardiopulmonary bypass or hemodialysis (Leikin et al., 2012). Cardiopulmonary bypass is the fastest core rewarming technique. However, this device is not available in all hospitals. It also requires specialized personnel and resources to operate it properly. Monitor for early signs of complications that can occur after rewarming, such as fluid, electrolyte, and metabolic abnormalities; acute respiratory distress syndrome (ARDS); acute renal failure; and pneumonia.

A long-standing principle in the treatment of patients with hypothermic cardiac arrest is that "no one is dead until they are warm and dead." There is a factual basis to this statement when considering the number of survivors who have suffered a prolonged hypothermic cardiac arrest. Prolonged resuscitation efforts may not be reasonable in cases in which survival appears highly unlikely, such as in an anoxic event

followed by a hypothermic cardiac arrest.

Frostbite

Pathophysiology

Another significant cold-related injury that may or may not be associated with hypothermia is frostbite. The main risk factor is inadequate insulation against cold weather; that is, either the skin is exposed to the cold or the person's clothing offers insufficient protection, leading to injury. Wet clothing, in particular, is a poor insulator and facilitates the development of frostbite. Fatigue, dehydration, and poor nutrition are other contributing factors. People who smoke, consume alcohol, or have impaired peripheral circulation have a higher incidence of frostbite. Any previous history of frostbite further increases a person's susceptibility.

NCLEX Examination Challenge

Health Promotion and Maintenance

An occupational health nurse is teaching a safety class to city employees who work outdoors year round. What does the nurse teach are risk factors for developing frostbite? **Select all that apply.**

A Excessive fatigue
B Prior episodes of frostbite
C Diabetes or other peripheral vascular disease
D Dehydration
E Smoking
F Wearing polyester socks

Patient-Centered Collaborative Care

Assessment

Frostbite occurs when body tissue freezes and causes damage. Like burns, frostbite injuries can be superficial, partial, or full thickness. By contrast, **frostnip** is a type of superficial cold injury that may produce pain, numbness, and pallor of the affected area but is easily relieved by applying warmth; it does not cause tissue damage (impaired tissue integrity). Frostnip typically develops on skin areas such as the face, nose, finger, or toes. Untreated, it is a precursor to more severe forms of frostbite.

First-degree frostbite, the least severe type of frostbite, involves

hyperemia (increased blood flow) of the involved area and edema formation. In *second-degree frostbite,* large fluid-filled blisters develop with partial-thickness skin necrosis (Fig. 9-7). *Third-degree frostbite* appears as small blisters that contain dark fluid and an affected body part that is cool, numb, blue, or red and does not blanch. Full-thickness and subcutaneous tissue necrosis occurs and requires débridement. In *fourth-degree frostbite,* the most severe form, there are no blisters or edema; the part is numb, cold, and bloodless. The full-thickness necrosis extends into the muscle and bone. At this stage, gangrene develops, which may require amputation of the affected part.

FIG. 9-7 Edema and blister formation 24 hours after frostbite injury occurring in an area covered by a tightly fitted boot.

Interventions

First Aid/Prehospital Care.

Recognition of frostbite is essential to early, effective intervention and prevention of further tissue damage. Asking a partner to frequently observe for early signs of frostbite such as a white, waxy appearance to exposed skin, especially on the nose, cheeks, and ears, is an effective strategy to identify the problem before it worsens. In persons with dark skin, skin becomes paler, waxy, and somewhat gray. In this case, the best remedy is to have the person seek shelter from the wind and cold and to attend to the affected body part. Superficial frostbite is easily managed using body heat to warm the affected area. Teach patients to place their warm hands over the affected areas on their face or to place cold hands under the arms.

Hospital Care.

Patients with more severe and deeper forms of frostbite need aggressive management. For all degrees of partial-thickness to full-thickness frostbite, rapid rewarming in a water bath at a temperature range of 104°

to 108° F (40° to 42° C) is indicated to thaw the frozen part (Auerbach et al., 2010). Because patients experience severe pain during the rewarming process, this intervention is best accomplished in a medical facility; however, it may be done in another setting if no other options exist for prompt transport or rescue. Administer analgesics, especially IV opiates, and IV rehydration.

Nursing Safety Priority QSEN

Critical Rescue

Do not apply dry heat or massage the frostbitten areas as part of the warming process. These actions can produce further tissue injury.

When the rewarming process is complete, handle the injured areas gently and elevate them above heart level if possible to decrease tissue edema. Sometimes splints are used to immobilize extremities during the healing process. Assess the person at least hourly for the development of compartment syndrome—a limb-threatening complication caused by severe neurovascular impairment. Observe for early manifestations, which include increasing pain (even after analgesics are given) and paresthesias (painful tingling and numbness). Compare the affected extremity with the unaffected one to assess for pallor. Assess for pulses and muscle weakness. Management of compartment syndrome is discussed in detail in Chapter 51.

Frostbite destroys tissue and produces a deep tetanus-prone wound; the patient should be immunized to prevent tetanus. Apply only loose, nonadherent sterile dressings to the damaged areas. Avoid compression of the injured tissues. Both topical and systemic antibiotics may be used. Once a patient's frozen part has thawed, do not allow it to refreeze, which worsens the injury. Antiprostaglandin therapy with ibuprofen may be used because it may decrease tissue damage for some patients (Auerbach et al., 2010).

In cases of severe, deep frostbite, débridement of necrotic tissue may be needed to evaluate tissue viability and provide wound management. Amputation may be indicated for patients with severe injuries or for those who develop gangrene or severe compartment syndrome.

Altitude-Related Illnesses

Pathophysiology

High altitude illnesses, also known as **high altitude disease (HAD)** or *altitude sickness*, cause pathophysiologic responses in the body as a result of exposure to low partial pressure of oxygen at high elevations. Although most consider high altitude to be an elevation over 5000 feet, millions of people worldwide who ascend to or live at altitudes above 2500 feet are at risk for acute and chronic mountain sickness.

As altitude increases, atmospheric (barometric) pressure decreases. Oxygen makes up 21% of the pressure. Therefore, as this pressure falls, the partial pressure of oxygen in the air decreases, resulting in less available oxygen to humans. The pathophysiologic consequence is hypoxia. Hypoxia is more pronounced as elevation increases. Elevations higher than 18,000 feet are extreme altitudes. Supplemental oxygen is necessary at these levels in non-acclimatized people to prevent altitude-related illnesses, including death, from occurring during abrupt ascent.

The cause of HAD is an interaction of environmental and genetic factors (Guoen et al., 2009). Those who are obese or have chronic illnesses, especially cardiovascular problems, are more at risk than those who are thinner and healthier. Dehydration and central nervous system depressants, such as alcohol, also increase the risk. The age of the person does not seem to be a factor in altitude-related illnesses.

Genetic/Genomic Considerations

Patient-Centered Care QSEN

Genetic differences among certain ethnic groups who live in high altitude areas have been studied. For example, chronic mountain sickness is less common in Tibetans and Sherpas than in Andeans, Hans, or Peruvian Quechuas (Guoen et al., 2009).

In addition, the pathogenesis of mountain sickness is associated with unidentified variations in hypoxia-related genes and the genes responsible for the human leukocyte antigen (HLA) system. Examples of genes with variants that may contribute to the development of HAD include:

- *EPO* (erythropoietin), which regulates red blood cell production
- *HIF1A* (hypoxia inducible factor), which mediates the effects of hypoxia on body cells
- *EDN1* (endothelin), which causes vasoconstriction and thus increases

blood pressure
- *NOS3* (endothelial nitric oxide synthase), which makes nitric acid in vascular tissue to maintain vessel tone and altitude adaptation

At this time, no clinical genetic testing to determine a person's risk for altitude sickness is available; however, further research is being conducted to identify specific gene variations that contribute to altitude-related illnesses.

The process of adapting to high altitude is called *acclimatization.* **Acclimatization** involves physiologic changes that help the body adapt to less available oxygen in the atmosphere. As the carotid bodies sense a decline in Pa_{O_2} at about 5000 feet, they increase the respiratory rate to improve oxygen delivery. This mechanism is called the "hypoxic-ventilatory response." Increased respiratory rate causes **hypocapnia** (decreased carbon dioxide) and respiratory alkalosis, which limit further increases in respiratory rate. Rapid eye movement (REM) sleep is impaired. Hypoxia can occur from periods of apnea. Within 24 to 48 hours of being at high altitude, the kidneys excrete the excess bicarbonate, which helps the pH to return to normal and ventilatory rate to again increase.

Increased sympathetic nervous system activity increases heart rate, blood pressure, and cardiac output. Pulmonary artery pressure rises as an effect of generalized hypoxia-induced pulmonary vasoconstriction. Cerebral blood flow increases to maintain cerebral oxygen delivery. Hypoxia also induces red blood cell production by stimulating the release of erythropoietin. The result is an increase in red blood cells and hemoglobin concentration. Over time, polycythemia can develop in people who remain in a high altitude environment.

People who plan to climb to high altitudes are advised to ascend slowly, over the course of days or even weeks, depending on the degree of elevation. Ascending too rapidly is the primary cause of altitude-related illnesses. They are much more common in people who sleep at elevations above 8000 feet.

The three most common clinical conditions that are considered high altitude illnesses are acute mountain sickness (AMS), high altitude cerebral edema (HACE), and high altitude pulmonary edema (HAPE). AMS may occur with HACE and/or HAPE; the underlying pathophysiology is hypoxia. Chronic mountain sickness can occur in people who live at high elevations. Although each syndrome has several unique manifestations, the basic assessment and management approach are the same.

Patient-Centered Collaborative Care

Assessment

Assessment findings for the typical patient with AMS include reports of throbbing headache, anorexia, nausea, and vomiting. Feeling chilled, irritable, and apathetic is also associated with AMS. The syndrome produces effects similar to an alcohol-induced hangover. The patient may relate a feeling of extreme illness. Vital signs are variable: the patient can be tachycardic or bradycardic, have normal blood pressure, or have postural hypotension. He or she may experience dyspnea both on exertion and at rest. Exertional dyspnea is expected as a person adjusts to high altitude. However, dyspnea at rest is abnormal and may signal the onset of HAPE.

If AMS progresses to *high altitude cerebral edema (HACE),* the extreme form of this disorder, the patient cannot perform ADLs and has extreme apathy. A key sign of HACE is the development of ataxia (defective muscular coordination). The patient also has a change in mental status with confusion and impaired judgment. Cranial nerve dysfunction and seizures may occur. If untreated, a further decline in the patient's level of consciousness results. Stupor, coma, and death can result from brain swelling and the subsequent damage caused by increased intracranial pressure over the course of 1 to 3 days.

High altitude pulmonary edema (HAPE) often appears in conjunction with HACE but may occur during the progression of AMS within the first 2 to 4 days of a rapid ascent to high altitude, commonly on the second night. It is the most common cause of death associated with high altitude. Patients notice poor exercise tolerance and a prolonged recovery time after exertion. Fatigue and weakness, as well as other signs and symptoms of AMS, are present. Important clinical indicators of HAPE include a persistent dry cough and cyanosis of the lips and nail beds. Tachycardia and tachypnea occur at rest. Crackles may be auscultated in one or both lungs. Pink, frothy sputum is a late sign of HAPE. A chest x-ray demonstrates pulmonary infiltrates and pulmonary edema. Arterial blood gas analysis shows respiratory alkalosis and hypoxemia (decreased oxygen). Pneumonia also may be present. Pulmonary artery pressure is usually very elevated because of pulmonary edema.

Interventions

First Aid/Prehospital Care.

The most important intervention to manage serious altitude-related illnesses is

descent to a lower altitude. Patients must be monitored carefully for any evidence of symptom progression. With mild AMS, the victim should be allowed to rest and acclimate at the current altitude. The person is instructed not to ascend to a higher altitude, especially for sleep, until symptoms lessen. If symptoms persist or worsen, he or she should be moved to a lower altitude as soon as possible. Even a descent of about 1600 feet may improve the patient's condition and reverse altitude-related pathologic effects. Oxygen should also be administered if available to effectively treat symptoms of AMS.

Prevention and Treatment.

The oral drug *acetazolamide* (Diamox, Apo-Acetazolamide) is commonly used to both prevent and treat AMS (Hackett & Roach, 2012). Acetazolamide is a carbonic anhydrase inhibitor. It acts by causing a bicarbonate diuresis, which rids the body of excess fluid, and induces metabolic acidosis. The acidotic state increases respiratory rate and decreases the occurrence of periodic respiration during sleep at night. In this way, it helps patients acclimate faster to a high altitude. For best results, the drug should be taken 24 hours before ascent and be continued for the first 2 days of the trip.

Nursing Safety Priority QSEN

Drug Alert

Because acetazolamide is a sulfa drug, ask about an allergy to sulfa before the patient takes the drug because it may cause hypersensitivity reactions in those who are sulfa-sensitive.

Another drug that is indicated in the treatment of moderate to severe AMS is dexamethasone (Decadron, Deronil). This drug's mechanism of action is unclear for AMS treatment, but it reduces cerebral edema by acting as an anti-inflammatory in the central nervous system. It does not speed acclimatization like acetazolamide does, but it does relieve the symptoms of AMS. Symptoms may recur when the drug is stopped, an effect termed the "rebound phenomenon" (Hackett & Roach, 2012).

For the treatment of HACE, early recognition of ataxia or a change in level of consciousness should prompt a rapid descent by rescuers or companions to a lower altitude. While undergoing descent, the patient can be given supplemental oxygen and dexamethasone. If mental status is severely impaired and the patient's airway is at risk, all drugs should

be given parenterally. Ultimately, the patient with HACE must be admitted to the hospital. Critical care management may be necessary.

Like HACE, early recognition of HAPE is essential to improve the patient's chance for survival. Phosphodiesterase inhibitors such as tadalafil (Cialis) and sildenafil (Viagra) may be used to prevent HAPE because of their pulmonary vasodilatory effects (Hackett & Roach, 2012). When it occurs, HAPE is a serious condition that requires quick evacuation to a lower altitude, oxygen administration, and bedrest to save the patient's life. If descent must be delayed because of weather conditions or other factors, oxygen administration is essential as soon as possible. Keep the patient warm at all times. Drugs are not substitutes for descent and oxygen. However, the treatment of HAPE may include the calcium channel blocker *nifedipine* (Procardia, Adalat PA, Apo-Nifed) to decrease pulmonary vascular resistance (Hackett & Roach, 2012). Hospital admission is required. In uncomplicated cases of HAPE, recovery occurs quickly but effects such as weakness and fatigue may persist for 2 weeks.

Chart 9-8 summarizes best practices for preventing, recognizing, and treating altitude-related illnesses.

Chart 9-8 Best Practice for Patient Safety & Quality Care QSEN

Preventing, Recognizing, and Treating Altitude-Related Illnesses

- Plan a slow ascent to allow for acclimatization.
- Learn to recognize clinical manifestations of altitude-related illnesses.
- Avoid overexertion and overexposure to cold; rest at present altitude before ascending further.
- Ensure adequate hydration and nutrition.
- Avoid alcohol and sleeping pills when at high altitude.
- For progressive or advanced acute mountain sickness (AMS), recognize symptoms and implement an immediate descent; provide oxygen at high concentration.
- To prevent the occurrence of AMS, discuss the use of acetazolamide (Diamox) and other agents as indicated with your health care provider.
- Protect skin and eyes from the sun's harmful ultraviolet rays at high altitude. Wear sunscreen (at least SPF 30) and high-quality wraparound sunglasses or goggles.

SPF, Sun protection factor.

NCLEX Examination Challenge

Physiological Integrity

A client on a climbing expedition reports a headache and nausea. The client rests 1 day at the current altitude and then climbs further the following day. The third day, other members of the climbing team note that the client has developed gross motor coordination difficulties. What action by the team nurse takes priority?

A Administering acetazolamide (Diamox)
B Providing 100% oxygen by facemask
C Having the client descend to a lower altitude
D Ensuring that the client stays warm at all times

Drowning

Pathophysiology

Drowning is a leading cause of accidental death in the United States. It occurs when a person suffers primary respiratory impairment from submersion or immersion in a liquid medium (usually water) (Szpilman et al., 2012). **Near-drowning** was previously defined as recovery after submersion; however, this term is no longer used because language that describes drowning incidents has been standardized. Today the drowning process is considered a continuum with outcomes that range from survival to death.

Health Promotion and Maintenance

Prevention is the key to avoiding drowning incidents. When providing health teaching, include these points:

- Constantly observe people who cannot swim and are in or around water.
- Do not swim alone.
- Test the water depth before diving in head first; never dive into shallow water.
- Avoid alcoholic beverages when swimming and boating and while in proximity to water.
- Ensure that water rescue equipment, such as life jackets, flotation devices, and rope, is immediately available when around water.

Patient-Centered Collaborative Care

Assessment

When water is aspirated into the lungs, the quantity and the makeup of the water are key factors in the pathophysiology of the drowning event. Aspiration of both fresh water and salt water causes surfactant to wash out of the lungs. Surfactant reduces surface tension within the alveoli, increases lung compliance and alveolar radius, and decreases the work of breathing. Loss of surfactant destabilizes the alveoli and leads to increased airway resistance. Salt water—a hypertonic fluid—also creates an osmotic gradient that draws protein-rich fluid from the vascular space into the alveoli. In both cases, pulmonary edema results. Salt water and fresh water aspiration cause similar degrees of lung injury (Szpilman et al., 2012). Another concern is water quality; the victim's outcome may be negatively affected by contaminants in the water such as chemicals,

algae, microbes, sand, and mud. These substances can worsen lung injury and cause a lung infection.

The duration and severity of hypoxia are the two most important factors that determine outcomes for victims of drowning. Very cold water seems to have a protective effect. Successful resuscitations have been reported even after prolonged arrest intervals. Hypothermia might offer some protection to the hypoxic brain by reducing cerebral metabolic rate. The diving reflex is a physiologic response to asphyxia, which produces bradycardia, a reduction in cardiac output, and vasoconstriction of vessels in the intestine, skeletal muscles, and kidneys. These physiologic effects are thought to reduce myocardial oxygen use and enhance blood flow to the heart and cerebral tissues. Survival may be linked to some combination of the effects of hypothermia and the diving reflex.

The cause of the drowning should also be determined, if possible. The patient may have suffered a medical condition or injury that caused the drowning event such as a seizure, myocardial infarction, stroke, or spinal cord injury while in the water. Injuries sustained from diving into shallow water or body surfing, such as cervical spine trauma, can also increase the difficulty of rescue and resuscitation efforts.

Interventions

First Aid/Emergency Care.

Immediate emergency care focuses on a safe rescue of the victim. Potential rescuers must consider their own swimming abilities and limitations, as well as any natural or human-made hazards, before attempting to save the victim; failure to do so could place additional lives in jeopardy. *Once rescuers gain access to the victim, the priority is safe removal from the water.* Spine stabilization with a board or flotation device should be considered only for those victims who are at high risk for spine trauma (e.g., history of diving, use of a water slide, signs of injury or alcohol intoxication), as opposed to all drowning victims (Szpilman et al., 2012). Time is of the essence; efforts directed toward a rapid rescue have the most potential benefit. Initiate airway clearance and ventilatory support measures, including delivering rescue breaths while the patient is still in the water, as soon as possible (Szpilman et al., 2012). If hypothermia is a concern, handle the victim gently to prevent ventricular fibrillation.

Nursing Safety Priority QSEN

Critical Rescue

Do not attempt to get the water out of the victim's lungs; deliver abdominal or chest thrusts only if airway obstruction is suspected.

Hospital Care.

Once the person is safely removed from the water, airway and cardiopulmonary support interventions begin, including oxygen administration, endotracheal intubation, CPR, and defibrillation, if necessary. In the clinical setting, gastric decompression with a nasogastric or orogastric tube is needed to prevent aspiration of gastric contents and improve ventilatory function. After a period of artificial ventilation by mask, the victim typically has a distended abdomen, which impairs movement of the diaphragm and decreases lung ventilation. Patients who experience drowning require complex care to support their major body systems. The full spectrum of critical care technology may be needed to manage the pathophysiologic complications of drowning, including pulmonary edema, infection, acute respiratory distress syndrome (ARDS), and CNS impairment. These complications are discussed elsewhere in this text.

Clinical Judgment Challenge

Patient-Centered Care QSEN

Emergency Medical Services (EMS) brought a drowning victim to the emergency department (ED). The patient is mildly hypothermic, bradycardic, and hypotensive.

1. What further information will the nurse need to obtain from the paramedics?
2. How does the nurse explain the major pathophysiologic event of drowning to the nursing student observing in the ED?
3. The paramedics state that the patient was submerged in a polluted, fresh water pond. How does that environment affect the patient?
4. What action does the nurse take to prevent a complication from CPR in this patient and why?

Nursing Concepts and Clinical Judgment Review

What might you NOTICE if the patient has impaired thermoregulation as a result of a cold-related injury?

- Body temperature below 95° F (35° C) (hypothermia)

- Shivering (hypothermia)
- Possible ventricular fibrillation (hypothermia)
- Cold, pale extremities (frostnip)
- Patient reports numbness or pain (frostnip)
- Hyperemia and edema (1st-degree frostbite)
- Fluid-filled blisters and deep skin necrosis (2nd-degree frostbite)
- Small blisters containing dark fluid, pale or red cool skin that does not blanch, patient reports numbness (3rd-degree frostbite)
- Numb, cold, bloodless body part that eventually develops necrosis (4th-degree frostbite)

What should you INTERPRET and how should you RESPOND to the patient with impaired thermoregulation as a result of a cold-related injury?

Perform focused physical assessment findings and interpret their relationship to impaired thermoregulation, including:

- Temperature
- Skin integrity
- Reports of pain or numbness
- Other vital signs
- Cardiac assessment
- Neurologic assessment
- Fluid status

Respond by:

- *Providing rewarming measures:* Remove patient from the environment; remove wet, cold clothing; initiate passive external rewarming, active external rewarming, or internal rewarming measures as appropriate for hypothermia; thaw frozen body parts in a warm water bath and handle gently; handle hypothermic patients gently to prevent ventricular fibrillation
- Providing pain control measures
- Applying loose, dry dressings
- Administering tetanus prophylaxis and possible antibiotics for open wounds
- Preparing patient for possible débridement
- Using caution when administering drugs because of unpredictable metabolism; alternatively consider withholding drugs except vasopressors until core temperature is at least 86° F (30° C)
- Initiating CPR if needed; one defibrillation attempt is appropriate but may be ineffective if core temperature is lower than 86° F (30° C)
- Providing hydration

On what should you REFLECT?

- Monitor the patient's response to pain medication and rewarming techniques.
- Monitor for further injury from rewarming techniques.
- Evaluate the patient's and family's knowledge about the injury and treatment plans.
- Educate the patient and family on ways to prevent future cold-related injury.
- Monitor the patient's nutrition and hydration status.

Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Collaborate with the health care team to assess high-risk patients, especially older adults, for their knowledge of safety precautions to prevent thermoregulation alterations such as heat-related and cold-related injuries. **Evidence-Based Practice** QSEN
- Assess high-risk patients, including those who do not know how to swim, for their knowledge of safety precautions to avoid drowning.

Health Promotion and Maintenance

- Teach people how to prevent heat-related illnesses as outlined in Chart 9-1.
- Educate people how to prepare for cold environments, including proper clothing (no cotton) and avoidance of wind and wet weather.
- Instruct people how to prevent arthropod bites and stings as described in Chart 9-5.
- Teach people how to avoid getting bitten by a snake as listed in Chart 9-4.

Physiological Integrity

- Recall that heat-related injuries can be mild (heat exhaustion) to severe (heat stroke).
- Recall that the priority for first aid for heat stroke, after a patent airway is established, is to cool the patient as quickly as possible (see Chart 9-3). **Patient-Centered Care** QSEN
- Remember that North American pit vipers can be identified by their triangular-shaped head and retractable fangs; nonpoisonous snakes do not have these features.
- Recall that the management of a patient who has a snakebite depends on the severity of envenomation (venom injection) (see Table 9-1); both local and systemic manifestations can occur.
- Remember that the priority for first aid/prehospital care when a patient has a snakebite is to decrease the venom circulation. **Patient-Centered Care** QSEN
- Administer antivenom drugs that are available for most types of

poisonous snakebites; monitor for an allergic response when these medications are given.
- Recall that the bite of a brown recluse spider can cause tissue necrosis; in rare cases, systemic manifestations can occur, including death.
- Remember that cold applications, such as ice, should be used as first aid/prehospital care for poisonous spider bites.
- Understand that the effect of the bark scorpion venom is neurotoxic; monitor the patient for signs of respiratory failure that may require mechanical ventilation.
- Recall that single bee and wasp stings cause only local reactions unless the person is allergic to them.
- Remember that epinephrine is the drug of choice for bee and wasp sting allergic reactions, followed by an antihistamine drug. **Patient-Centered Care** QSEN
- Teach people that the best way to prevent lightning injury is to avoid places where lightning is likely to strike (see Chart 9-6).
- Recall that lightning causes central nervous system and cardiovascular complications, as well as skin burns.
- Instruct people that two common cold injuries are hypothermia and frostbite; both may be prevented by selecting appropriate layered clothing; cotton should not be worn.
- Teach patients that in moderate to severe cases of hypothermia, coagulopathy (abnormal clotting) or cardiac failure can occur.
- Remember that the priority for care of a patient with a cold injury is warming; alcohol should be avoided. **Patient-Centered Care** QSEN
- Recall that frostbite causes various degrees of impaired tissue integrity and is classified as mild (frostnip) to serious (fourth degree); severe frostbite can result in amputation due to compartment syndrome or gangrene.
- Know that high altitude can cause a range of physiologic consequences in the body, primarily due to hypoxia.
- Teach people that the priority for care of the patient with illness related to high altitude is descent to a lower altitude.
- Recall that acetazolamide (Diamox, Apo-Acetazolamide 🍁) is the drug of choice for prevention and treatment of mild altitude-related illness.
- Review Chart 9-8, which outlines best practice strategies for preventing, recognizing, and treating altitude-related illnesses.
- Remember that drowning victims often require cardiopulmonary support, including CPR.
- Recall that a drowning victim is at risk for pulmonary infection, ARDS, and central nervous system impairment.

CHAPTER 10

Concepts of Emergency and Disaster Preparedness

Linda Laskowski-Jones

PRIORITY CONCEPTS

- Communication
- Safety
- Teamwork and Collaboration

Learning Outcomes

Safe and Effective Care Environment

1. Apply principles of triage to prioritize care delivery in a disaster situation.
2. Identify the roles of the nurse in emergency preparedness and response.
3. Compare the key personnel roles in an emergency preparedness and response plan.
4. Describe the components of an emergency preparedness and response plan.
5. Develop a personal emergency preparedness plan.
6. Identify which patients to recommend for hospital discharge in a disaster situation.

Psychosocial Integrity

7. Assess survivors for ability to adapt to the effects of disaster changes or traumatic events.
8. Provide support to the person and/or family in coping with life changes resulting from a disaster.

Physiological Integrity

9. Explain how to maintain physical safety when responding to disaster and mass casualty situations.

 http://evolve.elsevier.com/Iggy/

A **disaster** is commonly defined as an event in which illness or injuries exceed resource capabilities of a health care facility or community because of destruction and devastation. The disaster can be either *internal* to a health care facility or *external* from situations that create casualties in the community. Both internal and external disasters can occur simultaneously.

Types of Disasters

An *internal* disaster is any event inside a health care facility or campus that could endanger the safety of patients or staff. The event creates a need for evacuation or relocation. It often requires extra personnel and the activation of the facility's emergency preparedness and response plan (also called an *emergency management plan*). Examples of potential internal disasters include fire, explosion, loss of critical utilities (e.g., electricity, water, and communications capabilities), and violence. Each health care organization develops policies and procedures for preventing these events through organized facility and security management plans. The most important outcome for any internal disaster is to maintain patient, staff, and visitor safety.

An *external* disaster is any event outside the health care facility or campus, somewhere in the community, which requires the activation of the facility's emergency management plan. The number of facility staff and resources may not be adequate for the incoming emergency department (ED) patients. External disasters can be either natural, such as a hurricane, earthquake or tornado, or technologic, such as an act of terrorism with explosive devices or a malfunction of a nuclear reactor with radiation exposure. Recent external disasters include the Boston Marathon bombing on April 15, 2013, and the West, Texas, fertilizer plant explosion 2 days later. St. John's Regional Medical Center in Joplin, Missouri, had an internal disaster compounding an external disaster on May 2011 when it was directly hit by an EF-5 tornado that destroyed a large part of the town. Of the 142 dead, only 6 people inside the hospital died (Letner, 2011) (Fig. 10-1).

FIG. 10-1 St. John's Regional Medical Center in Joplin, Missouri, after a powerful tornado struck in May 2011.

Both internal and external disasters can result in many casualties, including death. Multi-casualty and mass casualty (disaster) events are not the same. The main difference is based on the scope and scale of the incident, considering the number and severity of victims or casualties involved. Both require specific response plans to activate necessary resources. In general, a **multi-casualty event** can be managed by a hospital using local resources; a **mass casualty event** overwhelms local medical capabilities and may require the collaboration of multiple agencies and health care facilities to handle the crisis (Smith, 2010). State, regional, and/or national resources may be needed to support the areas affected by the event. Trauma centers have a special role in all emergency preparedness activities because they provide a critical level of expertise and specialized resources for complex injury management.

To maintain ongoing disaster preparedness, hospital personnel participate in emergency training and drills regularly. In the United States, The Joint Commission (2008) mandates that hospitals have an emergency preparedness plan that is tested through drills or actual participation in a real event at least twice yearly. One of the drills or events must involve community-wide resources and an influx of actual or simulated patients to assess the ability of collaborative efforts and command structures. In addition, accredited health care organizations are required to take an "all-hazards approach" to disaster planning. Using this approach, preparedness activities must address *all credible*

threats to the safety of the community that could result in a disaster situation. Disaster drills, then, are ideally planned based on a risk assessment or vulnerability analysis that identifies the events most likely to occur in a particular community. For example, a flood is more likely in the Gulf of Mexico and an avalanche is more likely in ski areas of the Rocky Mountains. It is essential that staff actively participate in these drills and take them seriously to enable their ongoing competency. The importance of training was emphasized in all the recent disasters and is credited with saving lives (Caramenico, 2013).

Hospitals are not the only health care agencies that are required to practice disaster drills. Nursing homes and other long-term care (LTC) facilities are also mandated to have annual drills to prepare for mass casualty events. Part of the response plan must include a method for evacuation of residents from the facility in a timely and safe manner as was demonstrated in the West, Texas, nursing home evacuation.

An evacuation plan is also part of fire prevention and preparedness plans for health care facilities. The Life Safety Code® published by the National Fire Protection Association (2013) provides guidelines for building construction, design, maintenance, and evacuation. The Centers for Medicare and Medicaid Services (CMS) (2012) requires every health care facility to practice at least one fire drill or actual fire response once a year. Patient evacuation is not required if the event is a drill. All facility personnel are mandated to have training on fire prevention and responsiveness each year. Chart 10-1 lists general guidelines for fire responsiveness and building evacuation to ensure safety.

Chart 10-1 Best Practice for Patient Safety & Quality Care QSEN

Nurse's Role in Responding to Health Care Facility Fires

- Remove any patient or staff from immediate danger of the fire or smoke.
- Discontinue oxygen for all patients who can breathe without it.
- For patients on life support, maintain their respiratory status manually until removed from the fire area.
- Direct ambulatory patients to walk to a safe location.
- If possible, ask ambulatory patients to help push wheelchair patients out of danger.
- Move bedridden patients from the fire area in bed, by stretcher, or in a wheelchair; if needed, have one or two staff members move patients on

blankets or carry them.

- After everyone is out of danger, seek to contain the fire by closing doors and windows and using an ABC extinguisher (can put out any type of fire), if possible.
- Do not risk injury to you or staff members while moving patients or attempting to extinguish the fire.

Impact of External Disasters

The events of September 11, 2001, substantially changed hospital and community disaster planning efforts (Wielawski, 2006). With the shocking terrorist attacks on the Twin Towers of the World Trade Center and the Pentagon and the actual and perceived threat of domestic terrorism, including the anthrax exposure that followed, hospital emergency preparedness concepts became much more fully integrated into the daily operations of emergency departments (EDs) by necessity. Weapons of mass destruction (WMD) rapidly became a focus of public health risk.

The term "NBC" was coined to describe **n**uclear, **b**iologic, and **c**hemical threats. In response, emergency medical services (EMS) agencies and hospitals improved safety by upgrading their decontamination facilities, equipment, and all levels of personal protective equipment to better protect staff. ED physician and nursing staff now routinely undergo hazardous materials (HAZMAT) training and learn how to recognize patterns of illness in patients who present for treatment that potentially indicate biologic terrorism agents, such as anthrax or smallpox (Fig. 10-2). Protocols for the pharmacologic treatment of infectious disease agents, as well as stockpiles of antibiotics and nerve agent antidotes, are readily available.

FIG. 10-2 Hazardous materials (HAZMAT) training to decontaminate people exposed to toxic agents in an outdoor decontamination area.

The most immediate outcome of improving emergency preparedness after September 11 is that the ability to competently handle the more typical multi-casualty or mass casualty incident such as a bus crash, tornado, or building collapse has been greatly improved in many communities. However, disaster situations can still exceed the scope of usual day-to-day crisis operations, pointing to the necessity of well-defined regional and national emergency preparedness plans and the need for ongoing drills.

In 2005, Hurricane Katrina made landfall in Louisiana and other Gulf states as a category 4 storm and caused more than 1000 deaths and devastating environmental and property damage. Volunteers from all over the United States, as well as local, regional, and federal agencies, took part in the large-scale disaster evacuation, rescue, and relief effort that severely challenged available resources and established disaster plans. Critical systems failed and were eventually re-established through collaboration with multiple agencies to ensure that the most basic human needs were met (Fig. 10-3). Hurricane Katrina overwhelmed the existing emergency care system and caused the mobilization of a national mutual aid response on a level that had not been experienced in recent U.S. history.

FIG. 10-3 Temporary shelter set up for homeless victims of Hurricane Katrina in New Orleans.

Many health care facilities still have not made structural changes that would offer safety and protection from flooding and utilities failures. A case in point is the devastation brought by "Superstorm Sandy" that made landfall on New York City in October 2012. Though it was downgraded from a category 1 hurricane, the flooding that occurred destroyed critical equipment, including emergency power generators, in the lower levels of several health care facilities, causing the loss of utilities and crippling hospital operations. Hospitals that were severely impacted had to evacuate patients to other facilities, many of which were already overwhelmed by an influx of patients from the storm's damage in the community. Staff worked for several days in harsh conditions, evacuating critical patients via stairwells since elevators were nonfunctional, carrying glow sticks and flashlights and wearing headlamps (Evans, 2012).

Lessons learned from Hurricane Katrina and other natural disasters, as well as worldwide incidents such as Superstorm Sandy, the earthquakes in Japan and Haiti, tsunamis, and terrorist attacks, enable improved facility design, staff preparation, and coordination of efforts that are beneficial for future disasters. These insights also can be applied to health care facility and community agency plans for pandemic infections, including influenza.

A **pandemic** (an infection or disease that occurs throughout the population of a country or the world) leads a vast number of people to

seek medical care, even the "worried well." Though not yet ill, the "worried well" want evaluation, preventive treatment, or reassurance from a health care provider. A pandemic influenza outbreak, such as the 2009-2010 swine flu outbreak caused by the H1N1 virus, raised significant concerns that the resource capabilities of the entire health care system could be overwhelmed and that community systems and critical supply chains could be severely damaged. Worker illness, absenteeism, and personal choices to remain quarantined to avoid being exposed to the illness negatively affect the number of health care staff available to care for patients. Fortunately, because of widespread vaccination programs and public information campaigns, the swine flu pandemic of 2009-2010 was well managed. Concern remains that avian influenza A strain (H5N1), also known as "bird flu," could pose a global pandemic threat if a gene mutation occurs to allow easy human-to-human spread. Because of the mass casualty nature of pandemic influenza, emergency preparedness planners must collaborate to incorporate strategies for handling an influx of ill patients into the system as part of ongoing disaster readiness. Quarantine of selected nursing units or the entire hospital could become necessary, prompting closure until the risk has passed.

Common to all mass casualty events, the goal of **emergency preparedness** is to effectively meet the extraordinary need for resources such as hospital beds, staff, drugs, personal protective equipment (PPE), supplies, and medical devices, such as mechanical ventilators. The U.S. government stockpiles critical equipment and supplies in case they are needed for a pandemic influenza outbreak and organizes large-scale vaccination programs (see Chapter 23 for more information on emerging infections). Each state has its own specific emergency preparedness plan for pandemic influenza, including who would receive vaccines in a mass casualty event.

Emergency Preparedness and Response

Mass Casualty Triage

A key process in any multi-casualty or mass casualty response is effective **triage** to rapidly sort ill or injured patients into priority categories based on their acuity and survival potential.

Triage functions may be performed by EMS providers in the field, such as:

- Emergency medical technicians (EMTs) and paramedics
- Nurse and physician field teams who are called from the hospital to a disaster scene to assist EMS providers
- Nurse and physician hospital teams to assess and reassess incoming patients

Triage concepts in a mass casualty incident differ from the "civilian triage" methods discussed in Chapter 8 that are practiced during usual emergency department operations (Table 10-1). Although disaster triage practices can vary widely based on local EMS protocols, some concepts are fairly universal. Most mass casualty response teams both in the field (at the disaster site) and in the hospital setting use a **disaster triage tag system** that categorizes triage priority by color and number (Smith, 2010):

TABLE 10-1

Comparison of Triage Under Usual Versus Mass Casualty Conditions

TRIAGE UNDER USUAL CONDITIONS	TRIAGE UNDER MASS CASUALTY CONDITIONS
Emergent (immediate threat to life)	Emergent or class I (red tag) (immediate threat to life)
Urgent (major injuries that require immediate treatment)	Urgent or class II (yellow tag) (major injuries that require treatment)
Nonurgent (minor injuries that do not require immediate treatment)	Nonurgent or class III (green tag) (minor injuries that do not require immediate treatment)
Does not apply	Expectant or class IV (black tag) (expected and allowed to die)

- Emergent (class I) patients are identified with a red tag.
- Patients who can wait a short time for care (class II) are marked with a yellow tag.
- Nonurgent or "walking wounded" (class III) patients are given a green tag.
- Patients who are expected to die or are dead are issued a black tag (class IV).

Nursing Safety Priority QSEN

Action Alert

In mass casualty or disaster situations, implement a military form of triage with the overall desired outcome of doing the greatest good for the greatest number of people (Smith, 2010). This means that patients who are critically ill or injured and might otherwise receive attempted resuscitation during usual operations may be triaged into an "expectant" or "black-tagged" category and allowed to die or not be treated until others received care.

Typical examples of black-tagged patients are those with massive head trauma, extensive full-thickness body burns, and high cervical spinal cord injury requiring mechanical ventilation. The rationale for this seemingly heartless decision is that limited resources must be dedicated to saving the most lives rather than expending valuable resources to save one life at the possible expense of many others.

In general, *red-tagged* patients have immediate threats to life, such as airway obstruction or shock, and require immediate attention. *Yellow-tagged* patients have major injuries, such as open fractures with a distal pulse and large wounds that need treatment within 30 minutes to 2 hours. *Green-tagged* patients have minor injuries that can be managed in a delayed fashion, generally more than 2 hours. Examples of green-tag injuries include closed fractures, sprains, strains, abrasions, and contusions.

Green-tagged patients are often referred to as the "walking wounded" because they may actually evacuate themselves from the mass casualty scene and go to the hospital in a private vehicle. Green-tagged patients usually make up the greatest number in most large-scale multi-casualty situations. Therefore they can overwhelm the system if provisions are not made to handle them as part of the disaster plan. Also, because they often come to the hospital on their own, the hospital may not be able to determine how many actual casualties will arrive. A related concern is that green-tagged patients who self-transport may unknowingly carry contaminants from a nuclear, biologic, or chemical incident into the hospital environment with potentially disastrous consequences. ED staff must anticipate these issues and collaborate to devise emergency response plans accordingly, including appropriate decontamination measures.

NCLEX Examination Challenge

Physiological Integrity

The nurse is triaging clients arriving at the hospital after a large scale disaster. Which of these clients is correctly classified?

A Young adult with closed fractures of her right leg and arm: Yellow tag

B Older adult with severe abdominal pain who is dazed and confused: Black tag

C Middle-aged adult with third-degree burns over 90% of his body: Red tag

D Young adult with bruises and superficial lacerations: Green tag

Once patients are in the triage area of the hospital, they typically receive a special bracelet with a disaster number. Preprinted labels with this number can be applied to the patients' chart forms and personal belongings. Digital photos may be used as part of the identification process in some systems. The standard hospital registration process and identification band can be applied after the patient's identity is confirmed.

Automated tracking systems using infrared and radiofrequency technology (RFT) are available in some emergency departments to track a patient's triage priority upon arrival, location, and process of care. The interactions the patient has with caregivers can also be tracked, an important safety strategy if the patient is later found to have contaminants or a disease that could pose a risk to staff members who had close contact and require decontamination or prophylaxis (Laskowski-Jones, 2008). These systems are valuable components of the hospital's emergency preparedness infrastructure because they can rapidly portray the overall census and acuity of patients. They also enable ED leaders to determine how many casualties of a particular acuity level a hospital can safely accept from the incident scene.

Notification and Activation of Emergency Preparedness/Management Plans

When the number of casualties exceeds the usual resource capabilities, a disaster situation exists. What may be a routine day in the emergency department of a large urban trauma center could be defined as a disaster for a small rural community hospital if the same number of patients were to arrive. Each facility, then, decides when criteria are met to declare a disaster. Flexibility is needed because resources may change by time of

day and by day of the week. For instance, hospitals typically have the fewest staff available after midnight on the weekend. An incident that occurs in this time frame may require activation of the emergency preparedness plan to bring extra resources into the hospital. The same incident during weekday business hours might be handled with on-site personnel alone without the need for activation of the plan.

Notification that a multi-casualty or mass casualty situation exists usually occurs by radio, cellular, or electronic communication between the ED and EMS providers at the scene. A state or regional emergency management agency may also notify the ED of the event. Each hospital has its own policy that specifies *who* has the authority to activate and *how* to activate the disaster or emergency preparedness plan. Group paging systems, telephone trees, and instant computer-based alert messages are the most common means of notifying essential personnel of a mass casualty incident or disaster.

A catastrophic event, such as a major earthquake or tornado, or a terrorist incident involving weapons of mass destruction (WMD) also requires the collaboration of volunteers from all levels of health care providers in the region. In this case, the media may be contacted to broadcast messages to the health care community-at-large via television, radio, and electronic announcements. For such incidents, the National Guard, the American Red Cross, the public health department, various military units, a Medical Reserve Corps (MRC), or a Disaster Medical Assistance Team (DMAT) can be activated by state and federal government authorities.

- An MRC is made up of a group of volunteer medical and public health care professionals, including physicians and nurses. They offer their services to health care facilities or to the community in a supportive or supplemental capacity during times of need such as a disaster or pandemic disease outbreak. This group may help staff hospitals or community health settings that face personnel shortages and establish first aid stations or special-needs shelters. As a means to alleviate emergency department and hospital overcrowding, the MRC may also set up an acute care center (ACC) in the community for patients who need acute care (but not intensive care) for days to weeks.
- A DMAT is a medical relief team made up of civilian medical, paraprofessional, and support personnel that is deployed to a disaster area with enough medical equipment and supplies to sustain operations for 72 hours (U.S. Department of Health & Human Services, 2013).DMATs are part of the National Disaster Medical System (NDMS) in the United States. They provide relief services ranging from

primary health care and triage to evacuation and staffing to assist health care facilities that have become overwhelmed with casualties (Merchant et al., 2010). *Because licensed health care providers such as nurses act as federal employees when they are deployed, their professional licenses are recognized and valid in all states.* Additional examples of services provided by the NDMS include:

- Disaster Mortuary Operational Response Teams (DMORTs) to manage mass fatalities
- National Veterinary Response Teams (NVRTs) for emergency animal care
- International Medical Surgical Response Teams (IMSuRTs) to establish fully functional field surgical facilities wherever they are needed in the world

Nurses can join these teams, complete the required training, and offer their expertise as part of a coordinated federal response team in times of critical need (U.S. Department of Health & Human Services, 2013).

Before going to the incident in the field, nurses, physicians, and support staff must have adequate training to prepare them to recognize the risks in an unstable environment (Laskowski-Jones, 2010; Olchin & Krutz, 2012; Yin et al., 2012). Such risks can include the potential for structural collapse, becoming the secondary target of a terrorist attack, interpersonal violence in unsecured locales, and working in an environment in which contagious diseases and natural hazards are common (e.g., poisonous snake bites and mosquito-borne illnesses). Disaster workers must take measures such as obtaining prophylactic medications and vaccinations, having a personal evacuation plan, and ensuring access to necessary supplies and protective equipment so that they do not become victims as well.

The National Disaster Life Support Foundation, Inc. (2013) offers Core, Basic, and Advanced Disaster Life Support training courses that include all essential aspects of disaster response and management. They include the core competencies of disaster management to all levels of health care professionals. In addition, the Federal Emergency Management Agency (FEMA) (2013) provides numerous online resources, including Community Emergency Response Team (CERT) training so that people are better prepared for disasters and are able to respond more self-sufficiently to incidents and hazard situations in their own communities. These courses include mass casualty triage education.

Hospital Emergency Preparedness: Personnel Roles

and Responsibilities

Nurses play a major role in the emergency preparedness or emergency management plan. In the event of a disaster, the Hospital Incident Command System is established for organization and structure.

Hospital Incident Command System

The facility-level organizational model for disaster management is the **Hospital Incident Command System (HICS),** which is a part of the National Incident Management System (NIMS) implemented by the Department of Homeland Security and FEMA to standardize disaster operations. In this system, roles are formally structured under the hospital or long-term care facility incident commander with clear lines of authority and accountability for specific resources (FEMA, 2013). Officers are named to oversee essential emergency preparedness functions such as public information, safety and security, and medical command. Chiefs are appointed to manage logistics, planning, finance, and operations as appropriate to the type and scale of the event. In turn, chiefs delegate specific duties to other departmental officers and unit leaders. The idea is to achieve a manageable span of control over the personnel or resources allocated to achieve efficiency. FEMA offers free courses on the NIMS model and HICS structure through their website (www.training.fema.gov/IS/).

Because mass casualty events typically involve large numbers of people and can create a chaotic work environment, many EMS agencies and health care facilities use brightly colored vests with large lettering to help identify key leadership positions. Specific job action sheets are distributed to all personnel with leadership roles in HICS that pre-define reporting relationships and list prioritized tasks and responsibilities. The HICS personnel also establish an **emergency operations center (EOC)** or **command center** in a designated location with accessible communication technology. They then use their collective expertise to manage the overall incident. All internal requests for additional personnel and resources, as well as communication with field teams and external agencies, should be coordinated through the EOC to maintain unity of command.

The roles and responsibilities of health care personnel in a mass casualty event or disaster are defined within the institution's emergency response or preparedness plan (Table 10-2). Each plan can be as individual as the particular facility's operations. However, virtually all plans identify certain key functions. For example, one of the primary roles in a hospital to be established at the onset of an incident is that of a

hospital incident commander who assumes overall leadership for implementing the institutional plan. This person is usually either a physician in the ED or a hospital administrator who has the authority to activate resources. The role can also be fulfilled by a nursing supervisor functioning as the on-site hospital administrator after usual business hours. The hospital incident commander's role is to take a global view of the entire situation and facilitate patient movement through the system. The commander brings in both personnel and supply resources to meet patient needs. For example, a hospital incident commander might dictate that all patients due to be discharged from an inpatient unit be moved to a lounge area immediately to free up hospital beds for mass casualty victims. He or she could also direct departments such as physical therapy or a surgical clinic to cancel their usual operations to convert the space into a minor treatment area. The incident commander assists in the organization of hospital-wide services to rapidly expand hospital capacity, recruit paid or volunteer staff, and ensure the availability of medical supplies.

TABLE 10-2

Summary of Key Personnel Roles and Functions for Emergency Preparedness and Response Plan

PERSONNEL ROLE	PERSONNEL FUNCTION
Hospital incident commander	Physician or administrator who assumes overall leadership for implementing the emergency plan
Medical command physician	Physician who decides the number, acuity, and resource needs of patients
Triage officer	Physician or nurse who rapidly evaluates each patient to determine priorities for treatment
Community relations or public information officer	Person who serves as a liaison between the health care facility and the media

Another typical role defined in hospital or other health care emergency preparedness plans is that of the **medical command physician.** He or she focuses on determining the number, acuity, and medical resource needs of victims arriving from the incident scene to the hospital and organizing the emergency health care team response to the injured or ill patients. Responsibilities include identifying the need for and calling in specialty-trained providers such as:

- Trauma surgeons
- Neurosurgeons
- Orthopedic surgeons
- Pulmonologists

- Plastic surgeons
- Burn surgeons
- Infectious disease physicians
- Industrial hygienists
- Radiation safety personnel

In smaller hospitals with limited specialty resources, the medical command physician might also help determine which patients should be transported out of the facility to a higher level of care or to a specialty hospital (e.g., burn center).

Closely affiliated with the medical command physician is the **triage officer.** This person is generally a physician in a large hospital who is assisted by triage nurses. When physician resources are limited, an experienced nurse may assume this role. The triage officer rapidly evaluates each person who presents to the hospital, even those who come in with triage tags in place. Patient acuity is re-evaluated for appropriate disposition to the area within the ED or hospital best suited to meet the patient's medical needs.

Many other roles and responsibilities can be defined within the institutional emergency response plan and may include the supply officer, the communications officer, the infection control officer, and the community relations/public information officer, to name a few. The community relations or public information officer is an especially important role to delineate in advance. Mass casualty incidents tend to attract a large amount of media attention. This staff member can draw media away from the clinical areas so that essential hospital operations are not hindered. He or she can also serve as the liaison between hospital administration and the media to release only appropriate and accurate information.

Role of Nursing in Health Care Facility Emergency Preparedness and Response

Nurses play key roles before, during, and after a disaster. Before an event, they contribute to developing internal and external emergency response plans, including defining specific nursing roles. Nurses take into account the security needs, communication methods, training, alternative treatment areas, staffing for high-demand or surge situations, and requirements for resources, equipment, and supplies. They then test the plans by actively participating in disaster drills and evaluating the outcomes.

During an actual disaster, the ED charge nurse, trauma program

manager, and other ED nursing leadership personnel act in collaboration with the medical command physician and triage officer to organize nursing and ancillary services to meet patient needs. Telephone trees may be activated to call in ED nurses who are not working or are not scheduled to work. ED areas are identified and prepared to stage, triage, resuscitate, and treat the disaster victims. Efforts are made to quickly discharge or admit other ED patients as appropriate to make room for the new arrivals. ED nurses apply principles of triage as disaster victims enter the system to prioritize care delivery and direct patients to the designated areas best suited to meet their needs.

Nursing roles in a disaster extend to all areas within a health care facility. The level of involvement is determined by the scope and scale of the disaster. In any mass casualty event, nurses from medical-surgical nursing units may be asked, in collaboration with the health care provider, to recommend patients for discharge to free up inpatient beds for disaster victims. Patients who are the most medically stable may be discharged early, including those who:

- Were admitted for observation and are not bedridden
- Are having diagnostic evaluations and are not bedridden
- Are soon scheduled to be discharged or could be cared for at home with support from family or home health care services
- Have had no critical change in condition for the past 3 days
- Could be cared for in another health care facility, such as rehabilitation or long-term care

NCLEX Examination Challenge

Safe and Effective Care Environment

The ED charge nurse is assigning duties to nurses who have been floated to the ED or who have volunteered to help staff the ED during a mass casualty situation. Which assignments are most appropriate?

Select all that apply.

A GI laboratory nurse assigned to orthopedic clients having sedation procedures

B Critical care nurse assigned to client, not related to the mass casualty, having chest pain

C Medical-surgical nurse assigned to accompany clients to radiology

D Nursing manager from an inpatient unit assigned to monitor clients in the waiting room

E Liaison nurse from the operating room assigned to work with families

General staff nurses also may be recruited to collaborate in providing care for stable ED patients, thus allowing ED nurses to focus their efforts on aiding the mass casualty victims. Critical care unit nurses need to identify patients who can be transferred out of the unit to rapidly expand critical care bed capacity. In addition, they can supplement ED nurses in the resuscitation setting or assist in monitored care and transport to critical care units. Hospital and ED nurse leaders also typically direct the ancillary departments to deliver supplies, instrument trays, medications, food, and personnel to meet service demands.

Hospital staff of all levels may be required to alter their routine operations to accommodate a high volume of patients, including those with special needs such as decontamination, burn management, or quarantine. Emergency plans dictate specific actions by staff members, such as who should be called when the plan is activated, who should report, where to report, what supplies or equipment carts should be brought to a pre-designated location, and what type of paperwork or system should be implemented for patient identification in a large-scale event. Some staff may even have their roles changed completely. For example, nurses from the performance improvement department or case management may be reassigned to fulfill a clinical responsibility for a nursing unit. The key concept is that staff members are expected to remain flexible in a mass casualty situation and perform at their highest level to address the needs of both the health care system and the patients. The greatest good for the greatest number of people is still the organizing principle when considering roles and responsibilities in mass casualty events—not necessarily individual staff preferences. However, the safety of all patients is vital.

Creativity and flexibility of nursing leaders and nursing staff are essential to provide the staffing coverage necessary for a large-scale or extended incident. The willingness of staff to show up for work is directly impacted by their concerns for their home and family in a disaster; inadequate staffing can jeopardize a facility's ability to provide care. A **personal emergency preparedness plan** developed by each nurse can help in such situations. It should outline the preplanned specific arrangements that are to be made for childcare, pet care, and older adult care if the need arises, especially if the event prevents returning home for an extended period.

Nursing Safety Priority QSEN

Action Alert

Include emergency contact names, addresses, and telephone numbers to use in a crisis as part of a personal emergency preparedness plan. In addition, pre-assemble **personal readiness supplies** or **"go bag"** (disaster supply kit) for the home and automobile with clothing and basic survival supplies, which allows for a rapid response for disaster staffing coverage (Table 10-3). "Go bags" are needed for all members of the family, including pets, in the event the disaster requires evacuation of the community or people to take shelter in their own homes.

TABLE 10-3

Basic Supplies for Personal Preparedness (3-Day Supply)

- Backpack
- Clean clothing, sturdy footwear
- Potable water—at least 1 gallon per person per day for at least 3 days
- Food—non-perishable, no cooking required
- Headlamp or flashlight—battery powered; extra batteries and/or chemical light sticks (NOTE: a headlamp is superior because it allows hands-free operation)
- Pocket knife or multi-tool
- Personal identification (ID) with emergency contacts and phone numbers, allergies, and medical information; lists of credit card numbers and bank accounts (keep in watertight container)
- Towel and washcloth; towelettes, soap, hand sanitizer
- Paper, pens, and pencils; regional maps
- Cell phone and charger
- Sunglasses/protective and/or corrective eyewear
- Emergency blanket and/or sleeping bag and pillow
- Work gloves
- Personal first aid kit with over-the-counter (OTC) and prescription medications/vitamins
- Rain gear
- Roll of duct tape and plastic sheeting
- Radio—battery powered or hand-crank generator
- Toiletries (toothbrush and toothpaste, comb, brush, razor, shaving cream, mirror, feminine supplies, deodorant, shampoo, lip balm, sunscreen, insect repellent, toilet paper)
- Plastic garbage bags and ties, resealable plastic bags
- Matches in a waterproof container
- Whistle
- Household liquid bleach for disinfection

When called to respond to work during a mass casualty event, some nurses may experience ethical and moral conflict between their family obligations and professional responsibilities (Chaffee, 2006). The American Nurses Association's (ANA's) *Code of Ethics for Nurses with Interpretive Statements* (2001) does not offer clear guidance in this situation. Each person has to make a choice about whether to be involved in helping during the emergency or when to become involved.

Event Resolution and Debriefing

When the last major casualties have been treated and no more are expected to arrive in numbers that could overwhelm the health care system, the incident commander considers "standing down" or deactivating the emergency response plan. However, although the casualties may have left the ED, other areas in the hospital may still be under stress and need the support of the supplemental resources provided by emergency plan activation. Before terminating the response, it is essential to ensure that the needs of the other hospital departments have been met and all are in agreement to resume normal operations.

A vital consideration in event resolution is staff and supply availability to meet ongoing operational needs. If nursing staff and other personnel were called in from home during their off hours or if they worked well beyond their scheduled shifts to meet patient and departmental needs, provision for adequate rest periods should be made. Exhaustion poses a risk not only to patient safety but also to the nurse when he or she must drive home. Sleeping quarters at the hospital might be necessary in this case, especially if the disaster event contributed to treacherous travel conditions.

Severe shortages of supplies also pose a threat to usual operations at the conclusion of a mass casualty incident. Taking inventory and restocking the ED are high priority assignments. Collaboration between the ED and the central supply department is essential to resolving stock availability problems. Instrument trays must be washed, packaged, and re-sterilized. Critical supplies that have been depleted from hospital stores must be reordered and delivered to the hospital quickly. Contracts with key vendors outlining emergency re-supply expectations and arrangements should be a part of the hospital's overall emergency preparedness plan.

Two general types of **debriefing,** or formal systematic review and analysis, occur after a mass casualty incident or disaster. The first type entails bringing in critical incident stress debriefing (CISD) teams to provide sessions for small groups of staff to promote effective coping strategies. The second type of debriefing involves an administrative review of staff and system performance during the event to determine whether opportunities for improvement in the emergency management plan exist.

Critical Incident Stress Debriefing

CISD is only one component of a much broader critical incident stress

management (CISM) program. CISM programming addresses pre-crisis through post-crisis interventions for small to large groups, including communities. After working through the turmoil and the emotional impact of the incident as well as the aftermath, the staff may find it difficult to "get back to normal." Without intervention during *and* after the emergency, they may develop post-traumatic stress disorder (PTSD). PTSD can lead to multiple characteristic psychological and physical effects, including flashbacks, avoidance, less interest in previously enjoyable events, and detachment, as well as rapid heart rate and insomnia. People suffering from PTSD can have great difficulty relating in their usual way to family and friends. Ultimately, professional "burnout" can stem from the inability to cope with the stress effectively. A resource for CISM is the International Critical Incident Stress Foundation, Inc. (2013); their mission is "to provide leadership, education, training, consultation, and support services in comprehensive crisis intervention and disaster behavioral health services to the emergency response professions, other organizations, and communities worldwide" (www.icisf.org/who-we-are). Chart 10-2 lists recommendations proposed by several national organizations to help prevent PTSD during the emergency situation.

Chart 10-2

Best Practice for Patient Safety & Quality Care QSEN

Preventing Staff Post-Traumatic Stress Disorder (PTSD) During a Mass Casualty Event

- Use available counseling.
- Encourage and support co-workers.
- Monitor each other's stress level and performance.
- Take breaks when needed.
- Talk about feelings with staff and managers.
- Drink plenty of water, and eat healthy snacks for energy.
- Keep in touch with family, friends, and significant others.
- Do not work for more than 12 hours per day.

Adapted from Papp, E. (2005). Preparing for disasters: Helping yourself as you help others. *AJN, 105*(5), 112.

A CISD team comprises two or three specially trained people who come together quickly when called to deal with the emotional needs of health care team members after a particularly devastating or disturbing

incident. The team leader typically has background in a mental health/behavioral health field. The co-leader is ideally a peer of the group being debriefed. Thus, if nurses are debriefed, then a nurse member of the CISD team is generally assigned to the session. CISD-trained physicians, police, firefighters, EMTs, and paramedics may also be used, depending on the needs of the group. The third member of the team is known as the "doorkeeper." This person is responsible for keeping inappropriate people out (e.g., media, spectators) and talking with anyone who leaves the session early in an effort to have him or her return or accept follow-up. Staff involved in the incident need protected time to undergo stress debriefing, which generally lasts from 1 to 3 hours per session.

Typical "ground rules" for stress debriefing include strict confidentiality of information shared during the session and unconditional acceptance of the thoughts and feelings expressed by people within the group. The usual arrangement for the most effective group interaction is a circular configuration of chairs in a private setting. Food should be available so that hunger is not a distraction. CISD group leaders encourage group discussion through asking a series of questions designed to get everyone involved to tell his or her own story about the incident and explain the personal impact. The group leaders enable participants to place the incident into perspective and dispel any feelings of blame or guilt. They also educate participants about self-care concepts and coping strategies to use immediately. People who require more than a CISD session may need referral for mental health/behavioral health counseling.

Administrative Review

The second type of debriefing is an administrative evaluation directed at analyzing the hospital or agency response to an event while it is still in the forefront of the minds of everyone who participated in it. The goal of this type of debriefing is to discern what went right and what went wrong during activation and implementation of the emergency preparedness plan so that needed changes can be made. Typically, representatives from all groups that were involved in the incident come together soon after plan activation has been discontinued. They each are given an opportunity to hear and express both positive and negative comments related to their experiences with the event. Then, in the days after the plan activation, written critique forms are also solicited to gain additional information after participants have had time to consider their overall

impressions of the response as well as the impact it had on their respective departments or clinical areas.

Although drills are important, implementing the emergency preparedness plan during an actual mass casualty event is the most effective means of “reality testing” the plan's utility. Feedback provided by participants can be used to modify or revise the plan and create new processes in preparation for future events.

Role of Nursing in Community Emergency Preparedness and Response

During a community disaster, nurses and other emergency personnel may be needed for triage, first aid/emergency care, and shelter assistance. The first action of first-responders in a disaster is to remove people from danger, both the injured and uninjured. This job is typically managed by firefighters and other disaster-trained emergency personnel; unless they have had specific search and rescue training, nurses are not usually involved in this process. In all cases, developing and maintaining accurate *situational awareness* is critical for appropriate priority setting and safety in a rapidly changing environment (Busby & Witucki-Brown, 2011).

After removal from danger, victims are triaged by health care personnel as described earlier in this chapter. After triage, nurses often provide on-site first aid and emergency care. They may also be involved in teaching and supervising volunteers. The American Red Cross sets up shelters for people who have lost their homes or have been evacuated from their homes.

Nurses may also need to teach those living temporarily in shelters about procedures that will be needed for safety when they return home. For example, clean drinking water may not be available for several days or longer. Community residents may need to boil their water before drinking. If electricity and gas are not available, an outdoor grill or camp stove can be used. As alternative procedures, commercial water purification filters, sterilizing ultraviolet pens, or tablets or 10 to 20 drops of chlorine bleach added to a gallon of water will make the water safe to drink.

Human waste management creates another challenge if toilets do not flush. If not managed safely, enteric pathogens spread disease. A toilet bowl or bucket lined with a plastic bag can be used for human waste. To sanitize it and provide odor control, chlorine bleach can be added and the bag tied and sealed. Portable toilet chemicals or chlorinated lime may be used as alternatives. To prevent a toxic gas reaction, remind residents not to mix any chemicals. Treated human waste bags can be buried in the ground. In an austere environment, a pit can be dug in the ground as an improvised toilet. In all cases, emphasize the importance of handwashing with soap and water or using a hand sanitizer to prevent disease transmission.

Psychosocial Response of Survivors to Mass Casualty Events

One of the most important roles of the nurse after a community disaster is health assessment, including psychosocial health. Experiencing a disaster can produce both immediate and long-lasting psychosocial effects in people personally affected by the event. Depending on the nature and magnitude of the incident, survivors experience the tragic loss of loved ones, property, and valued possessions. They and their family members may have suffered injuries or illnesses brought about by the catastrophe. Lifestyles, roles, and routines are drastically altered, preventing people from achieving any sense of normalcy in the hours, the days, and perhaps even the weeks and months that follow a disaster. Coping abilities in survivors are severely stressed, leading to many individual responses that can range from functional and adaptive behaviors to maladaptive coping.

Survivors have to confront feelings of vulnerability resulting from the devastating event, knowing that it could occur again—a particularly relevant issue for people who live in areas prone to acts of terrorism or to natural disasters. The decision—be it voluntary or involuntary—to abandon a family home or geographic region and then relocate to a "safe" area either temporarily or permanently results in a further sense of loss and grief. Some people may feel guilty about living through an event that caused so many others to die. The range of intense emotions can appear as physical illness, as well as psychological and social dysfunction.

When helping people in crisis after a mass casualty event, be calm and reassuring. Establish rapport through active listening and honest communication. Survivors benefit from talking about their experiences and being helped as they work to problem-solve. Offer choices whenever possible to help survivors gain a sense of personal control. Help survivors adapt to their new surroundings and routines through simple, concrete explanations. Convey caring behaviors, and provide a sense of safety and security to the best extent possible. If available, request that crisis counselors respond and assist in providing compassionate support to victims and their families (Kallman & Feury, 2011).

A disaster may cause some survivors to develop post-traumatic stress disorder (PTSD), which can potentially last for a lifetime. People who are unable to sleep, are easily startled, have "flashbacks" to relive the disaster, or report "feeling numb" 2 weeks or more after a disaster or traumatic event are at risk for PTSD (Hyer & Brown, 2008).

Clinical Judgment Challenge

Patient-Centered Care QSEN

An ED nurse has gone on an emergent medical mission trip to a Third World country after an earthquake with multiple building collapses in a remote rural area. Hundreds are reported missing, and even more are injured. Medical resources in this country are scarce.

1. What challenges does this nurse face in terms of his or her own safety and health?
2. How can the nurse manage basic hygiene and meet basic needs?
3. Some local residents are so distraught that they are unable to function and are not eating or sleeping. What assistance can the nurse provide?
4. After returning from the mission trip, the nurse feels apathetic, disengaged with regular employment, and is often short tempered with co-workers and staff. What resources exist for the nurse?

Nurses caring for survivors with these manifestations should perform further assessment. One tool that can be used to assess survivor response to a disaster is the Impact of Event Scale—Revised (IES-R). The IES-R is a 22-item self-administered questionnaire including several subscales, such as avoidance. Before giving the tool, determine the patient's reading level because it is written at a 10th-grade reading level. The tool should not be used for patients with short-term memory loss. For that reason, many older survivors are often not adequately assessed for post-disaster PTSD (Hyer & Brown, 2008). However, assess all older survivors of a disaster for this complication when possible.

Nursing Safety Priority QSEN

Action Alert

A high score on any IES-R subscale indicates a need for further evaluation and counseling. Refer the patient to a social worker or qualified mental health counselor. A high score on all subscales requires referral to a psychiatrist or clinical psychologist to evaluate the possibility of current or past trauma, such as abuse or neglect.

Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Describe the hospital emergency preparedness and response team that all hospitals are required to have in case of mass casualty (disaster). **Teamwork and Collaboration** QSEN
- Use the guidelines in Chart 10-1 to respond to a fire in any facility. **Safety** QSEN
- Apply principles of triage by using the typical triage system for a mass casualty situation, which includes an additional category for those patients allowed to die (black-tagged) (see Table 10-1).
- Describe the special roles that are assigned in a mass casualty incident as identified in Table 10-2.
- Understand how to assist in determining the need for initiating the emergency preparedness plan based on available resources, including staffing. **Teamwork and Collaboration** QSEN
- Be prepared for an emergency by developing a personal emergency preparedness plan, including a plan for child, pet, and older adult care; have a "go bag," or disaster supply kit, packed for both the automobile and the home (see Table 10-3).
- Compare key personnel roles in an emergency preparedness and response plan, including those involved in the two types of debriefing that occur after a mass casualty event or period—critical incident stress debriefing and an administrative review or evaluation. **Teamwork and Collaboration** QSEN
- Identify the important roles of nurses in preparing for, managing, and debriefing after internal health care facility and community disasters.
- Recall that nurses play a major role in triage, first aid and emergency care, and shelter assistance in external community disasters.
- Understand how to identify which patients to recommend for hospital discharge in a disaster situation. **Patient-Centered Care** QSEN

Psychosocial Integrity

- Assess survivors and families for their ability to adapt to the effects of disaster changes or traumatic events, including post-traumatic stress disorder (PTSD). **Patient-Centered Care** QSEN
- Provide emotional support to the person and/or family in coping with

life changes resulting from a disaster by encouraging relaxation, listening to survivor feelings, and referring for appropriate counseling. **Patient-Centered Care** QSEN

- Be honest with victims and their families, and help them adapt to their changed or new surroundings.
- Provide support by taking precautions to prevent staff from developing PTSD as outlined in Chart 10-2.

Physiological Integrity

- Take precautions for meeting basic needs in a mass casualty situation; know your own limitations, and develop situational awareness when responding. **Safety** QSEN

UNIT III

Management of Patients with Fluid, Electrolyte, and Acid-Base Imbalances

OUTLINE

CHAPTER 11

Assessment and Care of Patients with Fluid and Electrolyte Imbalances

M. Linda Workman

PRIORITY CONCEPTS

- Fluid and Electrolyte Imbalance

Learning Outcomes

Safe and Effective Care Environment

1. Protect the patient with a change in fluid and electrolyte balance.

Health Promotion and Maintenance

2. Teach people how to prevent, recognize, and manage a change in fluid and electrolyte balance.

Psychosocial Integrity

3. Reduce the psychological impact for the patient experiencing a change in fluid and electrolyte balance.

Physiological Integrity

4. Use knowledge from anatomy and physiology to assess the patient's fluid and electrolyte balance.
5. Use laboratory data and clinical manifestations to determine the effectiveness of interventions to restore fluid and electrolyte balance.
6. Prioritize interventions for a patient who has a change in fluid and electrolyte balance.

 http://evolve.elsevier.com/Iggy/

Homeostasis

The body works best when fluid and electrolyte balance is kept within a narrow range of normal. For example, no body system works well if 2 liters of blood volume are gained or lost. To keep conditions as close to normal as possible (known as **homeostasis**), the body has many control actions (known as **homeostatic mechanisms**) to prevent dangerous changes.

Homeostasis requires that the body's volume and composition of fluids remain within normal limits. Water (fluid) is the most common substance in the body, making up about 55% to 60% of total weight for healthy younger adults and 50% to 55% of total weight for healthy older adults. This water is divided into two main compartments (spaces)—the fluid outside the cells **(extracellular fluid [ECF])**; and the fluid inside the cells **(intracellular fluid [ICF])**. The ECF space is about one third (about 15 L) of the total body water. The ECF includes **interstitial fluid** (fluid between cells, sometimes called the "third space"); blood, lymph, bone, and connective tissue water; and the transcellular fluids. **Transcellular fluids** are in special body spaces and include cerebrospinal fluid, synovial fluid, peritoneal fluid, and pleural fluid. ICF is about two thirds (about 25 L) of total body water. Fig. 11-1 shows normal total body water distribution.

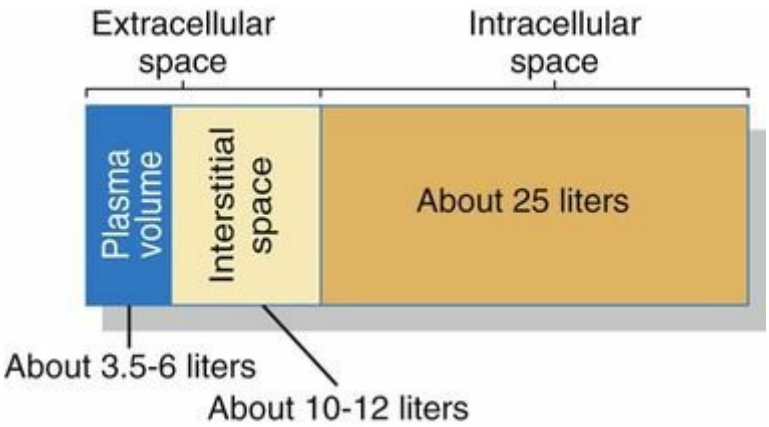

FIG. 11-1 Normal distribution of total body water in adults.

Water is needed to deliver dissolved nutrients, electrolytes, and other substances to all organs, tissues, and cells. In health, the volume of water in the fluid compartments remains within the normal range although the water moves constantly between compartments. Changes in either the amount of water or the amount of electrolytes in body fluids can affect the functioning of all cells, tissues, and organs. *For proper function, the volume of all body fluids and the types and amount of dissolved substances must be carefully balanced.*

Physiologic Influences on Fluid and Electrolyte Balance

Body fluids are composed of water and particles dissolved or suspended in water. The **solvent** is the water portion of fluids. **Solutes** are the particles dissolved or suspended in the water. Solutes vary in type and amount from one fluid space to another. When solutes express an overall electrical charge, they are known as *electrolytes.* Body function depends on keeping the correct fluid and electrolyte balance within each body fluid space (compartment).

Three processes control fluid and electrolyte balance so the internal environment remains stable even when the external environment changes. These processes—filtration, diffusion, and osmosis—determine how, when, and where fluids and particles move across cell membranes.

Filtration

Physiologic Action

Filtration is the movement of fluid (water) through a cell or blood vessel membrane because of water pressure **(hydrostatic pressure)** differences on both sides of the membrane. Water pressure is related to water volume pressing against confining membranes.

Fluid weight in a space is related to the amount of fluid present in that area. Water molecules in a confined space constantly press outward against the membranes, creating hydrostatic pressure. This is a "water-pushing" pressure, because it is the force that pushes water outward from a confined space through a membrane (Fig. 11-2).

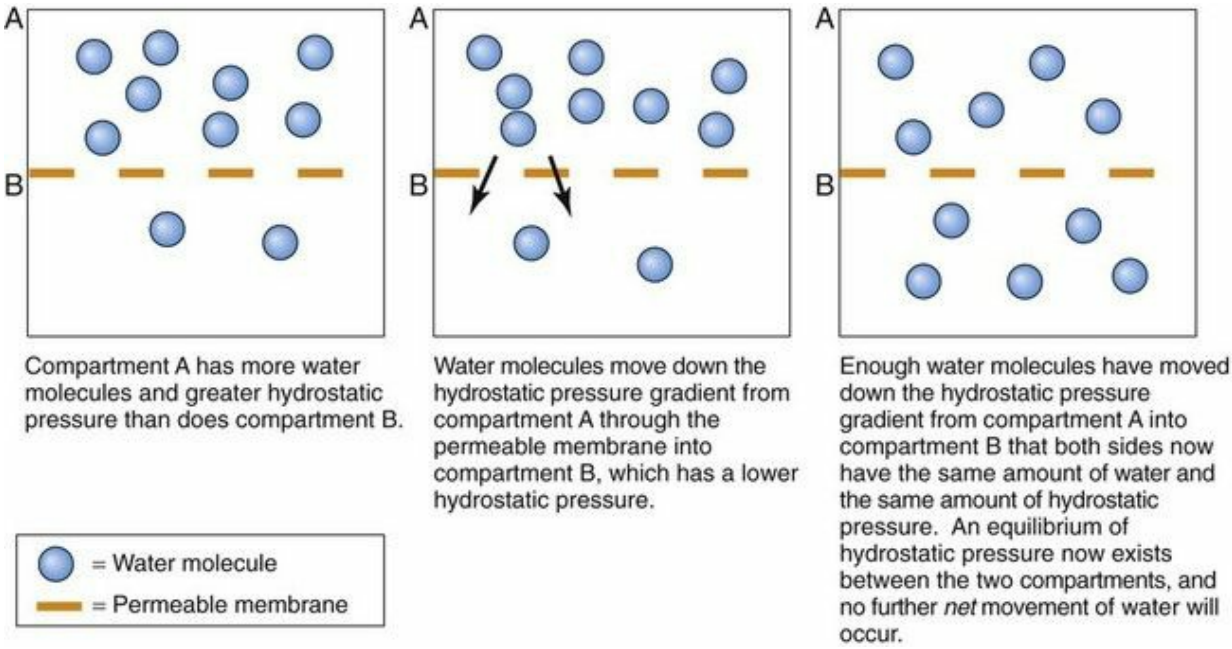

FIG. 11-2 The process of filtration.

The amount (volume) of water in any body fluid space determines the hydrostatic pressure of that space. Blood, which is "thicker" than water (more *viscous*), is confined within the blood vessels. Blood has hydrostatic pressure because of its weight and volume. Another factor that affects blood hydrostatic pressure in arteries is the pumping action of the heart.

The hydrostatic pressures of two fluid spaces can be compared whenever a porous **(permeable)** membrane separates the two spaces. If the hydrostatic pressure is the same in both fluid spaces, there is no pressure difference between the two spaces and the hydrostatic pressure is at *equilibrium.* If the hydrostatic pressure is not the same in both spaces, **disequilibrium** exists. This means that the two spaces have a graded difference *(gradient)* for hydrostatic pressure: one space has a higher hydrostatic pressure than the other. *The human body constantly seeks equilibrium.* When a gradient exists, water movement (filtration) occurs until the hydrostatic pressure is the same in both spaces (see Fig. 11-2).

Water moves through the membrane **(filters)** from the space with higher hydrostatic pressure to the space with lower pressure. Filtration continues only as long as the hydrostatic pressure gradient exists. Equilibrium is reached when enough fluid leaves one space and enters the other space to make the hydrostatic pressure in both spaces equal. In equilibrium, water molecules are evenly exchanged between the two spaces but no net further filtration of fluid occurs. Neither space gains or loses water molecules, and the hydrostatic pressure in both spaces remains the same.

Clinical Significance

Blood pressure is an example of a hydrostatic filtering force. It moves whole blood from the heart to capillaries where filtration can occur to exchange water, nutrients, and waste products between the blood and the tissues. The hydrostatic pressure difference between the capillary blood and the interstitial fluid (fluid in the tissue spaces) determines whether water leaves the blood vessels and enters the tissue spaces.

Capillary membranes are only one cell layer thick, making a thin "wall" to hold blood in the capillaries. Large spaces **(pores)** in the capillary membrane help water filter freely when a hydrostatic pressure gradient is present (Fig. 11-3).

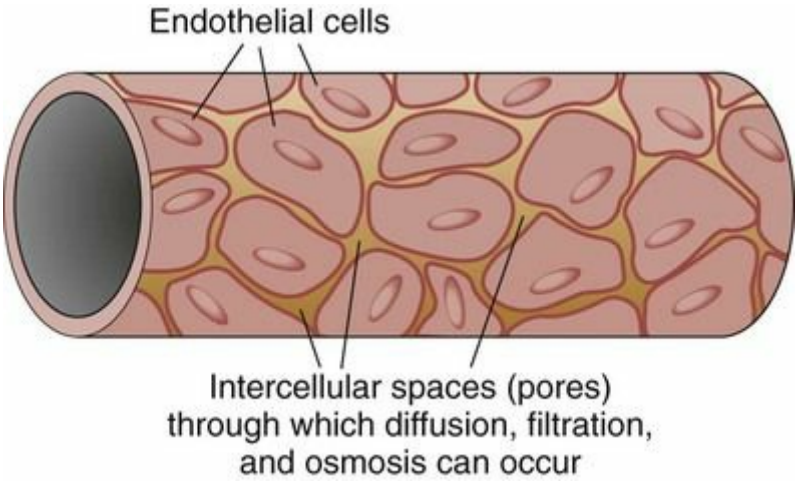

FIG. 11-3 The basic structure of a capillary.

Edema (tissue swelling from excess fluid) forms with changes in hydrostatic pressure differences between the capillary blood and the interstitial fluid, such as in patients with right-sided heart failure. In this condition, the volume of blood in the right side of the heart increases because the right ventricle is too weak to pump blood efficiently into the lung blood vessels. As blood backs up into the venous and capillary systems, the capillary hydrostatic pressure rises until it is higher than the hydrostatic pressure in the interstitial space. Then, excess filtration of fluids from the capillaries into the interstitial tissue space occurs, forming visible edema.

Diffusion

Physiologic Action

Diffusion is the movement of particles (solute) across a permeable

membrane from an area of higher particle concentration to an area of lower particle concentration (down a *concentration gradient*). Particles in a fluid have totally random movement from the vibration of atoms in the nucleus. This random movement allows molecules to bump into each other within a confined fluid space. Each collision increases the speed of particle movement. The more particles (higher concentration) present in the confined fluid space, the greater the number of collisions.

As a result of the collisions, molecules in a solution spread out evenly through the available space. They move from an area of higher amounts (higher concentration) of molecules to an area of lower amounts until an equal amount is present in all areas. Fluid spaces with many particles have more collisions and faster particle movement than spaces with fewer particles.

A concentration gradient exists when two fluid spaces have different amounts of the same type of particles. Particle collisions cause them to move down the concentration gradient. Any membrane that separates two spaces is struck repeatedly by particles. When the particle strikes a pore in the membrane that is large enough for it to pass through, diffusion occurs (Fig. 11-4). The chance of any single particle hitting the membrane and going through a pore is much greater on the side of the membrane with a higher solute particle concentration.

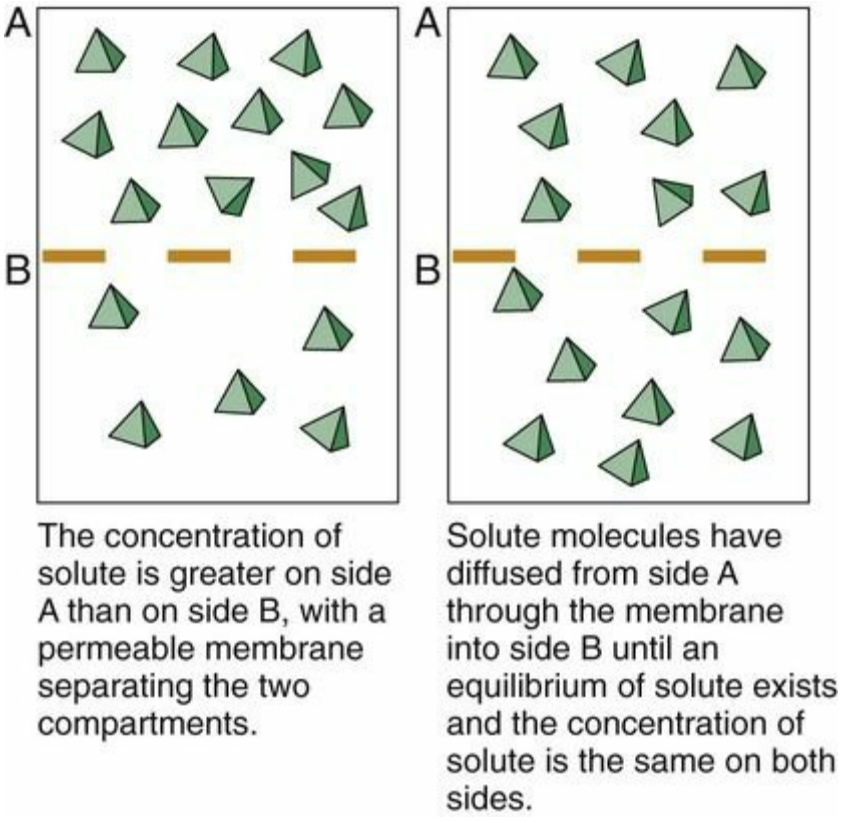

FIG. 11-4 Diffusion of solute particles through a permeable membrane from an area of higher solute concentration to an area of lower solute concentration until an equilibrium is reached.

The speed of diffusion is related to the difference in amount of particles (concentration gradient) between the two sides of the membrane. The degree of difference is the *steepness* of the gradient: the larger the concentration difference between the two sides, the steeper the gradient. Diffusion is more rapid when the gradient is steeper (just as a ball rolls downhill faster when the hill is steep than when the hill is nearly flat). Particles move from the fluid space with a higher concentration of solute particles to the fluid space with a lower concentration of solute particles.

Particle diffusion continues as long as a concentration gradient exists between the two sides of the membrane. When the concentration of particles is the same on both sides of the membrane, the particles are in equilibrium and only an equal exchange of particles continues.

Clinical Significance

Diffusion is what transports most electrolytes and other particles through cell membranes. Unlike capillary membranes, which permit the diffusion of most small-size particles down a gradient, cell membranes are *selective* for which particles can diffuse. They permit diffusion of some particles

but not others. Some particles cannot move across a cell membrane, even when a steep "downhill" gradient exists, because the membrane is **impermeable** (closed) to that particle. For these particles, the concentration gradient is maintained across the membrane.

Impermeability and special transport systems cause differences in the amounts of specific particles from one fluid space to another. For example, usually the fluid outside the cell (the extracellular fluid [ECF]) has ten times more sodium ions than the fluid inside the cell (the intracellular fluid [ICF]). This extreme difference is caused by cell membrane impermeability to sodium and by special "sodium pumps" that move any extra sodium present inside the cell out of the cell "uphill" against its concentration gradient and back into the ECF.

For some particles, diffusion cannot occur without help, even down steep concentration gradients, because of selective membrane permeability. One example is glucose. Even though the amount of glucose may be much higher in the ECF than in the ICF (creating a steep gradient for glucose), glucose cannot cross many cell membranes without the help of insulin. When insulin is present, it binds to insulin receptors on cell membranes, which then makes the membranes much more permeable to glucose. As a result, glucose can cross the cell membrane down its concentration gradient until equilibrium of glucose concentration is achieved.

Diffusion across a cell membrane that requires the assistance of a membrane-altering system (e.g., insulin) is called **facilitated diffusion** or **facilitated transport.** This type of movement is still a form of diffusion.

Osmosis

Physiologic Action

Osmosis is the movement of water only through a selectively permeable *(semipermeable)* membrane. For osmosis to occur, a membrane must separate two fluid spaces and one space must have particles that cannot move through the membrane. (The membrane is impermeable to this particle.) A concentration gradient of this particle must also exist. Because the membrane is impermeable to these particles, they cannot cross the membrane but water molecules can. (Usually water can *always* move through a cell membrane.)

For the fluid spaces to have equal concentrations of the particle, the water molecules move down their concentration gradient from the side with the higher concentration of water molecules (and thus a lower

concentration of particles along with a greater hydrostatic pressure) to the side with the lower concentration of water molecules (and a higher concentration of particles along with a lower hydrostatic pressure). This movement continues until both spaces contain the same proportions of particles to water. Dilute (less concentrated) fluid has fewer particles and more water molecules than the more concentrated fluid. Thus water moves by osmosis down its hydrostatic pressure gradient from the dilute fluid to the more concentrated fluid until a concentration equilibrium occurs (Fig. 11-5).

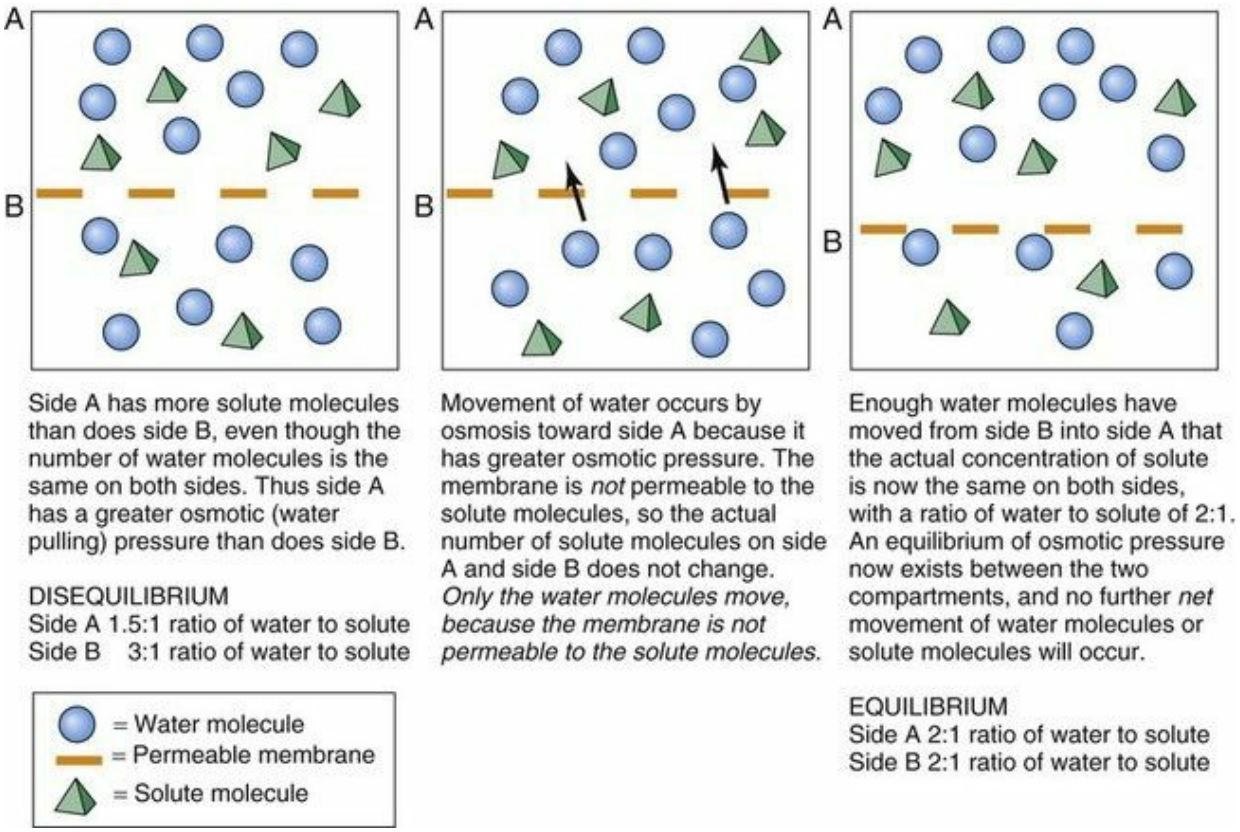

FIG. 11-5 The process of osmosis to generate a concentration equilibrium (but not a volume equilibrium) for a solute particle that cannot move through a cell membrane.

At this point, the *concentrations* of particles in the fluid spaces on both sides of the membrane are equal even though the total amounts of particles and volumes of water are different. *The concentration equilibrium occurs by the movement of water molecules rather than the movement of solute particles.*

Particle concentration in body fluid is the major factor that determines whether and how fast osmosis and diffusion occur. This concentration is expressed in milliequivalents per liter (mEq/L), millimoles per liter (mmol/L), and milliosmoles per liter (mOsm/L). **Osmolarity** is the

number of milliosmoles in a *liter* of solution; **osmolality** is the number of milliosmoles in a *kilogram* of solution. The normal osmolarity value for plasma and other body fluids ranges from 270 to about 300 mOsm/L. The body functions best when the osmolarity of all body fluid spaces is close to 300 mOsm/L. When all fluids have this particle concentration, the fluids are **isosmotic** or **isotonic** (also called **normotonic**) to each other.

Fluids with osmolarities greater than 300 mOsm/L are **hyperosmotic,** or **hypertonic,** compared with isosmotic fluids. These fluids have a *greater* osmotic pressure than do isosmotic fluids and tend to pull water from the isosmotic fluid space into the hyperosmotic fluid space until an osmotic balance occurs. If a hyperosmotic IV solution (e.g., 3% or 5% saline) were infused into a patient with normal ECF osmolarity, the infusing fluid would make the person's blood hyperosmotic. To balance this situation, the interstitial fluid would be pulled into the circulation in an attempt to dilute the blood osmolarity back to normal. As a result, the interstitial volume would shrink and the plasma volume would expand.

Fluids with osmolarities of less than 270 mOsm/L are **hypo-osmotic,** or **hypotonic,** compared with isosmotic fluids. Hypo-osmolar fluids have a *lower* osmotic pressure than isosmotic fluids, and water is pulled from the hypo-osmotic fluid space into the isosmotic fluid space. An example of a hypotonic IV fluid is 0.45% saline.

Clinical Significance

Osmosis and filtration act together at the capillary membrane to maintain both extracellular fluid (ECF) and intracellular fluid (ICF) volumes within their normal ranges. The thirst mechanism is an example of how osmosis helps maintain homeostasis. The feeling of thirst is caused by the activation of cells in the brain that respond to changes in ECF osmolarity. These cells, so very sensitive to changes in ECF osmolarity, are called *osmoreceptors.* When a person loses body water but most of the particles remain, such as through excessive sweating, ECF volume is decreased and osmolarity is increased (is hypertonic). The cells in the thirst center shrink as water moves from the cells into the hypertonic ECF. The shrinking of these cells triggers a person's awareness of thirst and increases the urge to drink. Drinking replaces the amount of water lost through sweating and dilutes the ECF osmolarity, restoring it to normal. The thirst mechanism is less sensitive in older adults, increasing their risk for dehydration.

Fluid Balance

Body Fluids

Fluid balance is closely linked to and affected by electrolyte concentrations. Table 11-1 lists the normal ranges of the major serum electrolytes. Chart 11-1 lists the normal electrolyte values for people older than 60 years.

Chart 11-1 Nursing Focus on the Older Adult

Normal Plasma Electrolyte Values for People Older Than 60 Years

ELECTROLYTE	REFERENCE RANGE		INTERNATIONAL RECOMMENDED UNITS	
	60-90 YEARS	>90 YEARS	60-90 YEARS	>90 YEARS
Calcium (Ca^{2+})	9.0-10.5 mg/dL	8.2-9.6 mg/dL	2.2-2.62 mmol/L	2.05-2.40 mmol/L
Chloride (Cl^-)	98-106 mEq/L	98-111 mEq/L	98-106 mmol/L	98-111 mmol/L
Magnesium (Mg^{2+})	1.3-2.1 mEq/L	1.3-2.1 mEq/L	0.65-1.05 mmol/L	0.65-1.05 mmol/L
Phosphorus (P)	3.0-4.5 mg/dL	3.0-4.5 mg/dL	0.97-1.45 mmol/L	0.97-1.45 mmol/L
Potassium (K^+)	3.5-5.0 mEq/L	3.5-5.0 mEq/L	3.5-5.0 mmol/L	3.5-5.0 mmol/L
Sodium (Na^+)	136-145 mEq/L	132-146 mEq/L	136-145 mmol/L	132-146 mmol/L

Data for adults 60 to 90 years from Pagana, K., & Pagana, T. (2014). *Mosby's manual of diagnostic and laboratory tests* (5th ed). St. Louis: Mosby.

Data for adults >90 years from Tietz, N.W. (Ed.). (1995). *Clinical guide to laboratory tests* (3rd ed.). Philadelphia: Saunders.

TABLE 11-1

Major Serum Electrolyte Concentrations and Significance of Abnormal Values

ELECTROLYTE	REFERENCE RANGE	INTERNATIONAL RECOMMENDED UNITS	SIGNIFICANCE OF ABNORMAL VALUES
Sodium (Na^+)	136-145 mEq/L	136-145 mmol/L	*Elevated:* Hypernatremia; dehydration; kidney disease; hypercortisolism *Low:* Hyponatremia; fluid overload; liver disease; adrenal insufficiency
Potassium (K^+)	3.5-5.0 mEq/L	3.5-5.0 mmol/L	*Elevated:* Hyperkalemia; dehydration; kidney disease; acidosis; adrenal insufficiency; crush injuries *Low:* Hypokalemia; fluid overload; diuretic therapy; alkalosis; insulin administration; hyperaldosteronism
Calcium (Ca^{2+})	9.0-10.5 mg/dL	2.25-2.62 mmol/L	*Elevated:* Hypercalcemia; hyperthyroidism; hyperparathyroidism *Low:* Hypocalcemia; vitamin D deficiency; hypothyroidism; hypoparathyroidism; kidney disease; excessive intake of phosphorus-containing foods and drinks
Chloride (Cl^-)	98-106 mEq/L	98-106 mmol/L	*Elevated:* Hyperchloremia; metabolic acidosis; respiratory alkalosis; hypercortisolism *Low:* Hypochloremia; fluid overload; excessive vomiting or diarrhea; adrenal insufficiency; diuretic therapy
Magnesium (Mg^{2+})	1.3-2.1 mEq/L	0.65-1.05 mmol/L	*Elevated:* Hypermagnesemia; kidney disease; hypothyroidism; adrenal insufficiency *Low:* Hypomagnesemia; malnutrition; alcoholism; ketoacidosis
Phosphorus (P) (Phosphate [PO_4^{3+}]P)	3.0-4.5 mg/dL	0.97-1.45 mmol/L	*Elevated:* Hyperphosphatemia; kidney disease; hypoparathyroidism; acidosis; hypocalcemia *Low:* Hypophosphatemia; chronic antacid use; hyperparathyroidism; hypercalcemia; vitamin D deficiency; alcoholism; malnutrition

Data from Pagana, K., & Pagana, T. (2014). *Mosby's manual of diagnostic and laboratory tests* (5th ed). St. Louis: Mosby.

A person's age, gender, and amount of fat affect the amount and distribution of body fluids. An older adult has less total body water than a younger adult. Chart 11-2 discusses age-related changes in fluid balance. An obese person has less total water than a lean person of the same weight because fat cells contain almost no water.

Chart 11-2 Nursing Focus on the Older Adult

Impact of Age-Related Changes on Fluid Balance

SYSTEM	CHANGE	RESULT
Skin	Loss of elasticity Decreased turgor Decreased oil production	Skin becomes an unreliable indicator of fluid status, especially the back of the hand Dry, easily damaged skin
Kidney	Decreased glomerular filtration Decreased concentrating capacity	Poor excretion of waste products Increased water loss, increasing the risk for dehydration
Muscular	Decreased muscle mass	Decreased total body water Greater risk for dehydration
Neurologic	Diminished thirst reflex	Decreased fluid intake, increasing the risk for dehydration
Endocrine	Adrenal atrophy	Poor regulation of sodium and potassium, increasing the risk for hyponatremia and hyperkalemia

Gender Health Considerations

Patient-Centered Care QSEN

Women of any age have less total body water than men of similar sizes and ages. This difference is because men tend to have more muscle mass than women and because women have more body fat. (Muscle cells contain mostly water, and fat cells have little water.) This difference in water distribution may be responsible for differences seen in women's and men's responses to drugs.

Body fluids are constantly filtered and replaced as fluid balance is maintained through intake and output. The total amount of water within each fluid space is stable, but individual water molecules move continually among all spaces. As a result, water in all spaces is exchanged continually while maintaining constant fluid volume.

Fluid intake is regulated through the thirst drive. Fluid enters the body as liquids and as solid foods, which contain up to 85% water (Table 11-2).

TABLE 11-2

Routes of Fluid Ingestion and Excretion

INTAKE	OUTPUT
Measurable	
Oral fluids	Urine
Parenteral fluids	Emesis
Enemas*	Feces
Irrigation fluids*	Drainage from body cavities
Not Measurable	
Solid foods	Perspiration
Metabolism	Vaporization through the lungs

*Measured by subtracting the amount returned from the amount instilled.

A rising blood osmolarity or a decreasing blood volume triggers the sensation of thirst. Sensations such as mouth dryness or the thought that a person has not had a drink recently also triggers the thirst drive. An adult takes in about 2300 mL of fluid daily from food and liquids.

Fluid loss occurs through several routes (see Table 11-2). The kidney is the most important and the most sensitive water loss route because it is regulated and is adjustable. The volume of urine excreted daily varies depending on the amount of fluid taken in and the body's need to conserve fluids.

The minimum amount of urine per day needed to excrete toxic waste products is 400 to 600 mL. This minimum volume is called the **obligatory urine output.** If the 24-hour urine output falls below the obligatory output amount, wastes are retained and can cause lethal electrolyte imbalances, acidosis, and a toxic buildup of nitrogen.

The ability of the kidneys to make either concentrated or very dilute urine helps maintain fluid balance. The kidney works with various hormones to maintain fluid balance when extracellular fluid concentrations, volumes, or pressures change.

Other normal water loss occurs through the skin, the lungs, and the intestinal tract. Water losses also can result from salivation, drainage from fistulas and drains, and GI suction.

Water loss from the skin, lungs, and stool is called **insensible water loss** because there are no mechanisms to control this loss. In a healthy adult, insensible water loss is about 500 to 1000 mL/day. This loss increases greatly during thyroid crisis, trauma, burns, states of extreme stress, and fever. Insensible water loss also increases when the environment is hot and dry. Patients at risk for increased insensible water loss include those being mechanically ventilated, those with rapid respirations *(tachypnea)*, and those undergoing continuous GI suctioning. Loss by sweating is variable and can reach a maximum rate of about 2 L/hr. Water loss through stool is normally minimal. However, this loss can increase greatly with severe diarrhea or excessive fistula drainage. If not balanced by intake, insensible loss can lead to severe dehydration and electrolyte imbalances.

Hormonal Regulation of Fluid Balance

Three hormones help control fluid and electrolyte balance. These are aldosterone, antidiuretic hormone (ADH), and natriuretic peptide (NP).

Aldosterone is a hormone secreted by the adrenal cortex whenever sodium levels in the extracellular fluid (ECF) are decreased. Aldosterone prevents both water and sodium loss. When aldosterone is secreted, it acts on the kidney nephrons, triggering them to reabsorb sodium and water from the urine back into the blood. This action increases blood osmolarity and blood volume. Aldosterone prevents excessive kidney excretion of sodium. It also helps prevent blood potassium levels from becoming too high.

Antidiuretic hormone (ADH), or vasopressin, is released from the posterior pituitary gland in response to changes in blood osmolarity. The hypothalamus contains the osmoreceptors that are sensitive to changes

in blood osmolarity. Increased blood osmolarity, especially an increase in the level of plasma sodium, results in a slight shrinkage of these cells and triggers ADH release from the posterior pituitary gland. Because the action of ADH retains just water, it only indirectly regulates electrolyte retention or excretion.

ADH acts directly on kidney tubules and collecting ducts, making them more permeable to water only. As a result, more water is *reabsorbed* by these tubules and returned to the blood, decreasing blood osmolarity by making it more dilute. When blood osmolarity decreases with low plasma sodium levels, the osmoreceptors swell slightly and inhibit ADH release. Less water is then reabsorbed, and more is lost from the body in the urine. As a result, the amount of water in the extracellular fluid (ECF) decreases, bringing osmolarity up to normal.

Natriuretic peptides (NPs) are hormones secreted by special cells that line the atria of the heart (atrial natriuretic peptide [ANP]) and the ventricles of the heart. (The peptide secreted by the heart ventricular cells is known as *brain natriuretic peptide [BNP]* because it was first discovered in the brain.) These peptides are secreted in response to increased blood volume and blood pressure, which stretch the heart tissue. NP binds to receptors in the nephrons, creating effects that are opposite of aldosterone. Kidney reabsorption of sodium is inhibited at the same time that glomerular filtration is increased, causing increased urine output. The outcome is decreased circulating blood volume and decreased blood osmolarity.

Significance of Fluid Balance

The Renin-Angiotensin II Pathway

The human body requires fluid and electrolyte balance, as well as a balance of acids and bases, for best function. The most important fluids to keep in balance are the blood volume (plasma volume) and the fluid inside the cells (intracellular fluid). Of these two, the most critical fluid balance to prevent death is maintaining blood volume at a sufficient level for blood pressure to remain high enough to ensure adequate perfusion and gas exchange of all organs and tissues. Balance of both water and electrolytes is needed for this very vital function.

Because low blood volume and low blood pressure can rapidly lead to death, the body has many specific actions (compensatory mechanisms) that guard against excessive fluid loss from the plasma volume. These actions involve specific hormone levels, kidney function, and blood

vessel responses to change how water and sodium are handled to maintain blood pressure.

Because the kidney is a major regulator of water and sodium balance to maintain blood pressure and perfusion to all tissues and organs, the kidneys monitor blood pressure, blood volume, blood oxygen levels, and blood osmolarity (related to sodium concentration). When the kidneys sense that any one of these parameters is getting low, they begin to secrete a substance called *renin* that sets into motion a group of hormonal and blood vessel responses to ensure that blood pressure is raised back up to normal. Fig. 11-6 summarizes these responses.

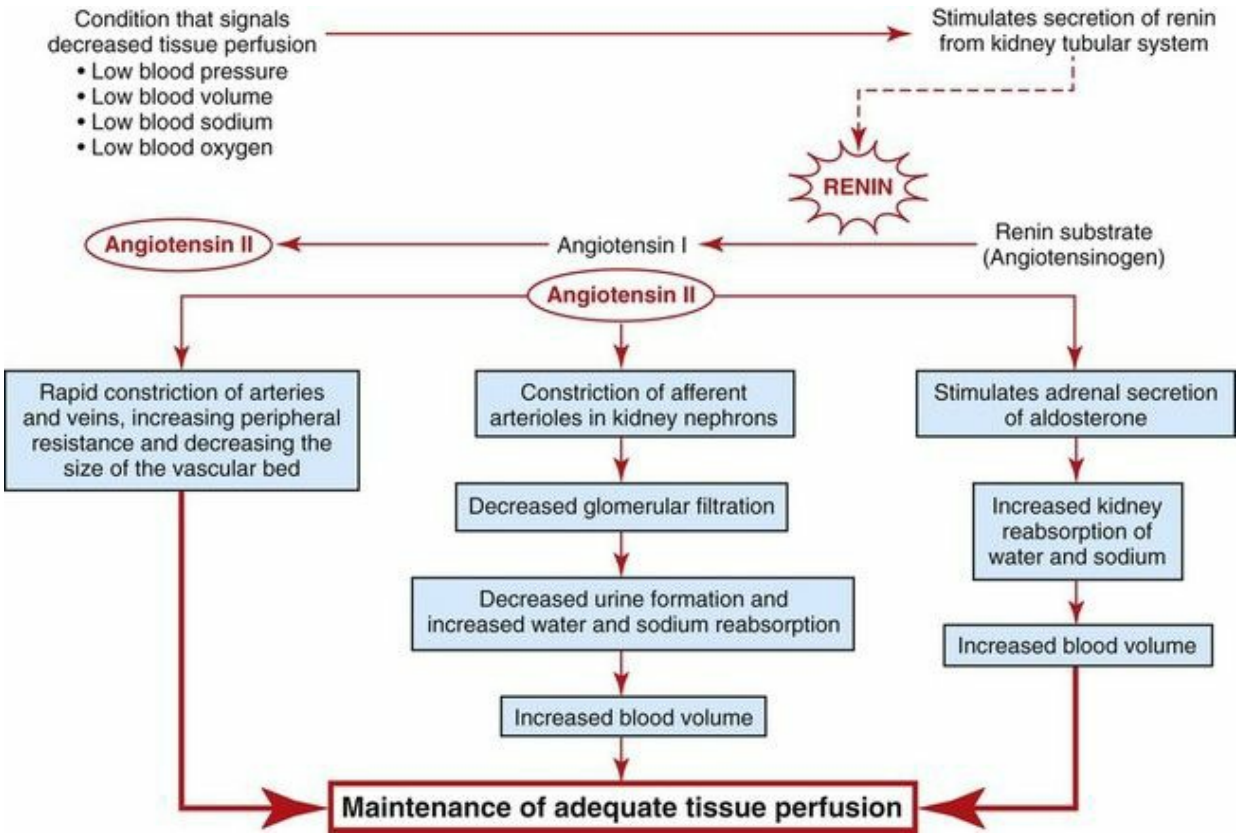

FIG. 11-6 The role of the renin-angiotensin II pathway in fluid and electrolyte balance and blood pressure regulation.

So, the triggering event is any change in the blood that indicates to the kidney that tissue and organ perfusion are at risk. Low blood pressure is a triggering event because when it gets too low, blood cannot flow through vessels into tissues and organs. Anything that reduces blood volume (e.g., dehydration, hemorrhage) below a critical level *always* lowers blood pressure. Low blood oxygen levels also are triggering events because with too little oxygen in the blood, even if the blood reaches the tissues and organs, it cannot supply the needed oxygen and the tissues and organs could die. A low blood sodium level also is a triggering event

because sodium and water are closely linked. Where sodium goes, water follows. So, anything that causes the blood to have too little sodium prevents water from staying in the blood. The result is low blood volume with low blood pressure and poor tissue perfusion.

Once the kidneys sense that tissue and organ perfusion are at risk, special cells in the kidney tubule begin to secrete renin into the blood. Renin then activates some blood proteins, one of which is *angiotensinogen.* Activated angiotensinogen is *angiotensin I,* which is relatively weak and has little action. It is then acted on by another enzyme known as *angiotensin-converting enzyme* or *ACE,* which converts angiotensin I into its most active form, angiotensin II.

Angiotensin II starts several different activities that all work to increase blood volume and blood pressure. First, because angiotensin II is a powerful vasoconstrictor, it causes constriction of small arteries and veins throughout the body. This action increases peripheral resistance and reduces the size of the vascular bed, which raises blood pressure as a compensatory mechanism without adding more blood volume. At the same time, a second action of angiotensin II is that it constricts the size of the arterioles that feed the kidney nephrons. This action results in a lower glomerular filtration rate and a huge reduction of urine output. Decreasing urine output prevents further loss of water so that more is retained in the blood to help raise blood pressure. The last and slightly slower action of angiotensinogen II is to cause the adrenal glands to secrete the hormone *aldosterone.* Aldosterone is nicknamed the "water-and-sodium-saving hormone" because it causes the kidneys to reabsorb water and sodium, preventing them from being excreted into the urine. This response allows more water and sodium to be returned to the blood, increasing blood pressure and blood volume. All of these actions help maintain perfusion to vital organs.

Clinical Application

The renin-angiotensin II pathway is highly stimulated whenever the patient is in shock or when the stress response occurs. This is why urine output is used as an indicator of perfusion adequacy after surgery or any time the patient has undergone an invasive procedure and is at risk for hemorrhage.

An additional application of this pathway is related to management of *hypertension* (high blood pressure). Patients who have hypertension are often asked to limit their intake of sodium. The reason for this is that a high sodium intake raises the blood level of sodium, causing more water to be retained in the blood volume and raising blood pressure. Drug

therapy for hypertension management may include diuretic drugs that increase the excretion of sodium so that less is present in the blood, resulting in a lower blood volume. Another class of drugs often used to manage blood pressure is the "ACE inhibitors." These drugs disrupt the renin-angiotensin II pathway by reducing the amount of angiotensin-converting enzyme (ACE) made so that less angiotensin II is present. With less angiotensin II, there is less vasoconstriction and reduced peripheral resistance, less aldosterone production, and greater excretion of water and sodium in the urine. All of these responses lead to decreased blood volume and blood pressure. Another class of drugs used to manage hypertension is the angiotensin receptor blockers (ARBs). These drugs disrupt the renin-angiotensin II pathway by blocking the receptors that bind with angiotensin II so that the tissues cannot respond to it and blood pressure is lowered.

Fluid Imbalances

All patients are at risk for some degree of fluid imbalance because many health problems can disrupt fluid intake or output. Fluid imbalances can occur in any setting.

Dehydration

Pathophysiology

In **dehydration,** fluid intake or retention is less than what is needed to meet the body's fluid needs, resulting in a fluid volume deficit, especially a plasma volume deficit. It is a condition rather than a disease and can be caused by many factors (Table 11-3). Dehydration may be an *actual* decrease in total body water caused by either too little intake of fluid or too great a loss of fluid. It also can occur without an actual loss of total body water, such as when water shifts from the plasma into the interstitial space. This condition is called *relative* dehydration.

TABLE 11-3

Common Causes of Fluid Imbalances

Dehydration
• Hemorrhage • Vomiting • Diarrhea • Profuse salivation • Fistulas • Ileostomy • Profuse diaphoresis • Burns • Severe wounds • Long-term NPO status • Diuretic therapy • GI suction • Hyperventilation • Diabetes insipidus • Difficulty swallowing • Impaired thirst • Unconsciousness • Fever • Impaired motor function
Fluid Overload
• Excessive fluid replacement • Kidney failure (late phase) • Heart failure • Long-term corticosteroid therapy • Syndrome of inappropriate antidiuretic hormone (SIADH) • Psychiatric disorders with polydipsia • Water intoxication

Considerations for Older Adults

Patient-Centered Care QSEN

Older patients are at high risk for dehydration because they have less total body water than younger adults. In addition, many older adults have decreased thirst sensation and may have difficulty with walking or other motor skills needed for obtaining fluids. They also may take drugs such as diuretics, antihypertensives, and laxatives that increase fluid excretion.

Dehydration may occur with just water (fluid) loss or with water and electrolyte loss (isotonic dehydration). *Isotonic dehydration is the most common type of fluid loss problem.* Fluid is lost only from the extracellular fluid (ECF) space, including both the plasma and the interstitial spaces. There is no shift of fluids between spaces, so the intracellular fluid (ICF) volume remains normal (Fig. 11-7). Circulating blood volume is decreased **(hypovolemia)** and leads to inadequate tissue perfusion. The body's defenses adapt (compensate) during dehydration to maintain adequate blood flow to vital organs in spite of hypovolemia. The main defense is increasing vasoconstriction and peripheral resistance to maintain blood pressure and circulation.

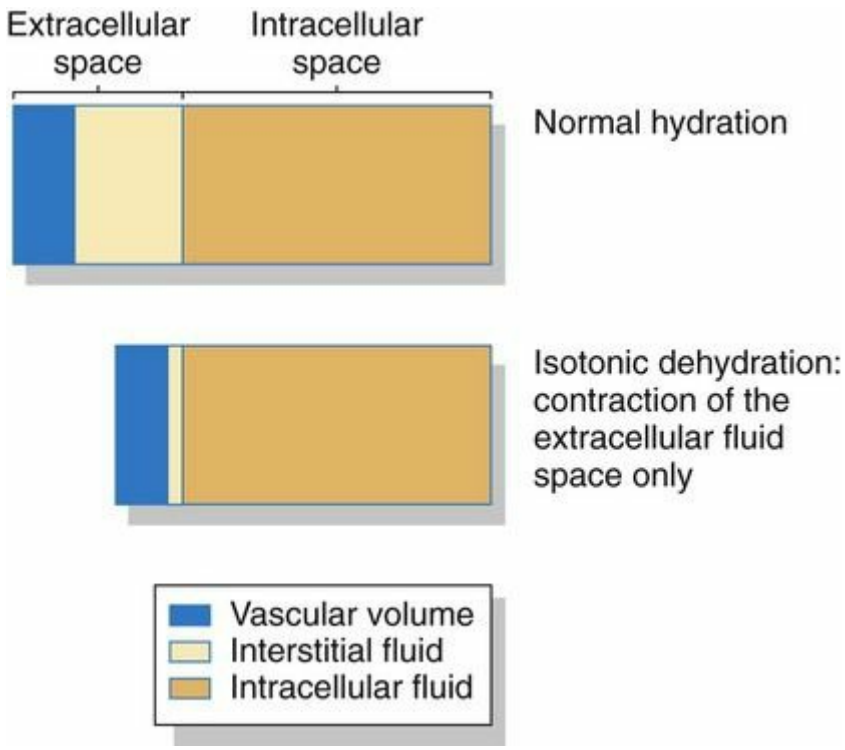

FIG. 11-7 Changes in fluid compartment volumes with dehydration.

Health Promotion and Maintenance

Mild dehydration is very common among healthy adults and is corrected or prevented easily by matching fluid intake with fluid output. Teach all patients to drink more fluids, especially water, whenever they engage in heavy or prolonged physical activity or live in dry climates or at higher altitudes. Beverages with caffeine can increase fluid loss, as can drinks containing alcohol; thus these beverages should not be used to prevent or treat dehydration.

Moderate to severe dehydration is more likely to occur in people who are unable to obtain fluids without help, such as some older adults. Dehydration in older adults in long-term care facilities can be prevented with programs that include routinely offering residents fluids every hour or two during the day and when administering medications.

Patient-Centered Collaborative Care

Assessment

History.

The nutrition history can reveal problems that affect fluid balance. Ask specific questions about food and liquid intake. Also assess the types of fluids and foods ingested to determine amount and osmolarity. Many patients do not know that solid foods contain liquid. Other foods such as ice cream, gelatin, and ices are liquids at body temperature, and these must be included when calculating fluid intake.

Collect specific information about exact intake and output volumes, and obtain serial daily weight measurements. If possible, weigh the patient directly rather than asking what he or she weighs because weight loss is an indication of dehydration. *Because 1 L of water weighs 2.2 pounds (1 kg), changes in daily weights are the best indicators of fluid losses or gains. A weight change of 1 pound corresponds to a fluid volume change of about 500 mL.*

Output includes losses not only as urine but also as sweat, diarrhea, and insensible loss during fevers. Ask specific questions about prescribed and over-the-counter drugs, and check the dosage, the length of time taken, and the patient's adherence with the drug regimen.

Other important areas of the patient history include a sense of thirst or excessive drinking, exposure to hot environments, living at higher altitudes, and the presence of kidney or endocrine diseases. Assess the patient's level of consciousness and mental status, because changes in mental status occur with fluid imbalance. Ask the patient about changes

in ring or shoe tightness. A sudden decrease in tightness may indicate dehydration.

Older adults may use diuretics or laxatives that can lead to fluid and electrolyte imbalance. An important issue for older adults is that they may depend on other people to provide assistance in meeting fluid needs (Collins & Claros, 2011).

Physical Assessment/Clinical Manifestations.

Nearly all body systems are affected by dehydration to some degree. The most obvious changes occur in the cardiovascular and integumentary systems.

Cardiovascular changes are good indicators of hydration status because of the relationship between plasma fluid volume and blood pressure. Heart rate increases in an attempt to maintain blood pressure with less blood volume. Peripheral pulses are weak, difficult to find, and easily blocked with light pressure. The blood pressure also decreases, as does the pulse pressure, with a greater decrease in the systolic blood pressure. Hypotension is more severe with the patient in the standing position than in the sitting or lying position (**orthostatic** or **postural hypotension**). Because the blood pressure with the patient standing may be much lower than in other positions, first measure blood pressure with the patient lying down, then sitting, and finally standing. (These measures are also called "ortho checks" or "ortho changes.") As the blood pressure decreases when changing position, the person may not have sufficient blood flow to the brain, causing the sensations of light-headedness and dizziness. This problem increases the risk for falling, especially among older adults.

Neck veins are normally distended when a patient is in the supine position, and hand veins are distended when lower than the level of the heart. Neck veins normally flatten when the patient moves to a sitting position. With dehydration, neck and hand veins are flat, even when the neck and hands are not raised above the level of the heart.

Respiratory changes include an increased rate because the decreased blood volume reduces perfusion and oxygenation. The increased respiratory rate is a compensatory mechanism that attempts to maintain oxygen delivery when perfusion is decreased.

Skin changes can indicate dehydration. Assess the skin and mucous membranes for color, moisture, and turgor. In older patients, this information is less reliable because of poor skin turgor resulting from the loss of elastic tissue and increased skin dryness from the loss of tissue fluid with aging. Assess skin turgor by checking:

- How easily the skin over the back of the hand and arm can be gently pinched between the thumb and the forefinger to form a "tent"
- How soon the pinched skin resumes its normal position after release

In dehydration, skin turgor is poor, with the tent remaining for minutes after pinching the skin. The skin is dry and scaly.

Considerations for Older Adults

Patient-Centered Care QSEN

Assess skin turgor in an older adult by pinching the skin over the sternum or on the forehead, rather than the back of the hand (Fig. 11-8). With aging, the skin loses elasticity and tents on hands and arms even when the person is well hydrated.

FIG. 11-8 Examining the skin turgor of an older patient.

In dehydration, oral mucous membranes are not moist. They may be covered with a thick, sticky coating and may have cracks and fissures. The surface of the tongue may have deep furrows. This manifestation may not be accurate for assessing dehydration in patients taking drugs that have the side effect of dry mouth.

Neurologic changes with dehydration include changes in mental status and temperature with reduced blood flow in the brain. Confusion is more common among older adults and may be the first indication of a fluid imbalance. Check to determine whether the patient is alert and

oriented. Chapter 41 provides more information about assessment of mental status.

The patient with dehydration often has a low-grade fever, and fever can also cause dehydration. A patient with a temperature higher than 102° F (39° C) for longer than 6 hours is especially at risk because the increased body temperature increases the rate at which fluid is lost. For every degree (Celsius) increase in body temperature above normal, a minimum of an additional 500 mL of body fluid is lost.

Kidney changes in dehydration affect urine volume and concentration. Monitor urine output, comparing total output with total fluid intake and daily weights. The urine may be concentrated, with a specific gravity greater than 1.030. The color is dark amber and has a strong odor. *Urine output below 500 mL/day for any patient without kidney disease is cause for concern.* Use daily weights to assess fluid loss. Weight loss over a half pound per day is fluid loss.

Laboratory Assessment.

No single laboratory test result confirms or rules out dehydration. Instead, dehydration is determined by laboratory findings along with clinical manifestations (see Table 11-1). Usually, laboratory findings with dehydration show elevated levels of hemoglobin, hematocrit, serum osmolarity, glucose, protein, blood urea nitrogen, and various electrolytes because more water is lost and other substances remain, increasing blood concentration **(hemoconcentration).** Hemoconcentration is not present when dehydration is caused by hemorrhage, because loss of all blood and plasma products occurs together.

◆ Interventions

The focus of management for the patient with dehydration is to prevent injury, prevent further fluid loss, and increase fluid volumes to normal. Nursing priorities include patient safety, fluid replacement, and drug therapy.

Patient safety issues and strategies are priorities of care before and during other therapies for dehydration. Monitor vital signs, especially heart rate and blood pressure. The patient with dehydration is at risk for falls because of orthostatic hypotension, dysrhythmia, muscle weakness, and possible confusion. Assess his or her muscle strength, gait stability, and level of alertness. Instruct the patient to get up slowly from a lying or sitting position and to immediately sit down if he or she feels light-headed. Implement the falls precautions listed in Chart 2-4 in Chapter 2.

Fluid replacement is key to correcting dehydration and preventing death

from reduced perfusion. Best practices for nursing care of the patient with dehydration are listed in Chart 11-3. Mild to moderate dehydration is corrected with oral fluid replacement if the patient is alert enough to swallow and can tolerate oral fluids. Encourage fluid intake, and measure the amount ingested.

Chart 11-3 Best Practice for Patient Safety & Quality Care QSEN

The Patient with Dehydration

- When possible, provide oral fluids that meet the patient's dietary restrictions (e.g., sugar-free, low-sodium, thickened).
- Collaborate with other members of the health care team to determine the amount of fluids needed during a 24-hour period.
- Ensure the fluids are offered and ingested on an even schedule at least every 2 hours throughout 24 hours.
- Teach unlicensed assistive personnel to actively participate in the hydration therapy and not to withhold fluids to prevent incontinence.
- Administer prescribed IV fluids at a rate consistent with hydration needs and any known cardiac, pulmonary, or kidney problems.
- Monitor the patient's response to fluid therapy at least every 2 hours for indicators of adequate rehydration or the need for continuing therapy, especially:
  - Pulse quality
  - Urine output
  - Pulse pressure
  - Weight (every 8 hours)
- Monitor for and report indicators of fluid overload, including:
  - Bounding pulse
  - Difficulty breathing
  - Neck vein distention in the upright position
  - Presence of dependent edema
- Assess the IV and the infusion site at least hourly for indications of infiltration, extravasation, or phlebitis (e.g., swelling around the site, pain, cordlike veins, reduced drip rate).
- Administer drugs prescribed to correct the underlying cause of the dehydration (e.g., antiemetics, antidiarrheals, antibiotics, antipyretics).

Determine whether the patient has any special fluid needs (e.g., sugar-free fluids, thickened fluids). Provide fluid the patient enjoys, and time the

intake schedule. Dividing the total amount of fluids needed by nursing shifts helps meet fluid needs more evenly over 24 hours with less danger of overload. Offer the conscious patient small volumes of fluids hourly.

Coordinate with unlicensed assistive personnel (UAP) to meet patients' specific fluid needs. Teach UAP to offer 2 to 4 ounces of fluid every hour to patients who are dehydrated or who are at risk for dehydration. If incontinence is a concern, ensure that UAP understand that withholding fluids is not appropriate to prevent the problem. Instruct them to take the time to stay with patients while they drink the fluid and to note the exact amount ingested. Direct UAP to report any difficulties patients may have in swallowing or managing fluids.

Oral rehydration solutions (ORS) for rehydration therapy are an effective way to replace fluids. Specifically formulated solutions containing glucose and electrolytes are absorbed even when the patient is vomiting or has diarrhea. These are more often used in the home setting, in long-term care, and for patients who have poor veins, making IV therapy difficult. A variety of commercial ORS are available over the counter.

Drug therapy for dehydration is directed at restoring fluid balance and controlling the causes of dehydration. Whenever possible, fluid is replaced orally. When dehydration is severe or the patient cannot tolerate oral fluids, IV fluid replacement is needed. Calculation of how much fluid to replace is based on the patient's weight loss and clinical manifestations. The rate of fluid replacement depends on the degree of dehydration and the patient's cardiac, pulmonary, or kidney status.

The type of fluid prescribed varies with the patient's cardiovascular status and the osmolarity of the blood. Table 11-4 lists the composition of common IV fluids. The two most important areas to monitor during rehydration are pulse rate and quality and urine output.

TABLE 11-4

Characteristics of Common Intravenous Therapy Solutions

SOLUTION	OSMOLARITY (mOsm/L)	pH	CALORIES (Kcal) per Liter	TONICITY
0.9% saline	308	5	0	Isotonic
0.45% saline	154	5	0	Hypotonic
5% dextrose in water (D_5W)	272	3.5-6.5	170	Isotonic*
10% dextrose in water ($D_{10}W$)	500	3.5-6.5	340	Hypertonic*
5% dextrose in 0.9% saline	560	3.5-6.5	170	Hypertonic*
5% dextrose in 0.45% saline	406	4	170	Hypertonic*
5% dextrose in 0.225% saline	321	4	170	Isotonic*
Ringer's lactate	273	6.5	9	Isotonic
5% dextrose in Ringer's lactate	525	4-6.5	179	Hypertonic*

*Solution tonicity at the time of administration. Within a short time after administration, the dextrose is metabolized and the tonicity of the infused solution decreases in proportion to the osmolarity or tonicity of the non-dextrose components (electrolytes) within the water.

Data from Trissel, L. (2013). *Handbook on injectable drugs* (17th ed.). Bethesda, MD: American Society of Hospital-System Pharmacists.

Drug therapy may correct some causes of the dehydration. For example, antidiarrheal drugs are prescribed when diarrhea causes dehydration. Antimicrobial therapy may be used in patients with bacterial diarrhea. Antiemetics may be used when vomiting causes dehydration. Antipyretics to reduce fever are helpful when fever makes dehydration worse.

NCLEX Examination Challenge

Safe and Effective Care Environment

Which assessment finding indicates to the nurse that fluid resuscitation therapy for the client with isotonic dehydration is effective?

A Respiratory rate has changed from 16 to 18 breaths/min.
B Urine specific gravity has increased from 1.040 to 1.050.
C Neck veins are flat when the client moves to a sitting position.
D Pulse pressure has changed from 22 mm Hg to 32 mm Hg.

Fluid Overload

Pathophysiology

Fluid overload, also called *overhydration*, is an excess of body fluid. It is not

a disease but, rather, a clinical indication of a problem in which fluid intake or retention is greater than the body's fluid needs. The most common type of fluid overload is hypervolemia (Fig. 11-9) because the problems result from excessive fluid in the extracellular fluid (ECF) space. Most problems caused by fluid overload are related to excessive fluid in the vascular space or to dilution of specific electrolytes and blood components. The conditions leading to fluid overload are related to excessive intake or inadequate excretion of fluids. See Table 11-3 for causes of fluid overload. Fig. 11-10 outlines the adaptive changes the body makes in response to mild or moderate fluid overload, especially increased urine output and edema formation. When overload is severe or occurs in a person with poor cardiac or kidney function, it can lead to heart failure and pulmonary edema. Dilution of electrolytes, especially sodium and potassium, can lead to seizures, coma, and death (McGraw, 2012).

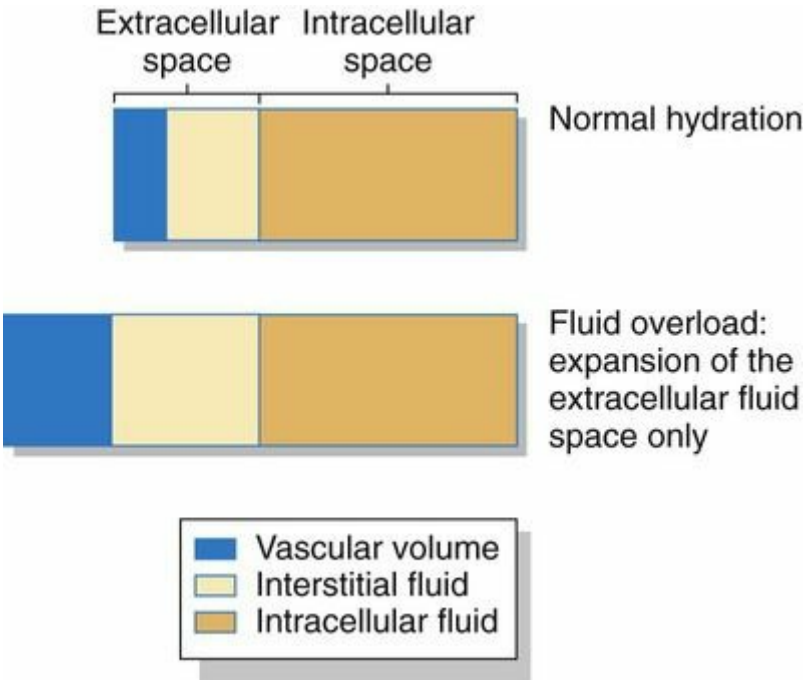

FIG. 11-9 Changes in fluid compartment volumes with fluid overload.

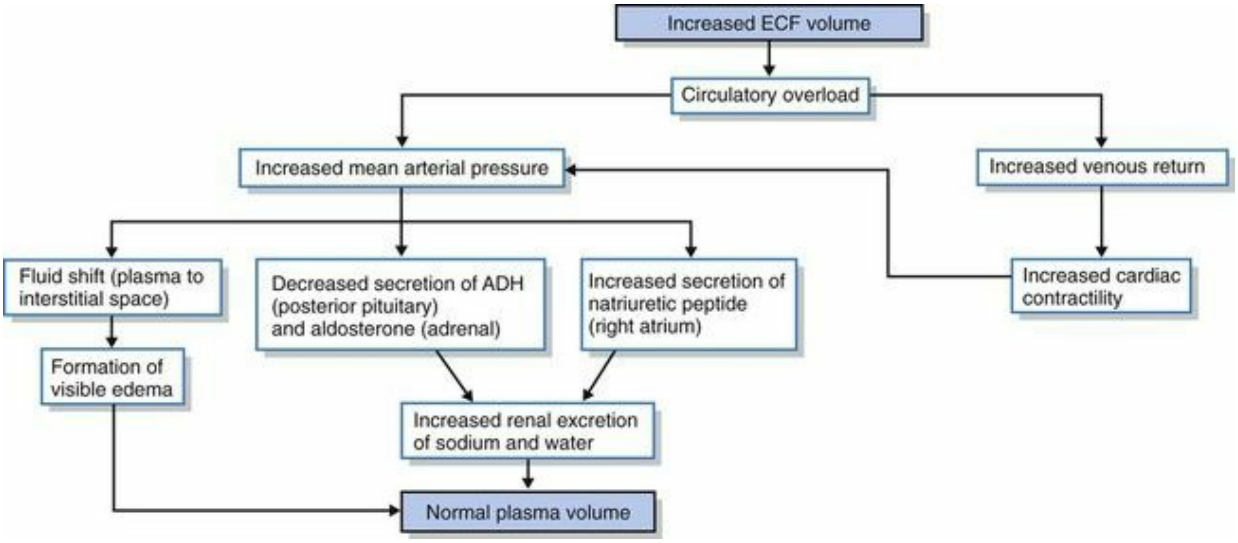

FIG. 11-10 Adaptive actions and mechanisms to prevent cardiac and pulmonary complications during fluid overload. (*ADH,* Antidiuretic hormone; *ECF,* extracellular fluid.)

❖ Patient-Centered Collaborative Care

◆ Assessment

Patients with fluid overload often have pitting edema (Fig. 11-11). Other manifestations are usually seen in the cardiovascular, respiratory, neuromuscular, integumentary, and GI systems (Chart 11-4).

Chart 11-4 Key Features

Fluid Overload

Cardiovascular Changes

- Increased pulse rate
- Bounding pulse quality
- Elevated blood pressure
- Decreased pulse pressure
- Elevated central venous pressure
- Distended neck and hand veins
- Engorged varicose veins
- Weight gain

Respiratory Changes

- Increased respiratory rate
- Shallow respirations
- Shortness of breath

• Moist crackles present on auscultation

Skin and Mucous Membrane Changes

• Pitting edema in dependent areas
• Skin pale and cool to touch

Neuromuscular Changes

• Altered level of consciousness
• Headache
• Visual disturbances
• Skeletal muscle weakness
• Paresthesias

Gastrointestinal Changes

• Increased motility
• Enlarged liver

FIG. 11-11 Pitting edema of the left foot and ankle.

Fluid overload is diagnosed based on assessment findings and the results of laboratory tests. Usually, serum electrolyte values are normal but decreased hemoglobin, hematocrit, and serum protein levels may result from excessive water in the vascular space **(hemodilution)**.

◆ Interventions

The focus of priority nursing interventions for patients with fluid overload is to ensure patient safety, restore normal fluid balance, provide

supportive care until the imbalance is resolved, and prevent future fluid overload. Drug therapy, nutrition therapy, and monitoring are the basis of intervention.

Patient safety is the first priority. Interventions are implemented to prevent fluid overload from becoming worse, leading to pulmonary edema, heart failure, and complications of electrolyte dilution. Any patient with fluid overload, regardless of age, is at risk for these complications. Older adults or those with cardiac problems, kidney problems, pulmonary problems, or liver problems are at greater risk.

Monitor for indicators of increased fluid overload (bounding pulse, increasing neck vein distention, presence of crackles in lungs, increasing peripheral edema, reduced urine output) at least every 2 hours.

Nursing Safety Priority QSEN

Critical Rescue

Pulmonary edema can occur very quickly and can lead to death. Notify the health care provider of any change that indicates the fluid overload either is not responding to therapy or is becoming worse.

The patient with fluid overload and edema is at risk for skin breakdown. Use a pressure-reducing or pressure-relieving overlay on the mattress. Assess skin pressure areas daily for signs of redness or open area, especially the coccyx, elbows, hips, and heels. Because many patients with fluid overload may be receiving oxygen by mask or nasal cannula, check the skin integrity around the mask, nares, and ears and under the elastic band. Help the patient change positions every 2 hours, or ensure that unlicensed assistive personnel (UAP) perform this action.

Drug therapy focuses on removing the excess fluid. Diuretics are prescribed for fluid overload if kidney failure is not the cause. Prescribed drugs may include high-ceiling (loop) diuretics, such as furosemide (Lasix, Furoside). If there is concern that too much sodium and other electrolytes would be lost using loop diuretics or if the patient has syndrome of inappropriate antidiuretic hormone (SIADH), conivaptan (Vaprisol) or tolvaptan (Samsca) may be prescribed.

Monitor the patient for response to drug therapy, especially weight loss and increased urine output. Observe for manifestations of electrolyte imbalance, especially changes in electrocardiogram (ECG) patterns. Assess laboratory findings, especially sodium and potassium values, every 8 hours or whenever they are drawn.

Nutrition therapy for the patient with *chronic* fluid overload may involve restrictions of both fluid and sodium intake. Often sodium restriction involves only "no added salt" to ordinary table foods when fluid overload is mild. For more severe fluid overload, the patient may be restricted to 2 g/day to 4 g/day of sodium. When sodium restriction is ongoing, teach the patient and family how to check food labels for sodium content and how to keep a daily record of sodium ingested. Explain to the patient and family the reason for any fluid restriction and the importance of adhering to the restriction.

Monitoring intake and output and weight provides information on therapy effectiveness. Teach UAP that these measurements need to be accurate, not just estimated, because treatment decisions are based on these findings. Schedule fluid offerings throughout the 24 hours. Teach UAP to check urine for color and character and to report these findings. Check the urine specific gravity (a specific gravity below 1.005 may indicate fluid overload). If the patient is receiving IV therapy, infuse the exact amount prescribed.

Fluid retention may not be visible. Rapid weight gain is the best indicator of fluid retention and overload. Metabolism can account for only a half pound of weight gain in one day. Each pound of weight gained (after the first half pound) equates to about 500 mL of retained fluid. Weigh the patient at the same time every day (before breakfast), using the same scale. Whenever possible, have the patient wear the same type of clothing for each weigh-in. When in-bed weights are taken, lift tubing and equipment off the bed. Record the number of blankets and pillows on the bed at the initial weigh-in, and ensure ongoing weights always include the same number.

If the patient is discharged to home before the fluid overload has completely resolved or has continuing risk for fluid overload, teach him or her and the family to monitor weight at home. Suggest that a record of these daily weights be kept to show the health care provider at checkups. Patients may choose to use mobile "apps" to record and trend this information. Also, instruct the patient to call his or her health care provider for more than a 3-pound gain in a week or more than a 2-pound gain in 24 hours.

Clinical Judgment Challenge

Patient-Centered Care; Safety QSEN

A 39-year-old woman is brought to the emergency department by her

husband. She is conscious but confused and keeps repeating that her head hurts so much she feels it might "explode." The husband tells you that she has no health problems and takes no medications other than aspirin for occasional pain. He also tells you that she entered a contest earlier today to try and drink the most water in 1 hour. She drank 10 glasses of water in 1 hour but did not win the contest and came home. Her confusion and headache started about an hour later.

1. What type of fluid or electrolyte imbalance is she likely to have and from what cause? Explain your selection.
2. What physical assessment data are the priority to obtain? Explain your selection.
3. What laboratory data would you expect to be ordered?
4. Is this patient at risk for heart failure or pulmonary edema? Why or why not?

Electrolyte Balance and Imbalances

Electrolytes, or **ions,** are substances dissolved in body fluid that carry an electrical charge. **Cations** have positive charges; **anions** have negative charges. Body fluids are electrically neutral, which means that the number of positive ions is balanced by an equal number of negative ions. However, the distribution of ions differs in the extracellular fluid (ECF) and the intracellular fluid (ICF) (Fig. 11-12).

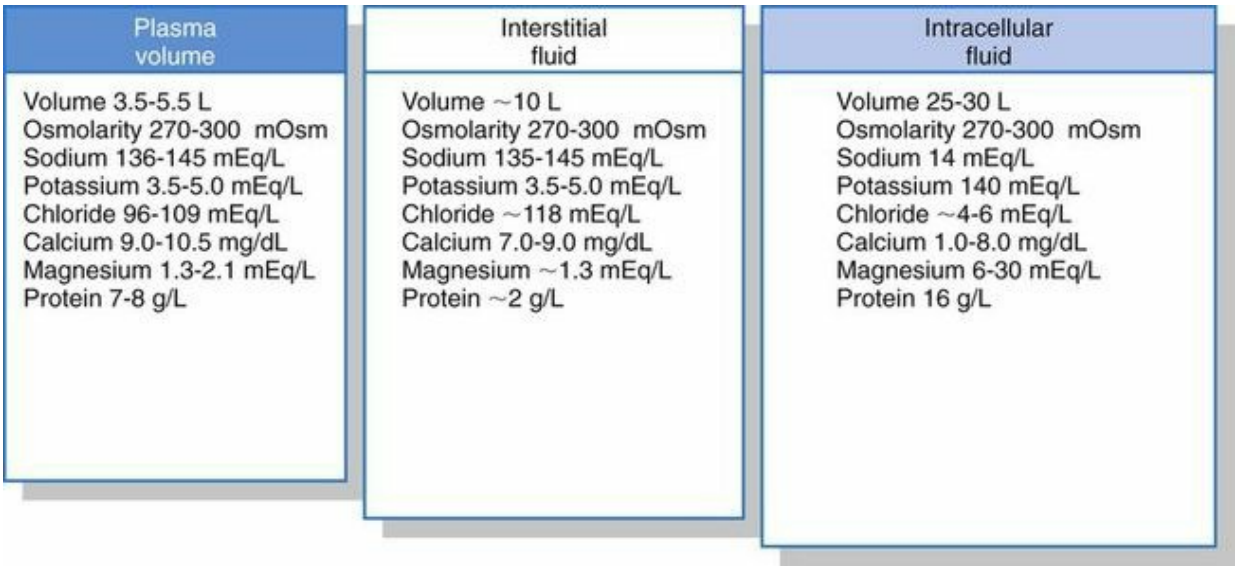

FIG. 11-12 The electrolyte composition of various body fluids.

Most electrolytes have different concentrations in the ICF and ECF. This concentration difference helps maintain membrane excitability and allows nerve impulse transmission. The normal ranges of electrolyte concentration are very narrow. So, even small changes in these levels can cause major problems.

Electrolyte imbalances can occur in healthy people as a result of changes in fluid intake and output. These imbalances are usually mild and are easily corrected. Severe electrolyte imbalances with actual losses or retention of specific electrolytes are life threatening and can occur in any setting. People at greatest risk for severe imbalances are older patients, patients with chronic kidney or endocrine disorders, and those who are taking drugs that alter fluid and electrolyte balance. *All ill people are at some risk for electrolyte imbalances.*

Table 11-1 lists the normal serum levels of the major electrolytes. Most electrolytes enter the body in ingested food. The normal concentration of blood electrolytes changes slightly with the aging process. Chart 11-1 lists the normal electrolyte values for people older than 60 years.

Electrolyte balance occurs by matching the dietary intake of electrolytes

with the kidney excretion or reabsorption of electrolytes. For example, the plasma level of potassium is maintained between 3.5 and 5.0 mEq/L (mmol/L). The high potassium level in foods such as meat and citrus fruit could increase the ECF potassium level and lead to major problems. In health, this does not occur because kidney excretion of potassium keeps pace with potassium intake and prevents major changes in the blood potassium level.

Considerations for Older Adults

Patient-Centered Care QSEN

Older adults are at risk for electrolyte imbalances as a result of age-related organ changes, especially reduced kidney function. They are more likely to be taking drugs that affect fluid or electrolyte balance.

Sodium

Sodium (Na^+), a mineral, is the major *cation* (positively charged particle) in the extracellular fluid (ECF) and maintains ECF osmolarity. Sodium levels of the ECF are high (136 to 145 mEq/L [mmol/L]), and the intracellular fluid (ICF) sodium levels are low (about 14 mEq/L [mmol/L]). Keeping this difference in sodium levels is vital for skeletal muscle contraction, cardiac contraction, and nerve impulse transmission. Sodium levels and movement influence water balance because "where sodium goes, water follows." The ECF sodium level determines whether water is retained, excreted, or moved from one fluid space to another.

To maintain electrical balance, the sodium (a cation) level within body fluids must be matched by an equal number of anions (negatively charged substances). When this balance is present, the fluid is electrically neutral. Changes in plasma sodium levels seriously change fluid volume and the distribution of other electrolytes.

Sodium enters the body through the ingestion of many foods and fluids. Foods with the highest sodium levels are those that are processed or preserved, such as smoked or pickled foods, snack foods, and many condiments. Foods lowest in sodium include fresh fish and poultry and most fresh vegetables and fruit.

Despite variation in sodium intake from one day to the next, the blood sodium level usually remains within the normal range. Serum sodium balance is regulated by the kidney under the influences of aldosterone, antidiuretic hormone (ADH), and natriuretic peptide (NP), as described on p. 153.

Low serum sodium levels inhibit the secretion of ADH and NP and trigger aldosterone secretion. Together these compensatory actions increase serum sodium levels by increasing kidney reabsorption of sodium and enhancing kidney loss of water.

High serum sodium levels inhibit aldosterone secretion and directly stimulate secretion of ADH and NP. Together these hormones increase kidney excretion of sodium and kidney reabsorption of water.

Hyponatremia

Pathophysiology

Hyponatremia is an electrolyte imbalance in which the serum sodium (Na^+) level is below 136 mEq/L (mmol/L). Sodium imbalances often occur with a fluid imbalance because the same hormones regulate both sodium and water balance. The problems caused by hyponatremia occur from two changes—reduced excitable membrane depolarization and cellular swelling.

Excitable cell membrane depolarization depends on high extracellular fluid (ECF) levels of sodium being available to cross cell membranes and move into cells in response to a stimulus. Hyponatremia makes depolarization slower so that excitable membranes are less excitable.

With hyponatremia, the osmolarity of the ECF is lower than that of the intracellular fluid (ICF). As a result, water moves into the cell, causing swelling. Even a small amount of swelling can reduce cell function. Larger amounts of swelling can make the cell burst *(lysis)* and die.

Many conditions and drugs can lead to hyponatremia (Table 11-5). A common cause of low sodium levels is the prolonged use and overuse of diuretics, especially in older adults. When these drugs are used to manage fluid overload, sodium is lost along with the extra water. Hyponatremia can result from the loss of total body sodium, the movement of sodium from the blood to other fluid spaces, or the dilution of serum sodium from excessive water in the plasma.

TABLE 11-5

Common Causes of Hyponatremia

Actual Sodium Deficits
• Excessive diaphoresis • Diuretics (high-ceiling diuretics) • Wound drainage (especially gastrointestinal) • Decreased secretion of aldosterone • Hyperlipidemia • Kidney disease (scarred distal convoluted tubule) • Nothing by mouth • Low-salt diet • Cerebral salt-wasting syndrome • Hyperglycemia
Relative Sodium Deficits (Dilution)
• Excessive ingestion of hypotonic fluids • Psychogenic polydipsia • Freshwater submersion accident • Kidney failure (nephrotic syndrome) • Irrigation with hypotonic fluids • Syndrome of inappropriate antidiuretic hormone secretion • Heart failure

❖ Patient-Centered Collaborative Care

◆ Assessment

The manifestations of hyponatremia are caused by its effects on excitable cellular activity. The cells especially affected are those involved in cerebral, neuromuscular, intestinal smooth muscle, and cardiovascular functions.

Cerebral changes are the most obvious problems of hyponatremia. Behavioral changes result from cerebral edema and increased intracranial pressure. Closely observe and document the patient's behavior, level of consciousness, and mental status. A sudden onset of acute confusion or increased confusion is often seen in older adults who have low serum sodium levels. When sodium levels become very low, seizures, coma, and death may occur (McGraw, 2012).

Neuromuscular changes are seen as general muscle weakness. Assess the patient's neuromuscular status during each nursing shift for changes from baseline. Deep tendon reflexes diminish, and muscle weakness is worse in the legs and arms. Test arm muscle strength by having the patient squeeze your hand. Another way to test arm muscle strength is to have the patient flex his or her arms against the chest and keep them flexed while you attempt to pull them away from the chest. Test leg muscle strength by having the patient push both feet against a flat surface (like a box or a board) while you apply resistance to the opposite side of the flat surface.

Nursing Safety Priority QSEN

Action Alert

If muscle weakness is present, immediately check respiratory effectiveness because ventilation depends on adequate strength of respiratory muscles.

Intestinal changes include increased motility, causing nausea, diarrhea, and abdominal cramping. Assess the GI system by listening to bowel sounds and observing stools. Bowel sounds are hyperactive, with rushes and gurgles over the splenic flexure and in the lower left quadrant. Bowel movements are frequent and watery.

Cardiovascular changes are seen as changes in cardiac output. The cardiac responses to hyponatremia with **hypovolemia** (decreased plasma volume) include a rapid, weak, thready pulse. Peripheral pulses are difficult to palpate and are easily blocked with light pressure. Blood pressure is decreased, and the patient may have severe orthostatic hypotension, leading to light-headedness or dizziness. The central venous pressure is low.

When hyponatremia occurs with **hypervolemia** (fluid overload), cardiac changes include a full or bounding pulse with normal or high blood pressure. Peripheral pulses are full and difficult to block; however, they may not be palpable if edema is present.

Interventions

The specific cause of the low sodium level is determined to plan the most appropriate management. Interventions with drug therapy and nutrition therapy are used to restore serum sodium levels to normal and prevent complications from fluid overload or a too-rapid change in serum sodium level. *The priorities for nursing care of the patient with hyponatremia are monitoring the patient's response to therapy and preventing hypernatremia and fluid overload.*

Drug therapy involves reducing the doses of any drugs that increase sodium loss, such as most diuretics. Other regimens vary depending on whether a fluid imbalance occurs with hyponatremia. When hyponatremia occurs with a fluid deficit, IV saline infusions are prescribed to restore both sodium and fluid volume. Severe hyponatremia may be treated with small-volume infusions of hypertonic saline, most often 3% saline (Schreiber, 2013b) although 5% saline can be used for extreme hyponatremia. These infusions are delivered using a controller to prevent

accidental increases in infusion rate. Monitor the infusion rate and the patient's response.

When hyponatremia occurs with fluid excess, drug therapy includes giving drugs that promote the excretion of water rather than sodium, such as conivaptan (Vaprisol) or tolvaptan (Samsca). Drug therapy for hyponatremia caused by inappropriate secretion of antidiuretic hormone (ADH) may include lithium and demeclocycline (Declomycin). Assess hourly for signs of excessive fluid loss, potassium loss, and increased sodium levels.

Nutrition therapy can help restore sodium balance in mild hyponatremia. Collaborate with the registered dietitian (RD) to teach the patient about which foods to increase in the diet. Therapy involves increasing oral sodium intake and restricting oral fluid intake. Fluid restriction may be needed long-term when fluid overload is the cause of the hyponatremia or when kidney fluid excretion is impaired. Nursing actions for patient safety, skin protection, monitoring, and patient and family teaching are the same as those for fluid overload on pp. 161-162.

Hypernatremia

Pathophysiology

Hypernatremia is an electrolyte imbalance in which the serum sodium level is over 145 mEq/L (mmol/L). It can be caused by or can cause changes in fluid volume. Table 11-6 lists causes of hypernatremia.

TABLE 11-6

Common Causes of Hypernatremia

Actual Sodium Excesses
• Hyperaldosteronism • Kidney failure • Corticosteroids • Cushing's syndrome or disease • Excessive oral sodium ingestion • Excessive administration of sodium-containing IV fluids
Relative Sodium Excesses
• Nothing by mouth • Increased rate of metabolism • Fever • Hyperventilation • Infection • Excessive diaphoresis • Watery diarrhea • Dehydration

As serum sodium level rises, a larger difference in sodium levels occurs between the extracellular fluid (ECF) and the intracellular fluid

(ICF). More sodium is present to move rapidly across cell membranes during depolarization, making excitable tissues more easily excited. This condition is called **irritability,** and excitable tissues over-respond to stimuli. In addition, water moves from the cells into the ECF to dilute the hyperosmolar ECF. So, when serum sodium levels are high, severe cellular dehydration with cellular shrinkage occurs. Eventually the dehydrated excitable tissues may no longer be able to respond to stimuli.

Patient-Centered Collaborative Care

Assessment

The manifestations of hypernatremia vary with the severity of sodium imbalance and whether a fluid imbalance is also present. Changes are first seen in excitable membrane activity, especially nerve, skeletal muscle, and cardiac function.

Nervous system changes start with altered cerebral function. Assess the patient's mental status for attention span and cognitive function. In hypernatremia with normal or decreased fluid volumes, the patient may have a short attention span and be agitated or confused. When hypernatremia occurs with fluid overload, the patient may be lethargic, drowsy, stuporous, and even comatose.

Skeletal muscle changes vary with the degree of sodium increases. Mild rises cause muscle twitching and irregular muscle contractions. As hypernatremia worsens, the muscles and nerves are less able to respond to a stimulus and muscles become progressively weaker. Late, the deep tendon reflexes are reduced or absent. Muscle weakness occurs bilaterally and has no specific pattern. Observe for twitching in muscle groups. Assess muscle strength by having the patient perform handgrip and arm flexion against resistance as described on pp. 161-162. Assess deep tendon reflexes by lightly tapping the patellar (knee) tendons and Achilles (heel) tendons with a reflex hammer and measuring the movement.

Cardiovascular changes include decreased contractility because high sodium levels slow the movement of calcium into the heart cells. Measure blood pressure and the rate and quality of the apical and peripheral pulses. Pulse rate and blood pressure may be normal, above normal, or below normal, depending on the fluid volume and how rapidly the imbalance occurred.

Pulse rate is increased in patients with hypernatremia and hypovolemia. Peripheral pulses are difficult to palpate and are easily blocked. Hypotension and severe orthostatic (postural) hypotension are

present, and pulse pressure is reduced.

Patients with hypernatremia and hypervolemia have slow to normal bounding pulses. Peripheral pulses are full and difficult to block. Neck veins are distended, even with the patient in the upright position. Blood pressure, especially diastolic blood pressure, is increased.

Interventions

Drug and nutrition therapies are used to prevent further sodium increases and to decrease high serum sodium levels. Interventions used when sodium levels become life threatening include hemodialysis. *Priorities for nursing care of the patient with hypernatremia include monitoring his or her response to therapy and ensuring patient safety by preventing hyponatremia and dehydration.*

Drug therapy is used to restore fluid balance when hypernatremia is caused by fluid loss. Isotonic saline (0.9%) and dextrose 5% in 0.45% sodium chloride are most often prescribed (Schreiber, 2013a). Although the dextrose 5% in 0.45% sodium chloride is hypertonic in the IV bag, once it is infused, the glucose is rapidly metabolized and the fluid is really hypotonic. Hypernatremia caused by poor kidney excretion of sodium requires drug therapy with diuretics that promote sodium loss, such as furosemide (Lasix, Furoside) or bumetanide (Bumex). Assess the patient hourly for symptoms of excessive losses of fluid, sodium, or potassium.

Nutrition therapy to prevent or correct mild hypernatremia involves ensuring adequate water intake, especially among older adults. Dietary sodium restriction may be needed to prevent sodium excess when kidney problems are present. Collaborate with the dietitian to teach the patient how to determine the sodium content of foods, beverages, and drugs. Nursing actions for patient safety, skin protection, monitoring, and patient and family teaching are similar to those for fluid overload on pp. 158-160.

NCLEX Examination Challenge

Physiological Integrity

Which condition or manifestation in the client with a serum sodium level of 149 mEq/L indicates to the nurse that this electrolyte imbalance may be caused by excessive fluid loss?

A The client has twitching muscle contractions in the lower extremities.

B The client's skin is cool and clammy.

C The urine specific gravity is increased.
D The hematocrit is 52%.

Potassium

Potassium (K^+) is the major cation of the intracellular fluid (ICF). The normal plasma potassium level ranges from 3.5 to 5.0 mEq/L (mmol/L) (see Table 11-1). The normal ICF potassium level is about 140 mEq/L (mmol/L). Because of its high levels inside cells, potassium has some control over intracellular osmolarity and volume. Keeping this large difference in potassium concentration between the ICF and the extracellular fluid (ECF) is critical for excitable tissues to depolarize and generate action potentials.

Because potassium levels in the blood and interstitial fluid are so low, any change seriously affects physiologic activities. For example, a decrease in blood potassium of only 1 mEq/L (from 4 mEq/L to 3 mEq/L) is a 25% difference in total ECF potassium concentration. In contrast, a 1 mEq/L decrease in blood sodium level (from 130 mEq/L to 129 mEq/L) is, overall, a much smaller change (less than 1%) in total ECF sodium concentration.

Almost all foods contain potassium. It is highest in meat, fish, and many (but not all) vegetables and fruits. It is lowest in eggs, bread, and cereal grains. Typical potassium intake is about 2 to 20 g/day. Despite heavy potassium intake, the healthy adult keeps plasma potassium levels within the narrow range of normal values.

The main controller of ECF potassium level is the sodium-potassium pump within the membranes of all body cells. This pump moves extra sodium ions from the ICF and moves extra potassium ions from the ECF back into the cell. In this way, the serum potassium level remains low and the cellular potassium remains high. At the same time, this action also helps the serum sodium level remain high and the cellular sodium level remain low.

About 80% of potassium is removed from the body by the kidney. Kidney excretion of potassium is enhanced by aldosterone.

Hypokalemia

Pathophysiology

Because 98% of total body potassium (K^+) is inside cells, minor changes in extracellular potassium levels cause major changes in cell membrane excitability. **Hypokalemia** is an electrolyte imbalance in which the serum

potassium level is below 3.5 mEq/L (mmol/L). *It can be life threatening because every body system is affected.*

Low serum potassium levels increase the difference in the amount of potassium between the fluid inside the cells (ICF) and the fluid outside the cells (ECF). This increased difference reduces the excitability of cells. As a result, the cell membranes of all excitable tissues, such as nerve and muscle, are less responsive to normal stimuli. Gradual potassium loss may have no manifestations until the loss is extreme. Rapid reduction of serum potassium levels causes dramatic changes in function. Table 11-7 lists causes of hypokalemia.

TABLE 11-7

Common Causes of Hypokalemia

Actual Potassium Deficits

• Inappropriate or excessive use of drugs:
  • Diuretics
  • Digitalis
  • Corticosteroids
• Increased secretion of aldosterone
• Cushing's syndrome
• Diarrhea
• Vomiting
• Wound drainage (especially gastrointestinal)
• Prolonged nasogastric suction
• Heat-induced excessive diaphoresis
• Kidney disease impairing reabsorption of potassium
• Nothing by mouth

Relative Potassium Deficits
• Alkalosis • Hyperinsulinism • Hyperalimentation • Total parenteral nutrition • Water intoxication • IV therapy with potassium-poor solutions

Actual potassium depletion occurs when potassium loss is excessive or when potassium intake is not adequate to match normal potassium loss. Relative hypokalemia occurs when total body potassium levels are normal but the potassium distribution between fluid spaces is abnormal or it is diluted by excess water.

❖ Patient-Centered Collaborative Care

◆ Assessment

Age is important because urine concentrating ability decreases with aging, which increases potassium loss. Older adults are more likely to use drugs that lead to potassium loss.

Drugs, especially diuretics, corticosteroids, and beta-adrenergic

agonists or antagonists, can increase potassium loss through the kidneys. Ask about prescription and over-the-counter drug use. In patients taking digoxin (Lanoxin, Novo-Digoxin), hypokalemia increases the sensitivity of the cardiac muscle to the drug and may result in digoxin toxicity, even when the digoxin level is within the therapeutic range. Ask whether the patient takes a potassium supplement, such as potassium chloride (KCl), or eats foods that have high concentrations of potassium, such as bananas, citrus juices, raisins, and meat. The patient may not be taking the supplement as prescribed because of its unpleasant taste.

Disease can lead to potassium loss. Ask about chronic disorders, recent illnesses, and medical or surgical interventions. A thorough nutrition history, including a typical day's food and beverage intake, helps identify patients at risk for hypokalemia.

Respiratory changes occur because of respiratory muscle weakness resulting in shallow respirations. *Thus respiratory status should be assessed first in any patient who might have hypokalemia.* Assess the patient's breath sounds, ease of respiratory effort, color of nail beds and mucous membranes, and rate and depth of respiration.

Nursing Safety Priority QSEN

Action Alert

Assess the respiratory status of a patient who has hypokalemia at least every 2 hours because respiratory insufficiency is a major cause of death for these patients.

Musculoskeletal changes include skeletal muscle weakness. A stronger stimulus is needed to begin muscle contraction. A patient may be too weak to stand. Hand grasps are weak, and deep tendon reflexes may be reduced (hyporeflexia). Severe hypokalemia causes flaccid paralysis. Assess for muscle weakness and the patient's ability to perform ADLs.

Cardiovascular changes are assessed by palpating the peripheral pulses. In hypokalemia, the pulse is usually thready and weak. Palpation is difficult, and the pulse is easily blocked with light pressure. The pulse rate can range from very slow to very rapid, and an irregular heartbeat (dysrhythmia) may be present. Measure blood pressure with the patient in the lying, sitting, and standing positions, because orthostatic (postural) hypotension occurs with hypokalemia.

Neurologic changes from hypokalemia include altered mental status. The patient may have short-term irritability and anxiety followed by

lethargy that progresses to acute confusion and coma as hypokalemia worsens.

Behavioral changes caused by hypokalemia can occur quickly. The patient may be lethargic and unable to perform simple problem-solving tasks such as counting by threes. As hypokalemia progresses, confusion increases and coma may develop.

Intestinal changes occur with hypokalemia because GI smooth muscle contractions are decreased, which leads to decreased peristalsis. Bowel sounds are hypoactive, and nausea, vomiting, constipation, and abdominal distention are common. Measure abdominal girth, and auscultate for bowel sounds in all four abdominal quadrants. *Severe hypokalemia can cause the absence of peristalsis* ***(paralytic ileus)***.

Laboratory data confirm hypokalemia (serum potassium value below 3.5 mEq/L [mmol/L]). Hypokalemia causes ECG changes in the heart, including ST-segment depression, flat or inverted T waves, and increased U waves. *Dysrhythmias can lead to death, particularly in older adults who are taking digoxin.*

◆ Interventions

Interventions for hypokalemia focus on preventing potassium loss, increasing serum potassium levels, and ensuring patient safety. Drug and nutrition therapies help restore normal serum potassium levels. *The priorities for nursing care of the patient with hypokalemia are (1) ensuring adequate oxygenation, patient safety for falls prevention, and prevention of injury from potassium administration and (2) monitoring the patient's response to therapy.* Chart 11-5 highlights best practice activities when caring for a patient with hypokalemia.

Chart 11-5 Best Practice for Patient Safety & Quality Care QSEN

The Patient with Hypokalemia

- Question the continued use of drugs that increase excretion of potassium (e.g., thiazide and loop diuretics).
- Administer prescribed oral potassium supplement, well diluted and with a meal or just after a meal or snack to prevent nausea and vomiting.
- Prevent accidental overdose of IV potassium by checking and re-checking the concentration of potassium in the IV solution, ensuring that the maximum concentration is no greater than 1 mEq/10 mL of

solution.
- Establish an IV access in a large vein with a high volume of flow, avoiding the hand.
- Assess the IV access for placement and an adequate blood return *before* administering potassium-containing solutions.
- Use a controller for solution delivery, maintaining an infusion rate not faster than 5 to 10 mEq of potassium per hour.
- Assess the IV site hourly.
- Stop the infusion immediately if the patient reports pain or burning or if any manifestation of infiltration occurs.
- If possible, monitor electrocardiography (ECG) continuously.
- Monitor patient responses every 1 to 2 hours to determine therapy effectiveness and the potential for hyperkalemia.
  - Indications of therapy effectiveness:
    - Respiratory rate is greater than 12 breaths per minute
    - Oxygen saturation is at least 95% (or has returned to the patient's normal baseline)
    - The patient can cough effectively
    - Hand grasp strength increases
    - Deep tendon reflexes are present
    - Bowel sounds are present and active
    - Pulse is easily palpated and regular
    - Systolic blood pressure when standing remains within 20 mm Hg of the systolic pressure obtained when the patient is sitting or lying down
    - ST segment returns to the isoelectric line
    - T waves increase in size and are positive
    - U waves decrease or disappear
    - Patient's cognition resembles his or her prehypokalemic state
    - Serum potassium level is between 3.5 and 5.0 mEq/L
  - Indications of hyperkalemia:
    - Heart rate is less than 60 beats per minute
    - P waves are absent
    - T waves are tall
    - PR intervals are prolonged
    - QRS complexes are wide
    - Deep tendon reflexes are hyperactive
    - Bowel sounds are hyperactive
    - Numbness or tingling is present in the hands and feet and around the mouth
    - The patient is anxious

■ Serum potassium level is above 5.0 mEq/L

- Keep patient on bedrest until hypokalemia resolves, or provide assistance when out of bed to prevent falls.

Drug therapy for management and prevention of hypokalemia includes additional potassium and drugs to prevent potassium loss (Scotto et al., 2014). Most potassium supplements are potassium chloride, potassium gluconate, or potassium citrate. The amount and the route of potassium replacement depend on the degree of loss.

Potassium is given IV for severe hypokalemia. The drug is available in different concentrations, and this drug carries a high alert warning as a concentrated electrolyte solution. The Joint Commission's National Patient Safety Goals has mandated that concentrated potassium be diluted and added to IV solutions only in the pharmacy by a registered pharmacist and that vials of concentrated potassium not be available in patient care areas. *Before infusing any IV solution containing potassium chloride (KCl), check and recheck the dilution of the drug in the IV solution container.*

Nursing Safety Priority QSEN

Drug Alert

A dilution no greater than 1 mEq of potassium to 10 mL of solution is recommended for IV administration. The maximum recommended infusion rate is 5 to 10 mEq/hr; this rate is never to exceed 20 mEq/hr under any circumstances. In accordance with National Patient Safety Goals (NPSGs), potassium is not given by IV push to avoid causing cardiac arrest.

Potassium is a severe tissue irritant and is never given by IM or subcutaneous injection. Tissues damaged by potassium can become necrotic, causing loss of function and requiring surgery. IV potassium solutions irritate veins and cause phlebitis. Check the prescription carefully to ensure that the patient receives the correct amount of potassium. Assess the IV site hourly, and ask the patient whether he or she feels burning or pain at the site.

Nursing Safety Priority QSEN

Action Alert

If infiltration of solution containing potassium occurs, stop the IV solution immediately, remove the venous access, and notify the health care provider or Rapid Response Team. Document these actions along with a complete description of the IV site.

Oral potassium preparations may be taken as liquids or solids. Potassium has a strong, unpleasant taste that is difficult to mask, although it can be mixed with many liquids. Because potassium chloride can cause nausea and vomiting, give the drug during or after a meal and advise patients using the drug at home not to take it on an empty stomach.

Diuretics that increase the kidney excretion of potassium can cause hypokalemia, especially high-ceiling (loop) diuretics (e.g., furosemide [Lasix, Furoside] and bumetanide [Bumex]) and the thiazide diuretics. These drugs are avoided in patients with hypokalemia. A potassium-sparing diuretic may be prescribed to increase urine output without increasing potassium loss. Potassium-sparing diuretics include spironolactone (Aldactone, Novospiroton), triamterene (Dyrenium), and amiloride (Midamor).

Nutrition therapy involves collaboration with a dietitian to teach the patient how to increase dietary potassium intake. Eating foods that are naturally rich in potassium helps prevent further loss, but supplementation is needed to restore normal potassium levels.

Implement safety measures with a patient who has muscle weakness from hypokalemia, including the falls precautions listed in Chart 2-4 in Chapter 2. Be sure to have the patient wear a gait belt when ambulating with assistance.

Respiratory monitoring is performed at least hourly for severe hypokalemia, especially checking for increasing rate and decreasing depth. Also check oxygen saturation by pulse oximetry to determine breathing effectiveness. Assess respiratory muscle effectiveness by checking the patient's ability to cough. Examine the face, oral mucosa, and nail beds for pallor or cyanosis. Evaluate arterial blood gas values (when available) for decreased blood oxygen levels **(hypoxemia)** and increased arterial carbon dioxide levels **(hypercapnia)**, which indicate inadequate breathing effectiveness.

NCLEX Examination Challenge

Physiological Integrity

Which question is most important for the nurse to ask the client who has a serum potassium level of 2.9 mEq/L?
A "Do you use sugar substitutes?"
B "Do you use diuretics or laxatives?"
C "Have you had any muscle twitches or cramps, especially at night?
D "Have you or any member of your family ever been diagnosed with lung disease?"

Hyperkalemia

Pathophysiology

Hyperkalemia is an electrolyte imbalance in which the serum potassium level is higher than 5.0 mEq/L (mmol/L). Even small increases above normal values can affect excitable tissues, especially the heart.

A high serum potassium increases cell excitability; as a result, most excitable tissues respond to less intense stimuli and may even discharge spontaneously. The heart is very sensitive to serum potassium increases, and hyperkalemia interferes with electrical conduction, leading to heart block and ventricular fibrillation.

The problems that occur with hyperkalemia are related to how rapidly ECF potassium levels increase. Sudden potassium rises cause severe problems at serum levels between 6 and 7 mEq/L. When serum potassium rises slowly, problems may not occur until potassium levels reach 8 mEq/L or higher.

Hyperkalemia is rare in people with normal kidney function. Most cases of hyperkalemia occur in hospitalized patients and in those undergoing medical treatment. Those at greatest risk are chronically ill patients, debilitated patients, and older adults (Table 11-8).

TABLE 11-8

Common Causes of Hyperkalemia

Actual Potassium Excesses

• Overingestion of potassium-containing foods or medications
  • Salt substitutes
  • Potassium chloride
  • Rapid infusion of potassium-containing IV solution
  • Bolus IV potassium injections
• Transfusions of whole blood or packed cells
• Adrenal insufficiency
• Kidney failure
• Potassium-sparing diuretics
• Angiotensin-converting enzyme inhibitors (ACEIs)

Relative Potassium Excesses
• Tissue damage • Acidosis • Hyperuricemia • Uncontrolled diabetes mellitus

❖ Patient-Centered Collaborative Care

◆ Assessment

Age is important because kidney function decreases with aging. Ask about kidney disease, diabetes mellitus, recent medical or surgical treatment, and urine output, including frequency and amount of voidings. Ask about drug use, particularly potassium-sparing diuretics and angiotensin-converting enzyme (ACE) inhibitors. Obtain a nutrition history to determine the intake of potassium-rich foods and the use of salt substitutes (which contain potassium).

Collect specific information about manifestations related to hyperkalemia. Ask whether the patient has had palpitations, skipped heartbeats, other cardiac irregularities, muscle twitching, leg weakness, or unusual tingling or numbness in the hands, feet, or face. Ask about recent changes in bowel habits, especially diarrhea.

Cardiovascular changes are the most severe problems from hyperkalemia and are the most common cause of death in patients with hyperkalemia. Cardiac manifestations include bradycardia, hypotension, and ECG changes of tall, peaked T waves, prolonged PR intervals, flat or absent P waves, and wide QRS complexes. As serum potassium levels rise, ectopic beats may appear. Complete heart block, asystole, and ventricular fibrillation are life-threatening complications of severe hyperkalemia.

Neuromuscular changes with hyperkalemia have two phases. Skeletal muscles twitch in the early stages of hyperkalemia, and the patient may be aware of tingling and burning sensations followed by numbness in

the hands and feet and around the mouth **(paresthesia).** As hyperkalemia worsens, muscle weakness occurs followed by flaccid paralysis. The weakness moves up from the hands and feet and first affects the muscles of the arms and legs. Respiratory muscles are not affected until serum potassium levels reach lethal levels.

Intestinal changes include increased motility with diarrhea and hyperactive bowel sounds. Bowel movements are frequent and watery.

Laboratory data confirm hyperkalemia (potassium level over 5.0 mEq/L). If it is caused by dehydration, levels of other electrolytes, hematocrit, and hemoglobin also are elevated. Hyperkalemia caused by kidney failure occurs with elevated serum creatinine and blood urea nitrogen, decreased blood pH, and normal or low hematocrit and hemoglobin levels.

◆ Interventions

Interventions for hyperkalemia focus on reducing the serum potassium level, preventing recurrences, and ensuring patient safety. Drug therapy is key. *The priorities for nursing care of the patient with hyperkalemia are assessing for cardiac complications, patient safety for falls prevention, monitoring the patient's response to therapy, and health teaching.*

Drug therapy can restore normal potassium balance by enhancing potassium excretion and promoting the movement of potassium from the extracellular fluid (ECF) into the cells.

Stop potassium-containing infusions, and keep the IV access open. Withhold oral potassium supplements, and provide a potassium-restricted diet.

Increasing potassium excretion helps reduce hyperkalemia if kidney function is normal. Potassium-excreting diuretics, such as furosemide, are prescribed. When kidney problems exist, drug therapy to increase potassium excretion includes cation exchange resins that promote intestinal sodium absorption and potassium excretion, such as sodium polystyrene sulfonate (Kayexalate). However, this therapy may take hours to reduce potassium levels. If potassium levels are dangerously high, additional measures, such as dialysis, are needed.

Movement of potassium from the extracellular fluid (ECF) to the intracellular fluid (ICF) can help reduce serum potassium levels temporarily. Potassium movement into the cells is enhanced by insulin. Insulin increases the activity of the sodium-potassium pumps, which move potassium from the ECF into the cell. IV fluids containing glucose and insulin are prescribed to help decrease serum potassium levels (usually 100 mL of 10% to 20% glucose with 10 to 20 units of regular

insulin) (Cottrell, 2012). These IV solutions are hypertonic and are infused through a central line or in a vein with a high blood flow to avoid local vein inflammation. Observe the patient for manifestations of hypokalemia and hypoglycemia during this therapy.

Cardiac monitoring allows for the early recognition of dysrhythmias and other manifestations of hyperkalemia on cardiac muscle. Compare recent ECG tracings with the tracings obtained when the patient's serum potassium level was close to normal.

Nursing Safety Priority QSEN

Critical Rescue

Notify the health care provider or Rapid Response Team if the patient's heart rate falls below 60 beats per minute or if the T waves become spiked, both of which accompany hyperkalemia.

Health teaching is key to the prevention of hyperkalemia and the early detection of complications. The teaching plan includes diet, drugs, and recognition of the manifestations of hyperkalemia. Collaborate with the dietitian to teach the patient and family about which foods to avoid (those high in potassium). Foods that are low in potassium are listed in Chart 11-6. Instruct the patient and family to read the labels on drug and food packages to determine the potassium content. Warn them to avoid salt substitutes, which contain potassium.

Chart 11-6

Patient and Family Education: Preparing for Self-Management

Nutritional Management of Hyperkalemia

You Should Avoid

- Meats, especially organ meat and preserved meat
- Dairy products
- Dried fruit
- Fruits high in potassium:
  - Bananas
  - Cantaloupe
  - Kiwi
  - Oranges

- Vegetables high in potassium:
  - Avocados
  - Broccoli
  - Dried beans or peas
  - Lima beans
  - Mushrooms
  - Potatoes (white or sweet)
  - Seaweed
  - Soybeans
  - Spinach

You May Eat

- Eggs
- Breads
- Butter
- Cereals
- Sugar
- Fruits low in potassium (fresh, frozen, or canned):
  - Apples
  - Apricots
  - Berries
  - Cherries
  - Cranberries
  - Grapefruit
  - Peaches
  - Pineapple
- Vegetables low in potassium:
  - Alfalfa sprouts
  - Cabbage
  - Carrots
  - Cauliflower
  - Celery
  - Eggplant
  - Green beans
  - Lettuce
  - Onions
  - Peas
  - Peppers
  - Squash

Data from Pennington, J.A., & Spungen, J.S. (2010). *Bowes and Church's food values of portions commonly used* (19th ed.). Philadelphia: Lippincott Williams & Wilkins.

Calcium

Calcium (Ca^{2+}) is a mineral with functions closely related to those of phosphorus and magnesium. It is an ion having two positive charges *(divalent cation)* that exists in the body in a bound form and an ionized (unbound or free) form.

Bound calcium is usually attached to serum proteins, especially albumin. Ionized calcium is present in the blood and other extracellular fluid (ECF) as free calcium. Free calcium is the active form and must be kept within a narrow range in the ECF. The body functions best when blood calcium levels are maintained between 9.0 and 10.5 mg/dL, or between 2.25 and 2.62 mmol/L (see Table 11-1). Calcium has a steep gradient between ECF and intracellular fluid (ICF) because the amount of calcium in the ICF is very low. This mineral is important for maintaining bone strength and density, activating enzymes, allowing skeletal and cardiac muscle contraction, controlling nerve impulse transmission, and allowing blood clotting.

Calcium enters the body by dietary intake and absorption through the intestinal tract. Dairy products are common foods high in calcium. Absorption of dietary calcium requires the active form of vitamin D. Calcium is stored in the bones. When more calcium is needed, parathyroid hormone (PTH) is released from the parathyroid glands. PTH increases serum calcium levels by:

- Releasing free calcium from bone storage sites (bone *resorption* of calcium)
- Stimulating vitamin D activation to help increase intestinal *absorption* of dietary calcium
- Inhibiting kidney calcium excretion
- Stimulating kidney calcium *reabsorption*

When excess calcium is present in plasma, PTH secretion is inhibited and the secretion of *thyrocalcitonin (TCT)*, a hormone secreted by the thyroid gland, is increased. TCT causes the plasma calcium level to decrease by inhibiting bone resorption of calcium, inhibiting vitamin D–associated intestinal uptake of calcium, and increasing kidney excretion of calcium in the urine.

Hypocalcemia

❖ Pathophysiology

Hypocalcemia is an electrolyte imbalance in which a total serum calcium (Ca^{2+}) level is below 9.0 mg/dL or 2.25 mmol/L. Calcium is stored in bone,

with only a small amount of total body calcium present in extracellular fluid (ECF). Because the normal blood level of calcium is so low, any change in calcium levels has major effects on function.

Calcium is an excitable membrane stabilizer, regulating depolarization and the generation of action potentials. It decreases sodium movement across excitable membranes, slowing the rate of depolarization. Low serum calcium levels increase sodium movement across excitable membranes, allowing depolarization to occur more easily and at inappropriate times.

Hypocalcemia is caused by many chronic and acute conditions, as well as medical or surgical treatments. Table 11-9 lists causes of hypocalcemia. Acute hypocalcemia results in the rapid onset of life-threatening manifestations. Chronic hypocalcemia occurs slowly over time, and excitable membrane manifestations may not be severe because the body has adjusted to the gradual reduction of serum calcium levels.

TABLE 11-9

Common Causes of Hypocalcemia

Actual Calcium Deficits

• Inadequate oral intake of calcium
• Lactose intolerance
• Malabsorption syndromes:
  • Celiac sprue
  • Crohn's disease
• Inadequate intake of vitamin D
• End-stage kidney disease
• Diarrhea
• Steatorrhea
• Wound drainage (especially gastrointestinal)

Relative Calcium Deficits

• Hyperproteinemia
• Alkalosis
• Calcium chelators or binders
  • Citrate
  • Mithramycin
  • Penicillamine
  • Sodium cellulose phosphate (Calcibind)
  • Aredia
• Acute pancreatitis
• Hyperphosphatemia
• Immobility
• Removal or destruction of parathyroid glands

Actual calcium loss (a reduction in total body calcium) occurs when the absorption of calcium from the GI tract slows or when calcium is lost from the body. Relative calcium loss causes total body calcium amounts to remain normal while serum calcium levels are low. This problem occurs when the unbound calcium in the body is reduced or when parathyroid gland function is decreased.

Gender Health Considerations

Patient-Centered Care QSEN

Postmenopausal women are at risk for chronic calcium loss. This problem is related to reduced weight-bearing activities and a decrease in estrogen levels. As they age, many women decrease weight-bearing activities such as running and walking, which allows osteoporosis to occur at a more rapid rate. Also, the estrogen secretion that protects against osteoporosis diminishes. (See Chapter 50 for a complete discussion of osteoporosis.)

Patient-Centered Collaborative Care

Assessment

Assess the nutrition history for the risk for hypocalcemia. Ask the patient about his or her intake of dairy products and whether he or she takes a calcium supplement regularly.

One indicator of hypocalcemia is a report of frequent, painful muscle spasms ("charley horses") in the calf or foot during rest or sleep. Ask about a history of recent orthopedic surgery or bone healing. Endocrine disturbances and treatments are risk factors for hypocalcemia. A history of thyroid surgery, therapeutic irradiation of the upper middle chest and neck area, or a recent anterior neck injury increases the risk for hypocalcemia. Most manifestations of acute hypocalcemia are caused by overstimulation of the nerves and muscles.

Neuromuscular changes often occur first in the hands and feet. Paresthesias occur at first, with sensations of tingling and numbness. If hypocalcemia continues or worsens, muscle twitching or painful cramps and spasms occur. Tingling may also affect the lips, nose, and ears. These problems may signal the onset of neuromuscular overstimulation and tetany (Crawford & Harris, 2012).

Assess for hypocalcemia by testing for Trousseau's and Chvostek's signs. To test for Trousseau's sign, place a blood pressure cuff around the upper arm, inflate the cuff to greater than the patient's systolic pressure, and keep the cuff inflated for 1 to 4 minutes. Under these hypoxic conditions, a positive Trousseau's sign occurs when the hand and fingers go into spasm in palmar flexion (Fig. 11-13). To test for Chvostek's sign, tap the face just below and in front of the ear (over the facial nerve) to trigger facial twitching of one side of the mouth, nose, and cheek (Fig. 11-14).

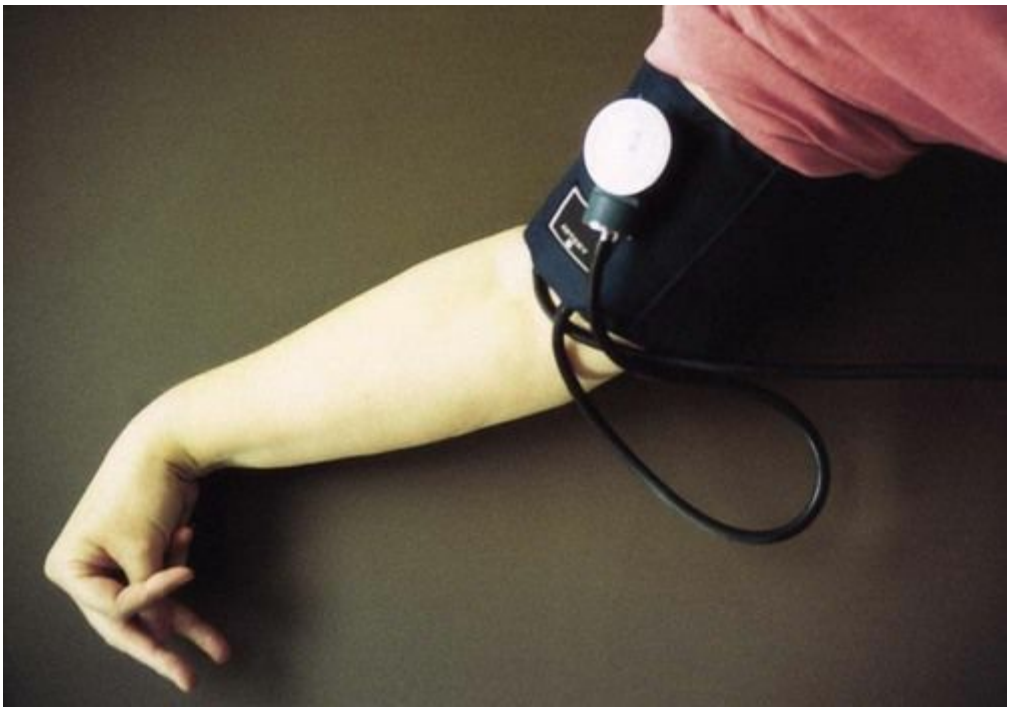

FIG. 11-13 Palmar flexion indicating a positive Trousseau's sign in hypocalcemia.

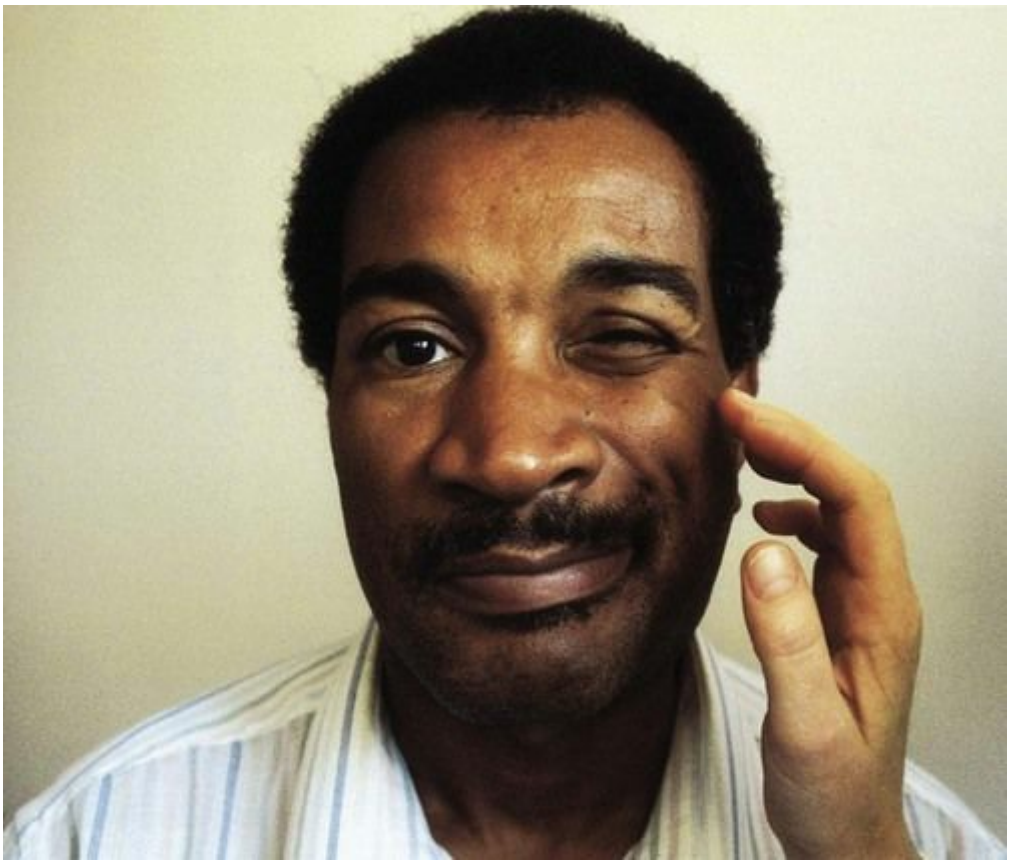

FIG. 11-14 Facial muscle response indicating a positive Chvostek's sign in hypocalcemia.

Cardiovascular changes involve heart rate and ECG changes. The heart

rate may be slower or slightly faster than normal, with a weak, thready pulse. Severe hypocalcemia causes severe hypotension and ECG changes of a prolonged ST interval and a prolonged QT interval.

Intestinal changes include increased peristaltic activity. Auscultate the abdomen for hyperactive bowel sounds. The patient may report painful abdominal cramping and diarrhea.

Skeletal changes are common with chronic hypocalcemia. Calcium leaves bone storage sites, causing a loss of bone density (osteoporosis). The bones are less dense, more brittle, and fragile and may break easily with slight trauma. Vertebrae become more compact and may bend forward, leading to an overall loss of height. See Chapter 50 for discussion of osteoporosis.

Ask about changes in height and any unexplained bone pain. Observe for spinal curvatures and any unusual bumps or protrusions in bones that may indicate old fractures.

◆ Interventions

Interventions focus on restoring normal calcium levels and preventing complications. These include drug therapy, nutrition therapy, reducing environmental stimuli, and preventing injury. Patient safety during restoration of serum calcium levels is a nursing care priority.

Drug therapy for hypocalcemia includes direct calcium replacement (oral and IV) and drugs that enhance the absorption of calcium, such as vitamin D. When hypocalcemia is a result of hyperphosphatemia, aluminum hydroxide may help raise serum calcium levels. When neuromuscular manifestations are troublesome, drugs that decrease nerve and muscle responses also may be used.

Nutrition therapy involves a high-calcium diet for patients with mild hypocalcemia and for those who are at continuing risk for hypocalcemia. Collaborate with the dietitian to assist the patient in selecting calcium-rich foods.

Environmental management for safety is needed because the excitable membranes of the nervous system and the skeletal system are overstimulated in hypocalcemia. Reduce stimulation by keeping the room quiet, limiting visitors, adjusting the lighting, and using a soft voice.

Use seizure precautions for the patient with hypocalcemia (see Chapter 42). Keep emergency equipment (e.g., oxygen, suction) at the bedside.

Injury prevention strategies are needed because the patient with long-standing calcium loss may have brittle, fragile bones that fracture easily

and cause little pain. When lifting or moving a patient with fragile bones, use a lift sheet rather than pulling the patient. Observe for normal range of joint motion and for any unusual surface bumps or depressions over bony areas that may indicate bone fracture.

Hypercalcemia

Pathophysiology

Hypercalcemia is an electrolyte imbalance in which the total serum calcium level is above 10.5 mg/dL or 2.62 mmol/L. Even small increases above normal have severe effects. Although the effects of hypercalcemia occur first in excitable tissues, all systems are affected.

Hypercalcemia means either that the amount of serum calcium is so great that the normal calcium-controlling actions cannot keep pace or that a control action is not functioning properly (Table 11-10). Hypercalcemia causes excitable tissues to be less sensitive to normal stimuli, thus requiring a stronger stimulus to function. The excitable tissues affected most by hypercalcemia are the heart, skeletal muscles, nerves, and intestinal smooth muscles.

TABLE 11-10

Common Causes of Hypercalcemia

Actual Calcium Excesses
• Excessive oral intake of calcium • Excessive oral intake of vitamin D • Kidney failure • Use of thiazide diuretics
Relative Calcium Excesses
• Hyperparathyroidism • Malignancy • Hyperthyroidism • Immobility • Use of glucocorticoids • Dehydration

Patient-Centered Collaborative Care

Assessment

The manifestations of hypercalcemia are related to its severity and how quickly the imbalance occurred. The patient with a mild but rapidly occurring calcium excess often has more severe problems than the patient whose imbalance is severe but has developed slowly.

Cardiovascular changes are the most serious and life-threatening

problems of hypercalcemia. Mild hypercalcemia at first causes increased heart rate and blood pressure. Severe or prolonged calcium imbalance depresses electrical conduction, slowing heart rate.

Measure pulse rate and blood pressure, and observe for indications of poor tissue blood flow, such as cyanosis and pallor. Examine ECG tracings for dysrhythmias, especially a shortened QT interval.

Hypercalcemia allows blood clots to form more easily whenever blood flow is poor. Blood clotting is more likely in the lower legs, the pelvic region, areas where blood flow is blocked by internal or external constrictions, and areas where venous obstruction occurs.

Assess for slowed or impaired blood flow. Measure and record calf circumferences with a soft tape measure. Assess the feet for temperature, color, and capillary refill to determine the blood flow to and from the area.

Neuromuscular changes include severe muscle weakness and decreased deep tendon reflexes without paresthesia. The patient may be confused and lethargic.

Intestinal changes are first reflected as decreased peristalsis. Constipation, anorexia, nausea, vomiting, and abdominal distention and pain are common. Bowel sounds are hypoactive or absent. Assess abdominal size by measuring abdominal girth with a soft tape measure in a line circling the abdomen at the umbilicus.

◆ Interventions

Interventions for hypercalcemia focus on reducing serum calcium levels through drug therapy, rehydration, and, depending on the cause and severity, dialysis. Cardiac monitoring is also important.

Drug therapy involves preventing increases in calcium, as well as drugs to lower calcium levels. IV solutions containing calcium (e.g., Ringer's lactate) are stopped. Oral drugs containing calcium or vitamin D (e.g., calcium-based antacids) are discontinued.

Fluid volume replacement can help restore normal serum calcium levels. IV normal saline (0.9% sodium chloride) is usually given because sodium increases kidney excretion of calcium.

Thiazide diuretics are discontinued and are replaced with diuretics that enhance the excretion of calcium, such as furosemide (Lasix, Furoside 🍁). Calcium chelators (calcium binders) help lower serum calcium levels. Such drugs include plicamycin (Mithracin) and penicillamine (Cuprimine, Pendramine 🍁).

Drugs to prevent hypercalcemia include agents that inhibit calcium resorption from bone, such as phosphorus, calcitonin (Calcimar),

bisphosphonates (etidronate), and prostaglandin synthesis inhibitors (aspirin, NSAIDs).

Cardiac monitoring of patients with hypercalcemia is needed to identify dysrhythmias and decreased cardiac output. Compare recent ECG tracings with the patient's baseline tracings. Especially look for changes in the T waves and the QT interval and changes in rate and rhythm.

NCLEX Examination Challenge

Health Promotion and Maintenance

Which intervention is most important for the nurse to teach the client who is at continuing risk for hypercalcemia and has normal kidney function?

A "Report a weight gain of 1 lb or more a day to your health care provider immediately."
B "Keep track of the number of bowel movements you have each day."
C "Avoid taking aspirin or any aspirin-containing products."
D "Be sure to drink at least 2 liters of fluids each day."

Phosphorus

Normal serum levels of phosphorus range from 3.0 to 4.5 mg/dL, or 0.97 to 1.45 mmol/L (see Table 11-1). Most phosphorus (80%) can be found in the bones. It is the major anion in the ICF, and its levels inside cells are much higher than in the ECF. Phosphorus is needed for activating vitamins and enzymes, forming energy supplies, and assisting in cell growth and metabolism. It also functions in acid-base balance and calcium homeostasis.

Phosphorus balance and calcium balance are intertwined. Plasma levels of calcium and phosphorus exist in a balanced, reciprocal relationship, which means that when you multiply the two values, the product remains constant. Therefore a change in the level of serum phosphorus results in an equal and opposite change in the level of serum calcium (and vice versa).

The regulation of ECF phosphorus occurs through the activity of parathyroid hormone (PTH). Increased PTH levels cause a net loss of phosphorus. Reduced PTH levels enhance kidney reabsorption of phosphorus, resulting in increased plasma levels of phosphorus.

Hypophosphatemia

Pathophysiology

Hypophosphatemia is an electrolyte imbalance in which the serum phosphorus level is below 3.0 mg/dL. Body functions are not usually impaired with rapid changes in serum phosphorus levels. Reduced function occurs more often with chronic hypophosphatemia. Table 11-11 lists causes of phosphorus imbalance.

TABLE 11-11

Common Causes of Phosphorus Imbalance

Hypophosphatemia
• Malnutrition • Starvation • Use of aluminum hydroxide–based antacids • Use of magnesium-based antacids • Hyperparathyroidism • Hypercalcemia • Kidney failure • Malignancy • Hyperglycemia • Hyperalimentation • Respiratory alkalosis • Uncontrolled diabetes mellitus • Alcohol abuse
Hyperphosphatemia
• Decreased kidney excretion resulting from kidney disease • Tumor lysis syndrome • Increased intake of phosphorus • Hypoparathyroidism

Most effects of hypophosphatemia are related to decreased energy metabolism, as well as to other fluid and electrolyte imbalances. Because phosphorus and calcium are inter-related, *decreases* in serum phosphorus levels cause *increases* in serum calcium levels.

Patient-Centered Collaborative Care

Assessment

Manifestations of hypophosphatemia are most apparent in the cardiac, musculoskeletal, hematologic, and central nervous systems. Cardiac changes include weak contractility, decreased stroke volume, and decreased cardiac output. Peripheral pulses are slow, difficult to find, and easy to block. Prolonged hypophosphatemia causes progressive but reversible cardiac muscle damage.

Musculoskeletal changes include weak skeletal muscles that may progress to acute muscle breakdown **(rhabdomyolysis).** With profound muscle weakness, respiratory efforts are ineffective, leading to respiratory failure. Assess for muscle strength, and observe respiratory

effort.

The manifestations of *chronic* hypophosphatemia are most evident in the skeletal system. Bone density is decreased, which leads to fractures. Assess the patient for unusual lumps or depressions over bony areas that indicate bone fractures.

Central nervous system changes are not apparent until hypophosphatemia is severe. These first appear as irritability and may progress to seizure activity followed by coma.

◆ Interventions

Drugs that promote phosphorous loss (e.g., antacids, osmotic diuretics, calcium supplements) are discontinued. Oral replacement of phosphorus along with a vitamin D supplement may correct moderate hypophosphatemia. IV phosphorus is given only when serum phosphorus levels fall below 1 mg/dL and the patient has serious manifestations. Infuse IV phosphorus slowly because the problems caused by hyperphosphatemia are equally serious.

Nutrition therapy involves increasing the intake of phosphorus-rich foods while decreasing the intake of calcium-rich foods. Collaborate with the dietitian to teach the patient and family which foods to eat and which to avoid.

Hyperphosphatemia

Hyperphosphatemia is an electrolyte imbalance in which the serum phosphorus level is above 4.5 mg/dL. High levels are well tolerated by most body systems. Causes of increased serum phosphorus levels include kidney disease, certain cancer treatments, increased phosphorus intake, and hypoparathyroidism. Table 11-11 lists common causes of hyperphosphatemia.

The problems caused by hyperphosphatemia center on the hypocalcemia that results when serum phosphorus levels increase. These problems include increased membrane excitability and can cause life-threatening side effects (see p. 168). Thus the management of hyperphosphatemia entails the management of hypocalcemia (see p. 169).

Magnesium

Magnesium (Mg^{2+}) is a mineral that forms a cation when dissolved in water. Most magnesium is stored in bones and cartilage. Little magnesium is present in the extracellular fluid (ECF). Plasma levels of

free magnesium range from 1.3 to 2.1 mEq/L, or 0.65 to 1.05 mmol/L (see Table 11-1). The intracellular fluid (ICF) has more magnesium and it has more functions inside the cells than in the blood. It is important for skeletal muscle contraction, carbohydrate metabolism, generation of energy stores, vitamin activation, blood coagulation, and cell growth. Magnesium regulation occurs through the kidney and the intestinal tract although the exact mechanisms are not known. When blood magnesium levels are low, ingested magnesium is rapidly absorbed and kidney excretion of magnesium stops. When blood magnesium levels are high, little magnesium is absorbed from food and kidney magnesium excretion increases.

Hypomagnesemia

Hypomagnesemia is an electrolyte imbalance in which the serum magnesium (Mg^{2+}) level is below 1.3 mEq/L. It is most often caused by decreased absorption of dietary magnesium or increased kidney magnesium excretion. Table 11-12 lists the specific causes of hypomagnesemia.

TABLE 11-12

Common Causes of Magnesium Imbalance

Hypomagnesemia
• Malnutrition • Starvation • Diarrhea • Steatorrhea • Celiac disease • Crohn's disease • Drugs (diuretics, aminoglycoside antibiotics, cisplatin, amphotericin B, cyclosporine) • Citrate (blood products) • Ethanol ingestion
Hypermagnesemia

• Increased magnesium intake:
  • Magnesium-containing antacids and laxatives
  • IV magnesium replacement
• Decreased kidney excretion of magnesium resulting from kidney disease

The effects of hypomagnesemia are caused by increased membrane excitability and the accompanying serum calcium and potassium imbalances. Excitable membranes, especially nerve cell membranes, may depolarize spontaneously.

Neuromuscular changes are caused by increased nerve impulse transmission. Normally, magnesium inhibits nerve impulse transmission at synapse areas. Decreased levels increase impulse transmission from nerve to nerve or from nerve to skeletal muscle. The patient has

hyperactive deep tendon reflexes, numbness and tingling, and painful muscle contractions. Positive Chvostek's and Trousseau's signs may be present because hypomagnesemia may occur with hypocalcemia (see the earlier discussion of these assessment signs of neuromuscular changes on p. 168 in the Hypocalcemia section). The patient may have tetany and seizures as hypomagnesemia worsens.

Intestinal changes are from decreased intestinal smooth muscle contraction. Reduced motility, anorexia, nausea, constipation, and abdominal distention are common. A paralytic ileus may occur when hypomagnesemia is severe.

Interventions for hypomagnesemia aim to correct the imbalance and manage the specific problem that caused it. In addition, because hypocalcemia often occurs with hypomagnesemia, interventions also aim to restore normal serum calcium levels.

Drugs that promote magnesium loss, such as high-ceiling (loop) diuretics, osmotic diuretics, aminoglycoside antibiotics, and drugs containing phosphorus, are discontinued. Magnesium is replaced intravenously with magnesium sulfate ($MgSO_4$) when hypomagnesemia is severe. Assess deep tendon reflexes at least hourly in the patient receiving IV magnesium to monitor effectiveness and prevent hypermagnesemia. If hypocalcemia is also present, drug therapy to increase serum calcium levels is prescribed.

Hypermagnesemia

Hypermagnesemia is an electrolyte imbalance in which the serum magnesium level is above 2.1 mEq/L. Table 11-12 lists the specific causes of hypermagnesemia.

Magnesium is a membrane stabilizer. Most manifestations of hypermagnesemia occur as a result of reduced membrane excitability. They usually are not apparent until serum magnesium levels exceed 4 mEq/L.

Cardiac changes include bradycardia, peripheral vasodilation, and hypotension. These problems become more severe as serum magnesium levels increase. ECG changes show a prolonged PR interval with a widened QRS complex. Bradycardia can be severe, and cardiac arrest is possible. Hypotension is also severe, with a diastolic pressure lower than normal. *Patients with severe hypermagnesemia are in grave danger of cardiac arrest.*

Central nervous system changes result from depressed nerve impulse transmission. Patients may be drowsy or lethargic. Coma may occur if the

imbalance is prolonged or severe.

Neuromuscular changes include reduced or absent deep tendon reflexes. Voluntary skeletal muscle contractions become progressively weaker and finally stop.

Hypermagnesemia has no direct effect on the lungs; however, when the respiratory muscles are weak, respiratory insufficiency can lead to respiratory failure and death.

Interventions for hypermagnesemia focus on reducing the serum level and correcting the underlying problem that caused the imbalance. All oral and parenteral magnesium is discontinued. When kidney failure is not present, giving magnesium-free IV fluids can reduce serum magnesium levels. High-ceiling (loop) diuretics such as furosemide (Lasix, Furoside) can further reduce serum magnesium levels. When cardiac problems are severe, giving calcium may reverse the cardiac effects of hypermagnesemia.

Chloride

Chloride (Cl^-) is the major anion of the extracellular fluid (ECF) and works with sodium to maintain ECF osmotic pressure. The normal plasma concentration of chloride ranges from 98 to 106 mEq/L or mmol/L (see Table 11-1). It enters the body through dietary intake and is important in the formation of hydrochloric acid in the stomach.

Only a small amount of chloride is present inside the cells because negative charges on the cell membrane repel chloride and prevent it from crossing the membrane. However, extracellular chloride can enter cells when exchanged for another anion that is leaving the cell. This situation, called a *chloride shift*, decreases plasma chloride without a net body loss of chloride. Bicarbonate (HCO_3^-) is the anion most commonly exchanged for chloride.

Imbalances of chloride usually occur as a result of other electrolyte imbalances. An exception is chloride loss from excessive vomiting or prolonged gastric suction. Imbalances of chloride are usually corrected by interventions for correcting other electrolyte or acid-base problems.

Clinical Judgment Challenge

Patient-Centered Care; Safety QSEN

The patient is a 29-year-old woman admitted 20 hours ago for an acute exacerbation of Crohn's disease with intense abdominal pain. She is

NPO and receiving normal saline intravenously at 175 mL per minute. She was last given hydromorphone (Dilaudid) 4 mg IV 30 minutes ago. Because she did have an episode of hypotension earlier after Dilaudid, you now take her vital signs. On inflating the blood pressure cuff, she develops palmar flexion. The flexion remains after the cuff is deflated.

1. What is most likely the cause of this problem?
2. What electrolytes are most likely to be out of balance and why?
3. What is your best first action?
4. Should the Rapid Response Team be called? Why or why not?
5. What additional assessment data are most important to collect? Explain your selection.

Nursing Concepts and Clinical Judgment Review

What might you NOTICE in a patient who has adequate fluid and electrolyte balance?

Vital signs:

- Heart rate and rhythm within usual range for the patient
- Respiratory rate and depth within usual range for the patient

Physical assessment:

- Skin turgor normal, no tenting, no edema
- Skin color normal (no cyanosis or pallor)
- Oral mucous membrane and nail beds pink with rapid capillary refill
- Strong and equal peripheral pulses
- Deep tendon reflexes present and normal
- Muscle strength consistent with what is normal for the patient
- Urine output about equal to fluid intake

Psychological assessment:

- Oriented and not confused
- Easily aroused from sleep

Laboratory assessment:

- Serum electrolyte values within normal limits
- Normal electrocardiogram

Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Assess any patient with a problem of fluid and electrolyte balance for falls risk.
- Ensure access to adequate fluids for patients who cannot talk or who have limited mobility.
- Supervise the oral fluid therapy and intake and output measurement aspects of care delegated to unlicensed assistive personnel.
- Use a pump or controller to deliver IV fluids to patients with fluid overload. **Safety** QSEN
- Do not give IV potassium at a rate greater than 20 mEq/hr.
- Never give potassium supplements by the IM, subcutaneous, or IV push routes. **Safety** QSEN
- Use a pump or controller when giving IV potassium-containing solutions. **Safety** QSEN
- Use a gait belt when assisting a patient with muscle weakness to walk or transfer. **Safety** QSEN
- Collaborate with the dietitian to teach patients about diets that are restricted in potassium, sodium, or calcium.
- Use a lift sheet to move or reposition a patient with chronic hypocalcemia. **Safety** QSEN

Health Promotion and Maintenance

- Encourage all patients to maintain an adequate fluid intake (minimum of 2 L per day) unless another condition requires fluid restriction.
- Teach all people to increase fluid intake when exercising, when in hot or dry environments, or during conditions that increase metabolism (e.g., fever).
- Instruct patients at risk for fluid imbalance to weigh themselves on the same scale daily, close to the same time each day, and with about the same amount of clothing on each time and to monitor these daily weights for changes or trends. **Patient-Centered Care** QSEN
- Instruct patients who exercise heavily (athletes) to take scheduled fluid replacement breaks.
- Instruct caregivers of older adults who have cognitive impairments or mobility problems to schedule offerings of fluids at regular intervals throughout the day. **Patient-Centered Care** QSEN

- Teach patients how to determine electrolyte content of processed foods by reading labels.
- Teach patients who are prescribed to take diuretics to take the drugs as prescribed.
- Teach patients who are taking digoxin to measure their pulse for rate, rhythm, and quality.
- Teach patients who are taking diuretics to measure their pulse for rate, rhythm, and quality.

Psychosocial Integrity

- Explain the purpose of fluid restriction to the patient and the family to ensure cooperation and prevent any misunderstandings.
- Assess patients who have a sudden change in cognition for a change in fluid and electrolyte balance. **Safety** QSEN
- Determine the patient's food preferences and dislikes when planning an electrolyte-restricted diet.

Physiological Integrity

- Assess skin turgor on the forehead or the sternum of older patients.
- Use daily weights to determine fluid gains or losses. **Evidence-Based Practice** QSEN
- Ask patients about the use of drugs such as diuretics, laxatives, salt substitutes, and antihypertensives that may alter fluid and electrolyte balance.
- Correctly interpret laboratory electrolyte values.
- Do not give oral fluids to an unconscious patient.
- Monitor the cardiac and pulmonary status at least every hour when patients with dehydration are receiving IV fluid replacement therapy.
- Offer or ensure that oral care is performed at least every 4 hours for patients with dehydration.
- Assess the IV site hourly of a person receiving IV solutions containing potassium, and document its condition. **Safety** QSEN
- Immediately stop the infusion of potassium-containing solutions if infiltration is suspected.
- Assess all patients with hyperkalemia for cardiac dysrhythmias and ECG abnormalities, especially tall T waves, conduction delays, and heart block.
- Assess the respiratory status of all patients with hypokalemia.
- Assess the bowel sounds; heart rate, rhythm and quality; and muscle strength to evaluate the patient's responses to therapy for an electrolyte

imbalance.

CHAPTER 12

Assessment and Care of Patients with Acid-Base Imbalances

M. Linda Workman

PRIORITY CONCEPTS

- Acid-Base Balance

Learning Outcomes

Safe and Effective Care Environment

1. Identify patients at risk for falls as a result of problems with acid-base balance, especially older adults.

Health Promotion and Maintenance

2. Teach patients measures to take to maintain acid-base balance and avoid imbalances.

Psychosocial Integrity

3. Reduce the psychological impact for the patient experiencing a problem with acid-base balance.

Physiological Integrity

4. Apply knowledge of anatomy and physiology to explain regulation of acid-base balance.
5. Assess the patient for acid-base balance status, using laboratory data and clinical manifestations.
6. Prioritize nursing care for the patient with a problem affecting acid-base balance.

http://evolve.elsevier.com/Iggy/

Acid-base balance occurs through control of hydrogen ion (H^+) production and elimination. Body fluid **pH** is a measure of the body fluid's free hydrogen ion level. *This value has the narrowest range of normal and the tightest control mechanisms of all the electrolytes.* The level of free hydrogen ions, formed from acids, must be rigidly controlled. Even small changes in the free hydrogen ion level (pH) of body fluids can cause major problems in function. Keeping the pH within the normal range involves balancing acids and bases in body fluids. Normal pH ranges from 7.35 to 7.45 for arterial blood and from 7.31 to 7.41 for venous blood.

The normal free hydrogen ion level of blood and other body fluids is quite low (less than 0.0001 mEq/L) compared with other electrolytes (see Chapter 11). Because it is so low, the hydrogen ion concentration is not measured directly but, instead, is calculated in negative logarithm units. The value of pH is *inversely* related (negatively related) to the level of free hydrogen ions. Thus the *lower* the pH value of a fluid, the *higher* the level of free hydrogen ions in that fluid. The pH of a solution may range from 1 (as acidic as possible) to 14 (as alkaline as possible), with 7 being neutral. *A change of 1 pH unit actually represents a tenfold change in free hydrogen ion level.* Therefore any pH unit change (e.g., a change from 7.4 to 7.3) represents a large increase in the free hydrogen ion level.

Keeping the pH of the blood within the normal range by regulating acid-base balance is important because changes from normal interfere with many functions. These include:

- Changing the shape and reducing the function of hormones and enzymes
- Changing the distribution of other electrolytes, causing fluid and electrolyte imbalances
- Changing excitable membranes, making the heart, nerves, muscles, and GI tract either less or more active than normal
- Decreasing the effectiveness of many drugs

Acid-Base Balance

Most body fluids have a pH value between 7.35 and 7.45 even though they contain acidic substances and basic substances. This value is slightly alkaline rather than strictly neutral (7.0 is neutral). Normal body fluid pH remains at this near-neutral value when the acids and bases are nearly balanced, limiting the total number of free or unbalanced hydrogen ions. Acid-base balance occurs by matching the rate of hydrogen ion production (which is a continuous normal process) with hydrogen ion loss.

Acid-Base Chemistry

Acids

Acids are substances that release hydrogen ions when dissolved in water (H_2O), *increasing* the amount of free hydrogen ions in that solution. The strength of an acid is measured by how easily it releases a hydrogen ion in solution. A strong acid, such as hydrochloric acid (HCl), separates completely in water and releases *all* of its hydrogen ions, as shown in Fig. 12-1.

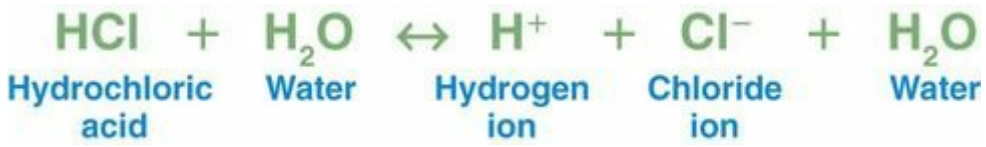

FIG. 12-1 Release of hydrogen ions by a strong acid (hydrochloric acid) in which the strong acid completely dissociates in water.

A weak acid releases only *some*, not all, of its hydrogen ions. In the following example, each molecule of acetic acid (CH_3COOH), a weak acid, contains a total of four hydrogen molecules. When acetic acid combines with water, as shown in Fig. 12-2, it releases only one of its four hydrogen molecules, keeping the other three hydrogen molecules bound to the molecule (CH_3COO^-).

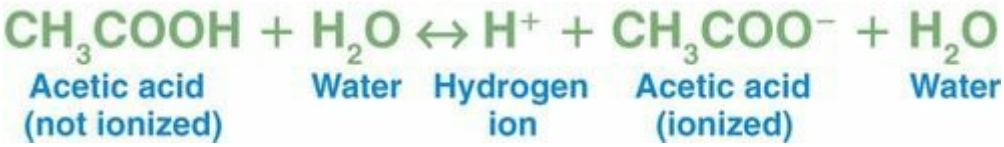

FIG. 12-2 Release of hydrogen ions by a weak acid (acetic acid) in which the weak acid only partially dissociates in water and most of its hydrogen ions remain bound.

Bases

A **base** binds free hydrogen ions in solution and *lowers* the amount of free hydrogen ions in solution. Strong bases bind hydrogen ions easily. Examples are sodium hydroxide (NaOH) and ammonia (NH_3).

Weak bases bind hydrogen ions less readily. An example of a weak base is bicarbonate (HCO_3^-). Although a weak base, the many bicarbonate ions in the body are critical in preventing major changes in body fluid pH.

Buffers

Buffers are critical in keeping body fluid pH at normal levels because they can react either as an acid (releasing a hydrogen ion) or as a base (binding a hydrogen ion). How a buffer reacts depends on the existing acid-base balance of that fluid. Buffers always try to bring the fluid as close as possible to the normal body fluid pH of 7.35 to 7.45. If the fluid is basic (with few free hydrogen ions), the buffer *releases hydrogen ions* into the fluid (Fig. 12-3). If the fluid is acidic (with many free hydrogen ions), the buffer *binds some of the excess hydrogen ions*. In this way, buffers act like hydrogen ion "sponges," soaking up hydrogen ions when too many are present and squeezing out hydrogen ions when too few are present. This flexibility allows buffers to keep body fluid pH in the normal range.

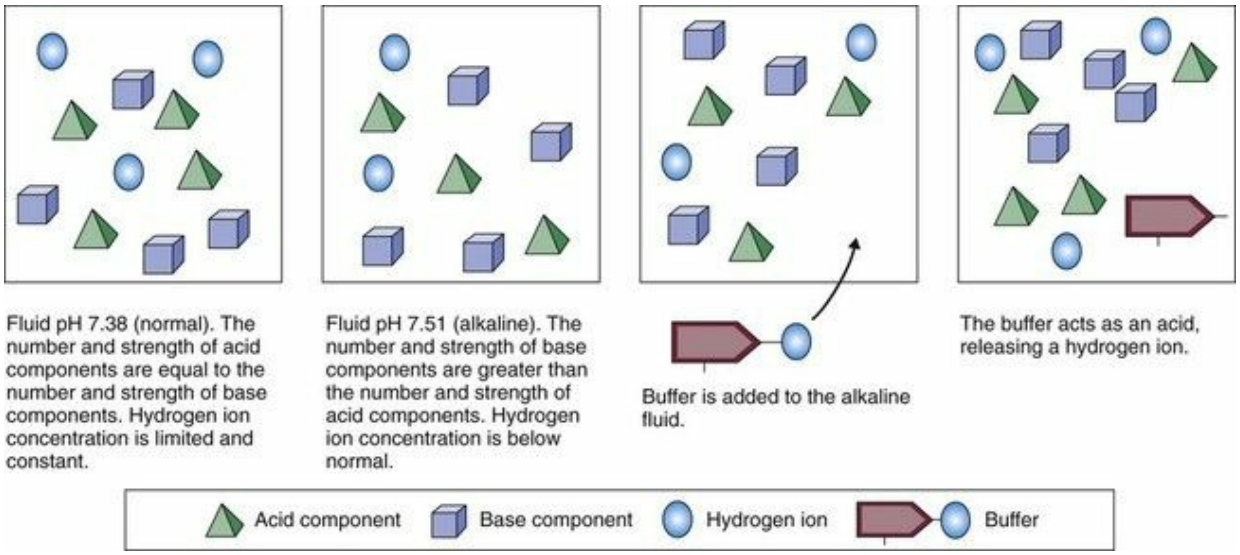

FIG. 12-3 Action of buffer in solution.

Liquids with a pH of 7.0 are neutral by having a free hydrogen ion level in which the amount and strength of acids and bases are equal. Fig. 12-4 shows the concept of neutral pH in which the combined *strength* and *amount* of all acids are equal to the combined *strength* and *amount* of all bases in a given solution. With human acid-base homeostasis, the relative amounts and strengths of acids and bases are nearly equal and, normally, hydrogen ion production is balanced with hydrogen ion loss so that the overall free hydrogen ion levels remain constant.

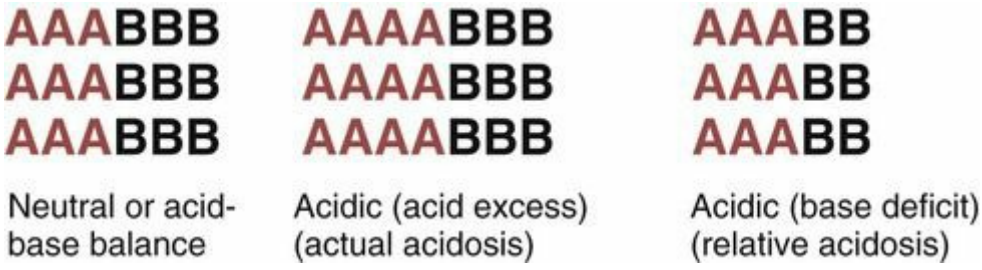

FIG. 12-4 Concept of acidic versus normal pH. (A = acid; B = base.)

Liquids with a pH ranging from 1.0 to 6.99 have more or stronger (or both) acids compared with bases. These liquids are *acidic* (see Fig. 12-4), with more free hydrogen ions released than bound, increasing the amount of free hydrogen ions in the liquid.

Liquids with a pH ranging from 7.01 to 14.0 have more or stronger (or both) bases compared with acids. These liquids are *basic,* in which more hydrogen ions are being bound than released, decreasing the amount of free hydrogen ions (Fig. 12-5).

FIG. 12-5 Concept of alkaline versus normal pH. (A = acid; B = base.)

Body Fluid Chemistry

Bicarbonate Ions

Body fluids contain different types of acids and bases. The most common base in human body fluid is bicarbonate (HCO_3^-); the most common acid is carbonic acid (H_2CO_3). In health, the body keeps these substances at a constant ratio of 1 molecule of carbonic acid to 20 free bicarbonate ions (1 : 20) (Fig. 12-6). To maintain this ratio, both carbonic acid and bicarbonate must be carefully controlled. This constant ratio is related to balancing the production and elimination of carbon dioxide (CO_2) and hydrogen ions (H^+).

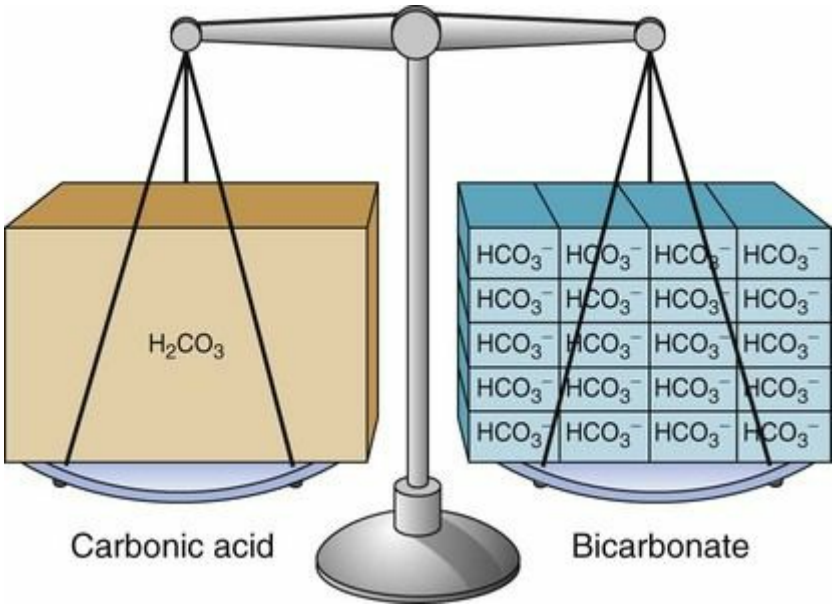

FIG. 12-6 Normal ratio of carbonic acid to bicarbonate is 1 : 20.

Relationship Between Carbon Dioxide and Hydrogen Ions

A key process in understanding acid-base balance is the carbonic anhydrase

equation. This equation, driven by the enzyme *carbonic anhydrase,* shows how hydrogen ion levels and carbon dioxide levels are directly related to one another, so that an increase in one causes an equal increase in the other (Fig. 12-7).

FIG. 12-7 The carbonic anhydrase equation showing that the concentration of carbon dioxide is directly related to the concentration of hydrogen ions.

Carbon dioxide is a gas that forms carbonic acid when combined with water, making carbon dioxide a part of carbonic acid. Carbonic acid is not stable, and the body needs to keep a 1 : 20 ratio of carbonic acid to bicarbonate. When carbonic acid is formed from water and carbon dioxide, it begins to separate into free hydrogen ions and bicarbonate ions. *Therefore the carbon dioxide content of a fluid is directly related to the amount of hydrogen ions in that fluid. Whenever conditions cause carbon dioxide to increase, more free hydrogen ions are created. Likewise, whenever free hydrogen ion production increases, more carbon dioxide is produced.*

When excess carbon dioxide is produced, the equation shifts to the *right,* causing an *increase* in hydrogen ions (and a *decrease* in pH), as shown in Fig. 12-8. When very little carbon dioxide is produced, no free hydrogen ions are created by this equation.

FIG. 12-8 Increased carbon dioxide levels force the equation to the right and increase the concentration of hydrogen ions proportionately.

When excess hydrogen ions are present, the carbonic anhydrase equation shifts to the *left,* causing the creation of more carbon dioxide, as shown in Fig. 12-9. When the amount of free hydrogen ions in body fluids is low, no extra carbon dioxide is produced.

FIG. 12-9 Increased hydrogen ion levels force the equation to the left and increase the concentration of carbon dioxide levels proportionately.

How is the relationship between free hydrogen ions and carbon dioxide helpful? Carbon dioxide is a gas that can be eliminated during exhalation, and this action is important for acid-base balance. When any condition causes the hydrogen ion concentration of body fluids to increase, extra CO_2 is produced in the same proportion. This extra CO_2 is eliminated during exhalation, helping to bring the hydrogen ion concentration down to normal. Whenever the CO_2 level changes, the pH changes to the same degree, in the opposite direction. Thus when the CO_2 level of a liquid increases, the pH drops, indicating more free hydrogen ions (more acidic). Likewise, when the CO_2 level of a liquid decreases, the pH rises, indicating fewer free hydrogen ions (more alkaline).

An increase in bicarbonate causes the amount of hydrogen ions to decrease and the pH to increase, or become more alkaline (basic). Likewise, a decrease in bicarbonate causes the free hydrogen ion level to increase and the pH to decrease, or become more acidic.

Because the kidneys control bicarbonate levels and the lungs control CO_2 levels in the healthy person, pH is also described as the function of the kidneys divided by the function of the lungs (Fig. 12-10).

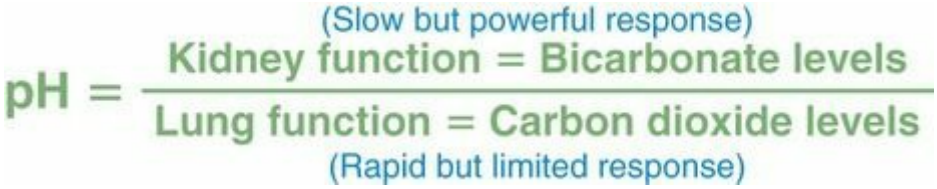

FIG. 12-10 Contribution of pH balance by kidney and lung function.

Sources of Acids and Bicarbonate

When acids are present in body fluids, free hydrogen ions are released and must be controlled for pH balance. Acids and hydrogen ions are produced continuously through normal body physiologic work and metabolism.

Normal metabolism of carbohydrate, protein, and fat creates natural waste products. Carbohydrate metabolism forms carbon dioxide (CO_2). Carbon dioxide is exhaled by the lungs during breathing. One factor that determines blood pH is how much CO_2 is produced by body cells during metabolism versus how rapidly that CO_2 is removed by breathing. Protein breakdown forms sulfuric acid. Fat breakdown forms fatty acids and ketoacids.

Incomplete breakdown of glucose, which occurs whenever cells metabolize under **anaerobic** (no oxygen) conditions, forms lactic acid. Anaerobic conditions occur with hypoxia, sepsis, and shock. Incomplete breakdown of fatty acids, occurring when large amounts of fatty acids are being metabolized, forms ketoacids.

Cell destruction allows cell contents to be released, including the structures that contain acids. These released acids in the extracellular fluid (ECF) increase free hydrogen ion levels.

Bicarbonate, a weak base, is the main buffer of the ECF. It comes from the GI absorption of ingested bicarbonate, pancreatic production of bicarbonate, movement of cellular bicarbonate into the ECF, kidney reabsorption of filtered bicarbonate, and the breakdown of carbonic acid. Once bicarbonate is in the ECF, it is kept at a level 20 times greater than that of carbonic acid.

Acid-Base Regulatory Actions and Mechanisms

As long as body cells are healthy, they continuously produce acids, carbon dioxide, and free hydrogen ions. Despite this production, hydrogen ion, bicarbonate, oxygen, and carbon dioxide levels are kept within normal limits when acid-base balance controlling actions are normal. Chart 12-1 lists their normal values in arterial and venous blood. This homeostasis depends on:

Chart 12-1

Laboratory Profile

Acid-Base Assessment

TEST	NORMAL RANGE FOR ADULTS: ARTERIAL	VENOUS	SIGNIFICANCE OF ABNORMAL FINDINGS
pH			
Adult <90 yr	7.35-7.45	7.31-7.41	Increased: metabolic alkalosis, loss of gastric fluids, decreased potassium intake, diuretic therapy, fever, salicylate toxicity, respiratory alkalosis, hyperventilation Decreased: metabolic or respiratory acidosis, ketosis, renal failure, starvation, diarrhea, hyperthyroidism
>90 yr	7.25-7.45	7.31-7.41	
Pa_{O_2}			
Adult <90 yr	80-100 mm Hg		Increased: increased ventilation, oxygen therapy, exercise Decreased: respiratory depression, high altitude, carbon monoxide poisoning, decreased cardiac output
>90 yr	70-90 mm Hg		
$Paco_2$	35-45 mm Hg	40-50 mm Hg	Increased: respiratory acidosis, emphysema, pneumonia, cardiac failure, respiratory depression Decreased: respiratory alkalosis, excessive ventilation, diarrhea
Bicarbonate	21-28 mEq/L	24-29 mEq/L	Increased: metabolic alkalosis, bicarbonate therapy Decreased: metabolic acidosis, diarrhea, pancreatitis
Lactate	3-7 mg/dL	5-20 mg/dL	Increased: hypoxia, exercise, insulin infusion, alcoholism, pregnancy Decreased: fluid overload
	0.3-0.8 mmol/L	0.6-2.2 mmol/L	

$Paco_2$, Partial pressure of arterial carbon dioxide; *Pa_{O_2}*, partial pressure of arterial oxygen.

Data from Pagana, K., & Pagana, T. (2014). *Mosby's manual of diagnostic and laboratory tests* (5th ed). St. Louis: Mosby.

- Hydrogen ion production being consistent and not excessive
- CO_2 loss from the body through breathing keeping pace with all forms of hydrogen ion production

To keep the free hydrogen ion level (pH) of the ECF within the narrow normal range, the body has chemical, respiratory, and kidney actions (mechanisms) for acid-base balance (Table 12-1).

TABLE 12-1

Acid-Base Regulatory Mechanisms

MECHANISM TYPE	KEY CHARACTERISTICS
Chemical	
Protein buffers (albumin, globulins, hemoglobin) Chemical buffers (bicarbonate, phosphate)	Very rapid response Provide immediate response to changing conditions Can handle relatively small fluctuations in hydrogen ion production during normal metabolic and health conditions
Respiratory	
Increased hydrogen ions or increased carbon dioxide: Triggers the brain to increase the rate and depth of breathing, causing more carbon dioxide to be lost and decreasing the hydrogen ion concentration Decreased hydrogen ions or decreased carbon dioxide: Inhibits brain stimulation, leading to decreased rate and depth of breathing, causing carbon dioxide to be retained and increasing the hydrogen ion concentration	Primarily assist buffering systems when the fluctuation of hydrogen ion concentration is acute
Kidney	
Actions to decrease pH: Increased kidney excretion of bicarbonate Increased kidney reabsorption of hydrogen ions Actions to increase pH: Decreased kidney excretion of bicarbonate Decreased kidney reabsorption of hydrogen ions	The most powerful regulator of acid-base balance Respond to large or chronic fluctuations in hydrogen ion production or elimination Slowest response (hours to days) Longest duration

Chemical Acid-Base Control Actions and Mechanisms

Buffers are the first line of defense against changes in free hydrogen ion levels. These buffers are always present in body fluids and act fast to reduce or raise the amount of free hydrogen ions to normal. By acting as hydrogen ion "sponges," buffers can bind hydrogen ions when too many are present or release hydrogen ions when not enough are present.

Buffers are composed of chemicals or proteins. The two most common chemical buffers are bicarbonate (which is active in both the extracellular fluid [ECF] and intracellular fluid [ICF]) and phosphate (which is active in the ICF). Protein buffers are the most common buffers. Extracellular protein buffers are albumin and globulins. A major intracellular protein buffer is hemoglobin. When the amount of free hydrogen ions in the blood increases, some of the excess hydrogen ions cross the membranes of red blood cells and bind to the large numbers of hemoglobin molecules in each red blood cell. This binding of hydrogen ions to hemoglobin results in fewer hydrogen ions remaining in the blood, bringing blood pH back up toward normal.

Respiratory Acid-Base Control Actions and Mechanisms

When chemical buffers alone cannot prevent changes in blood pH, the respiratory system is the second line of defense against changes. Breathing controls the amount of free hydrogen ions by controlling the amount of carbon dioxide (CO_2) in arterial blood. Because CO_2 is converted into hydrogen ions with the carbonic anhydrase reaction, the CO_2 level is *directly* related to the hydrogen ion level. Breathing rids the body of any excess CO_2.

The CO_2 level in venous blood increases with metabolism. This CO_2 moves into lung capillary blood. Because the amount (pressure) of CO_2 is far higher in lung capillary blood than it is in the air in the alveoli, CO_2 diffuses freely from the blood into the alveolar air. Once in the alveoli, CO_2 is exhaled during breathing and is lost from the body. Because the amount (pressure) of CO_2 in room air is nearly zero, CO_2 can continue to be exhaled even when breathing is impaired.

Respiratory regulation of acid-base balance is under the control of the central nervous system (Fig. 12-11). Special receptors in the respiratory areas of the brain are sensitive to changes in the amount of CO_2 in brain tissues. As the amount of CO_2 begins to rise above normal in brain blood and tissues, these central receptors trigger the neurons to increase the rate and depth of breathing **(hyperventilation).** As a result, more CO_2 is

exhaled ("blown off") from the lungs and the CO_2 level in the ECF decreases. When the arterial CO_2 level returns back down to normal, the rate and depth of breathing return to levels that are normal for the person.

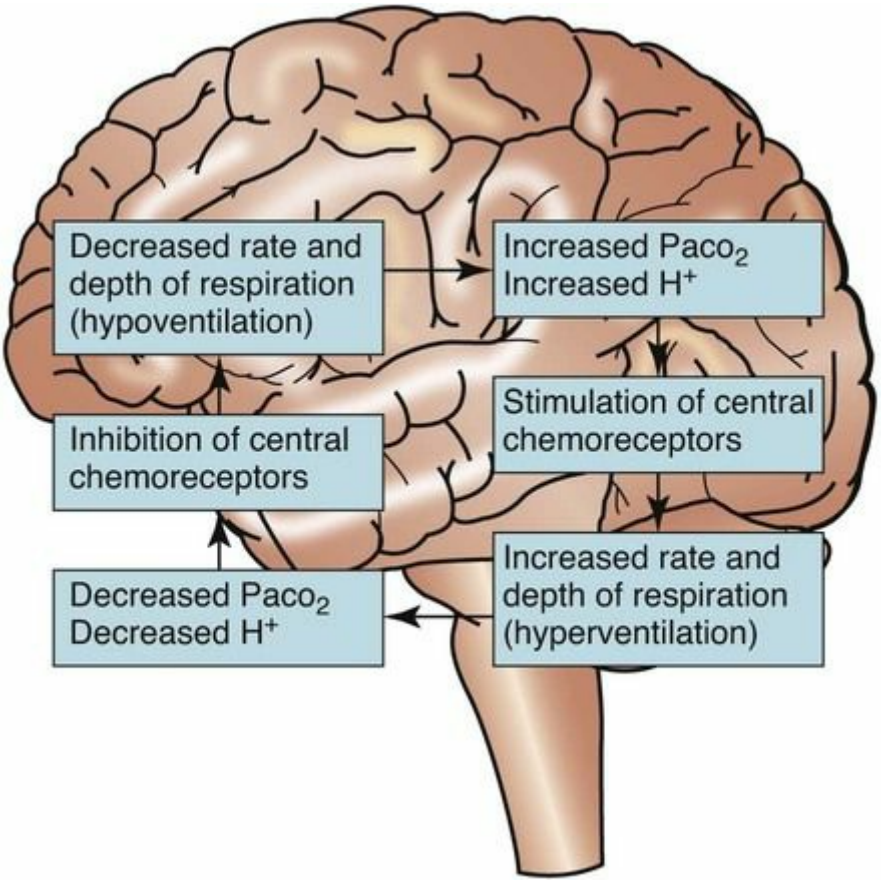

FIG. 12-11 Neural regulation of respiration and hydrogen ion concentration. (H^+, Hydrogen ion, $Paco_2$, partial pressure of arterial carbon dioxide.)

If the amount of ECF free hydrogen ions is too low, then the CO_2 level also is too low. Central receptors sense these low CO_2 levels and stop or slow the neuron activity in the respiratory centers of the brain, decreasing the rate and depth of breathing **(hypoventilation).** As a result, less CO_2 is lost through the lungs and more CO_2 is retained in arterial blood. This retention of already-formed CO_2, together with the normal production of CO_2 from metabolism, results in a rapid return of the arterial CO_2 levels (and hydrogen ion levels) back up to normal. When these levels are normal, the rate and depth of breathing also return to normal levels.

The respiratory system's response in acid-base balance is rapid.

Changes in the rate and depth of breathing occur within minutes after changes in the hydrogen ion level or CO_2 level of the ECF occur.

Kidney Acid-Base Control Actions and Mechanisms

The kidneys are the third line of defense against wide changes in body fluid pH. Kidney actions are stronger for regulating acid-base balance but take 24 to 48 hours to completely respond. When blood pH changes are persistent, kidney actions to increase excretion and reabsorption rates of acids or bases (depending on which way pH changes) start. These actions are kidney movement of bicarbonate, formation of acids, and formation of ammonium.

Kidney movement of bicarbonate is the first kidney pH control action. It occurs in the kidney tubules in two ways: (1) kidney movement of bicarbonate produced elsewhere in the body and (2) kidney movement of bicarbonate produced in the kidneys. Much of the bicarbonate made in other body areas is excreted in the urine. When blood hydrogen ion levels are high, this bicarbonate is reabsorbed from the kidneys back into circulation, where it can help buffer excess hydrogen ions. The kidney tubules also can make additional bicarbonate and reabsorb it to increase the buffer effect. When blood hydrogen ion levels are low, the bicarbonate stays in the urine and is excreted.

Formation of acids occurs through the phosphate-buffering system inside the cells of the kidney tubules. When the newly created bicarbonate made in kidney cells is reabsorbed into the blood, the urine has an excess of anions, including phosphate (HPO_4^{2-}). This negatively charged fluid draws hydrogen ions (which have a positive charge) into the urine. Once in the urine, the hydrogen ion binds to phosphate ions, forming an acid (H_2PO_4) that is then excreted in the urine.

Formation of ammonium converts the ammonia (NH_3), which is formed during normal protein breakdown, into ammonium (NH_4^+) in the urine. The ammonium "traps" the hydrogen ions and then allows them to be excreted in the urine. The result is a loss of hydrogen ions and an increase in blood pH.

Compensation

In the process of *compensation,* the body adapts to attempt to correct changes in blood pH and maintain acid-base balance. A pH below 6.9 or above 7.8 is usually fatal. The normal pH range for human extracellular fluid (ECF) is 7.35 to 7.45. Both the kidneys and the lungs can compensate for

acid-base imbalances, but they are not equal in their final responses. The respiratory system is much more sensitive to acid-base changes and can begin compensation efforts within seconds to minutes after a change in pH. However, these efforts are limited and can be overwhelmed easily. The kidney compensatory actions are much more powerful and result in rapid changes in ECF composition. However, these more powerful actions are not fully triggered unless the acid-base imbalance continues for several hours to several days.

Respiratory compensation occurs through the lungs, usually to correct for acid-base imbalances from metabolic problems. For example, when prolonged running causes buildup of lactic acid, hydrogen ion levels in the ECF increase and the pH drops. To bring the pH back to normal, breathing is triggered in response to increased carbon dioxide levels. Both the rate and depth of respiration increase. These respiratory efforts cause the blood to lose carbon dioxide with each exhalation, so ECF levels of carbon dioxide and free hydrogen ions gradually decrease. When the lungs can *fully compensate,* the pH returns to normal.

Kidney compensation results when a healthy kidney works to correct for changes in blood pH that occur when the respiratory system either is overwhelmed or is not healthy. For example, in a person with chronic obstructive pulmonary disease (COPD), the respiratory system cannot exchange gases adequately. Carbon dioxide is retained continuously, hydrogen ion levels increase, and the blood pH falls (becomes more acidic). To oppose this process, the kidney excretes more hydrogen ions and increases the reabsorption of bicarbonate back into the blood. As a result, the blood pH remains either within or closer to the normal range. When these backup actions are completely effective, acid-base problems are *fully compensated* and the pH of the blood returns to normal even though the levels of oxygen and bicarbonate may be abnormal (Blevins, 2014).

Sometimes, however, the respiratory problem causing the acid-base imbalance is so severe that kidney actions can only *partially compensate* and the pH is not quite normal. Partial compensation helps because it prevents the acid-base imbalance from becoming severe (Blevins, 2014).

Acid-Base Imbalances

Acid-base imbalances are problems of acid-base balance resulting from changes in the blood hydrogen ion level or pH. These changes are caused by problems with the acid-base regulatory actions or by exposure to dangerous conditions. Imbalances in which blood pH is below normal reflect **acidosis,** and imbalances in which blood pH is above normal reflect **alkalosis.** Acid-base imbalances impair the function of many organs and can be life threatening.

Acidosis

Pathophysiology

In acidosis, the acid-base balance of the blood and other extracellular fluid (ECF) is upset by an excess of hydrogen ions (H^+). This is seen as an arterial blood pH below 7.35. The amount of acids present is greater than normal compared with the amount or strength of bases.

Acidosis is not a disease; it is a condition caused by a disorder or pathologic process. It can be caused by metabolic problems, respiratory problems, or both. Patients at greatest risk for acute acidosis are those with problems that impair breathing. Older adults with chronic health problems are at greater risk for developing acidosis (Chart 12-2).

Chart 12-2 Nursing Focus on the Older Adult

The Older Patient Experiencing Acid-Base Imbalance

When Obtaining a Patient's History

- Assess risk factors for acid-base imbalance, including drugs, chronic health problems (especially kidney disease, pulmonary disease), and acute health problems.
- Ask the patient to list all prescribed and over-the-counter drugs (especially diuretics and antacids). If the patient is unable to provide this information, ask the family to bring the drugs in from home.
- Ask the patient to recall what liquids were taken in the past 24 hours and whether urination amounts have changed.

When Assessing the Patient

- Compare the patient's mental status with what the family, significant other, or health record states is the patient's baseline.
- Observe the rate and depth of respiration.

■ Determine whether the patient can complete a sentence without stopping for breath.
- Examine the color of nail beds and mucous membranes.
- Obtain a urine specimen, and observe for color and character. Test for specific gravity and pH.
- Examine skin turgor for dehydration. Attempt to pinch the skin to form a tent over the sternum and on the forehead. If a tent forms, record how long it remains.
- Measure the rate and quality of the pulse.
- Monitor clinical responses and laboratory values while the acid-base imbalance is being corrected.
- Administer IV therapy by pump or controller.

Acidosis can result from an actual or relative increase in the amount or strength of acids. An *actual acid excess* results in acidosis by either overproducing acids (and release of hydrogen ions) or undereliminating normally produced acids (retention of hydrogen ions). Either way, more hydrogen ions are present than should be. Problems that increase acid production include diabetic ketoacidosis and seizures. Problems that decrease acid elimination include respiratory impairment and kidney impairment.

In *relative* acidosis, the amount of acids does not increase. Instead, the amount or strength of the bases decreases (to create a *base deficit*), which makes the fluid relatively more acidic than basic. A relative acidosis *(base deficit)* is caused by either overeliminating or underproducing bicarbonate ions (HCO_3^-) (see Fig. 12-4). Problems that underproduce bases include pancreatitis and dehydration. A condition that overeliminates bases is diarrhea.

Regardless of its cause, acidosis causes major changes in body function. The main problems occur because hydrogen ions are positively charged ions. An increase in hydrogen ions creates imbalances of other positively charged electrolytes, especially potassium. The changes in potassium levels because of excess hydrogen ions is described in the Laboratory Assessment section for acidosis. These electrolyte imbalances then disrupt the functions of nerves, cardiac muscle, and skeletal muscle. Manifestations of acidosis first appear in the musculoskeletal, cardiac, respiratory, and central nervous systems. Even slight increases in blood hydrogen ion levels reduce the activity of many hormones and enzymes, leading to death.

Acidosis can be caused by metabolic problems, respiratory problems,

or combined metabolic and respiratory problems. Specific causes of acidosis are listed in Table 12-2.

TABLE 12-2
Common Causes of Acidosis

PATHOLOGY	CONDITION
Metabolic Acidosis	
Overproduction of hydrogen ions	Excessive oxidation of fatty acids: Diabetic ketoacidosis Starvation Hypermetabolism: Heavy exercise Seizure activity Fever Hypoxia, ischemia Excessive ingestion of acids: Ethanol or methanol intoxication Salicylate intoxication
Underelimination of hydrogen ions	Kidney failure
Underproduction of bicarbonate	Kidney failure Pancreatitis Liver failure Dehydration
Overelimination of bicarbonate	Diarrhea
Respiratory Acidosis	
Underelimination of hydrogen ions	Respiratory depression: Anesthetics Drugs (especially opioids) Electrolyte imbalance Inadequate chest expansion: Muscle weakness Airway obstruction Alveolar-capillary block

Metabolic Acidosis

Four processes can result in metabolic acidosis: overproduction of hydrogen ions, underelimination of hydrogen ions, underproduction of bicarbonate ions, and overelimination of bicarbonate ions.

Overproduction of hydrogen ions can occur with excessive breakdown of fatty acids, anaerobic glucose breakdown *(lactic acidosis)*, and excessive intake of acids. Excessive breakdown of fatty acids occurs with diabetic ketoacidosis or starvation. When insufficient glucose is available for fuel, the body breaks down fats (lipids). The products of excessive fatty acid breakdown are strong acids *(ketoacids)*, which release large amounts of hydrogen ions.

Lactic acidosis occurs when cells use glucose without adequate oxygen

(anaerobic metabolism); glucose then is incompletely broken down and forms lactic acid. This acid releases hydrogen ions, causing acidosis. Lactic acidosis occurs whenever the body has too little oxygen to meet metabolic oxygen demands (e.g., heavy exercise, seizure activity, reduced oxygen).

Excessive intake of acids floods the body with hydrogen ions. Agents that cause acidosis when ingested in excess include ethyl alcohol, methyl alcohol, and acetylsalicylic acid (aspirin).

Underelimination of hydrogen ions leads to acidosis when hydrogen ions are produced at the normal rate but are not removed at the same rate they are produced. Most hydrogen ion loss occurs through the lungs and the kidneys. Kidney failure causes acidosis when the kidney tubules cannot secrete hydrogen ions into the urine and they are retained. Severe lung problems also can result in retention of CO_2 with a corresponding retention of hydrogen ions.

Underproduction of bicarbonate ions (base deficit) leads to acidosis when hydrogen ion production and removal are normal but too few bicarbonate ions are present to balance the hydrogen ions. Because bicarbonate is made in the kidneys and in the pancreas, kidney failure and impaired liver or pancreatic function can cause a base-deficit acidosis.

Overelimination of bicarbonate ions (base deficit) leads to acidosis when hydrogen ion production and removal are normal but too many bicarbonate ions have been lost. One cause of base deficit acidosis is diarrhea.

Respiratory Acidosis

Respiratory acidosis results when respiratory function is impaired and the exchange of oxygen (O_2) and carbon dioxide (CO_2) is reduced. This problem causes CO_2 retention, which leads to the same increase in hydrogen ion levels and acidosis. (See the carbonic anhydrase equation in Fig. 12-7.)

Unlike metabolic acidosis, respiratory acidosis results from only one cause—retention of CO_2, causing increased production of free hydrogen ions. Table 12-2 lists the four types of respiratory problems and their possible causes.

Respiratory depression results from depressed function of the brainstem neurons that trigger breathing movements. This lowered rate and depth of breathing leads to poor gas exchange and retention of carbon dioxide. Common causes include anesthetic agents, opioids, and poisons.

Physical respiratory depression occurs when respiratory neurons are damaged or destroyed by trauma or when problems in the brain increase the intracranial pressure. Problems causing cerebral edema and respiratory depression include brain tumors, cerebral aneurysm, stroke, and overhydration.

Inadequate chest expansion reduces gas exchange and leads to acidosis. Chest expansion can be restricted by skeletal trauma or deformities, respiratory muscle weakness, or external constriction. Respiratory muscle weakness, caused by electrolyte imbalances, fatigue, muscular dystrophy, muscle damage, or muscle breakdown, reduces chest movement. External conditions, such as casts, tight scar tissue around the chest, obesity, and ascites, can restrict chest movement.

Airway obstruction prevents air movement into and out from the lungs *(ventilation)* and leads to poor gas exchange, CO_2 retention, and acidosis. External obstruction can be caused by clothing, neck edema, and local lymph node enlargement. Internal obstruction can be caused by aspiration of foreign objects, bronchoconstriction, mucus, and edema.

Reduced alveolar-capillary diffusion causes poor gas exchange and leads to CO_2 retention and acidosis. Disorders that reduce diffusion include pneumonia, pneumonitis, tuberculosis, emphysema, acute respiratory distress syndrome, chest trauma, pulmonary emboli, pulmonary edema, and drowning.

Combined Metabolic and Respiratory Acidosis

Metabolic and respiratory acidosis can occur at the same time. Uncorrected acute respiratory acidosis always leads to poor oxygenation and lactic acidosis (McCance et al., 2014). For example, a person who has diabetic ketoacidosis and chronic obstructive pulmonary disease has a combined metabolic and respiratory acidosis. Combined acidosis is more severe than either metabolic acidosis or respiratory acidosis alone.

Patient-Centered Collaborative Care

Assessment

History.

Collect data about risk factors related to the development of acidosis. Information about age, nutrition, and current manifestations are especially important.

Older adults are more at risk for problems leading to acid-base

imbalance, including cardiac, kidney, or pulmonary impairment. Also, older adults may be taking drugs that disrupt acid-base balance, especially diuretics and aspirin. Ask about specific risk factors, such as any type of breathing problem, kidney failure, diabetes mellitus, diarrhea, pancreatitis, and fever.

Obtain a detailed nutrition history to determine total caloric intake and the proportions of carbohydrates, fats, and proteins ingested. Ask whether the patient has fasted or followed a strict diet within the past week.

Ask about headaches, behavior changes, increased drowsiness, reduced alertness, reduced attention span, lethargy, anorexia, abdominal distention, nausea or vomiting, muscle weakness, or increased fatigue. Ask the patient to relate activities of the previous 24 hours to identify activity intolerance, behavior changes, and fatigue. Because the central nervous system is often depressed in acidosis, you may need to obtain this information from the patient's family.

Physical Assessment/Clinical Manifestations.

Manifestations of acidosis are similar whether the cause is metabolic or respiratory (Chart 12-3). Acidosis reduces the ability of excitable membranes to respond appropriately, especially in cardiovascular tissue, neurons, skeletal muscle, and GI smooth muscle.

Chart 12-3 Key Features

Acidosis

Cardiovascular Manifestations

- Delayed electrical conduction:
  - Ranges from bradycardia to heart block
  - Tall T waves
  - Widened QRS complex
  - Prolonged PR interval
- Hypotension
- Thready peripheral pulses

Central Nervous System Manifestations

- Depressed activity (lethargy, confusion, stupor, coma)

Neuromuscular Manifestations

- Hyporeflexia

- Skeletal muscle weakness
- Flaccid paralysis

Respiratory Manifestations

- Kussmaul respirations (in metabolic acidosis with respiratory compensation)
- Variable respirations (generally ineffective in respiratory acidosis)

Integumentary Manifestations

- Warm, flushed, dry skin in metabolic acidosis
- Pale to cyanotic and dry skin in respiratory acidosis

Cardiovascular changes are first seen with mild acidosis and are more severe as the condition worsens. Early changes include increased heart rate and cardiac output. With worsening acidosis or with acidosis and **hyperkalemia** (elevated blood potassium levels), heart rate decreases, T waves become tall and peaked, and QRS complexes are widened. Peripheral pulses may be hard to find and are easily blocked. Hypotension occurs with vasodilation.

Nursing Safety Priority QSEN

Critical Rescue

Assess the cardiovascular system first in any patient at risk for acidosis, because acidosis can lead to cardiac arrest from the accompanying hyperkalemia.

Central nervous system (CNS) changes include depression of CNS function. Problems may range from lethargy to confusion, especially in older patients. As acidosis worsens, the patient may become unresponsive. Assess the patient's mental status (see Chapter 41).

Neuromuscular changes include reduced muscle tone and deep tendon reflexes as a result of the accompanying hyperkalemia. Assess arm muscle strength and leg muscle strength. Test arm muscle strength by having the patient squeeze your hand. Test leg muscle strength by having the patient push both feet against a flat surface (like a box or a board) while you apply resistance to the opposite side of the flat surface. Muscle weakness is bilateral and can progress to paralysis.

Respiratory changes may cause the acidosis and can be caused by the acidosis. Assess the patient's rate, depth, and ease of breathing. Use pulse oximetry to determine how well oxygen is delivered to the

peripheral tissues.

If acidosis is metabolic in origin, the rate and depth of breathing increase as the hydrogen ion level rises. Breaths are deep and rapid and not under voluntary control, a pattern called **Kussmaul respiration.**

If acidosis is caused by respiratory problems, breathing efforts are reduced. Respirations are usually shallow and rapid. Muscle weakness makes this problem worse.

Skin changes occur with metabolic or respiratory acidosis. With metabolic acidosis, breathing is unimpaired and the rate is increased and CO_2 is lost. This causes vasodilation and makes the skin and mucous membranes warm, dry, and pink. With respiratory acidosis, breathing is ineffective and skin and mucous membranes are pale to cyanotic.

Psychosocial Assessment.

Behavioral changes may be the first manifestations of acidosis. Observe and document the patient's behavior by description (objectively) rather than by interpretation (subjectively). Ask family members if the patient's behavior is typical for him or her, and establish a baseline for comparison with later assessment findings.

Laboratory Assessment.

Arterial blood pH is the laboratory value used to confirm acidosis. Acidosis is present when arterial blood pH is less than 7.35. However, this test alone does not indicate what is causing the acidosis. Manifestations of metabolic acidosis and respiratory acidosis are similar, but their treatments are different. *Therefore it is critical to obtain and interpret other laboratory data, such as arterial blood gas (ABG) values and blood levels of electrolytes* (Chart 12-4).

Chart 12-4 Laboratory Profile

Acid-Base Imbalances (Uncompensated)

LABORATORY VALUE CHANGES							
IMBALANCE	pH	HCO_3^-	Pao_2	$Paco_2$	K^+	Ca^{2+}	Cl^-
Metabolic acidosis	↓	↓	Ø	Ø and ↓	↑	Ø	Ø and ↑
Respiratory acidosis	↓	Ø	↓	↑	↑	Ø	↑↓
Combined acidosis	↓	↓↑	↓	↑	↑	Ø	↑
Metabolic alkalosis	↑	↑	Ø	Ø and ↑	↓	↓	↓
Respiratory alkalosis	↑	Ø	Ø	↓↓	↓	↓	↑
Combined alkalosis	↑	↑	Ø	↓	↓	↓	↓

↑, Above normal; ↓, below normal; ↑ ↓, value can increase or decrease depending on other factors; Ø, normal; Ca^{2+}, calcium ions; Cl^-, chloride ions; $Paco_2$, partial pressure of arterial carbon dioxide; Pao_2, partial pressure of arterial oxygen; HCO_3^-, bicarbonate ions; K^+, potassium ions.

Metabolic acidosis is reflected by several changes in ABG values. The pH is low (<7.35) because buffering and respiratory compensation are not adequate to keep the amount of free hydrogen ions at a normal level. The bicarbonate level is low (<21 mEq/L). It is low because (1) bicarbonate has been lost, causing a base-deficit acidosis; (2) bicarbonate production is inadequate, causing a base-deficit acidosis; or (3) bicarbonate may be bound to other substances. The partial pressure of arterial oxygen (Pao_2) is normal because gas exchange is not impaired. The partial pressure of arterial carbon dioxide ($Paco_2$) is normal or even slightly decreased because gas exchange is adequate and carbon dioxide retention is not a factor (Jones, 2010).

The serum potassium level is often high in acidosis as the body attempts to maintain electroneutrality during buffering. Fig. 12-12 shows the movement of potassium ions as serum pH changes. As the blood hydrogen ion level rises, some of the excess hydrogen ions enter red blood cells for intracellular buffering. The movement of hydrogen ions into the cells creates an excess of positive ions inside the cells. To balance these extra positive charges, an equal number of potassium ions (that also have a positive charge) move from the cells into the blood. This increases the blood potassium level, causing hyperkalemia.

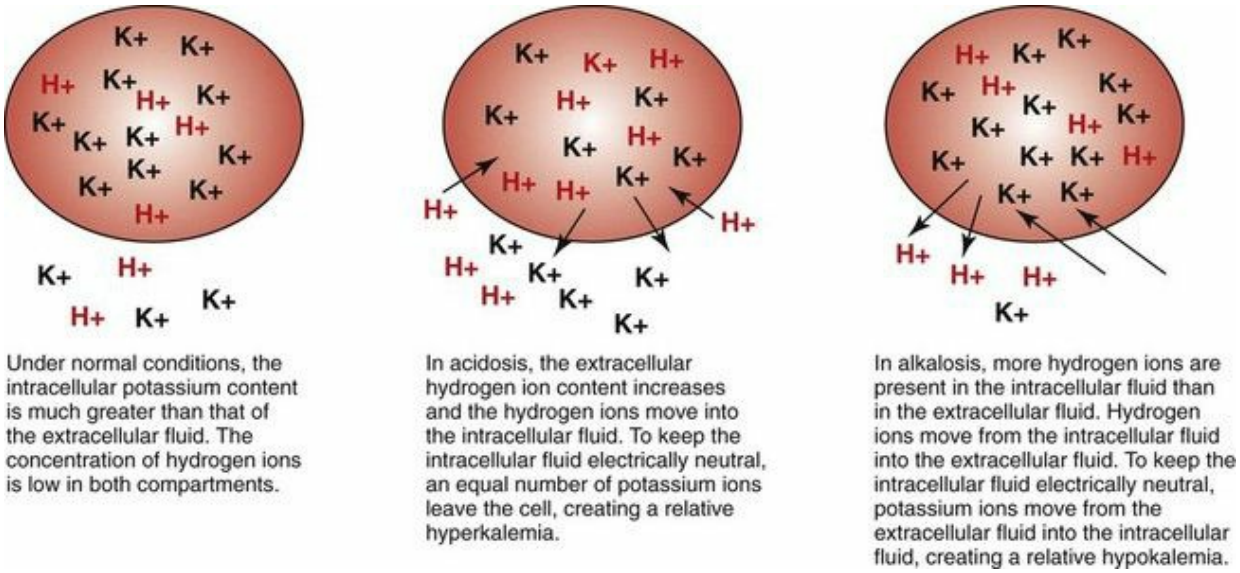

FIG. 12-12 Movement of potassium *(K^+)* in response to changes in the extracellular fluid hydrogen ion *(H^+)* concentration.

Respiratory acidosis is reflected by several changes in ABG values. The pH is low (<7.35) because of the increased amount of free hydrogen ions in the blood. Buffering and kidney compensation are not adequate to keep the amount of free hydrogen ions at a normal level. If the kidneys partially compensate for this acidosis, pH is low but not as abnormal as could be expected with the degree of CO_2 retention.

The partial pressure of arterial oxygen (Pa_{O_2}) is low and the partial pressure of arterial carbon dioxide (Pa_{CO_2}) is high because the pulmonary problem impairs gas exchange, causing poor oxygenation and CO_2 retention. *(The hallmarks of respiratory acidosis are a decreasing Pa_{O_2} coupled with a rising Pa_{CO_2}.)* Because carbon dioxide diffuses more easily across the alveolar membrane than oxygen, a decreased Pa_{O_2} usually occurs before an increased Pa_{CO_2}.

The serum bicarbonate level is variable. A patient with rapid onset of respiratory acidosis often has a normal bicarbonate level because kidney compensation has not started. When the acidosis persists for 24 hours or longer, kidney compensation increases the levels of bicarbonate. Chronic respiratory acidosis is indicated by an elevated bicarbonate level and increased Pa_{CO_2}.

Serum potassium levels are elevated in acute respiratory acidosis. They are normal or low in chronic respiratory acidosis when kidney compensation is present.

Priority Patient Problems.

Priority problems for the patient experiencing acidosis are associated with the decreased function of excitable membranes. These problems include hypotension and decreased perfusion, impaired memory and cognition, and increased risk for falls.

Interventions

Interventions for acidosis focus on correcting the underlying problem and monitoring for changes. To ensure appropriate interventions, first identify the specific type of acidosis present.

Metabolic Acidosis.

Interventions for metabolic acidosis include hydration and drugs or treatments to control the problem causing the acidosis. For example, if the acidosis is a result of diabetic ketoacidosis, insulin is given to correct the hyperglycemia and halt the production of ketone bodies. Rehydration and antidiarrheal drugs are given if the acidosis is a result of prolonged diarrhea. *Bicarbonate is administered only if serum bicarbonate levels are low.*

Nursing priorities include continuously monitoring the patient for changes that indicate either he or she is responding to the treatment or the acidosis is becoming worse. The cardiovascular system and the skeletal muscle system are sensitive to acidosis and are the most important systems to monitor. Interpreting ABG results is an important part of monitoring.

Respiratory Acidosis.

Priority interventions for respiratory acidosis are focused on improving ventilation and oxygenation and maintaining a patent airway. These include drug therapy, oxygen therapy, pulmonary hygiene (positioning and breathing techniques), ventilatory support, and prevention of complications. (See Chapter 30 for disorders causing respiratory acidosis.)

Drug therapy is focused on improving ventilation and oxygenation rather than directly on altering pH. Drug categories useful for respiratory acidosis include bronchodilators, anti-inflammatories, and mucolytics.

Oxygen therapy helps promote gas exchange for patients with respiratory acidosis. Carefully monitor oxygen saturation to ensure that the lowest flow of oxygen that prevents hypoxemia is used to avoid oxygen-induced tissue damage.

Ventilation support with mechanical ventilation may be needed for patients who cannot keep their oxygen saturation at 90% or who have respiratory muscle fatigue. Chapter 32 discusses the nursing care needs

of patients who are being mechanically ventilated.

Preventing complications is a nursing priority when caring for a patient with respiratory acidosis. Monitoring breathing status hourly and intervening when changes occur are critical in preventing complications. Listen to breath sounds, and assess how easily air moves into and out of the lungs. Check for any muscle retractions, the use of accessory muscles (especially the neck muscles [sternocleidomastoids]), and whether breathing produces a grunt or wheeze that can be heard without a stethoscope. Assess nail beds and oral membranes for cyanosis (a late finding).

NCLEX Examination Challenge

Physiological Integrity

What type of acid-base problem does the nurse expect in a client who is being insufficiently mechanically ventilated and whose most recent arterial blood gas results include a pH of 7.29?

A Metabolic acidosis with an acid excess
B Metabolic acidosis with a base deficit
C Respiratory acidosis with an acid excess
D Respiratory acidosis with a base deficit

Alkalosis

Pathophysiology

In patients with alkalosis, the acid-base balance of the blood is disturbed and has an excess of bases, especially bicarbonate (HCO_3^-). The amount or strength of the bases is greater than normal compared with the amount of the acids. Alkalosis is a *decrease* in the free hydrogen ion level of the blood and is reflected by an arterial blood pH *above* 7.45. Like acidosis, alkalosis is not a disease but, rather, is a manifestation of a problem. It can be caused by metabolic problems, respiratory problems, or both (Table 12-3).

TABLE 12-3

Common Causes of Alkalosis

PATHOLOGY	CONDITION
Metabolic Alkalosis	
Increase of base components	Oral ingestion of bases: Antacids Parenteral base administration: Blood transfusion Sodium bicarbonate Total parenteral nutrition
Decrease of acid components	Prolonged vomiting Nasogastric suctioning Hypercortisolism Hyperaldosteronism Thiazide diuretics
Respiratory Alkalosis	
Excessive loss of carbon dioxide	Hyperventilation, fear, anxiety Mechanical ventilation Salicylate toxicity High altitudes Shock Early-stage acute pulmonary problems

Alkalosis can result from an actual or relative increase in the amount or strength (or both) of bases. In an actual base excess, alkalosis occurs when base (usually bicarbonate) is either overproduced or undereliminated.

In *relative* alkalosis, the actual amount or strength of bases does not increase but the amount of the acids decreases, creating an *acid deficit.* A relative base-excess alkalosis (actual acid deficit) results from an overelimination or underproduction of acids (Fig. 12-13).

FIG. 12-13 Concepts of actual and relative alkalosis. (A = acid; B = base.)

The problems of alkalosis are serious and can be life threatening. Management focuses on correcting the cause after identifying whether the alkalosis origin is respiratory or metabolic.

Whether metabolic, respiratory, or both, alkalosis affects specific functions. The pathologic effects are caused by the electrolyte imbalances that occur in response to decreased blood cation (positively charged particles) levels. Most problems of alkalosis are related to increased stimulation of the nervous, neuromuscular, and cardiac systems.

Metabolic alkalosis is an acid-base imbalance caused by either an increase of bases (base excess) or a decrease of acids (acid deficit). Base excesses are caused by excessive intake of bicarbonates, carbonates, acetates, and citrates. Excessive use of bicarbonate-containing antacids can cause a metabolic alkalosis. Other base excesses can occur during medical treatments, such as citrate excesses during massive blood transfusions and IV sodium bicarbonate given to correct acidosis. The hallmark of a base-excess acidosis is an ABG result with an elevated pH and an elevated bicarbonate level along with normal oxygen and carbon dioxide levels.

Acid deficits can be caused by disease processes or medical treatment. Disorders causing acid deficits include prolonged vomiting, excess cortisol, and hyperaldosteronism. Treatments that promote acid loss causing metabolic alkalosis include thiazide diuretics and prolonged gastric suctioning.

Respiratory alkalosis is usually caused by an excessive loss of CO_2 through hyperventilation (rapid respirations). Patients may hyperventilate in response to anxiety, fear, or improper settings on mechanical ventilators. Hyperventilation can also result from direct stimulation of central respiratory centers because of fever, central nervous system lesions, and salicylates. The hallmark of respiratory alkalosis is an ABG result with an elevated pH coupled with a low carbon dioxide level. Usually, the oxygen and bicarbonate levels are normal.

Patient-Centered Collaborative Care

Assessment

Manifestations of problems with acid-base balance are the same for metabolic and respiratory alkalosis. Many symptoms are the result of the low calcium levels **(hypocalcemia)** and low potassium levels **(hypokalemia)** that usually occur with alkalosis (see Fig. 12-12). These problems change the function of the nervous, neuromuscular, cardiac, and respiratory systems (Chart 12-5).

Chart 12-5

Key Features

Alkalosis

Central Nervous System Manifestations

- Increased activity
- Anxiety, irritability, tetany, seizures
- Positive Chvostek's sign
- Positive Trousseau's sign
- Paresthesias

Neuromuscular Manifestations

- Hyperreflexia
- Muscle cramping and twitching
- Skeletal muscle weakness

Cardiovascular Manifestations

- Increased heart rate
- Normal or low blood pressure
- Increased digitalis toxicity

Respiratory Manifestations

- Increased rate and depth of ventilation in respiratory alkalosis
- Decreased respiratory effort associated with skeletal muscle weakness in metabolic alkalosis

Central nervous system (CNS) changes are caused by overexcitement of the nervous systems. Patients have dizziness, agitation, confusion, and hyperreflexia, which may progress to seizures. Tingling or numbness may occur around the mouth and in the toes. Other indicators of alkalosis with hypocalcemia are positive Chvostek's and Trousseau's signs (see Chapter 11).

Neuromuscular changes are related to the hypocalcemia and hypokalemia that occur with alkalosis. Nervous system activity increases, causing muscle cramps, twitches, and "charley horses." Deep tendon reflexes are hyperactive. **Tetany** (continuous contractions) of muscle groups also may be present. Tetany is painful and indicates a rapidly worsening condition.

Skeletal muscles may contract as a result of nerve stimulation, but they become weaker because of the hypokalemia. Handgrip strength decreases, and the patient may be unable to stand or walk. Respiratory efforts become less effective as the respiratory muscles weaken.

Cardiovascular changes occur because alkalosis increases myocardial irritability, especially when accompanied by hypokalemia. Heart rate increases, and the pulse is thready. When decreased blood volume is also present, the patient may have severe hypotension. The hypokalemia increases heart sensitivity to digoxin, which increases the risk for digoxin toxicity.

Respiratory changes, especially increases in the rate of breathing, are the main causes of respiratory alkalosis. Although the volume of air inhaled and exhaled with each breath is nearly normal, the total volume of air inhaled and exhaled each minute rises with the increased respiratory rate. The increased minute volume may be caused by anxiety or physiologic changes.

Arterial blood pH greater than 7.45 confirms alkalosis, but this test alone does not identify its cause. Because the manifestations of metabolic alkalosis and respiratory alkalosis are similar, it is critical to obtain additional laboratory data, especially arterial blood gas (ABG) values and specific serum electrolyte levels (see Chart 12-4) (Blevins, 2014).

Interventions

Interventions are planned to prevent further losses of hydrogen, potassium, calcium, and chloride ions; to restore fluid balance; to monitor changes; and to provide for *patient safety.* Treatments that may have caused alkalosis (e.g., prolonged gastric suctioning, excessive infusion of certain IV solutions, drugs that promote hydrogen ion excretion) are modified or stopped. Drug therapy is prescribed to resolve the causes of alkalosis and to restore normal fluid, electrolyte, and acid-base balance. For example, the patient with metabolic alkalosis caused by diuretic therapy receives fluid and electrolyte replacement, and the diuretic therapy is adjusted or stopped. Antiemetic drugs are prescribed for vomiting. Monitor the patient's progress, and adjust fluid and electrolyte therapy. Monitor electrolytes daily until they return to near normal.

During correction of alkalosis, a nursing care priority is prevention of injury from falls. The patient with alkalosis has hypotension and muscle weakness, which increase the risk for falls, especially among older adults. Implement the general falls prevention nursing interventions and the high-risk falls prevention nursing interventions outlined in Chart 2-4 in Chapter 2.

Clinical Judgment Challenge

Patient-Centered Care; Safety QSEN

The patient is a 21-year-old college student brought to the emergency department by his friends when he was found unconscious during a fraternity party. He was seen drinking heavily at the party and had not eaten for 2 days before the event. He takes no prescription drugs, and his current vital signs are: T = 97.8° F; P = 48, slightly irregular and thready; R = 28, deep and regular; BP = 88/50. His current arterial blood gas results are: pH = 7.31; HCO_3^- = 25 mEq/L; Pa_{CO_2} = 28 mm Hg; Pa_{O_2} = 99 mm Hg.

1. What specific type of acid-base problem does this patient have? Explain your choice.
2. What is the most probable origin of the acid-base imbalance?
3. Should oxygen be applied? Why or why not?
4. What nursing interventions for safety are most appropriate for this patient?
5. What additional laboratory and assessment data should be performed? Provide a rationale for your selections.

Nursing Concepts and Clinical Judgment Review

What might you NOTICE in a patient with appropriate acid-base balance?

Vital signs:

- Respiratory rate and depth within usual range for the patient
- Heart rate and rhythm within usual range for the patient
- Oxygen saturation of 95% or higher

Physical assessment:

- Able to speak a sentence of 12 words without stopping for breath
- Able to walk and talk without stopping for breath
- Skin color normal (no cyanosis or pallor)
- Oral mucous membrane and nail beds pink with rapid capillary refill
- Breathing quiet
- Muscle strength consistent with what is normal for the patient
- Urine output about equal to fluid intake

Psychological assessment:

- Oriented and not confused
- Energy level good; can engage in desired work, recreational, and

personal activities

Laboratory assessment:

- Arterial blood gas values within normal limits
- Serum electrolyte values, especially potassium and calcium, within normal limits

Get Ready for the NCLEX® Examination!

Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Assess the acid-base balance of any patient with new-onset muscle weakness.
- Use fall precautions for any patient with a problem in acid-base balance.
  Safety QSEN

Health Promotion and Maintenance

- Teach patients to take drugs as prescribed, especially diuretics, antihypertensives, and cardiac drugs.
- Instruct patients at continuing risk for respiratory acidosis to stop smoking.

Psychosocial Integrity

- Assess the oxygenation status of any patient with acute confusion.
- Monitor the neurologic status at least every 2 hours in patients being treated for a problem with acid-base balance.
- Assist patients who have anxiety-induced respiratory alkalosis to identify causes of anxiety.

Physiological Integrity

- Be aware of how the following principles, processes, and mechanisms influence the regulation of acid-base balance:
  - The normal pH of the body's extracellular fluids (including blood) is 7.35 to 7.45.
  - The more hydrogen ions present, the more acidic the fluid; the fewer hydrogen ions present, the more alkaline the fluid.
  - pH values below 7.35 indicate acidosis; pH values above 7.45 indicate alkalosis.
  - Anything that increases the CO_2 level in the blood increases the hydrogen ion content and lowers the pH.
  - Acids are normally formed in the body as a result of metabolism.
  - Chemical blood buffers are the immediate way that acid-base imbalances are corrected.
  - The lungs control the amount of CO_2 that is retained or exhaled.

  - The kidneys regulate the amount of hydrogen and bicarbonate ions that are retained or excreted by the body.
  - If a lung problem causes retention of carbon dioxide, the healthy kidney compensates by increasing the amount of bicarbonate that is produced and retained.
  - Acidosis reduces the excitability of cardiovascular muscle, neurons, skeletal muscle, and GI smooth muscle.
  - Alkalosis increases the sensitivity of excitable tissues, allowing them to over-respond to normal stimuli and respond even without stimulation.
- Check the serum potassium level for any patient who has acidosis. **Evidence-Based Practice** QSEN
- Assess the cardiovascular system first in any patient at risk for acidosis because acidosis can lead to cardiac arrest from the accompanying hyperkalemia. **Evidence-Based Practice** QSEN
- Assess the airway of any patient who has acute respiratory acidosis.
- Assess heart rate and rhythm at least every 2 hours for any patient with an acid-base imbalance.
- Monitor arterial blood gas (ABG) values to evaluate the effectiveness of therapy for acid-base imbalances. **Evidence-Based Practice** QSEN

CHAPTER 13

Infusion Therapy*

Cheryl J. Dumont

PRIORITY CONCEPTS

- Fluid and Electrolyte Balance
- Tissue Integrity
- Infection
- Perfusion

Learning Outcomes

Safe and Effective Care Environment

1. Prevent IV administration errors by following best practices that ensure patient and staff safety.
2. Describe the benefits and limitations of selected safety-enhancing technologies used for infusion therapy.
3. Identify the evidence-based guidelines for prevention of intravenous (IV) catheter–related bloodstream infection (CR-BSI).

Health Promotion and Maintenance

4. Describe the special needs and care for older adults receiving IV therapy.
5. Teach the patient and family about the type and care related to the patient's infusion therapy.

Physiological Integrity

6. Explain how to check the accuracy of prescriptions for IV fluids and drug therapy.

7. Identify the appropriate veins for peripheral IV catheter insertion.
8. Differentiate types of vascular access devices (VADs) used for peripheral and central IV therapy.
9. Outline best practice for inserting peripheral VADs.
10. Assess the patient's infusion site frequently for local complications, such as phlebitis and infiltration.
11. Prioritize nursing interventions for maintaining an infusion system.
12. Assess, prevent, and manage systemic complications related to infusion therapy and VADs.
13. Describe nursing care associated with intra-arterial, intraperitoneal, subcutaneous, intraosseous, and intraspinal infusion therapy.

 http://evolve.elsevier.com/Iggy/

Infusion therapy is the delivery of medications in solution and fluids by parenteral (piercing of skin or mucous membranes) route through a wide variety of catheter types and locations using multiple procedures. IV therapy is the most common route for infusion therapy. It delivers solutions directly into the veins of the vascular system. This chapter focuses on access for and administration of all types of infusion therapy.

Overview

Infusion therapy is delivered in all health care settings, including hospitals, home care, ambulatory care clinics, physicians' offices, and long-term care facilities. The most common reasons for using infusion therapy are to:

- Maintain fluid balance or correct fluid imbalance
- Maintain electrolyte or acid-base balance or correct electrolyte or acid-base imbalance
- Administer medications
- Replace blood or blood products

IV therapy is the most common invasive therapy administered to hospitalized patients. Advances in medicine and technology have made it possible for people with chronic diseases such as diabetes mellitus, chronic kidney disease, and malabsorption syndromes to live long and productive lives. These patients often depend on long-term infusion therapy of some kind. They often have very poor vascular integrity and, therefore, accessing their peripheral veins takes a high level of skill.

Having a specialized team of infusion nurses to initiate and maintain infusion therapy has been recommended as best practice by the Centers for Disease Control and Prevention (CDC) to reduce complications of infusion therapy (O'Grady et al., 2011). These teams have demonstrated value in cost savings, patient satisfaction, and patient outcomes.

Infusion nurses may perform any or all of these activities:

- Develop evidence-based policies and procedures
- Insert and maintain various types of peripheral and central venous catheters
- Monitor patient outcomes of infusion therapy
- Educate staff, patients, and families regarding infusion therapy
- Consult on product selection and purchasing decisions
- Provide therapies such as blood withdrawal, therapeutic phlebotomy, hypodermoclysis, intraosseous infusions, and administration of medications including chemotherapy

The registered nurse (RN) generalist is taught to insert peripheral IVs; most institutions have a process for credentialing this skill. Depending on the state's nurse practice act, licensed practical/vocational nurses (LPNs/LVNs) and technicians may be trained and credentialed to perform the skill of peripheral IV insertion and assist with infusions. *The RN is ultimately accountable for all aspects of infusion therapy and delegation of associated tasks (Infusion Nurses Society [INS], 2011*). You have a strategic role in selection of the correct device and managing the patient requiring

infusion therapy (Santolim et al., 2012).

The Infusion Nurses Society (INS) publishes guidelines and standards of practice for policy and procedure development in all health care settings. These standards establish the criteria for all nurses delivering infusion therapy. The Infusion Nurses Certification Corporation (INCC) offers a written certifying examination. Nurses who successfully complete this examination have mastered an advanced body of knowledge in this specialty and may use the initials *CRNI*, which stand for *certified registered nurse infusion*.

Types of Infusion Therapy Fluids

Many types of parenteral fluids are used for infusion therapy. These fluids are IV solutions, including parenteral nutrition, blood and blood components, and drug therapy.

Intravenous Solutions

More than 200 IV fluids (solutions) are available that meet the requirements established by the United States Pharmacopeia (USP). Each solution is classified by its tonicity (concentration) and pH. Tonicity is typically categorized by comparison with normal blood plasma as osmolarity (mOsm/L). As discussed in Chapter 11, normal serum osmolarity for adults is between 270 and 300 mOsm/L. Parenteral solutions within that normal range are **isotonic;** those fluids greater than 300 mOsm/L are **hypertonic;** and those fluids less than 270 mOsm/L are **hypotonic.**

When an *isotonic* **infusate** (solution that is infused into the body) is used, water does not move into or out of the body's cells. Therefore patients receiving isotonic solutions are at risk for fluid overload, especially older adults (see Chapter 11). *Hypertonic* solutions are used to correct fluid and electrolyte and acid-base imbalances by moving water out of the body's cells and into the bloodstream. Electrolytes and other particles also move across cell membranes across a concentration gradient (from higher concentration to lower concentration). Parenteral nutrition solutions are hypertonic (see Chapter 60). Instead of moving water out of cells, *hypotonic* infusates move water into cells to expand them. Patients receiving either hypertonic or hypotonic fluids are at risk for phlebitis and infiltration. **Phlebitis** is the inflammation of a vein caused by mechanical, chemical, or bacterial irritation. **Infiltration** occurs when IV solution leaks into the tissues around the vein.

The pH of IV solutions is a measure of the acidity or alkalinity and

usually ranges from 3.5 to 6.2. Extremes of both osmolarity and pH can cause vein damage leading to phlebitis and **thrombosis** (blood clot in the vein). Thus fluids and medications with a pH value less than 5 and more than 9 and with an osmolarity more than 600 mOsm/L are best infused in the central circulation where greater blood flow provides adequate hemodilution (Perucca, 2010). For example, total parenteral nutrition (TPN) solutions have an osmolarity greater than 1400 mOsm/L. TPN should not be infused in peripheral circulation because it can damage blood cells and the endothelial lining of the veins and decrease perfusion.

Nursing Safety Priority QSEN

Drug Alert

Drugs such as amiodarone (Cordarone), vancomycin (Vancocin), and ciprofloxacin (Cipro I.V.) are venous irritants that have a pH less than 5. Phlebitis occurs when patients require long-term infusion of these drugs in peripheral circulation. Drugs with vasoconstrictive action (e.g., dopamine or chemotherapeutic agents [e.g., vinblastine]) are **vesicants** (chemicals that damage body tissue on direct contact) that can cause extravasation. **Extravasation** results in severe tissue integrity impairment as manifested by blistering, tissue sloughing, or necrosis from infiltration into the surrounding tissues. (See Complications of Intravenous Therapy section on p. 204 for further explanation and Chapter 22 for more detail.) Monitor the IV insertion site carefully for early manifestations of infiltration, including swelling, coolness, or redness. If any of these symptoms are present, discontinue the drug immediately and notify the infusion therapy team, if available. If an infusion specialist is not available, plan to remove the IV catheter and consider central line placement.

Blood and Blood Components

Blood transfusion is given by using packed red blood cells, created by removing a large portion of the plasma from whole blood. Other available blood components include platelets, fresh frozen plasma, albumin, and several specific clotting factors. Each component has detailed requirements for blood-type compatibility and infusion techniques. For patient safety, The Joint Commission's (TJC) 2014 National Patient Safety Goals (NPSGs) require agencies to ensure that blood components are properly ordered, handled and dispensed, and administered and that patients are appropriately monitored. Positive

patient identification using two patient identifiers and requiring two qualified health care professionals is essential before any blood or blood component is administered.

Most organizations use the International Society of Blood Transfusion (ISBT) universal bar-coding system to ensure the right blood for the right patient (Fig. 13-1). The ISBT system includes four components that must be present on the blood label both in bar code and in eye-readable format. These four components are (1) a unique facility identifier, (2) the lot number relating to the donor, (3) the product code, and (4) the ABO group and Rh type of the donor.

FIG. 13-1 Unit of blood showing the International Society of Blood Transfusion (ISBT) universal bar code for blood transfusions.

An acute hemolytic transfusion reaction caused by an incompatible blood transfusion is a "sentinel event." The Joint Commission defines a **sentinel event** as an unexpected occurrence involving serious physical or psychological injury or the risk thereof and requiring an intense analysis of the contributing factors and corrective action. As a measure to improve the quality of health care, The Joint Commission reviews organizations' activities in response to sentinel events. Established policies and procedures must be rigidly followed to ensure a safe

transfusion and reduce the risk for complications. (See Chapter 40 for a complete discussion of blood transfusion administration.)

Drug Therapy

IV drugs provide a rapid therapeutic effect but can lead to immediate serious reactions, called **adverse drug events (ADEs).** Hundreds of drugs are available for infusion by a variety of techniques. As with all drug administration, nurses must be knowledgeable about drug indications, proper dosage, contraindications, and precautions. IV administration also requires knowledge of appropriate dilution, rate of infusion, pH and osmolarity, compatibility with other IV medications, appropriate infusion site (peripheral versus central circulation), potential for vesicant/irritant effects, and specific aspects of patient monitoring because of its immediate effect. *Regardless of familiarity with the drug, never assume that IV administration is the same as giving that drug by other routes.* New information is continuously being published, and new drugs are rapidly being introduced.

Medication safety is extremely important in all health care settings today. The Joint Commission's 2014 NPSGs include as a major goal improving the safety of high-alert drugs. An example of these drugs is concentrated electrolyte solutions (e.g., potassium chloride), which require restricted access, prominent warnings about the concentration, and storage in a secured location.

Procedures must be established to prevent errors resulting from look-alike, sound-alike drugs such as Celebrex IV (celecoxib) and Cerebyx (fosphenytoin). Other strategies to reduce errors include limiting available concentrations of drugs and dispensing all drugs, including catheter flush solutions, in single-dose containers. Smart pumps with drug libraries (see Infusion Systems section), in combination with computer provider (physician, nurse practitioner, physician assistant) order entry (CPOE) and bar code medication administration (BCMA) systems, use recent technology to help reduce adverse drug events (ADEs). Electronic medication administration records (MARs) and multiple checks by pharmacists, as required by The Joint Commission's NPSGs, also help reduce errors.

Prescribing Infusion Therapy

A prescription for infusion therapy written by an authorized provider (physician, nurse practitioner, or physician assistant) is necessary before IV therapy begins. To be complete, the prescription for infusion fluids

should include:

- Specific type of fluid
- Rate of administration written in milliliters per hour (mL/hr) or the total amount of fluid and the total number of hours for infusion (e.g., 125 mL/hr or 1000 mL/8 hr)
- Drugs and the specific dose to be added to the solution, such as electrolytes or vitamins

A drug prescription should include:

- Drug name, preferably by generic name
- Specific dose and route
- Frequency of administration
- Time of administration
- Length of time for infusion
- Purpose (required in some health care agencies, especially nursing homes)

Some continuously infused drugs, such as those for pain management, are prescribed as milligrams per hour. The type and volume of dilution for infusion medications may be included in the prescription or calculated by the infusion pharmacist.

Nursing Safety Priority QSEN

Action Alert

Determine that the IV prescription is appropriate for the patient and clarify any questions with the health care provider before administration. Be sure to check for the accuracy and completeness of the treatment prescription. An example of an incomplete one is "5% dextrose in water to keep the vein open" (TKO or KVO). This statement does not specify the rate of infusion and is not considered complete.

Vascular Access Devices

An infusion catheter, also known as a **vascular access device (VAD),** is a plastic tube placed in a blood vessel to deliver fluids and medications. This catheter should not be confused with the ventricular assist device also called a VAD. In this chapter, VAD refers to vascular access devices. The specific type and purpose of the therapy determine whether the infusion can be given safely through peripheral veins or if the large central veins of the chest are needed. Advances in catheter materials and insertion techniques have radically expanded the types of VADs currently used. This discussion includes the description of each type of catheter

used for peripheral and central IV therapy. Seven major types are described:

- Short peripheral catheters
- Midline catheters
- Peripherally inserted central catheters (PICC)
- Nontunneled percutaneous central venous catheters (CVCs)
- Tunneled catheters
- Implanted ports
- Hemodialysis catheters

Assess the patient's needs for vascular access, and choose the device that has the best chance of infusing the prescribed therapy for the required length of time. Depending on the patient and type of VAD to be inserted, a topical anesthetic agent or intradermal lidocaine HCl 1% may be helpful to decrease patient discomfort. Obtain a health care provider's order and check for patient allergies before administering any anesthetic.

NCLEX Examination Challenge

Safe and Effective Care Environment

A client receiving ciprofloxacin intravenously reports that the peripheral IV insertion site has become painful and reddened. In what order will the nurse perform the needed actions to manage this problem?

A Report the patient's problem to the health care provider.
B Document findings and actions in the electronic health record.
C Change the IV insertion site to a new location.
D Stop the infusion of the drug immediately.

Peripheral Intravenous Therapy

Short infusion catheters are the most commonly used vascular access devices (VADs) for **peripheral IV therapy.** They are usually placed in the veins of the arm. Another catheter used for peripheral IV therapy is a midline catheter.

Short Peripheral Catheters

Short peripheral catheters are composed of a plastic cannula built around a sharp stylet extending slightly beyond the cannula (Fig. 13-2). The stylet (sharp) allows for the venipuncture, and the cannula is advanced into the vein. Once the cannula is advanced into the vein, the stylet is withdrawn. These catheters are designed with a safety mechanism to cover the sharp end of the stylet after it is removed from the patient. The stylet is a hollow-bore, blood-filled needle that carries a high risk for exposure to bloodborne pathogens if needle stick injury occurs. A federal law enacted in 2000 amended the Bloodborne Pathogen Standards from the Occupational Safety and Health Administration (OSHA) requiring the use of catheters with an engineered safety mechanism to prevent needle sticks.

FIG. 13-2 BD Insyte Autoguard IV catheter. With the push of a button, the needle instantly retracts, reducing the risk for accidental needle stick injuries.

Insertion and Placement Methods

Short peripheral catheters are most often inserted into superficial veins of the forearm using sterile technique. In emergent situations, these catheters can be used also in the external jugular vein of the neck. *Avoid the use of veins in the lower extremities of adults, if possible, because of an increased risk for deep vein thrombosis and infiltration.*

Short catheters range in length from ¾ inch to 1¼ inch with gauge sizes from 26 gauge (the smallest) to 14 gauge (large bore). *Choose the smallest gauge catheter capable of delivering the prescribed therapy.* Current design improves the fluid flow through the catheter while using a smaller gauge and thereby decreases the possibility of vein irritation

from a large catheter. For example, a thin-walled 24-gauge Insyte catheter has about the same flow-rate ability as a 22-gauge non–thin-walled Angiocath. Larger gauge sizes allow for faster flow rates but also cause phlebitis more often. Table 13-1 lists each gauge size and its common uses.

TABLE 13-1

Choosing the Gauge Size for Peripheral Catheters

CATHETER GAUGE	INDICATIONS	APPROXIMATE FLOW RATES
24-26 gauge Smallest, shortest (3/4 -inch length)	Not ideal for viscous infusions Expect blood transfusion to take longer Preferred for infants and small children	24 mL/min (1440 mL/hr)
22 gauge	Adequate for most therapies; blood can infuse without damage	38 mL/min (2280 mL/hr)
20 gauge (1- 1 1/4 -inch length)	Adequate for all therapies Most providers of anesthesia prefer not to use a smaller size than this for surgery cases	65 mL/min (3900 mL/hr)
18 gauge	Preferred size for surgery Vein needs to be large enough to accommodate the catheter	110 mL/min (6600 mL/hr)
14-16 gauge	For trauma and surgical patients requiring rapid fluid resuscitation Needs to be in a vein that can accommodate it	

The current recommendations for dwell (stay in) time of short peripheral catheters do not include a specific time frame. The recommendations from both the CDC and the INS are that the catheter should be removed and/or rotated to a different site based on clinical indications (e.g., signs of phlebitis [warmth, tenderness, erythema or palpable venous cord], infection, or malfunction) (CDC, 2011; INS, 2011). This process requires conscientious and frequent assessment of the site. However, if the patient's therapy is expected to be longer than 6 days, a midline catheter or PICC should be chosen (O'Grady et al., 2011). When selecting the site for insertion of a peripheral catheter, consider the patient's age, history, and diagnosis; the type and duration of the prescribed therapy; and, whenever possible, the patient's preference. Chart 13-1 lists the major criteria for the placement of peripheral VADs.

Chart 13-1 Best Practice for Patient Safety & Quality Care QSEN

Placement of Short Peripheral Venous Catheters

- Verify that the prescription for infusion therapy is complete and appropriate for infusion through a short peripheral catheter.
- For adults, choose a site for placement in the upper extremity. DO NOT USE THE WRIST.
- Choose the patient's nondominant arm when possible.

- Choose a distal site, and make all subsequent venipunctures proximal to previous sites.
- Do not use the arm on the side of a mastectomy, lymph node dissection, arteriovenous shunt or fistula, or paralysis.
- Avoid choosing a site in an area of joint flexion.
- Avoid choosing a site in a vein that feels hard or cordlike.
- Avoid choosing a site close to areas of cellulitis, dermatitis, or complications from previous catheter sites.
- Choose a vein of appropriate length and width to fit the size of the catheter required for infusion.

Vein transilluminators and ultrasound devices are now available as tools to assist in IV line placement. Several different types of portable *vein transilluminators* are available, such as VeinViewer, Veinlite LED, and AccuVein AV 300 (Fig. 13-3). Although they may have different mechanisms of action (some use infrared light and some use laser), these devices penetrate only up to about 10 mm and are limited to finding superficial veins.

FIG. 13-3 The AccuVein AV300 is a vein illumination device that helps health care professionals locate veins for blood draw, IV infusion, and blood donation by projecting a pattern of light on the patient's skin to reveal the position of underlying veins on the skin's surface. The device uses red and infrared light, which the hemoglobin in blood absorbs to detect the position of the vein.

Ultrasound-guided peripheral IV insertion can allow insertion into deeper veins (White et al., 2010). This technology has been shown to be very valuable in assisting with cannulation of peripheral veins that the nurse cannot access with sight and touch. However, there are risks the nurse must be aware of when using ultrasound guidance. This technology should be used only by nurses who have been trained and whose competencies are maintained. Arteries and nerves lie parallel to deep veins, and training is needed to learn to identify these structures and avoid damaging them. In addition, when deeper veins are accessed, infiltration may go undetected until a significant amount of fluid has collected in the tissues. This complication can be particularly devastating if the solution is an irritant or vesicant.

For patients who need IV access but are at risk for fluid overload or do not need extra IV fluids, the peripheral vascular access device (VAD) can be converted into an intermittent IV lock, also called a *saline lock*. This

device allows administration of specific drugs given IV push (e.g., furosemide [Lasix, Furoside]) or on an intermittent basis using a medication administration set. IV antibiotics are frequently given this way. In some cases, the saline lock is placed in case there is a need for emergency drug administration via IV push. The intermittent device is flushed with saline before and after drug administration to ensure patency and prevent occlusion with a blood clot.

Site Selection and Skin Preparation

The most appropriate veins for peripheral catheter placement include the dorsal venous network, basilic, cephalic, and median veins, as well as their branches (Fig. 13-4). *However, cannulation of veins on the hand is not appropriate for older patients with a loss of skin turgor and poor vein condition and for active patients receiving infusion therapy in an ambulatory care clinic or home care. Use of veins on the dorsal surface of the hands should be reserved as a last resort for short-term infusion of non-vesicant and non-irritant solutions in young patients.*

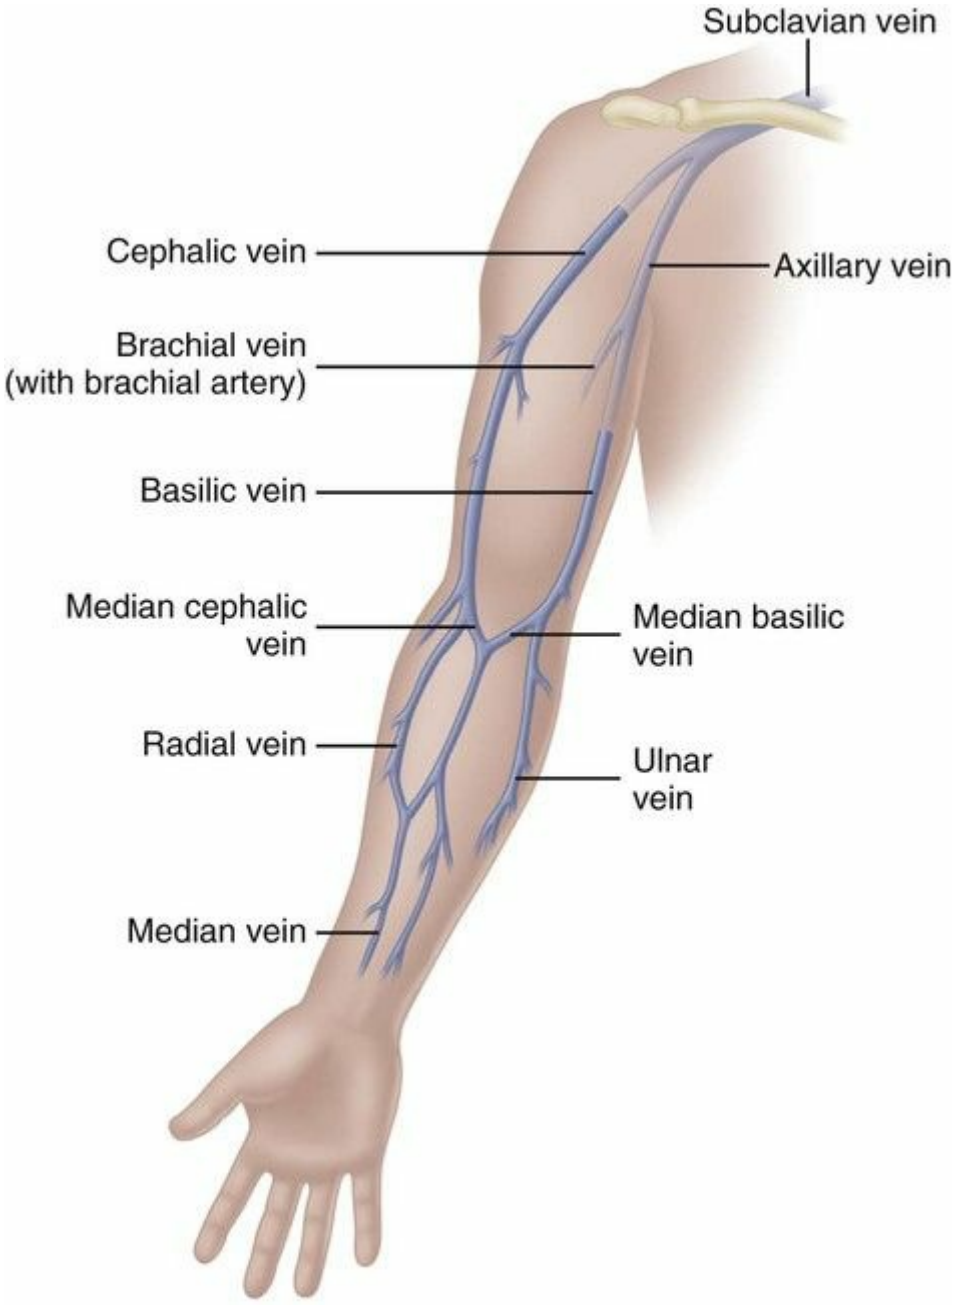

FIG. 13-4 Common IV sites in the inner arm.

Mastectomy, axillary lymph node dissection, lymphedema, paralysis of the upper extremity, and the presence of dialysis grafts or fistulas alter the normal pattern of blood flow through the arm. Using veins in the extremity affected by these conditions requires a physician's request. Short peripheral catheters are not recommended for obtaining routine blood samples.

Nursing Safety Priority QSEN

Critical Rescue

Avoid veins on the palmar side of the wrist because the median nerve

is located close to veins in this area, making the venipuncture more painful and difficult to stabilize. The cephalic vein begins above the thumb and extends up the entire length of the arm. This vein is usually large and prominent, appearing as a prime site for catheter insertion. Damage to the nerve from any injury can result in permanent loss of function or complex regional pain syndrome, type 2 (CRPS) (Watts & Kremer, 2011). Reports of tingling, feeling "pins and needles" in the extremity, or numbness during the venipuncture procedure can indicate nerve puncture. If any of these symptoms occur, stop the IV insertion procedure immediately, remove the catheter, and choose a new site.

Winged needles ("butterfly needles") are easy to insert but are associated with a high frequency of infiltration. They are most commonly used for injection of single-dose drugs or for drawing blood samples. Like a short peripheral catheter, winged needles should also have an engineered safety mechanism to house the needle when removed.

Aseptic skin preparation and technique before IV insertion are crucial. Catheter-related bloodstream infection (CR-BSI) can occur from a peripheral IV site. The CDC recommendations include:

- Perform evidence-based hand hygiene before palpating the insertion site.
- Clip hair—do not shave.
- Ensure that skin is clean. If visibly soiled, cleanse with soap and water.
- Wear clean gloves for peripheral IV insertion; do not touch the access site after application of antiseptics.
- Prepare clean skin with a skin antiseptic (chlorhexidine 2% with 70% alcohol, 70% isopropyl alcohol, or povidone-iodine) using a back-and-forth motion for 30 seconds, and allow the solution to dry before peripheral venous catheter insertion.

Midline Catheters

Midline catheters can be anywhere from 3 to 8 inches long, 3 to 5 Fr, and double or single lumen. They are inserted through the veins of the upper arm. The median antecubital vein is used most often if insertion is done without the aid of ultrasound guidance. With ultrasound guidance, deeper veins can be accessed and the insertion site can be further above the antecubital fossa. The basilic vein is preferred over the cephalic vein because of its larger diameter and straighter path. It also allows greater hemodilution of the fluids and medications being infused. The catheter tip is located in the upper arm with the tip residing no further into the

venous network than the axillary vein (Fig. 13-5). These catheters are used for therapies lasting from 1 to 4 weeks; however, there are no recommendations for the optimal dwell time. In a 2014 study, the average dwell time for midlines was identified as 6.9 days (Dumont, Getz, & Miller, 2014). Because of the extended dwell time, strict sterile technique is used for insertion and dressing changes for a midline catheter. Additional education and skill assessment are required for the nurse to be qualified to insert midline catheters.

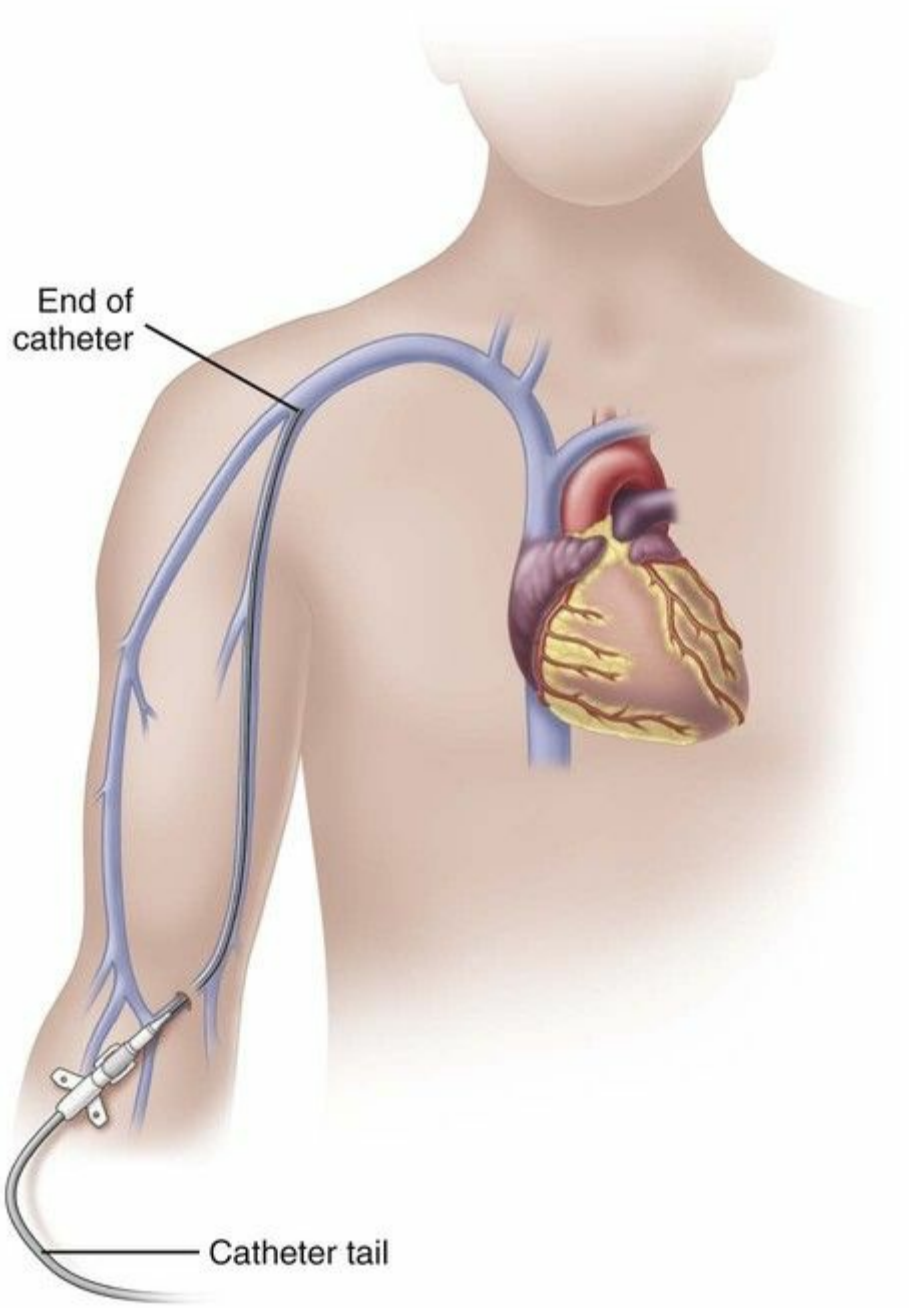

FIG. 13-5 Midline catheter; the tip of this catheter resides in a peripheral vein.

Midline catheters have been found to reduce the number of repeated IV cannulations, which reduces patient discomfort, increases patient satisfaction, and contributes to organizational efficiency (Alexandrou et al., 2011). A midline catheter can be used when skin integrity or limited peripheral veins make it difficult to maintain a short peripheral catheter. Indications for these catheters include fluids for hydration and drug therapy that is given longer than 6 days and up to 4 weeks, such as antibiotics, heparin, steroids, and bronchodilators.

Midline catheters are considered to dwell in the peripheral circulation;

the recommendations for infusates (fluids or drugs) are the same as for short peripheral IVs. Fluids and medications infused through a midline catheter should have a pH between 5 and 9 and a final osmolarity of less than 600 mOsm/L (Perucca, 2010). The pH and osmolarity outside these parameters increase the risk for complications like phlebitis and thrombosis. Midline catheters should not be used for infusion of **vesicant medications**—drugs that cause severe tissue damage if they escape into the subcutaneous tissue **(extravasation).** There is concern that at a midline tip location, larger amounts of the drug may extravasate before the problem is detected.

All parenteral nutrition formulas, including those with low concentrations of dextrose, and solutions that have an osmolarity greater than 600 mOsm/L should not be infused through a midline catheter. Do not draw blood from these catheters routinely. Midline catheters should not be placed in extremities affected by mastectomy with lymphedema, paralysis, or dialysis grafts and fistulas. When using a double-lumen midline catheter, do not administer incompatible drugs simultaneously through both lumens because the blood flow rate in the axillary vein is not high enough to ensure adequate hemodilution and prevention of drug interaction in the vein.

A new midline, PowerGlide, has been developed by Bard Access Systems. This catheter is approved for power injection of 5 mL/sec for computed tomography (CT) scans (Bard, 2013). There is no evidence in the literature to date on the efficacy of this practice.

NCLEX Examination Challenge

Physiological Integrity

The health care provider prescribes 1 L 5%D/0.9%NS to be infused over 10 hours. The nurse sets the rate at _____mL/hr of IV solution.

Central Intravenous Therapy

In **central IV therapy,** the vascular access device (VAD) is placed in the central circulation, specifically within the superior vena cava (SVC) near its junction with the right atrium, also called the *caval-atrial junction (CAJ)*. Blood flow in the SVC is about 2 L/min compared with about 200 mL/min in the axillary vein. Most central vascular access devices require confirmation of tip location at the CAJ by chest radiograph before solutions are infused. However, newer technologies use either a magnet tip locator or identification of the CAJ by electrocardiogram rather than by x-ray. Both the Sherlock 3CG by Bard and the VasoNova/Teleflex systems have received Food and Drug Administration (FDA) approval as an alternative to chest x-ray or fluoroscopy to verify PICC tip location.

A number of types of central vascular access devices (CVADs) are available, depending on the purpose, duration, and insertion site availability. Several recent improvements in catheter materials allow antimicrobial and heparin coatings to reduce infection risk and improve the longevity of the catheter. Not all central line catheters are approved for power injection used in radiologic tests. The catheter can rupture if it is not designed to handle the injection pressure necessary for some tests such as pulmonary CT angiography or CT angiography of the aorta (5 mL/sec and 300 per square inch [psi]). Check with the radiology department and read the indications on the packaging before using them for power injection (Macha et al., 2009).

Peripherally Inserted Central Catheters

A **peripherally inserted central catheter (PICC)** is a long catheter inserted through a vein of the antecubital fossa (inner aspect of the bend of the arm) or the middle of the upper arm. Nurses who insert these CVADs require special training and certification.

In adults, the PICC length ranges from 18 to 29 inches (45-74 cm) with the tip residing in the superior vena cava (SVC) ideally at the caval-atrial junction (CAJ) (Fig. 13-6). Placement of the catheter tip in veins distal to the SVC is avoided. This inappropriate tip location, often called a *mid-clavicular catheter*, is associated with much higher rates of thrombosis than when the tip is located in the SVC at the CAJ. Mid-clavicular tip locations are used only when anatomic or pathophysiologic changes prohibit placing the catheter into the SVC.

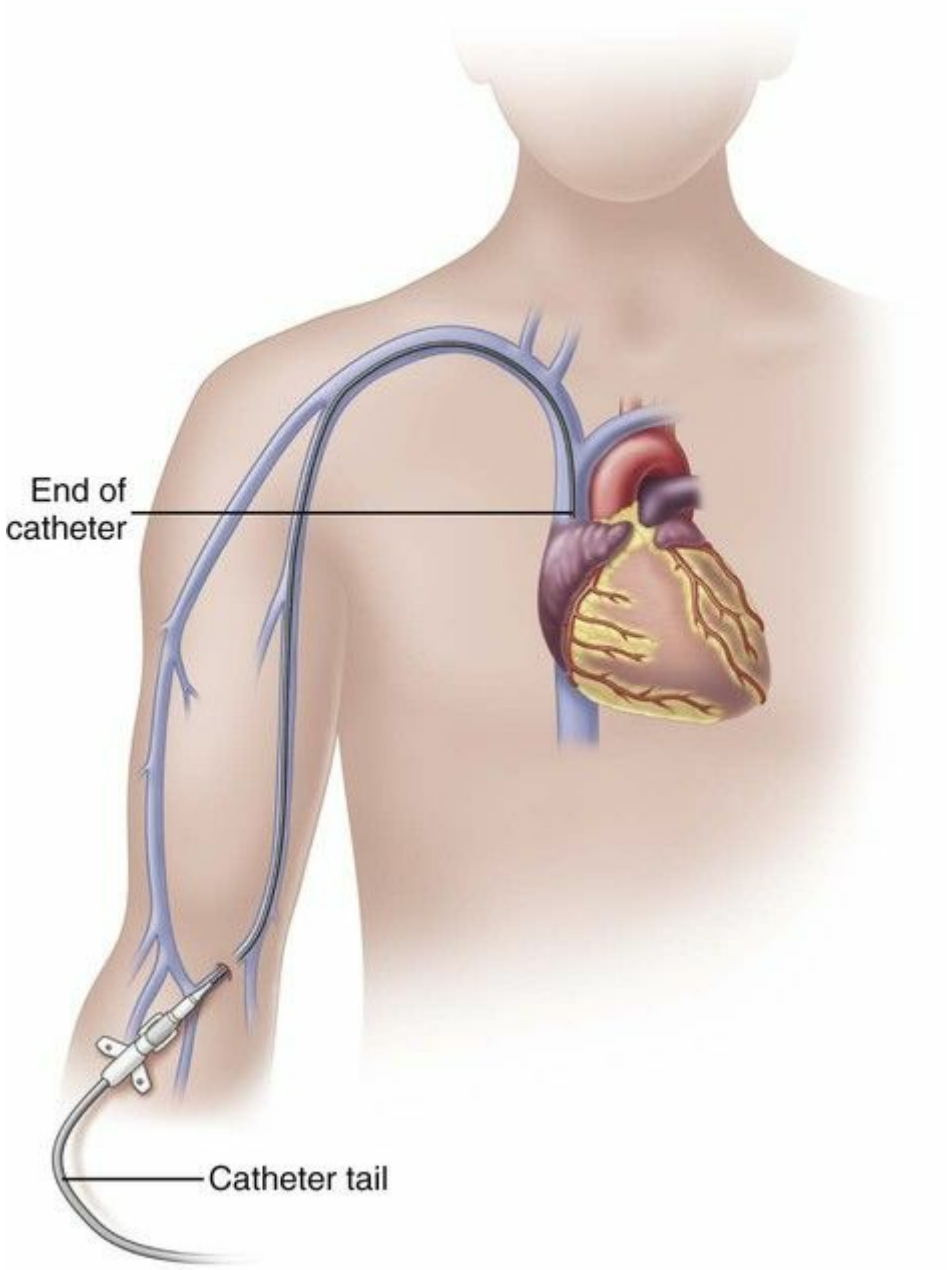

FIG. 13-6 Peripherally inserted central catheter (PICC) is placed peripherally in a vein of the upper arm with the tip resting in the superior vena cava.

PICCs should be inserted early in the course of therapy before veins of the extremity have been damaged from multiple venipunctures and infusions. Insertion methods using guidewires and ultrasound systems greatly improve insertion success. The basilic vein is the preferred site for insertion; the cephalic vein can be used if necessary. Two brachial veins are not recommended because they are more difficult to access; they are deeper in the arm and run close to the brachial artery. *Sterile technique is used for insertion to reduce the risk for catheter-related bloodstream* infection *(CR-BSI). Before the catheter can be used for infusion, a*

chest x-ray indicating that the tip resides in the lower SVC is required when the catheter is not placed under fluoroscopy or with the use of the electrocardiogram tip locator technique.

PICCs are available in single-, dual-, or triple-lumen configurations and are available with both the Groshong valve and the pressure-activated safety valve (PASV). PICCs are also available as "Power PICCs" and can be used for contrast injection at a maximum of 5 mL/sec and a maximum pressure of 300 psi. They can also be connected to transducers and used to monitor central venous pressure (Bard Access Systems, 2011).

The most common complications from PICCs include phlebitis, thrombophlebitis, deep vein thrombosis (DVT), and CR-BSIs. Thrombophlebitis and DVT can be very serious, threaten the integrity of the vein, and decrease perfusion. The smallest possible French size should be used to decrease the rate of upper extremity DVT, a potentially life-threatening event.

CR-BSI has been noted to be less common in PICCs than in other central venous catheters (CVCs) because of the insertion site in the upper extremity. The cooler, drier skin of the upper arm has fewer types and numbers of microorganisms, leading to lower rates of infection. Accidental arterial puncture or excessive bleeding can occur on insertion and is controlled by direct pressure. Infiltration and extravasation are rare. Insertion complications such as pneumothorax associated with other CVCs do not occur with PICCs.

PICCs can accommodate infusion of all types of therapy because the tip resides in the SVC where the rapid blood flow quickly dilutes the fluids being infused. Therefore there are no limitations on the pH or osmolality of fluids that can be infused through a PICC. For example, patients requiring lengthy courses of antibiotics, chemotherapy agents, parenteral nutrition formulas, and vasopressor agents can benefit from this type of catheter. PICCs have been reported to dwell successfully for months or even years; however, the optimal dwell time is not known.

PICCs can be used for blood sampling; however, lumen sizes of 4 Fr or larger are recommended. Using lumens with small diameters may not yield a sample capable of producing the needed test results. In addition, frequent entry into any central line should be minimized and treated with strict aseptic technique to prevent CR-BSI. Transfusion of blood through a PICC usually requires the use of an infusion pump. Packed red blood cells are cold and viscous. The length of the catheter adds resistance and may prevent the blood from infusing within the 4-hour limit.

Teach patients with a PICC to perform usual ADLs; however, they

should avoid excessive physical activity. Muscle contractions in the arm from physical activity like heavy lifting can lead to catheter dislodgment and possible lumen occlusion. PICCs may be contraindicated in paraplegic patients who rely on their arms for mobility and in patients using crutches that provide support in the axilla.

PICC insertion is commonly performed in the patient's hospital room, an ambulatory care treatment facility, or the imaging department. Regardless of where they are inserted, the same precautions must be taken as with any other central line insertion using the catheter-related bloodstream infection (CR-BSI) prevention bundle. Major components of this prevention bundle include:

- Hand hygiene
- Maximal barrier precautions upon insertion
- Chlorhexidine skin antisepsis
- Optimal catheter site selection and post-placement care with avoidance of the femoral vein for central venous access in adult patients
- Daily review of line necessity with prompt removal of unnecessary lines

Other helpful interventions include use of a check list for sterility during the procedure, a line cart with all equipment, and a stop sign on the door of the room to stop unnecessary traffic through the room during the procedure.

Nursing Safety Priority QSEN

Action Alert

The INS recommendation for flushing PICC lines not actively used is 5 mL of heparin (10 units/mL) in a 10-mL syringe at least daily when using a non-valved catheter and at least weekly with a valved catheter. Use 10 mL of sterile saline to flush before and after medication administration; 20 mL of sterile saline is flushed after drawing blood. *Always use 10-mL barrel syringes to flush any central line because the pressure exerted by a smaller barrel poses a risk for rupturing the catheter.*

Nontunneled Percutaneous Central Venous Catheters

Nontunneled percutaneous central venous catheters (CVCs) are inserted by a physician, trained physician assistant, or nurse practitioner through the subclavian vein in the upper chest or the internal jugular veins in the neck using sterile technique. Occasionally the patient's condition may require insertion of the CVC in a femoral vein, but the rate of infection is very high. If the femoral site must be used, it is removed as soon as

possible.

CVCs are usually 7 to 10 inches (18 to 25 cm) long and have one to as many as five lumens (Fig. 13-7). These catheters are also available with antimicrobial coatings such as chlorhexidine and silver sulfadiazine. The tip resides in the superior vena cava (SVC) and is confirmed by a chest x-ray. Nontunneled percutaneous CVCs are most commonly used for emergent or trauma situations, critical care, and surgery. There is no recommendation for optimal dwell time. However, these catheters are commonly used for short-term situations and are *not* the catheter of choice for home care or ambulatory clinic settings.

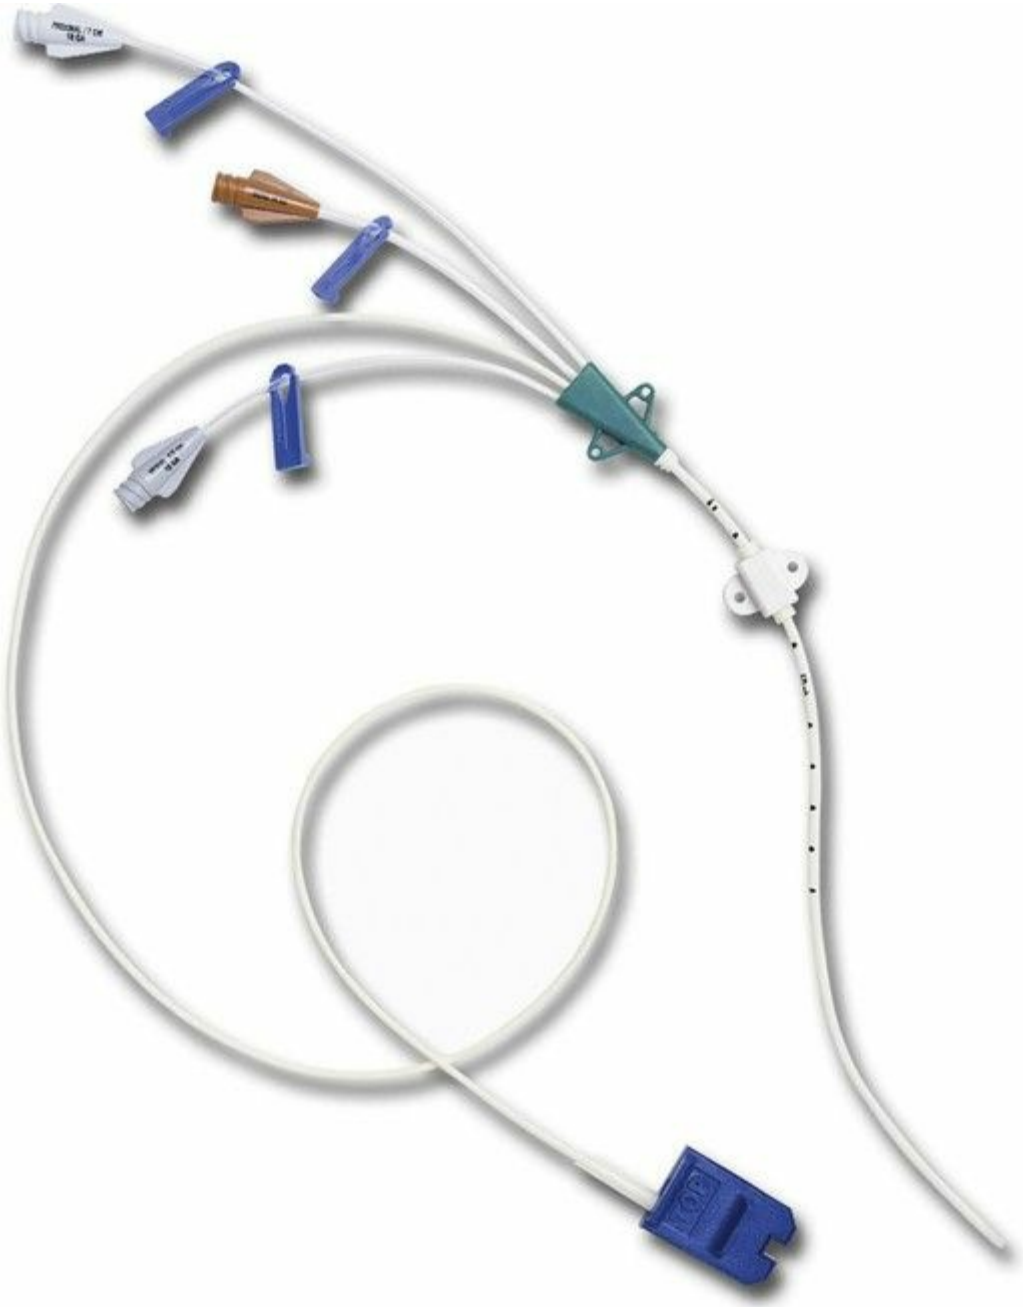

FIG. 13-7 The Edwards Lifesciences PreSep central venous catheter (CVC); often placed in the subclavian or internal jugular vein with the tip of the catheter resting in the superior vena cava.

Insertion of these central catheters requires the patient to be placed in the Trendelenburg position, usually with a rolled towel between the shoulder blades. This position may be difficult or contraindicated for patients with respiratory conditions, spinal curvatures, and increased intracranial pressure, especially for older adults. Trauma, surgery, or radiation in the neck or chest prohibits the use of these devices as well. Insertion with ultrasound guidance has been demonstrated to improve the safety of insertion in the internal jugular site (Griswold-Theodorson et al., 2009). The presence of a tracheotomy increases the risk for cross-

contamination of the insertion site. The warmer, moister skin of the neck and upper chest has more types and higher numbers of microorganisms, resulting in more CR-BSIs with this type of catheter.

Tunneled Central Venous Catheters

Tunneled central venous catheters are VADs that have a portion of the catheter lying in a subcutaneous tunnel, separating the points where the catheter enters the vein from where it exits the skin. This separation is intended to prevent the organisms on the skin from reaching the bloodstream (Fig. 13-8). Today these catheters are usually inserted by physicians in the radiology suite, rather than placed surgically. The catheter has a cuff made of a rough material that is positioned inside the subcutaneous tunnel. These cuffs commonly contain antibiotics, which also reduce the risk for infection. The tissue granulates into the cuff, providing a mechanical barrier to microorganisms and anchoring the catheter in place.

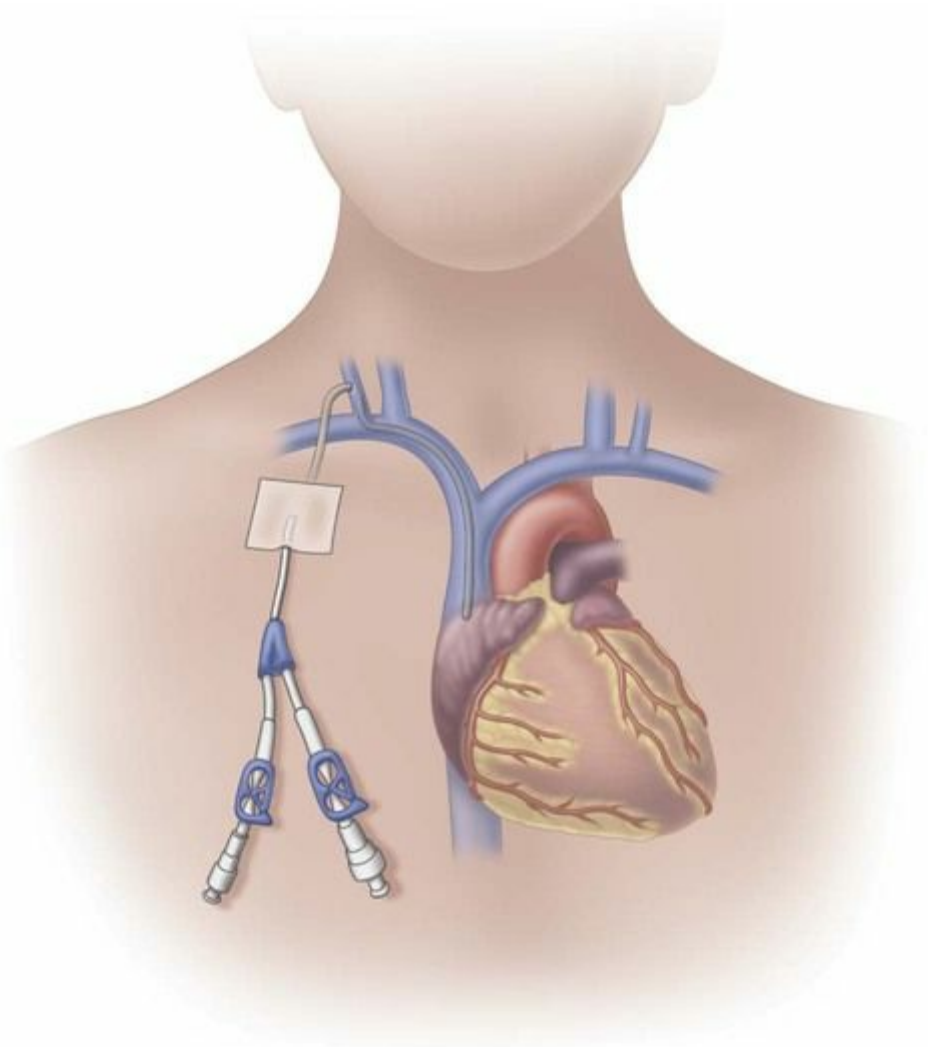

FIG. 13-8 Tunneled catheter. A portion of this catheter lies in a subcutaneous tunnel, separating the point where the catheter enters the vein from where it exits the skin.

The design of tunneled CVCs requires surgical techniques for insertion and removal. Single-, dual-, and triple-lumens are available. These catheters were originally named for the physicians who designed them, including Broviac, Hickman, and Leonard catheters.

Tunneled catheters are used primarily when the need for infusion therapy is frequent and long-term. Patients needing parenteral nutrition for months, years, or the remainder of their life commonly choose a tunneled catheter. Tunneled catheters are also chosen when several weeks or months of infusion therapy are needed and a PICC is not a good choice. For example, paraplegic patients needing 6 to 8 weeks of antibiotics are not good candidates for a PICC because of the excessive use of the upper extremities for mobility. Some oncology patients may prefer a tunneled catheter instead of an implanted port because they cannot tolerate the needle sticks required for accessing those devices.

Implanted Ports

Implanted ports are very different from other central vascular access devices (CVADs). This type of device is chosen for patients who are expected to require IV therapy for more than a year (Santolim et al., 2012). This device is typically inserted by a physician in the radiology department or by a surgeon in the operating suite. Implanted ports consist of a portal body, a dense septum over a reservoir, and a catheter. They can be single- or double-lumen and come in various sizes. A subcutaneous pocket is surgically created to house the port body. The catheter is inserted into the vein and attached to the portal body. The septum is made of self-sealing silicone and is located in the center of the port body over the reservoir; the catheter extends from the side of the port body. The incision is closed, and no part of the catheter is visible externally; therefore this device has the least impact on body image (Fig. 13-9).

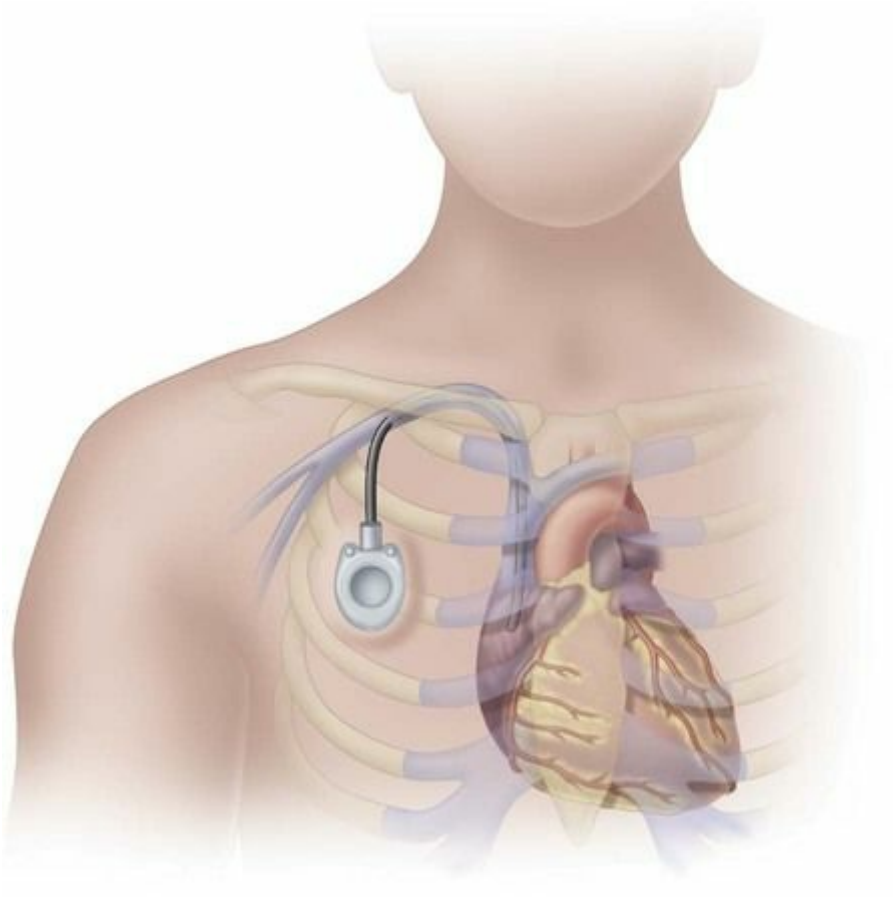

FIG. 13-9 Positioning of an implanted port.

Some implanted ports are power-injectable and can be used for obtaining contrast-enhanced computed tomography (CECT). These devices can withstand 5 mL/sec at up to 300 psi pressure. The BARD

PowerPort can be identified by palpation of three bumps on the top of the septum and a triangular-shaped port. Be careful not to press firmly on the bumps because it can be painful to the patient. Be sure to use a power-injection–rated noncoring needle with this type of port when it is used for this purpose. These needles come with labeling identifying that they are power-injection rated (Fig. 13-10).

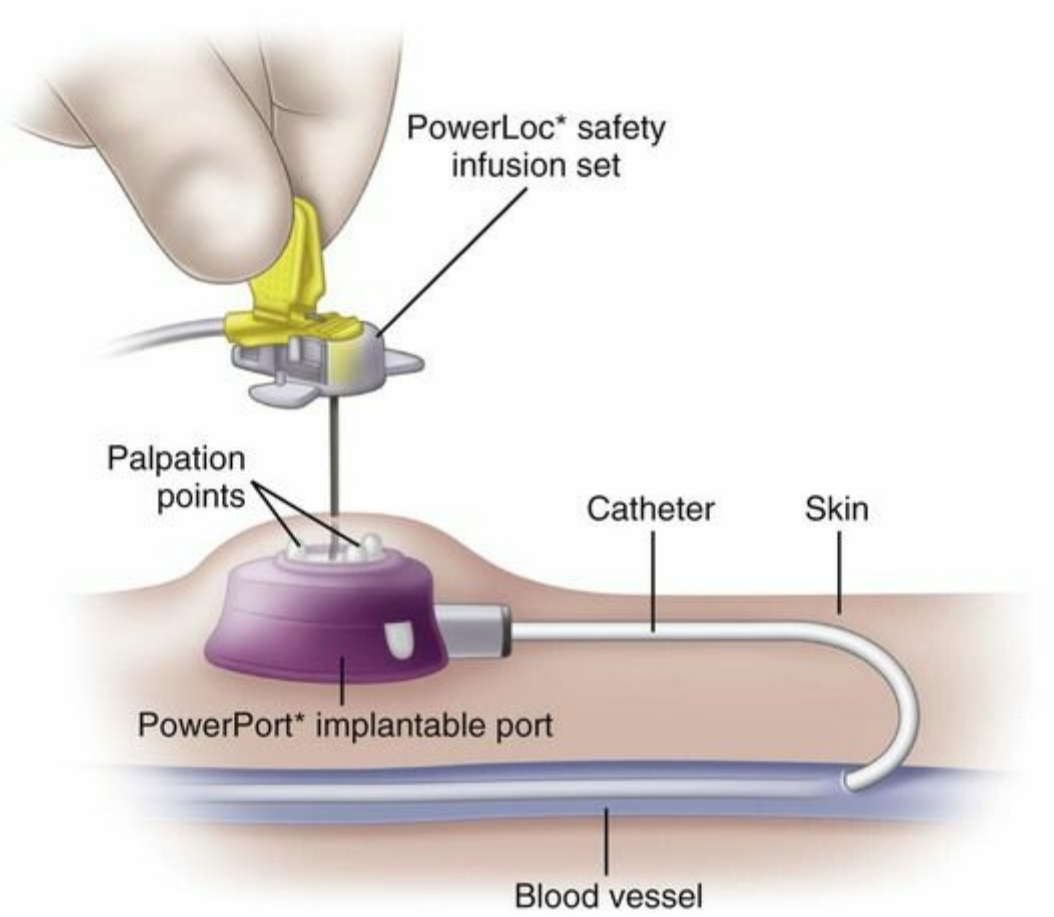

FIG. 13-10 A noncoring needle for accessing an implanted powerport.

Venous ports may be placed on the upper chest or the upper extremity. The venous catheter may enter either the subclavian or internal jugular vein. Although an implanted port is most commonly used in the venous system, the catheter may be placed in arteries, the epidural space, or the peritoneal cavity, with the port pocket located over a bony prominence.

Implanted ports are accessed by using a noncoring needle (a common brand name is *Huber*) that is specially designed with a deflected tip. This design slices through the dense septum without coring out a small piece of it, thus preserving the integrity of the septum. Port bodies placed in the chest have a larger septum and usually tolerate about 2000 punctures. Port bodies placed in the upper extremity are smaller and are rated to

tolerate about 750 punctures.

Port access should be done only by formally trained health care professionals using a mask and aseptic technique. Implanted ports are used most often for patients receiving chemotherapy. These patients are immune-compromised making them highly susceptible to infection. Before puncture, palpate the port to locate the septum. Carefully palpate to feel the shape and depth of the port body to ensure puncture of the septum, not the attached catheter. Some have attached extension sets and wings to stabilize the needle. One important feature is an engineered safety mechanism to contain the needle when it is removed from the septum. Because the dense septum holds tightly to the needle, there can be a rebound when it is pulled from the septum, which can result in needle stick injury to the nurse.

Implanted ports need to be flushed after each use and at least once a month between courses of therapy. This procedure is done to prevent clot formation in the internal chamber of the port and is often referred to as "locking" or "de-accessing." The INS recommendation for locking or de-accessing a port is 5 mL of 100 units heparin/mL (INS, 2011). When the port is not accessed, there is no external catheter requiring a dressing. Puncture of the skin over the port is required to gain access to the port body, causing pain for some patients. Topical anesthetic creams can be used to make the access procedure more tolerable.

Nursing Safety Priority QSEN

Drug Alert

Before giving a drug through an implanted port, always check for blood return. If there is no blood return, withhold the drug until patency and adequate noncoring needle placement of the port are established. Serious extravasations of vesicant drugs can occur because a fibrin sheath (flap or tail) may occur at the tip of the catheter, clot it, and cause retrograde subcutaneous leakage.

Hemodialysis Catheters

Hemodialysis catheters have very large lumens to accommodate the hemodialysis procedure or a pheresis procedure that harvests specific blood cells. They may be tunneled for long-term needs or nontunneled for short-term needs. A hemodialysis catheter is critical to the management of renal failure and must function well. CR-BSIs and vein thrombosis are common problems; therefore this catheter should not be

used for administration of other fluids or drugs except in an emergency.

The concentration of heparin used to lock hemodialysis catheters ranges from 1,000 to 10,000 units/mL. Researchers have demonstrated that using 1,000 units/mL reduces the incidence of postinsertion bleeding but may be associated with an increased need for recombinant tissue plasminogen activator (tPA) to maintain patency. A flush of 1,000 units heparin/mL or a solution of 4% sodium citrate in the amount of the dwell volume of each lumen has been recommended (Moran & Ash, 2008). Heparin is most often used because sodium citrate has not been as commercially available in the preparation needed. To prevent systemic anticoagulation and subsequent bleeding, be sure to aspirate the heparin from the lumens before use.

Infusion Systems

Nurses administering infusion therapies need to understand how infusion systems work. This knowledge ensures that the patient can benefit from a particular system's advantages while minimizing any potential complications.

Containers

Infusion containers are made of glass or plastic. *Glass* bottles were the original fluid container to be mass produced. They are easily sterilized, and it is easy to read the amount of fluid remaining in the bottle. Also, glass is inert and so cannot interact with some drugs like plastic can. However, glass bottles are heavy and cannot easily be used in many situations, such as patient transport during emergencies. These containers require an air vent for fluids to flow freely from them. The most common method is to use an administration set with a special filtered vent. Some bottles may have a straw tube open to the room air through the rubber stopper in the bottle and extending to above the level of the fluid. Bottles with a venting straw do not have a barrier to prevent contaminants in the air from entering the fluid.

Plastic containers are considered *closed systems* because they do not rely on outside air to allow the fluid to infuse. Instead, atmospheric pressure pushes against the flexible sides of the container, allowing the fluid to flow by gravity. For this reason, plastic containers do not require vented administration sets. These containers are lightweight, resistant to breaking, easier to store, and easy to use in emergency conditions. Therefore they are used more frequently than glass containers.

All plastic containers were commonly made of polyvinyl chloride (PVC). To increase flexibility and strength, PVC required the addition of a plasticizer, such as di-2-ethylhexyl-phthalate or DEHP. Concern has been growing in the past few years over the exposure of patients to this chemical because it can leach from the plastic fluid container or tubing and infuse into the patient with the IV fluid or medication. The FDA has determined that there is little to no risk posed to most patients by exposure to the amount of DEHP released from IV bags with infusion of crystalloids or drugs. However, there is concern about the buildup of chemical exposure from many sources over a lifetime and specifically the potential effects of DEHP on the development of the male reproductive system. Therefore many hospitals are using PVC-free and DEHP-free IV bags, especially for high-risk groups.

One disadvantage of removing DEHP from the plastic bags is that the

bags are less pliable and more prone to rupture. Some institutions do not allow these bags to be sent through a pneumatic tube system because the pressure exerted has caused the bags to rupture during transport.

A problem with plastic containers is that they are not compatible with insulin, nitroglycerin, lorazepam (Ativan), fat emulsions, and lipid-based drugs. Nitroglycerin and insulin adhere to the walls of the PVC container, making it impossible to know exactly how much medication the patient is receiving. There is evidence that a priming volume of 20 mL of insulin solution is required to minimize the effect of insulin absorption losses to the plastics in IV lines (Thompson et al., 2012).

Another concern with plastic bags is the accuracy of reading the amount of fluid remaining in the container. The middle graduations have been shown to be 10% above or below the actual amount of fluid, but the first and last markings could be inaccurate by as much as 40% (Perucca, 2010).

Nursing Safety Priority QSEN

Action Alert

Regardless of the type of fluid container being used, check it for cracks or pinholes before use. Always observe the fluid for **turbidity** (cloudiness) or any unusual color that could indicate contamination.

Administration Sets

The administration set is the connection between the catheter and the fluid container. Numerous sets are available in many different configurations. The type and purpose of the infusion determine the type of administration set needed. Some sets are *generic*, meaning that they are appropriate for most infusions. Other sets are used for specific types of infusions, such as blood transfusion. Still others are *dedicated*, meaning that they must be used with a specific manufacturer's infusion controlling device. Information that describes their proper use is provided on the packaging of administration sets.

Secondary Administration Sets

A primary continuous administration set is used to infuse the primary IV fluid by either a gravity infusion or an electronic infusion pump. A short **secondary administration set,** also known as a **piggyback set,** is attached to the primary set at a Y - injection site and is used to deliver intermittent

medications (Fig. 13-11). Directions and diagrams for use are typically on the packaging. Once attached, these sets should remain connected together as an infusion system. Primary and secondary continuous infusion administration sets used to infuse fluids other than parenteral nutrition, lipids, blood, or blood products should be changed no more frequently than every 96 hours (INS, 2011).

FIG. 13-11 Secondary IV administration set attached to the primary set at a Y-injection site.

Intermittent Administration Sets

When no primary continuous fluid is being infused, use an intermittent administration set to infuse multiple doses of medications through a catheter that has been capped with a needleless connection device. Remove the medication bag from the previous dose, and attach the new

one. Remove the sterile cap covering the distal end of the set, and attach the set to the catheter. Because both ends of the set are being manipulated with each dose, the INS standards of practice state that this set should be changed every 24 hours. When the administration set is used for infusion of parenteral nutrition or lipid solution, change it every 24 hours. Change blood tubing within 4 hours; use new tubing to infuse propofol (Diprivan) every 6 to 12 hours (McGoldrick, 2010).

Administration sets are sterile in the fluid pathway and under the sterile caps on each end of the set. The set is not packaged as a completely sterile product and cannot be added to a sterile field. Careful attention is required to maintain the sterility of the spike and the connection end of the tubing to prevent introduction of microorganisms into the catheter and bloodstream.

Add-on Devices

Several other types of add-on devices include short extension sets, injection caps, and filters. Extension sets may be packaged as a sterile product for adding to a sterile field; however, always check the product label for this information.

Administration sets have two ways to connect to the catheter hub: a slip lock or a Luer-Lok. The *slip lock* is a male end that slips into the female catheter hub. A *Luer-Lok* connection has the same male end with a threaded collar that requires twisting onto the corresponding threads of the catheter hub. All connections, including *extension sets*, should have a Luer-Lok design to ensure that the set remains firmly connected. Loose connections lead to fluid leakage and increase the risk for contamination and subsequent bloodstream infection. When using a central venous catheter, a Luer-Lok connection is critical to reduce the risk for air embolism. Tape is not considered an adequate mechanism for securing set connections.

Luer-Lok devices may be purposefully or accidentally disconnected. Patients or visitors may disconnect the system to allow the patient to get out of bed or the chair. Or, the device may become accidentally disconnected when the patient turns or moves. In either case, be sure to reconnect the device by following the proper sequence to reassemble the IV system components. Fatalities have resulted when nurses have accidently reconnected IV tubing to a tracheostomy or other inappropriate port.

Filters may be part of the administration set or may be separate add-on pieces. Their purpose is to remove particulate matter, microorganisms,

and air from the infusion system. Filter sizes depend on the pore size, with common sizes being 1.2 microns used to filter lipid-containing parenteral nutrition and 0.2 microns intended to remove all particles and bacteria. Filters should be placed as close to the catheter hub as possible.

Particulate matter in the IV fluid, a primary reason to use filters, comprises undissolved, unintended substances and may include rubber pieces, glass particles, cotton fibers, drug particles, paper, and metal fibers. These particles become trapped in the small circulation of the lungs. A red blood cell is about 5 microns in diameter and is the largest size that can pass through the pulmonary capillary bed; IV fluids may contain particles larger than 5 microns. For patients receiving infusion therapy for long periods, a significant number of particles could block the blood flow through the pulmonary circulation. Microcirculation in the spleen, kidneys, and liver could also be affected. Particulate matter has also been implicated in the development of phlebitis in peripheral veins.

Other concerns with using filters include the possibility for their rupture, their use with certain drugs that bind to the filter surface, using the incorrect size of filter for drugs with large molecules, and choosing a filter that will not tolerate the pressure exerted by infusion pumps. Rupture is most commonly associated with the exertion of high pressure exceeding the limit tolerated by the specific filter. Some drugs cannot be filtered because they are retained inside the filter because of their chemical nature or molecule size. For these reasons, medication filtration during the process of admixing is commonly used today as an alternative to final filtration at the bedside. Drugs of a very small quantity should be administered below the filter.

Filters used on blood administration sets have much larger pore size and are not interchangeable with filters used for fluids and medications. A standard blood filter ranges from 170 to 260 microns and removes microclots and other debris caused by blood collection and storage. Microaggregate filters have a pore size of 20, 40, or 80 microns and are used to remove degenerating platelets, white blood cells, and fibrin strands. Leukocyte-removal filters are used to remove white blood cells that cause febrile and allergic blood transfusion reactions.

Needleless Connection Devices

In July 1992, the Occupational Safety and Health Administration (OSHA) published guidelines entitled *Occupational Exposure to Bloodborne Pathogens, Final Rule*. This document requires health care organizations

to initiate engineering controls “that isolate or remove the bloodborne pathogen hazard from the workplace.” This standard was amended in 2001 with the passage of the Needlestick Safety and Prevention Act. This regulation requires the use of devices engineered with safety mechanisms and mandates that staff who perform these tasks be directly involved with selecting products. It also requires each employer to maintain a sharps injury log with details of each incident. Many products are designed to minimize health care workers' exposure to contaminated needles. Luer-activated devices are the most common design for needleless systems today.

Although these devices have reduced the incidence of accidental needle sticks for health care professionals, concern remains about a possible increase in the risk for catheter-related bloodstream infections (CR-BSIs) (Jarvis et al., 2009). This concern stems from the crevices created with the diaphragm and Luer-Lok design. Blood and bacteria can be trapped in the crevices, and meticulous cleaning is required with each use.

Various designs are available for connectors that provide positive or negative displacement of fluid when the needleless syringe is removed. Needleless positive-pressure valve (PPV) connectors were developed to prevent backflow of blood into the IV catheter, thereby decreasing chances of thrombus formation and CR-BSI. Several newer connectors are silver-impregnated to reduce bacterial growth (Fig. 13-12). Be sure to check which type of connector valve is used in your facility because the flushing technique differs depending on type. Researchers have found conflicting results about the relationships between these devices and CR-BSI and catheter occlusion (Khalidi et al., 2009; Mitchell et al., 2009; O'Grady et al., 2011).

FIG. 13-12 Example of a needleless connector.

Conclusive studies are needed to determine the best design for needleless systems. Until then, implement these interventions to reduce infection risk:

- Clean all needleless system connections vigorously with antimicrobial for 30 seconds (usually 70% alcohol or alcohol and 2% chlorhexidine swabs) before connecting infusion sets or syringes, paying special attention to the small ridges in the Luer-Lok device. There are newer caps that are impregnated with alcohol or chlorhexidine that may be used to keep the port aseptic; however, these will increase costs and research is needed to demonstrate the benefit.
- Do not tape connections between tubing sets.
- Use evidence-based hand hygiene guidelines from the CDC and OSHA

Rate-Controlling Infusion Devices

The ability to regulate the rate and volume of infusions is critical to the safe and accurate administration of medications and fluids to patients. Nurses have a choice of numerous devices that can be electronically or mechanically regulated.

Electronic infusion devices (IV pumps) are used universally in acute care institutions. They are also used in long-term care settings and at home. In addition, "smart pumps" provide the latest infusion computer technology to promote patient safety and save nursing time. *Remember that the use of pumps does not decrease your responsibility to carefully monitor the patient's infusion site and the infusion rate.*

In inpatient settings, IV pumps are pole-mounted. As their name implies, these electronic devices with battery backup pump drugs or fluids under pressure. They accurately measure the volume of fluid being infused by using one of three mechanisms:

• A syringe-type mechanism that fills and empties
• A wavelike, peristaltic action that pushes fluid along the tubing
• A series of microchambers that fill and empty

Regardless of the pumping mechanism, these devices require dedicated cassette tubing designed to match the pump.

Syringe pumps use an electronic or battery-powered piston to push the plunger continuously at a selected milliliter-per-hour rate. The use of syringe pumps is limited to small-volume continuous or intermittent infusions and depends on the syringe size. Antibiotics and patient-controlled analgesia are frequently delivered with syringe pumps. Patients requiring fluid restrictions can also benefit from using a syringe pump because smaller yet accurate volumes can be used to dilute medications.

Ambulatory pumps are generally used for home care patients and allow them to return to their usual activities while receiving infusion therapy. These pumps have a wide range of sizes, with some requiring a backpack, but they usually weigh less than 6 pounds. They are typically used to accurately deliver continuous infusions, such as parenteral nutrition, pain medication, and many programmable drug schedules. Frequent battery recharging or replacement is usually necessary.

Electronic infusion devices can be programmed in many different ways and require a thorough knowledge of the specific brand being used. Infusion rate and the volume to be infused are usually entered in single milliliter increments, but some can be programmed as fractions of a milliliter. Some pumps allow the rate to be programmed to taper or ramp up and down at the beginning and ending of the infusion. Secondary syringe infusion, secondary infusion rate, remote site programming, adjustable infusion pressure, and integration into the nurse call system also are possible.

Electronic infusion devices have a variety of alarms, such as air-in-line, upstream and downstream occlusion, infusion complete, and low-battery or power warnings. All devices must have some mechanism to prevent free flow of the infusing fluid or medication. When the cassette or tubing is removed from the pump, this mechanism automatically stops fluid flow until it is properly replaced in the pump. This safety measure prevents accidental rapid infusion of large amounts of fluid or medication, which could lead to serious clinical problems.

In the past few years, **smart pumps** (infusion pumps with dosage calculation software) have been promoted to reduce adverse drug events (ADEs). Incorrect programming of pumps without this feature is one of the most common types of drug errors, especially in hospitals. Multiple

libraries of drug information are stored in the pump manufacturer's medical management system. This software allows the facility to pre-program dosing limits, especially for high-alert drugs. Examples of smart pumps are the B. Braun Outlook 400ES and the Baxter Sigma Spectrum infusion system.

The newest development in smart pumps is a wireless network connection. Drug libraries can be updated via a wireless connection, thus eliminating the necessity of manually updating each pump. In addition to preventing drug errors, smart pump systems record potential errors that would have occurred without these safety mechanisms (Breland, 2010).

Dose-track technology is intended to transmit the infusion data to the institution's pharmacy so that the correct patient receives the correct medication. Dose-guard technology alerts the nurse if institution-defined dose limits are exceeded. These newer technologies provide safeguards for patients to keep them safe. However, the "smarter" the pump, the more extensive the programming steps are and the more alarms that the nurse must respond to. In addition, technology and wireless connections can fail. The challenge for nurses is to maintain the skill of manual dose calculation and rate control, to acknowledge and validate all alarms, and to guard against becoming desensitized to alarms.

Mechanically regulated devices can be used to deliver intermittent medications such as antibiotics or continuous pain medications in community-based health or home care settings. In acute care settings, devices called "infusers" may be found in surgical services. They are powered by positive pressure from the collapsing balloon or roller returning to its coiled position.

The systems include elastomeric balloons, spring-coiled syringes and containers, and a multi-chambered fluid container placed in a mechanical roller (Accufuser or On-Q PainBuster) (Fig. 13-13). These small portable devices do not require power sources such as batteries or electricity. They deliver a preset infusion rate, and fluid volume is determined by the size of the fluid container; however, most hold only 50 to 100 mL.

FIG. 13-13 On-Q PainBuster pump (mechanical infuser).

Nursing Care for Patients Receiving Intravenous Therapy

Educating the Patient

The current trend in health care demands that we partner with our patients to provide the best patient-centered care. In 2010, The Joint Commission added the requirement that all patients who have central lines placed in the hospital must have education on prevention of catheter-related bloodstream infection (CR-BSI). Before catheter insertion, educate the patient and family about:

- The type of catheter to be used
- Hand hygiene and aseptic technique for care of the catheter
- The therapy required
- Alternatives to the catheter and therapy
- Activity limitations
- Any signs or symptoms of complications that should be reported to a health care professional

Provide written information before placement of a long-term catheter, and continue to assess the patient's knowledge level and provide more information or answers as needed. Most manufacturers of PICCs, tunneled catheters, and implanted ports provide patient information booklets. However, specific information about the chosen procedures and supplies may be required. Conversation and pictures will be helpful for patients who are *literacy challenged* (have a low reading level ability).

Performing the Nursing Assessment

All central VADs require documentation of tip location at the CAJ by either electrocardiogram technology, fluoroscopy, or chest x-ray. The initial verbal and subsequent written report should contain specific information about the catheter tip location in relation to anatomic structures. The nurse's knowledge of accurate tip location is required before beginning infusion through the catheter. Repeating the x-ray during catheter use may be necessary if the patient reports unusual pain or sensation.

Nursing assessment for all infusion systems should be systematic. Begin with the insertion site and work upward, following the tubing. Know the type of catheter your patient has in place. Be sure to find out the length of catheter, the insertion site, and tip location to perform a complete assessment. Assess the insertion site by looking for redness, swelling, hardness, or drainage. Lightly palpate the area over the

dressing. When a midline catheter or PICC is used, assess the entire extremity and upper chest for signs of phlebitis and thrombosis. When a tunneled catheter is used, assess the exit site, the entire length of the tunnel, and the point where the catheter enters the vein. For a well-healed catheter, it may not be possible to detect the vein entrance site. On newly inserted catheters, there could be a small puncture site with a suture or other securement device. For implanted ports, assess the incision and surgically created subcutaneous pocket.

Assess the integrity of the dressing, making sure it is clean, dry, and adherent to the skin on all sides. Check all connections on the administration set, and ensure that they are secure. Be sure they are not taped. Check the rate of infusion for all fluids by either counting drops or checking the infusion pump. Assess the amount of fluid that has infused from the container. Is it accurate, or is it infusing too fast or too slow? Adjust the rate to the prescribed flow rate. Check all labels on containers for the patient's name and fluid or medication. *Be sure that the correct solution is being infused!*

Nursing Safety Priority QSEN

Action Alert

Remind unlicensed assistive personnel (UAP) to avoid taking blood pressures in an extremity with any type of catheter in place. If a short peripheral catheter is being used for continuous infusion, the compression while taking the blood pressure can increase venous pressure, causing fluid to overflow from the puncture site and infiltration. When a midline catheter or PICC is being used, compression from the blood pressure cuff could increase vein irritation and lead to phlebitis.

Draw blood samples in the extremity opposite from all catheters. Blood should not be drawn from a venipuncture site proximal to (above) an infusing peripheral catheter because the infusing fluid could alter the results of the test to be performed. Venipuncture at or near the insertion site of a midline catheter or PICC could damage the catheter, add to areas of venous inflammation, and decrease perfusion.

Securing and Dressing the Catheter

Adequate catheter securement is vital to prevent many complications. Tape, sutures, and specially designed securement devices can be used for this purpose. For a short peripheral catheter, tape strips are most

common; however, the tape should be *clean*. Tape strips from a peripheral IV start kit are preferred. Strips of tape should not be taken from rolls of tape moved between patient's rooms, from other procedures, or from uniform pockets. Precutting tape and placing it on the patient's bedrails, your uniform or scrubs, or other object should also be avoided to prevent infection.

Newer *securement devices* are designed for all catheter types and provide an evidence-based method to prevent VAD movement (INS, 2011). Recent studies have shown that these devices, such as the StatLock IV stabilization device, prevent peripheral and central catheters from becoming dislodged (Fig. 13-14) (see the Evidence-Based Practice box). In addition, they prevent complications like phlebitis and infiltration. To prevent skin tears, remove the adhesive on a StatLock with 70% alcohol.

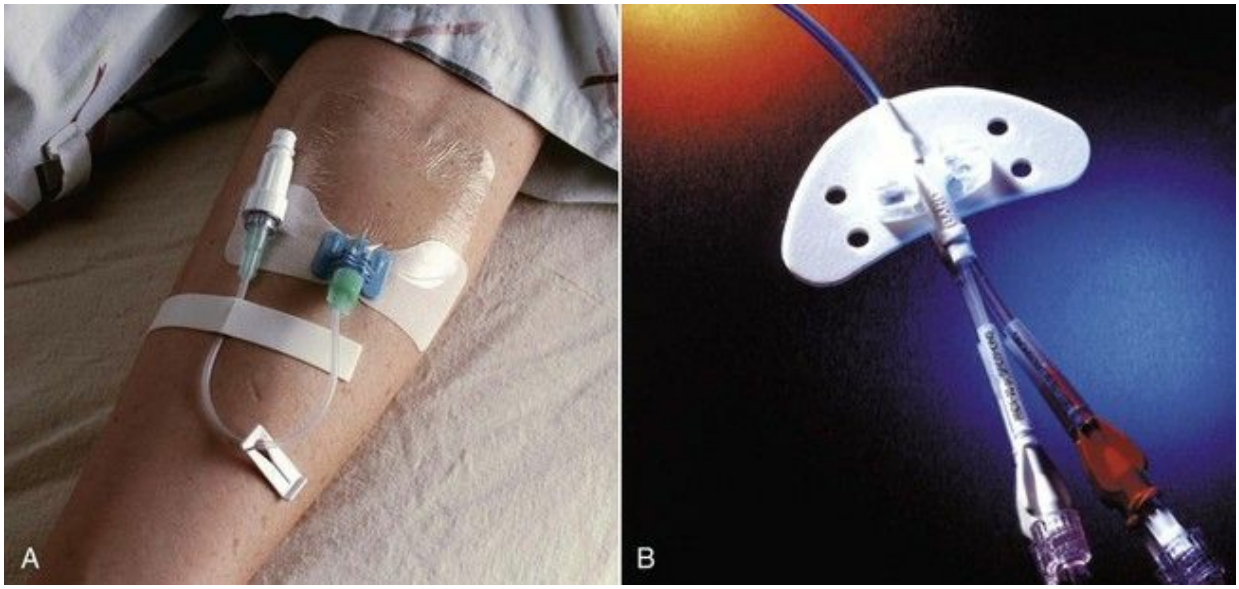

FIG. 13-14 The StatLock provides a standardized method to prevent catheter movement.

Evidence-Based Practice QSEN

What is the Best Method for Securing a Patient's Peripheral IV Line?

Alekseyev, S., Byrne, M., Carpenter, A., Franker, C., Kidd, C., & Hulton, L. (2012). Prolonging the life of a patient's IV: An integrative review of intravenous securement devices. *MEDSURG Nursing, 21*(5), 285-292.

Intravenous catheter stabilization is recognized as an important intervention to maintain peripheral IV therapy. The researchers sought to answer this clinical question: What is the best device or method for

securing a patient's IV to preserve its integrity and prevent migration and loss of access? A thorough literature search for available research was performed, and 13 articles were identified as usable for this review. Twelve of the reported studies found that manufactured catheter stabilization devices were preferred over traditional tape and surgical strips methods. Although most studies included use of the StatLock anchoring device, no one securement device was recommended. Studies of the StatLock device showed that it significantly improved peripheral IV survival rates and reduced complication rates. These findings reduced health care costs and staff time.

Level of Evidence: 1

This study used an integrative research review and analysis methodology to determine best practices for use of IV securement devices.

Commentary: Implications for Practice and Research

This research validated the effectiveness of manufactured IV catheter securement and stabilization devices for all patients receiving peripheral infusion therapy. These devices reduce the need for IV restarts, IV complications, and costs associated with IV therapy. Future studies are needed to determine which device(s) are the best to standardize care of patients receiving peripheral infusion therapy.

PICCs and nontunneled percutaneous central catheters may be sutured in place; however, this creates additional breaks in the skin that could become infected. If these sutures are loose or broken, notify the health care provider to replace them. IV catheter sutures are being replaced with securement devices and Dermabond glue in some facilities, which can decrease infection and avoid the need to remove sutures after infusion therapy is discontinued.

Tunneled catheters usually have sutures placed near the skin exit site, which are removed after the tunnel has healed. The incision over an implanted port pocket will have sutures until it has healed. After it is healed and when it is not accessed, no dressing is required. When an implanted port is accessed, the sterile occlusive dressing should cover the entire needle and site.

Sterile dressings used over the insertion site protect the skin and puncture site. For a short *peripheral* catheter, the transparent membrane dressings do not require routine changes. Short peripheral lines do not usually dwell longer than a few days, and as long as the dressing is dry,

clean, and intact, it does not have to be changed. Any VAD dressing should be changed when it is loose or soiled.

For central lines and midline catheters, tape and sterile gauze or a transparent membrane dressing may be used. Change tape and gauze dressings every 48 hours; change transparent membrane dressings, such as Tegaderm, every 5 to 7 days (INS, 2011). The initial dressing on a midline catheter or PICC is usually tape and gauze, changed within 24 hours after insertion because some bleeding is likely. Transparent membrane dressings can be used for subsequent dressing. For patients who develop erythema (redness) from Tegaderm, the IV3000 dressing from Smith and Nephew may be used. Document when you change the sterile dressing and your IV site assessments in the appropriate electronic health record according to agency policy.

Nursing Safety Priority QSEN

Action Alert

Site protection may be needed for short peripheral catheters or for port access needles. Plastic shields can be placed over the site to prevent accidental bumping or pressure from clothing. Make sure you can easily assess the site frequently. Never place a restraint or opaque dressing over a peripheral IV site, especially when infusing an irritant or vesicant.

When changing the dressing, remove it by pulling laterally from side to side. It can also be removed by holding the external catheter and pulling it off toward the insertion site. *Never pull it off by pulling away from the insertion site because this could dislodge the catheter!*

After removing the dressing from a midline catheter or any central venous catheter, note the external catheter length. Compare this length with the original length at insertion. If the length has changed, the catheter tip location has also changed and may no longer be in a vein appropriate for infusion. Follow agency policy or notify the health care provider about the length change. A chest x-ray may be needed, and careful assessment of the type of therapy and remaining length of therapy will likely be required.

Protect the external catheter, dressing, and all attached tubing from water because it is a source of contamination. *Remind unlicensed assistive personnel (UAP) to cover the extremity where the IV is located when giving the patient a bath*. A plastic bag or wrap can be taped over the extremity to keep the dressing and site dry.

Clinical Judgment Challenge

Evidence-Based Practice; Safety QSEN

A new graduate nurse is being oriented to your medical-surgical nursing unit. Today he is assigned to care for three patients. One patient is an older adult with an infiltrated peripheral IV in her forearm. The second patient has a PICC line for antibiotic therapy, and the third patient has an arterial implanted port for chemotherapy. As his preceptor, you are responsible for teaching him how to assess patients with these devices and prevent and/or monitor for complications. Your unit has several memory checklists for IV care that you plan to review with him.

1. What best clinical practices will you teach the new nurse about how to care for patients who have a PICC line?
2. For what life-threatening complication is the patient with the implanted port most at risk?
3. You observe the new nurse as he prepares to restart the IV for the older adult patient. He chooses a vein in the dorsum of the hand. What is your best response about his IV site selection?
4. What is the value of memory checklists to ensure consistency among nurses caring for patients receiving IV therapy?

Changing Administration Sets and Needleless Connectors

Plan the change of administration sets and fluid containers to occur at the same time, if possible, to minimize the number of times the system is opened. For short peripheral catheters, the administration set and catheter should also be changed at the same time to avoid excessive manipulation of the catheter. Document these changes per agency policy.

Needleless connector devices can be changed when the administration set is changed. If it is being used for intermittent infusions, the device should be changed at least once per week. Fluid leakage from the device indicates the integrity has been compromised, and it should be changed immediately.

Precautions to prevent *air emboli* are required when changing the set or connectors attached to any catheter; however, central venous catheters require special attention. Most catheters have a pinch clamp that can be closed during this procedure. Techniques used to increase the intrathoracic pressure and prevent air embolism during IV set change

include:

- Placing the patient in a flat or Trendelenburg position to ensure that the catheter exit site is at or below the level of the heart
- Asking the patient to perform a Valsalva maneuver by holding his or her breath and bearing down
- Timing the IV set change to the expiratory cycle when the patient is spontaneously breathing
- Timing the IV set change to the inspiratory cycle when the patient is receiving positive-pressure mechanical ventilation

Controlling Infusion Pressure

Fluid flow through the infusion system requires that the pressure on the external side be greater than the pressure at the catheter tip. Fluid flow can be slowed or obstructed by many causes. Inside the catheter lumen, resistance is created by the catheter length and diameter or by deposits of fibrin, thrombus, or drug precipitate. Near the catheter tip, resistance to flow comes from the catheter tip impinging on the vein wall, thrombus, or venous spasm.

All catheter manufacturers have warnings about the use of excessive pressure. Gravity and infusion pumps do not exert pressure too high for the catheter to handle; however, excessive pressure from syringes can lead to catheter damage. For this reason, use 10-mL syringes for central venous catheters. Although these larger syringes generate less pressure, it is still possible to reach excessive pressure levels if great force is applied against a syringe attached to a catheter that is partially occluded.

Flushing the Catheter

Catheter flushing prevents contact between incompatible drugs and maintains patency of the lumens. Normal saline alone or normal saline followed by heparinized saline may be used. When using valved catheters and certain positive fluid-displacement needleless devices, normal saline alone is acceptable because these devices have mechanisms that prevent the backflow of blood into the catheter lumen.

Nursing Safety Priority QSEN

Critical Rescue

Assess catheter patency carefully before each use. Use sterile technique to flush with normal saline while applying slow, gentle

pressure to the syringe plunger. If you feel any resistance, stop the procedure immediately! If you continue, catheter rupture or forcing a blood clot into circulation could result. During the flushing procedure, always aspirate for a brisk blood return from the catheter lumen.

If the catheter will not yield a blood return, further diagnostic studies may be needed to determine the cause of the problems. Thrombolytic agents such as alteplase (Cathflo Activase) may be used to dissolve blood clots in venous catheters (Genentech, 2011).

For short peripheral catheters, usually 3 mL normal saline is adequate to flush the catheter. For all other catheters, 5 to 10 mL of preservative-free normal saline is needed. Bacteriostatic normal saline is limited to no more than 30 mL in a 24-hour period in adults. By using 10 mL before and after each dose of medication, it is easy to exceed this limitation. Check your agency's policy and procedure about specific flushing amounts.

Flush catheters immediately after each use. Delay in disconnecting the intermittent administration set and flushing the catheter could cause lumen occlusion from blood that backflows into the lumen when the infusion pressure is lower than venous pressure.

All fluids used to flush catheters should be obtained from single-dose containers or prefilled syringes. Vials used for multiple doses contribute to medication errors and increase the risk for contamination.

Obtaining Blood Samples from Central Venous Catheters

Short peripheral catheters should not be used routinely for obtaining blood samples. This additional manipulation could lead to vein irritation that requires removal of the catheter. Central venous catheters and midlines can be used for obtaining blood samples after a careful assessment of the risks versus the benefits. If your patient has no peripheral venipuncture sites or is fearful of needles, using the central venous catheter may be appropriate. The risks associated with obtaining blood samples from a central venous catheter are numerous. This procedure requires additional hub manipulation, which is a major cause of CR-BSI. Consider the laboratory tests needed and the types of fluids that have recently been infused. For example, heparin interferes with coagulation studies and electrolytes in the fluid may alter the results of serum electrolytes. Drawing blood from catheters for blood culture should not be done within an hour of completion of antimicrobial infusions (Garcia & Isenberg, 2010).

If blood sampling from a central venous catheter is the best alternative, vigorous cleaning of the connections with 70% alcohol is necessary. Use methods that do not require exposed needles. Vacuum tubes attached via a "vacutainer" to the catheter hub eliminate the need to transfer the blood from a syringe into the tubes. For small-diameter catheters, the vacuum in the tube may cause the catheter to temporarily collapse, preventing the backflow of blood into the tube. In this situation, small syringes should be used because they create less pressure on aspiration, the opposite of what small syringes do on injection. Transfer of the blood from the syringe to the vacuum tube requires the use of a "vacutainer needle holder." This device keeps the needle housed in a plastic case and covered, preventing needle stick injuries (Fig. 13-15). After blood draw from any catheter, a flush of 10 to 20 mL sterile normal saline is necessary to ensure a patent line. Be sure to clear the line and cap of blood to prevent a breeding ground for infection.

FIG. 13-15 Vacutainer needle holder prevents needle stick injuries when drawing blood.

Removing the Vascular Access Device

To remove a short peripheral IV, lift opposite sides of the transparent dressing and pull laterally to remove the dressing from the site while stabilizing the catheter. Slowly withdraw the catheter from the skin, and immediately cover the puncture site with dry gauze. Hold pressure on the site until hemostasis is achieved. Assess the catheter tip to make sure it is intact and completely removed. Document the time of catheter removal and the appearance of the IV site.

Removal of midline catheters and PICCs must be performed with the same slow, gentle techniques used to insert the catheter. Veins can develop venospasms when rapid or forceful techniques are used. After explaining to the patient that this procedure will not be painful, remove the dressing and withdraw the catheter in short segments by pulling from the insertion site. *If you feel resistance, always stop and never apply force to the catheter. Extreme traction or force could cause the catheter to break*

and embolize (travel) to the heart or pulmonary circulation.

Simple distraction techniques and deep breathing may be sufficient to relax the patient and remove the catheter. If these fail, replace the dressing and apply heat; allow time for the vein wall to relax. Keeping the extremity warm and dry and asking the patient to drink warm liquids could facilitate removal. Use of medications to relax the vein wall may be required if the catheter cannot be removed after several hours. Imaging studies may also be needed to determine whether the cause is a thrombosis instead of venospasm.

Nontunneled percutaneous central catheters are removed by clipping any sutures and withdrawing the catheter in short segments. Venospasm does not commonly occur when removing these catheters because the vein diameter is large.

To prevent venous air embolism when removing any central venous catheter (including PICCs), position the patient in a flat supine or Trendelenburg position according to agency policy. To ensure the intrathoracic pressure is higher than atmospheric pressure, have the patient hold his or her breath or perform a Valsalva maneuver during removal. If the patient is mechanically ventilated, time the removal to the delivery of an inhalation by the ventilator. Be sure to keep the catheter clamped during this procedure. When a central venous catheter is removed, a tract between the skin and vein may create a conduit that could allow air to be pulled into the vein.

After removal, measure the catheter length and compare it with the length documented on insertion. *If the entire catheter length was not removed, contact the health care provider immediately!* Removal of tunneled catheters and implanted ports is usually performed by nurse practitioners or physicians.

Documenting Intravenous Therapy

Intravenous therapy is risk prone. Nurses can protect themselves from malpractice claims with conscientious assessment, intervention, and documentation. Be sure you document after insertion of a vascular access device (VAD) and throughout the course of the therapy. When inserting a venous catheter, remember to document the:

- Date and time of the VAD insertion
- Name of the nurse (you) who inserted the VAD
- Vein that was used for insertion
- Type of VAD used
- Number of insertion attempts and locations of attempts before

successful insertion
- Response of the patient to the VAD insertion process
- Type of dressing applied
- Type of securement device, if used
- Special barrier precautions used, if any
- Patient and family education provided related to IV therapy

During the course of the patient's infusion therapy, be sure to continue documenting in the electronic health record your assessments and any interventions needed as a result of complications. Follow your agency's policies and procedures for additional requirements.

Complications of Intravenous Therapy

Complications from IV therapy can be minor and limited or life threatening. Serious life-altering or life-threatening complications are dramatically increasing in frequency and severity and present a tremendous financial burden to the U.S. health care system. Catheter-related bloodstream infection (CR-BSI) is one of the most serious problems, often resulting in patient death. They are more common in patients with central VADs but can also occur with peripheral catheters.

Catheter-Related Bloodstream Infection

The Institute for Healthcare Improvement identified catheter-related bloodstream infection (CR-BSI) as one of several preventable hospital-acquired infections (HAIs). They report that CR-BSIs are responsible for up to 28,000 deaths per year. As part of their previous *100,000 Lives Campaign*, a number of evidence-based interventions were combined into the CR-BSI prevention bundle. As a nurse, your accountability is to ensure that these interventions are followed (Table 13-2).

TABLE 13-2

The Catheter-Related Bloodstream Infection (CR-BSI) Prevention Bundle

• Use a *checklist* during insertion to make sure everything is done correctly. Tell anyone who violates the correct steps to stop the procedure immediately.
• *Hand hygiene* before inserting a central line must be thorough (i.e., no quick scrub). Anyone who touches the central line must also perform thorough hand hygiene.
• *Maximal barrier precautions* during line insertion require that the patient be draped from head to toe with a sterile barrier.
• The health care provider who inserts the VAD wears sterile *gloves, gown, and mask*. Anyone in the room during the procedure must also wear a mask.
• *Traffic in and out of the room must be minimized*. Many institutions use a "stop" sign on the door of the room to prevent people from coming in and going out during the procedure and a special "central line cart" to ensure they have everything they need in the room.
• *Chlorhexidine is used for skin disinfection* because it has best outcomes for preventing infection.
• *Use preferred sites*. PICC in the upper arm and subclavian veins are the first choice. The next preference is the internal jugular vein, and the least preferred is the femoral vein.
• *Post-placement care* requires meticulous dressing changes and care of all parts of the IV system, such as keeping ports and stopcocks clean; hanging bags using sterile technique; vigorous scrub of catheter hub with alcohol when used.
• *Review daily the need* for the patient's VAD. The incidence of CR-BSI increases each day the device is in place. As soon as it is determined that the patient no longer needs the IV line, it should be removed.

PICC, Peripherally inserted central catheter; *VAD*, vascular access device.

Other Complications of Intravenous Therapy

Local complications of IV therapy occur at or near the catheter. A priority for care for patients with IV therapy is to prevent, assess, and detect these complications. In some cases, nurses also manage these problems. Definitions, causes, signs and symptoms, treatment, and prevention of local complications are summarized in Table 13-3. *Systemic complications* of IV therapy involve the entire vascular system or multiple systems. Information on common systemic complications can be found in Table 13-4. For central venous catheters (CVCs), complications can occur during the insertion procedure or during the dwell time (Table 13-5). Tables 13-6 and 13-7 are the INS criteria for grading phlebitis and

infiltrations. Document all assessments and complications in the patient's electronic health record. Notify the infusion therapy team and/or health care provider per agency policy when complications occur.

TABLE 13-3

Local Complications of Intravenous Therapy

COMPLICATION	CAUSE	SIGNS AND SYMPTOMS	TREATMENT	PREVENTION
Infiltration				
Leakage of a non-vesicant IV solution or medication into the extravascular tissue	Peripheral catheter has punctured opposite vein wall Obstruction of blood flow causing backflow through original entrance site Inflammatory process causing fluid leakage at the capillary level Fibrin sheath fully encasing a central venous catheter leading to retrograde flow and leakage from venipuncture site Damaged septum of implanted port Dislodged port access needle	IV rate slows Increasing edema around site Patient report of skin tightness; blanching or coolness of skin; burning, tenderness, or general discomfort at the insertion site; fluid leaking from puncture site; absence of a blood return (though this may not be reliable with a short peripheral catheter)	Stop infusion and remove short peripheral catheter immediately after identification of problem. Apply sterile dressing if weeping from tissue occurs. Elevate extremity. Warm or cold compresses may be used according to the solution infiltrated and organizational policy. Warm compresses increase circulation to the area and speed healing. Cool compresses may be used to relieve discomfort and reduce swelling. Insert a new catheter in the opposite extremity. For all central venous catheters, obtain a study to determine the cause of the problem. For implanted port, remove and insert a new port access needle. Rate the infiltration using the INS Infiltration Scale and document (Table 13-7).	Catheter stabilization—use smallest catheter appropriate; avoid area of flexion, or use arm board. Avoid placing restraints at the IV site. Make successive venipunctures proximal to the previous site. Monitor site frequently; educate patient about activities and signs and symptoms. Central venous catheters—obtain a brisk blood return before using the catheter for infusion. Frequently assess proper positioning of port access needle. Stabilize it well, and protect from clothing.
Extravasation				
Leakage of a vesicant IV solution or medication into the extravascular tissue This can occur with both peripheral and central catheters	Same as for infiltration	Same as for infiltration Blistering and tissue sloughing may not appear for a few days and resolves over 1-4 wk with infiltration of some chemotherapeutic agents such as anthracycline and alkylating agents	Stop infusion, and disconnect administration set. Aspirate drug from short peripheral catheter or port access needle. Leave short peripheral catheter or port access needle in place to deliver antidote, if indicated by established policy. If possible, aspirate residual drug from the exit site of a central venous catheter. Administer antidote according to established policy. Apply cold compresses for all drugs EXCEPT vinca alkaloids and epipodophyllotoxins. Photograph site. Monitor at 24 hr, 1 wk, 2 wk, and as needed. Surgical interventions may be required. Provide written instructions to patient and family.	Same as for infiltration. Know the vesicant potential before giving any IV medication. Prevention is key.
Phlebitis				

COMPLICATION	CAUSE	SIGNS AND SYMPTOMS	TREATMENT	PREVENTION
Inflammation of the vein Post-infusion phlebitis presents within 48-96 hr after the catheter has been removed	Mechanical cause from insertion technique, catheter size, and lack of catheter securement Chemical cause from extremes of pH and/or osmolarity of the fluid or medication Bacterial cause from a break in aseptic technique, poor securement, and extended dwell time	Patient may report pain at the IV site; nurse may observe that vein appears red and inflamed along the length; vein may become hard and cordlike (Table 13-6)	Remove short peripheral catheter at the first sign of phlebitis; use warm compresses to relieve pain. Monitor frequently. Document using Phlebitis Scale. Insert a new catheter using the opposite extremity. Mechanical phlebitis occurring in the first week after PICC insertion may be treated without catheter removal. Apply continuous heat; rest and elevate the extremity. Significant improvement is seen in 24 hr, and complete resolution is seen within 72 hr. Remove catheter if treatment is unsuccessful.	Choose the smallest-gauge catheter for the required therapy. Avoid sites of joint flexion, or stabilize with an armboard. Avoid infusing fluids or medications with a pH below 5 or above 9 through a peripheral vein. Avoid infusing fluids or medications with a final osmolarity above 500 mOsm/L through a peripheral vein. Rotate sites every 72-96 hr according to established policy. Adequately secure the catheter. Use aseptic technique. For PICCs, teach patient to avoid excessive physical activity with the extremity.
Thrombosis				
Blood clot inside the vein	Anything that damages the endothelial lining of the intima can initiate clot formation Traumatic venipuncture Multiple venipuncture attempts Use of catheters too large for the chosen vein Hypercoagulable state and venous stasis	Slowed or stopped infusion rate Swollen extremity Tenderness and redness Engorged peripheral veins of the ipsilateral chest and extremity	Stop infusion and remove short peripheral catheter immediately. Apply cold compresses to decrease blood flow and stabilize the clot. Elevate extremity. Surgical intervention may be required. For central venous catheters, notify the physician and obtain requests for a diagnostic study. Low-dose thrombolytic agents can be used to lyse the clot.	Use evidence-based venipuncture technique. Make only two attempts to perform venipuncture. Choose the smallest-gauge catheter in the largest vein possible. Secure catheter adequately. Use armboards if short peripheral catheters are placed in areas of joint flexion. Ensure adequate hydration to avoid changes in blood composition and flexion of the extremity. Prophylactic low-dose warfarin (Coumadin, Warfilone) may be prescribed for patients with a central venous catheter.
Thrombophlebitis				
The presence of a blood clot and vein inflammation	Same as for phlebitis and thrombosis	Same as for phlebitis and thrombosis	Same as for phlebitis and thrombosis. Apply cold compresses initially, followed by warm.	Same as for phlebitis and thrombosis.
Ecchymosis and Hematoma				

COMPLICATION	CAUSE	SIGNS AND SYMPTOMS	TREATMENT	PREVENTION
Ecchymosis results from infiltration of blood into the surrounding tissue Hematoma results from uncontrolled bleeding	Unskilled or multiple IV insertion attempts Patients with coagulopathy or fragile veins (e.g., older adults and patients on steroids) Accidental laceration of a large vein or artery	Swelling Bruising Pain or tenderness	When removing device, apply light pressure; excessive pressure could cause other fragile veins in the area to rupture. For hematoma, apply direct pressure until bleeding has stopped. Elevate extremity, apply ice for first 24 hours, and then warm compress for comfort.	Avoid veins that cannot be easily seen or palpated. Use extra caution in patients with coagulopathies. Use evidence-based venipuncture technique.
Site Infection				
Invasion of microorganisms at the insertion site in the absence of simultaneous bloodstream infection Infection localized at the insertion site, the port pocket, or subcutaneous tunnel	Break in aseptic technique during insertion or the handling of sterile equipment Lack of proper hand hygiene and skin antisepsis	Site appears red, swollen, and warm; patient may report tenderness at the site; may observe purulent or malodorous exudates	Clean exit site with alcohol, expressing drainage if present. For short peripheral catheter, midline catheter, or PICC, remove using sterile technique and avoid contact between skin and catheter. Send catheter tip for culture, if requested. Clean site with alcohol, and cover with dry sterile dressing; physician to evaluate for septic phlebitis and need for antimicrobial therapy or surgical intervention.	Use strict aseptic technique when inserting, maintaining, or removing catheters. Practice evidence-based hand hygiene. Ensure dressing remains clean, dry, and adherent to skin at all times.
Venous Spasm				
A sudden contraction of the vein	A normal response to irritation or injury of the vein wall	Cramping or pain at or above the insertion site Numbness in the area Slowing of the infusion rate Inability to withdraw midline catheter or PICC	Temporarily slow infusion rate. Apply warm compress. Do not immediately remove short peripheral catheter. If occurring during midline catheter or PICC removal, do not apply tension or attempt forceful removal. Reapply a dressing, apply heat, encourage patient to drink warm liquids, and keep extremity covered and dry. 12-24 hr may be required before catheter can be removed.	Allow time for vein diameter to return to normal after tourniquet removal and before advancing catheter. Infuse fluids at room temperature, if possible. For a midline catheter or PICC, gently withdraw the catheter in short segments.
Nerve Damage				
Inadvertent piercing or complete transection of a nerve	Venipuncture near known nerve locations Unanticipated nerve locations	Reports of tingling or feeling "pins and needles" at or below the insertion site Numbness at or near the insertion site	Immediately stop the insertion procedure if the patient reports extreme pain. Remove the catheter if reports of discomfort do not improve when the catheter is secured.	Avoid using the cephalic vein near the wrist. Avoid using veins on the palm side of the wrist. Adequately secure the catheter, but avoid tape that is too tight. Support areas of joint flexion with an armboard.

INS, Infusion Nurses Society; *PICC,* peripherally inserted central catheter.

TABLE 13-4

Systemic Complications of Intravenous Therapy

COMPLICATION	CAUSE	SIGNS AND SYMPTOMS	TREATMENT	PREVENTION
Circulatory Overload				
Disruption of fluid homeostasis with excess fluid in the circulatory system	Infusion of fluids at a rate greater than the patient's system can accommodate	Patient may report shortness of breath and cough; patient's blood pressure is elevated, and there is puffiness around the eyes and edema in dependent areas; patient's neck veins may be engorged, and nurse may hear moist breath sounds.	Slow the IV rate, and notify physician; raise patient to an upright position; monitor vital signs, and administer oxygen as prescribed; administer diuretics as prescribed.	Monitor intake and output carefully, and notify physician as soon as an imbalance is noticed between the patient's intake and output.
Speed Shock				
Systemic reaction to the rapid infusion of a substance unfamiliar to the patient's circulatory system	Rapid infusion of drugs or bolus infusion, which causes the drug to reach toxic levels quickly	Patient may report lightheadedness or dizziness and chest tightness; nurse may note that patient has a flushed face and an irregular pulse; without intervention, patient may lose consciousness and go into shock and cardiac arrest.	Immediately discontinue the drug infusion and hang isotonic solution to keep the vein open; monitor vital signs carefully, and notify physician for further treatments.	Be aware of the appropriate infusion rate of medications and adhere to them; use of infusion control devices assists in prevention of speed shock.
Catheter Embolism				
A shaving or piece of catheter breaks off and floats freely in the vessel	Anything that damages the catheter—during insertion, dressing change, excessive force with flushing or medication administration	Depending on where the catheter embolizes, this could be life threatening. Cardiopulmonary arrest could occur.	Emergently notify the physician. Remove the catheter, and apply a tourniquet high on the limb of the catheter site; inspect catheter to determine how much may have embolized; an x-ray is taken to determine the presence of any catheter piece; surgical intervention may be necessary.	When inserting over-the-needle catheters, never reinsert the needle into the catheter; avoid pulling a through-the-needle catheter back through the needle during insertion. Avoid scissors near the catheter with dressing changes.

TABLE 13-5

Complications During the Dwell of Central Venous Catheters

COMPLICATION	POSSIBLE CAUSES	SIGNS AND SYMPTOMS	TREATMENT	PREVENTION
Catheter Migration				
Movement of a properly placed catheter tip to another vein No change in the external catheter length	Changes in intrathoracic pressure caused by coughing, vomiting, sneezing, heavy lifting, and congestive heart failure	For migration to the jugular vein: reports of hearing a running stream or gurgling sound on the side of catheter insertion For migration to the azygos vein: back pain between the shoulder blades Neurologic complications if medications are infused	Stop all infusions, and flush catheter. Notify physician. Obtain a chest radiograph, if required, to assess tip location. Spontaneous repositioning back to the SVC is possible. Repositioning by radiology may be required.	Place catheter tip properly in the lower third of the SVC near the junction with the right atrium. Instruct patient to perform usual ADLs but to avoid excessive physical activity.
Catheter Dislodgment				
Movement of catheter into or out of the insertion site	Inadequate catheter securement Excessive physical activity with a PICC	External catheter length has changed, also changing the internal tip location No other signs or symptoms may be immediately noticed	Stop all infusions, and flush catheter. NEVER re-advance the catheter into the insertion site. Determine the amount of external catheter length, and compare with the length documented on insertion. Notify the physician or nurse inserting the catheter for further assessment.	Use proper catheter securement device. Instruct patient to perform normal ADLs but to avoid excessive physical activity.
Catheter Rupture				
Catheter is broken, damaged, or separated from hub or port body	Forcefully flushing a catheter with any size syringe against resistance Using scissors to remove a dressing Catheter compression of a subclavian inserted catheter between the clavicle and first rib (also known as *pinch-off syndrome*)	Fluid leaking from insertion site Pain or swelling during infusion Reflux of blood into the catheter extension Inability to aspirate blood from catheter	Repair the damaged segment; depends on the availability of a repair kit designed for the specific brand of catheter being used; repair may be considered a temporary measure instead of a permanent treatment. Remove catheter.	NEVER use excessive force when flushing a catheter, regardless of syringe size. On injection, small syringes generate more pressure than larger syringes. Use of a 10-mL syringe is generally recommended for flushing procedures. Insert catheter through jugular or upper extremity sites instead of subclavian site.
Lumen Occlusion				
Catheter lumen is partially or totally blocked	Drug or mineral precipitate (calcium, diazepam, and phenytoin are common) Lipid sludge from long-term infusion of fat emulsion Blood clots and fibrin sheath caused by blood reflux into lumen Allowing administration sets to remain connected for extended periods after medication has infused	Infusion stops, or pump alarm sounds Inability or difficulty administering fluids Inability or difficulty drawing blood Increased resistance to flushing of the catheter	Assess history of catheter use. A suddenly developing problem may indicate contact between incompatible medications. A problem that develops over an extended period may indicate a gradual clot formation. For drug precipitate, determine the pH of the precipitated drug. Use hydrochloric acid for acidic drug. Use sodium bicarbonate for alkaline drugs. For blood clot, use thrombolytic enzymes such as alteplase.	Always flush with normal saline between, before, and after each medication given through the catheter. Use positive-pressure flushing techniques when a negative fluid displacement needleless connector is being used. Use a positive fluid displacement needleless connector. Flush catheters immediately when medication infusion is complete.
Catheter-Related Bloodstream Infection (CR-BSI)				
Pathogenic organisms invade the patient's circulation The CDC has specific criteria to classify these infections	Lack of sterile field during insertion Inadequate skin antiseptic agents and application techniques Manipulation of the catheter hub leading to intraluminal contamination Inadequate hand hygiene Long dwell time	Early symptoms include fever, chills, headache, and general malaise	Change the entire infusion system from solution to IV device; notify physician, obtain cultures, and administer antibiotics as prescribed. If the infusate is the suspected cause, send a specimen to the laboratory for evaluation.	Maintain sterile technique. Use the recommended CR-BSI prevention bundle.

CDC, Centers for Disease Control and Prevention; *PICC,* peripherally inserted central catheter; *SVC,* superior vena cava.

IV Therapy and Care of the Older Adult

The aging process causes numerous changes in all body functions, and yet aging occurs differently in each person. Nutrition, environment, genetics, social factors, and education are just a few of the factors that influence the older adult's needs. Because all body functions are affected, IV therapy can be affected by these changes.

Skin Care

Aging skin becomes thinner and loses subcutaneous fat, decreasing the skin's ability for thermal regulation. Fewer nerve endings mean the decreased ability to feel pain. Older patients *may* not perceive acute pain from traumatic venipuncture requiring excessive probing or multiple attempts. However, this action increases the risk for fluid leakage and subsequent infiltration or extravasation injury. Inserting and removing a catheter and dressing could tear the skin layers.

Skin antisepsis is extremely important because of the decreased immunity seen as part of the aging process. Lipids are normally found in skin as a protective agent, and alcohol easily dissolves lipids. Although greater numbers of organisms may be killed, the skin can also become excessively dry and cracked. Current recommendations call for using friction when cleaning the skin to penetrate the layers of the epidermis. However, excessive friction may damage fragile skin and cause impaired tissue integrity. Chlorhexidine is the preferred agent, and the product currently available contains alcohol. Check for allergies to iodine before using iodine or iodophors. Iodophors such as povidone-iodine require contact with the skin for a minimum of 2 minutes to be effective. All antiseptic solutions must be thoroughly dry before applying the dressing or tape.

Skin should never be shaved before venipuncture, but excessive amounts of hair should be clipped. Shaving causes micro-abrasions that can lead to infection. The skin of an older adult may be more delicate and therefore more easily nicked while shaving.

Skin and tissue integrity can easily be compromised by the application of tape or dressings. Use of skin protectant solutions puts a protective barrier between the skin and dressing and improves the adherence of the dressing to the skin. Removal of tape and dressings may require adhesive remover solutions, or an alcohol pad may accomplish the same purpose. Securement devices like the StatLock require the use of a skin protectant (e.g., Skin-Prep) before applying the device. The protectant prevents skin tearing when the device is removed.

Vein and Catheter Selection

Vein and catheter selection are of highest importance in older adults. Choose insertion sites carefully after considering the patient's skin integrity, vein condition, and functional ability. The general principle of starting with the most distal sites usually indicates use of hand veins. *However, avoid fragile skin and small, tortuous veins on the back of the hand (dorsum); select the initial IV site higher on the arm.*

Venous distention must be accomplished with a flat tourniquet; however, the veins may require longer to adequately distend. Allowing a tourniquet to remain in place for extended periods causes an overfilling of the vein and can result in a hematoma when the vein is punctured. On extremely fragile skin, the tourniquet application can lead to ecchymotic areas or skin tears. Protect the skin by placing a wash cloth or the patient's gown between the skin and tourniquet. A tourniquet may not be required in veins that are already distended; however, carefully palpate these veins to determine their condition. Avoid hard, cordlike veins. Blood pressure cuffs can also be used for venous distention. Inflate the cuff and release until the pressure is slightly less than diastolic pressure. Other methods to distend veins include:

- Tapping lightly, but avoiding forceful slapping
- Asking the patient to open and close the fist so the muscles can force blood into the veins, making sure the hand is relaxed when the venipuncture is attempted
- Placing the extremity lower than the heart
- Applying warm compresses or a heating pad (be careful not to make it too hot) to the entire extremity for 10 to 20 minutes and removing just before making the venipuncture

As with all patients, venipuncture technique requires adequate skin and vein stabilization during the puncture and complete catheter advancement. Veins of an older adult are more likely to roll away from the needle. Low angles of 10 to 15 degrees between the skin and catheter will improve your success with venipuncture.

As soon as the catheter enters the vein, it may be necessary to release the tourniquet. Release of venous pressure from the puncture can lead to ecchymosis. Allowing the tourniquet to remain in place during the complete catheter advancement could increase this problem.

Nursing Safety Priority QSEN

Action Alert

Catheter securement may mean that administration sets are placed out of easy reach of a confused patient. Use flexible netting over the extremity to help prevent the patient from pulling at the dressing or tubing, while allowing easy access to the site. A device such as the I.V. House UltraDressing shown in Fig. 13-16 can also protect the site. Do not use rolled bandages to cover the extremity because they prevent insertion site assessment. Complications may progress to an advanced state before they are noticed.

FIG. 13-16 I.V. House UltraDressing IV site protector, a safety device used for IV site protection, guards the integrity of the older adult's skin while helping secure the site.

Choosing a midline catheter or PICC may be best in older patients with poor skin turgor, limited venous sites, or veins that are fragile, tortuous, or hard. These catheters are placed in the upper extremity

where venous distention techniques can be used. Inserting nontunneled percutaneous central catheters in older adults can be much more challenging. Venous distention for insertion requires the Trendelenburg position and a well-hydrated patient. fluid volume deficit prevents adequate distention of the subclavian or jugular veins. Patients with conditions like chronic obstructive pulmonary disease and kyphosis cannot tolerate the Trendelenburg position. Tunneled catheters and implanted ports may be appropriate after considering the surgical techniques required to insert these catheters.

Cardiac and Renal Changes

Because of changes in cardiac and renal status in older adults, the accuracy of infusion volume and flow rate measurements is very important in the older adult. The health care provider's prescription for infusion therapy should be assessed for appropriateness for the patient's condition. Older adults are very prone to fluid overload and resulting congestive heart failure. Electronic controlling devices may be required to ensure the necessary accuracy. Clinical manifestations of fluid overload are described in Chapter 11.

When fluid restrictions are required, medications could be diluted in small quantities and delivered using a syringe pump or a manual IV push. Consult with a pharmacist to determine the smallest amount of diluent required. This alternative may allow the patient to have more fluid to drink. Serum sodium levels should be considered when normal saline is routinely used for dilution in patients with hypertension or cardiac problems.

Clinical Judgment Challenge

Patient-Centered Care; Teamwork and Collaboration; Informatics QSEN

A 63-year-old obese, diabetic woman is transferred from the hospital to the skilled nursing facility (SNF) where you work as a charge nurse. The resident is being managed with IV cefoxitin 2 g IV piggyback (IVPB) every 8 hours for osteomyelitis resulting from an arterial foot ulcer. On review of her admission orders, you note that she has a newly inserted intermittent saline lock in her right forearm and is prescribed to receive the antibiotic for 4 more weeks.

1. The SNF policy for administration of drugs prescribed every 8 hours is

a 6 pm–2 am–10 am schedule. Would you schedule her antibiotic at these times? Why or why not?
2. Two days later as you are planning to end your shift, the resident reports that her IV site seems red and swollen. What action will you take at this time? What will you document on the resident's electronic health record?
3. Is a peripheral vascular access device (VAD) the best choice for this resident? Why or why not? With whom will you or the oncoming nurse collaborate to make this decision? What does the evidence say about the type of VAD that would be best to meet this resident's needs? Where would you go to find the answer to this clinical question?
4. Using the SBAR technique, what will you report to the oncoming nurse about the resident's IV complications?

An increasing number of patients with chronic illness require repeated and frequent IV therapies. Many of these patients are vein depleted and need vein preservation. Subcutaneous and intraosseous routes have demonstrated effectiveness in emergency resuscitation. These procedures may also be beneficial for routine infusion of isotonic, non-irritant, non-vesicant solutions in patients with chronic illness and vein depletion (Aguiar, 2010).

Specific therapies requiring infusion into arteries and peritoneal, epidural, and intrathecal space are also available. These therapies are most commonly used to administer chemotherapy, lytic therapy, or pain medication.

Subcutaneous Infusion Therapy

Subcutaneous infusion therapy has been used for a variety of drug infusions. Most commonly it is used for administration of pain medications and insulin therapy. It is beneficial for palliative care patients who cannot tolerate oral medications, when IM injections are too painful, or when vascular access is not available or is too difficult to obtain.

Hypodermoclysis or "clysis" involves the slow infusion of isotonic fluids into the patient's subcutaneous tissue. Although common in the early twentieth to mid-twentieth century, this method had not been widely used again until the 1990s. The growth of geriatric and palliative health care has helped spur the use of this method of infusion therapy for selected patients (Scales, 2011).

Hypodermoclysis can be used for short-term fluid volume replacement. The patient must have sufficient sites of intact skin without infection, inflammation, bruising, scarring, or edema. The most common sites are the front and sides of the thighs and hips, the upper abdomen, and the area under the clavicle. Unlike IV therapy, the upper extremities should not be used because fluid is absorbed more readily from sites with larger stores of adipose tissue. Hypodermoclysis is not appropriate for emergency resuscitations and should not be used if the fluid replacement needs exceed 2000 to 3000 mL/day and should not exceed 1500 mL/day at any single infusion site (Scales, 2011).

Hyaluronidase may be ordered by the health care provider and is mixed with each liter of infusion fluid. This substance is an enzyme that improves the absorption of the infusion from the subcutaneous tissue (Connolly et al., 2011; INS, 2011).

A small-gauge (25 to 27) winged infusion or "butterfly" needle, a small-gauge short peripheral catheter, or an infusion set specially designed for subcutaneous infusion can be chosen. The subcutaneous infusion sets have a small needle extending at a right angle from a flat disk that helps stabilize the needle.

When choosing the infusion site, consider the patient's level of activity. The area under the clavicle or the abdomen prevents difficulty with ambulation. Clip excess hair in the area, and clean the chosen site with the antiseptic solution, preferably 2% chlorhexidine gluconate in 70% isopropyl alcohol to prevent infection (Candon et al., 2010). Prime the infusion tubing and the attached subcutaneous infusion set or winged needle. Gently pinch an area of about 2 inches (5 cm), and insert the needle using sterile technique. After securing the needle, cover the site

with a transparent dressing. Flow rates for hydration fluids begin at 30 mL/hr. After 1 hour, the rate can be increased if the patient has experienced no discomfort. The maximum rate is usually 2 mL/min or 120 mL/hr. Assess the site every 4 hours while in a hospital setting and at least twice daily while at home. Redness, warmth, leakage, bruising, swelling, and reports of pain indicate tissue irritation and possible impaired tissue integrity. If these symptoms occur, remove the infusion needle. Rotate the site at least once a week. More frequent rotation may be needed depending on tissue integrity (INS, 2011).

Other complications include pooling of the fluid at the insertion site and an uneven fluid drip rate. Both of these problems may be resolved by restarting the infusion in another location. An infusion pump may also be used. Small ambulatory infusion pumps can be used to allow for greater mobility.

Intraosseous Infusion Therapy

Intraosseous (IO) therapy allows access to the rich vascular network in the red marrow of bones. Although IO has previously been regarded as a pediatric procedure, it is now considered acceptable for use in adults. Victims of trauma, burns, cardiac arrest, diabetic ketoacidosis, and other life-threatening conditions benefit from this therapy because often clinicians cannot access these patients' vascular systems for traditional IV therapy (Aguiar, 2010). Intraosseous catheters may be established in the prehospital setting when IV access cannot be readily obtained in an emergency.

Absorption rates of large-volume parenteral (LVP) infusions and drugs administered via the IO route are similar to those achieved with peripheral or central venous administration. The IO route should be used only during the immediate period of resuscitation and should not be used longer than 24 hours (Aguiar, 2010). After establishing access, efforts should continue to obtain IV access as well.

There are few contraindications for intraosseous infusion. The only absolute contraindication is fracture in the bone to be used as a site. Conditions such as severe osteoporosis, osteogenesis imperfecta, or other conditions that increase the risk for fracture with insertion of the IO needle and skin infection over the site may also be contraindications for some patients. Repeated attempts to access the same site should be avoided (Madigan, 2008).

Any needle could be used to provide therapy and access the medullary space (marrow). However, 15- or 16-gauge needles specifically designed for IO are preferred. New technology using a battery-powered drill has improved the ease of IO insertion. A number of sites can be used, including the proximal tibia (tibial tuberosity), distal femur, medial malleolus (inner ankle), proximal humerus, and iliac crest. The proximal tibia is the most common site accessed for IO therapy (Fig. 13-17).

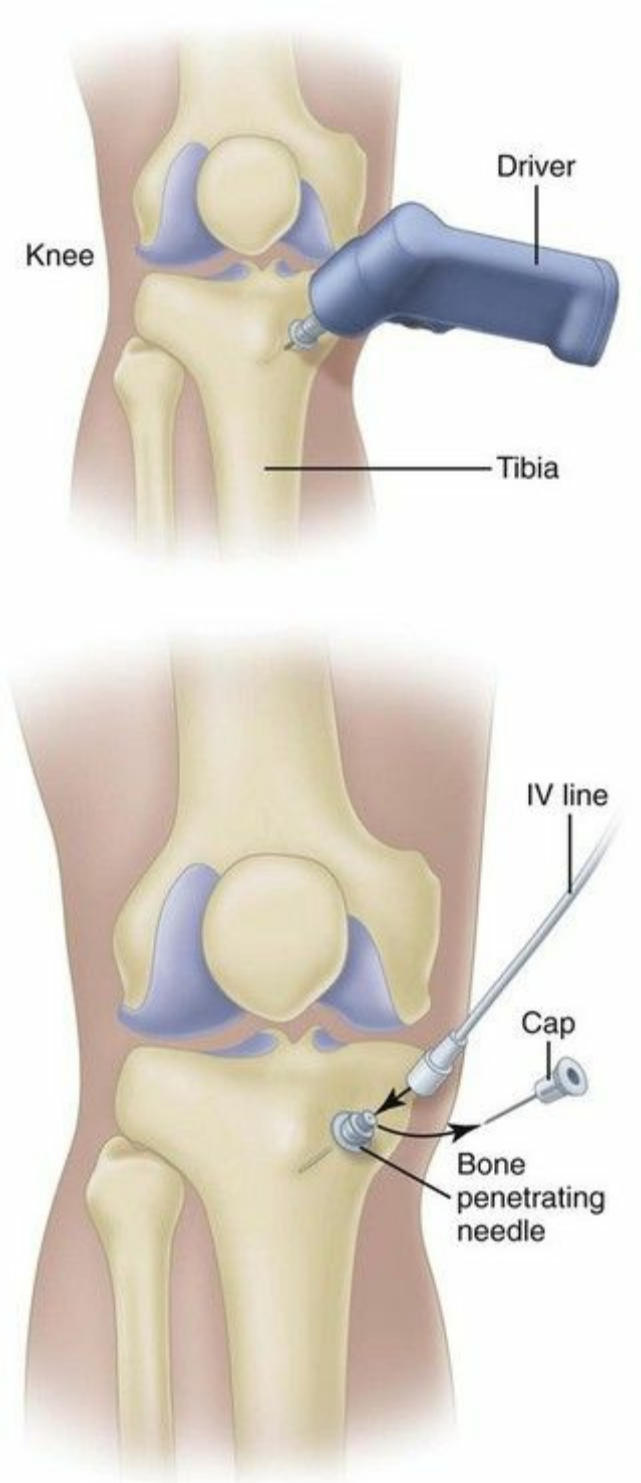

FIG. 13-17 Proximal tibial intraosseous (IO) access.

If IV access cannot be obtained within the first few minutes of resuscitation procedures, IO may be attempted. The leg is restrained, and the site is cleaned with an antiseptic agent such as chlorhexidine. After successful insertion, the needle must be secured to prevent movement out of the bone. The same doses of fluids and medications can be infused IO as IV. An infusion pump may be used for rapid flow rates.

During the procedure, most patients rate the pain as a 2 or 3 on a scale of 0 to 10. Lidocaine 1% is used to anesthetize the skin, the subcutaneous

tissue, and the periosteum to promote comfort (Madigan, 2008). Pain is also reported during the initial infusion. This may be reduced by injecting 0.5 mg/kg of preservative-free lidocaine through the intraosseous port before initiating the infusion (Phillips et al., 2010).

Improper needle placement with infiltration into the surrounding tissue is the most common complication of IO therapy. An accumulation of fluid under the skin at either the insertion site or on the other side of the limb indicates that the needle either is not far enough in to penetrate the bone marrow or is too far into the limb and has protruded through the other side of the shaft. Needle obstruction occurs when the puncture has been accomplished but flushing has been delayed. This delay may cause the needle to become clotted with bone marrow.

Osteomyelitis is an unusual but serious complication of IO therapy. You can help prevent this with meticulous aseptic technique, hand hygiene, and removal of the catheter as soon as it is no longer needed.

Compartment syndrome is a condition in which increased tissue pressure in a confined anatomic space causes decreased perfusion (blood flow to the area). The decreased circulation to the area leads to hypoxia and pain in the area. Although the complication is rare in IO therapy, the nurse should monitor the site carefully and alert the physician promptly if the patient exhibits any signs of decreased circulation to the limb, such as coolness, swelling, mottling, or discoloration. Without improvement in perfusion to the limb, the patient could ultimately require amputation of the limb. Nursing assessment and interventions for compartment syndrome are discussed in detail in Chapter 51.

Intra-Arterial Infusion Therapy

Catheters are placed into arteries to obtain repeated arterial blood samples, to monitor various hemodynamic pressures continuously, and to infuse chemotherapy agents or fibrinolytics **(intra-arterial infusion therapy).** Catheters placed in the radial, brachial, or femoral arteries are used for obtaining blood samples and arterial pressure monitoring. Arterial waveforms and pressures are converted to digital values displayed on attached monitors. Between the catheter and the monitor is a special administration set capable of handling high infusion pressure, a pressurized fluid container, a continuous flush attachment, a three-way stopcock, and a transducer. The transducer is positioned at the level of the patient's atrium and secured to an IV pole to enable correct arterial pressure measurements.

The pulmonary artery is used to monitor pressures in the heart and lungs. This artery is cannulated via the large central venous system and through the right side of the heart. Hemodynamic monitoring and how to interpret these values are described in Chapter 38.

Chemotherapy agents administered arterially allow infusion of a high concentration of drug directly to the tumor site before it is diluted in blood or metabolized by the liver or kidneys. Drug infusion through the same blood supply feeding the tumor optimizes cell destruction at the tumor site while minimizing systemic side effects. The most common arterial sites include the hepatic and celiac arteries for liver tumors, although the carotid artery for tumors of the head, neck, or brain and pelvic arteries for cervical tumors have been used. Arterial catheter insertion can be performed through the skin via a surgical procedure or by an interventional radiologist. Implanted ports are commonly used for extended therapies. For short-term therapy, an external catheter may be used for 3 to 7 days, although the risks for complications increase during dwell time.

Nursing Safety Priority QSEN

Critical Rescue

Carefully secure all junctions on the administration sets with Luer-Lok devices. Life-threatening hemorrhage can occur if an accidental disconnection occurs! When an infusion pump is used, be sure that it has a pressure high enough to overcome arterial pressure. Closely monitor the arterial insertion site and affected extremity. Assess the extremity for warmth, sensation, capillary refill, and pulse.

When the carotid artery is involved, perform neurologic assessments. When a femoral catheter is used, apply antiembolic stockings or other measures to prevent deep vein thrombosis. Complications from arterial catheters are similar to those from venous catheters, including infection, bleeding from the insertion site, hemorrhage from a catheter disconnection, catheter migration, infiltration, and catheter lumen or arterial occlusion. Specialized training is required to manage patients with arterial catheters.

Intraperitoneal Infusion Therapy

Intraperitoneal (IP) infusion therapy is the administration of chemotherapy agents into the peritoneal cavity. IP therapy is used to treat intra-abdominal malignancies such as ovarian and gastrointestinal tumors that have moved into the peritoneum after surgery.

Catheters used for IP therapy may be an implanted port for long-term treatment or an external catheter for temporary use. These catheters, including those attached to an implanted port, have large internal lumens with multiple side-holes along the catheter length to allow for delivery of large quantities of fluid. Administration of IP therapy includes three phases: the instillation phase; the dwell phase, usually 1 to 4 hours; and the drain phase. Because this treatment involves the delivery of biohazardous agents, additional competency is required to handle the infusion properly.

The patient should be in the semi-Fowler's position for the infusion. He or she may experience nausea and vomiting caused by increasing pressure on the internal organs from the infusing fluid. Pressure on the diaphragm may cause respiratory distress. Reducing the flow rate and treatment with antiemetic drugs may be needed. Severe pain may indicate that the catheter has migrated, and an abdominal x-ray is needed to determine its location.

During the dwell and drainage phases, the patient may need assistance in frequently moving from side to side to distribute the fluid evenly around the abdominal cavity. After the fluid has drained, the catheter is flushed with normal saline, although heparinized saline may be used in implanted ports. Catheter lumen occlusion is caused by the formation of fibrous sheaths or fibrin clots or plugs inside the catheter or around the tip.

Exit site infection, indicated by redness, tenderness, and warmth of the tissue around the catheter, can occur. Microbial peritonitis and inflammation of the peritoneal membranes from the invasion of microorganisms are other complications. If peritonitis occurs, the patient may experience a fever and report abdominal pain. Abdominal rigidity and rebound tenderness may be present. This condition is preventable by using strict aseptic technique in the handling of all equipment and infusion supplies. Management includes antimicrobial therapy administered either IV or intraperitoneally.

Intraspinal Infusion Therapy

The spinal column is covered by three layers: the dura mater, or outermost covering; the arachnoid, or middle layer; and the pia mater, which is closest to the spinal cord. Two spaces used for infusion are the **epidural** space between the dura mater and vertebrae and the **subarachnoid** space. The epidural space consists of fat, connective tissue, and blood vessels that protect the spinal cord. Medications infused into the epidural space must diffuse through the dura mater, and there is the possibility that some drug will be absorbed systemically. **Intrathecal** medications are infused into the subarachnoid space and directly into the cerebral spinal fluid, allowing reduced doses (McHugh et al., 2012). Care of patients with these therapies requires competency training and validation.

Postoperative and chronic pain is the primary indication for epidural infusion (see Chapter 3). Opioids administered epidurally slowly diffuse across the dura mater to the dorsal horn of the spinal cord. They lock onto receptors and block pain impulses from ascending to the brain. The patient receives pain relief from the level of the injection caudally (toward the toes). Local anesthetics administered epidurally work on the sensory nerve roots in the epidural space to block pain impulses. The physician administers the first dose of medication; then, depending on state law, the type of medication, and facility policies, nurses trained in epidural therapy may administer subsequent doses.

Intrathecal infusion of chemotherapy has been used for treating central nervous system (CNS) cancers. The belief was that lower total body doses delivered directly to the tumor would help prevent side effects. However, more recent studies have linked intrathecal infusion of methotrexate with increased neuromuscular impairments in acute lymphoblastic leukemia (ALL) survivors (Ness et al., 2012). Intrathecal infusion has also been used to manage chronic pain and to treat spasticity of neurologic diseases such as cerebral palsy, multiple sclerosis, reflex sympathetic dystrophy, and traumatic and anoxic acquired brain injuries (Hayek et al., 2011; McHugh et al., 2012).

A temporary catheter used for epidural therapy can be a percutaneous catheter that is secured at the site and extends up the back toward the shoulder. These catheters are used for postoperative pain management and usually dwell for only several hours or a few days. Infection and subsequent meningitis and catheter migration are the possible complications.

Epidural catheters used for longer periods include a tunneled catheter

and implanted port. Tunneled catheters are tunneled toward the abdomen and have a subcutaneous cuff to act as a barrier to infection. The external catheter exits the skin on the abdomen, so it can be easily reached for use by the patient or caregiver. An epidural implanted port is the same design as an IV implanted port and is accessed with the same noncoring needle. The catheter extends from the lumbar puncture site to the port pocket and is located over a bony prominence on the abdomen through a subcutaneous tunnel. Surgically implanted pumps can also be used to deliver epidural and intrathecal infusion.

Using sterile technique, an intraspinal catheter usually is inserted in the lumbar region. The external portion of a temporary epidural catheter is laid along the back toward the head and usually extends over the shoulder. The entire catheter length is taped for added security. Dressings are usually not routinely changed because they are used only for short periods. If bleeding or fluid leakage requires dressing removal, use extreme care to prevent dislodging the catheter.

For a tunneled catheter or implanted port, the entire subcutaneous tunnel and port pocket should be frequently assessed. Measurement of an external catheter segment could help identify catheter migration.

An in-line filter is used on all intraspinal infusions to block the infusion of particulate matter. Medications commonly contain preservatives such as alcohol, phenols, or sulfites; however, these are toxic to the CNS. All medications used for intraspinal infusion must be free of preservatives. Alcohol and products containing alcohol should not be applied to the insertion site because the solution could track along the catheter and cause nerve damage. Povidone-iodine solutions are preferred for skin antisepsis before insertion and during catheter dwell, including tunneled catheter exit sites and implanted port pockets.

Complications from epidural and intrathecal infusion can be caused by the type of medication being infused or can be related to the catheter. It is important to know the specific location of the intraspinal catheter because the doses of medications are quite different. When used for pain management, doses are usually 10 times greater for epidural than for intrathecal infusion. Assess the patient for response to the drugs being given, level of alertness, respiratory status, and itching.

Catheter-related complications include infection, bleeding, leakage of cerebrospinal fluid (CSF), occlusion of the catheter lumen, and catheter migration. It is important to be aware of coagulopathy and timing of anticoagulant therapy when epidural catheters are inserted. Epidural hematoma can cause neurologic damage if not corrected promptly. Infection in the patient receiving either epidural or intrathecal therapy

could be the result of a lack of asepsis when handling the medication or during the administration. Evidence of local infection, such as redness or swelling at the catheter exit site, may be present. The patient may also exhibit neurologic and systemic signs of infection (e.g., meningitis), such as headache, stiff neck, or temperature higher than 101° F (38.3° C). Report any neurologic change to the health care provider immediately!

Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Check IV administration orders for accuracy and completeness before implementing them. **Safety** QSEN
- Prevent IV administration errors by using smart pumps and other emerging technology-based safety infusion systems; these devices do not replace careful monitoring and assessment of the patient receiving infusion therapy. **Informatics** QSEN
- Devices engineered with safety mechanisms are required by the Occupational Safety and Health Administration (OSHA) to prevent staff injuries from needles, thus preventing bloodborne pathogen hazards. **Safety** QSEN
- Use the evidence-based catheter-related bloodstream infection (CR-BSI) prevention bundle during insertion and care of patients who have central lines, including using a checklist during insertion, hand hygiene, maximal barrier precautions, and chlorhexidine for skin disinfection (see Table 13-2). **Evidence-Based Practice** QSEN

Health Promotion and Maintenance

- Older adults present special challenges when infusion therapy is used; physiologic changes of the skin and cardiac/renal systems must be considered.
- Use small IV catheters for older adults, and insert using a 10- to 15-degree angle to prevent rolling of the vein. **Patient-Centered Care** QSEN
- Teach patients and their families about the patient's infusion therapy, including purpose, type, and safety precautions.

Physiological Integrity

- Infusion therapy is the delivery of parenteral medications and fluids through a wide variety of catheters and locations.
- Infusion therapy is used for establishing fluid and electrolyte balance, achieving optimum nutrition, maintaining hemostasis, and treating or preventing illnesses with medications.
- Vascular access devices (VADs) are catheters that are used to deliver

fluids and electrolytes and medications into the intravascular space.

- Common types of VADs include short peripheral catheters, midline catheters, peripherally inserted central catheters (PICCs), nontunneled percutaneous and tunneled central catheters, implanted ports, and hemodialysis catheters.
- Use best practice for placement of short peripheral VADs, including avoiding the small veins of the hands (see Chart 13-1). **Evidence-Based Practice** QSEN
- Document care for the patient receiving IV therapy, including the type of VAD inserted. **Informatics** QSEN
- The type of VAD that is used depends on the reason for infusion therapy, the patient's condition, and the length of therapy.
- Choose the appropriate peripheral catheter gauge size of the VAD depending on its purpose (see Table 13-1).
- PICCs, tunneled central catheters, and implanted ports are commonly used for long-term infusion therapy.
- Infusion controllers and pumps are electronic devices used to regulate the flow of infusion fluids and medications, but be sure to monitor the infusion rate.
- Nursing care for patients receiving all types of infusion therapy includes using sterile technique when starting the therapy and when changing components of the infusion system, changing and securing the site dressing, and assessing the site for local complications (see Table 13-3). **Evidence-Based Practice** QSEN
- Assess and document the presence of phlebitis using the INS Phlebitis Scale (see Table 13-6). **Evidence-Based Practice** QSEN
- Use normal saline to flush IV catheters on a periodic basis per agency policy.
- Assess, prevent, and manage systemic complications related to IV therapy as outlined in Table 13-4.
- Assess, prevent, and manage complications during the course of central IV therapy as listed in Table 13-5.
- Subcutaneous therapy of fluids (hypodermoclysis) involves a slow infusion for a short time; the thighs, hips, and abdomen are commonly used.
- Intraosseous infusion therapy allows fluids and medications to be absorbed by the rich vascular network of the bones; it is used for both children and adults, particularly in emergency situations.
- Arterial therapy is used primarily for the administration of chemotherapy agents directly into a tumor site; the liver is the most common arterial site for this purpose.

- Intraperitoneal therapy is used for chemotherapy agent administration into the peritoneal cavity, especially for ovarian and gastrointestinal tumors that have metastasized into the peritoneum.
- Epidural and intrathecal administration of medications are the common uses for intraspinal infusion. Epidural infusions are usually for pain management; intrathecal infusions are usually chemotherapy agents used for cancers that cross the blood-brain barrier into the central nervous system.

UNIT IV

Management of Perioperative Patients

OUTLINE

CHAPTER 14

Care of Preoperative Patients

Robin Chard

PRIORITY CONCEPTS

- Infection

Learning Outcomes

Safe and Effective Care Environment

1. Differentiate among the various types and purposes of surgery.
2. Examine personal factors for each patient for potential threats to safety, especially with older adults.
3. Protect the patient from injury and infection during the perioperative period.

Health Promotion and Maintenance

4. Teach patients about dietary restrictions, preoperative preparations, and interventions to perform after surgery to prevent complications.

Psychosocial Integrity

5. Reduce the psychological impact for the patient and family regarding the preoperative experience.
6. Ensure patient concerns and needs are communicated to other members of the health care team.

Physiological Integrity

7. Use knowledge of physiology and behavioral principles to describe an accurate and complete preoperative assessment.
8. Implement interventions to reduce the risk for perioperative

complications.

9. Use laboratory and clinical data to assess for changes that may affect the patient's response to drugs, anesthesia, and surgery.

http://evolve.elsevier.com/Iggy/

Patients undergoing surgery have benefitted greatly from advances in surgical techniques, anesthesia, pharmacology, medical devices, and supportive interventions. Research defining best practices has resulted in improved outcomes in all areas of the perioperative experience. New interventions, such as robotics and other types of minimally invasive surgeries (MISs), are continually being developed. Advances in anesthetic agents and techniques have made surgery safer than ever before. Many surgical procedures have moved from the operating room to other departments such as interventional radiology, cardiac catheterization, and endoscopy. Ambulatory care facilities, known as ambulatory surgical centers (ASCs), are being used for many surgical procedures outside acute care hospitals and account for more than 23 million surgical procedures performed annually (Ambulatory Surgery Center Association, 2013). These changes affect the role of the perioperative nurse and have an impact on how patient teaching is performed.

Cost-reduction is a driving force for the management of the surgical patient. Shortened stays and ambulatory surgeries are common. Patient histories may be conducted by telephone or online before surgery rather than in person. Some patients may be observed only after surgery and not admitted as an inpatient. In response to the ongoing health care delivery changes and the use of multiple settings, nurses have modified their interventions, remaining focused on patient care before **(preoperative),** during **(intraoperative),** and after **(postoperative)** surgery. Together, these time periods are known as the **perioperative** experience.

Patient safety throughout the perioperative period is the number-one priority for all personnel. Fig. 14-1 shows an overview of a surgical safety checklist as recommended by the World Health Organization (WHO). Quality measures such as wrong-site surgery, patient falls, hospital-acquired pressure ulcers, and vascular catheter–associated infections must now be reported to the Centers for Medicare and Medicaid Services (CMS). These data are used for tracking patient outcomes and ensuring patient-centered care and accountability on the part of health care facilities.

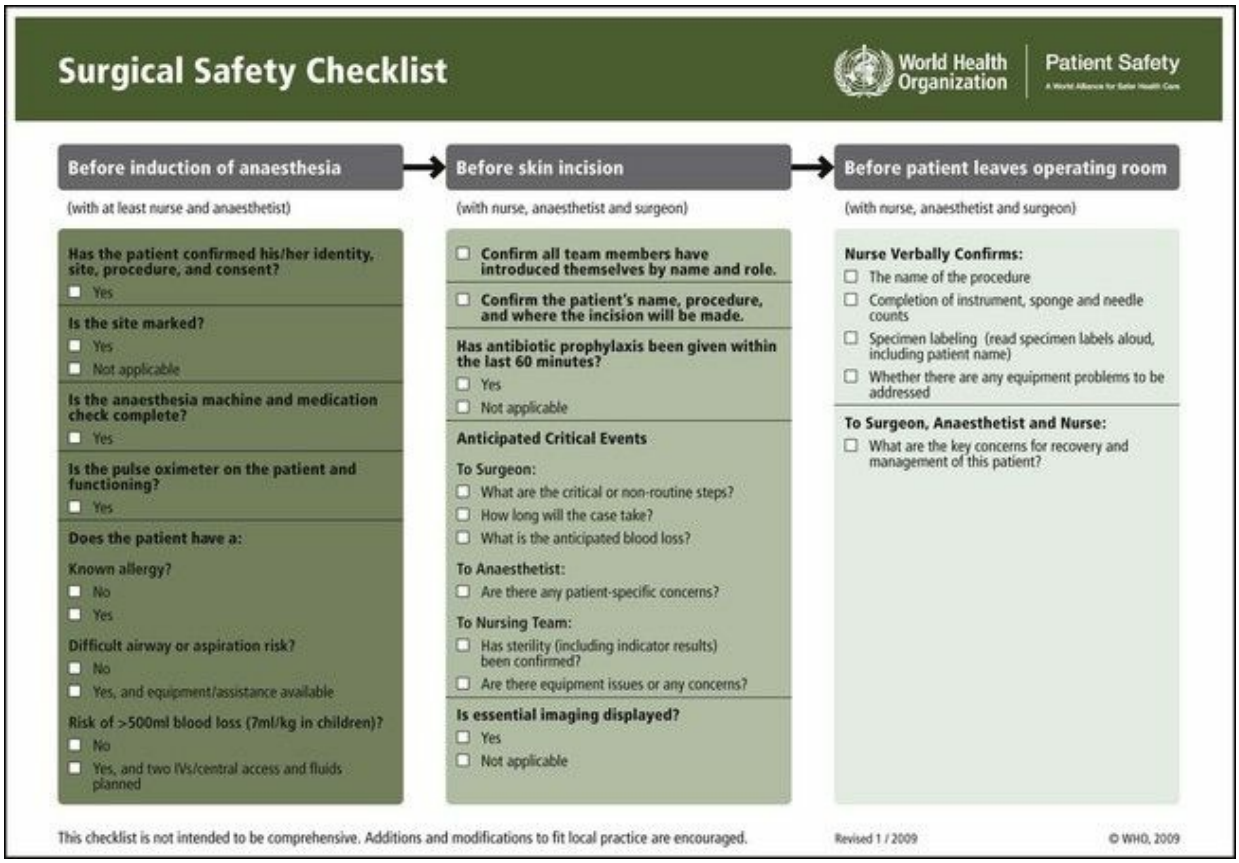

FIG. 14-1 A surgical safety checklist.

Because surgery is invasive and involves exposure to various anesthetic agents and drugs, as well as positioning and other environmental hazards, complications are common. Some complications are predictable and are considered preventable or "never events." As a result, The Joint Commission (TJC) has partnered with other groups and agencies and developed a plan for the reduction and eventual elimination of preventable surgical complications known as the *Surgical Care Improvement Project (SCIP)*. Implementation of these core measures is now mandatory for patient safety. The current plan focuses on infection prevention, prevention of serious cardiac events, and prevention of venous thromboembolism (VTE) (also known as *deep vein thrombosis [DVT]*). Ten specific core measures have been identified as actions required for prevention of these complications in patients identified as at risk. Table 14-1 provides an overview of these core measures areas. (The numbers associated with the core measures are not always chronologic, indicating that some areas are still in development.) The preoperative areas of responsibility for these core measures and their prevention strategies are highlighted in the appropriate areas of this chapter. In addition, some core measures also are discussed in patient care chapters most associated with the complication.

TABLE 14-1

Surgical Care Improvement Project (SCIP) Core Measure Overview

CORE MEASURE IDENTIFICATION	MEASUREMENT NAME/DESCRIPTION
SCIP Infection-1 (SCIP Inf-1)	*Prophylactic Antibiotic Received Within One Hour Prior to Surgical Incision* The purpose is to use short-duration antibiotics to establish bactericidal blood and tissue levels by the time the surgical incision is made.
SCIP Infection-2 (SCIP Inf-2)	*Prophylactic Antibiotic Selection for Surgical Patients* The purpose is to ensure that prophylactic antibiotics are used for patients who are at increased risk for surgical site infections. The guidelines for risk and for the exact antibiotic to be used are specific to each type of surgical procedure and follow evidence-based published recommendations.
SCIP Infection-3 (SCIP Inf-3)	*Prophylactic Antibiotics Discontinued Within 24 Hours After Surgery End Time* The purpose is to ensure that prophylactic antibiotic therapy provides benefit without risk. Prolonged prophylactic antibiotic therapy has not been shown to increase benefit and is known to increase the risk for *C. difficile* infection and the development of microorganisms that are resistant to antimicrobial drugs.
SCIP Infection-4 (SCIP Inf-4)	*Cardiac Surgery Patients with Controlled 6 am Postoperative Blood Glucose* (Applies to cardiac surgery patients only) The purpose is to avoid hyperglycemia (which is defined as blood glucose levels above 200 mg/dL and is associated with increased complications and mortality) in cardiac surgery patients, especially patients undergoing coronary artery bypass graft surgery and patients with diabetes who are having cardiac surgery.
SCIP Infection-6 (SCIP Inf-6)	*Surgery Patients with Appropriate Hair Removal* The purpose is to avoid hair removal procedures, specifically shaving, that cause skin abrasions and increase the risk for surgical site infections. If hair must be removed from the surgical site, removal is performed with electric clippers or chemical depilatories.
SCIP Infection-9 (SCIP Inf-9)	*Urinary Catheter Removed on Postoperative Day 1 (POD 1) or Postoperative Day 2 (POD 2) with Day of Surgery Being Day Zero* The purpose is to avoid urinary catheter–associated urinary tract infections, which increase with longer duration indwelling catheters. It is unacceptable to have an indwelling urinary catheter in place longer than 48 hours after surgery unless there is a documented specific and medically validated reason for it.
SCIP Infection-10 (SCIP Inf-10)	*Surgery Patients with Perioperative Temperature Management* The purpose is to prevent prolonged hypothermia, which is associated with impaired wound healing, serious cardiac complications, altered drug metabolism, coagulation problems, and a higher incidence of surgical site infections. Temperature must be measured within 15 minutes from the end of anesthesia administration. Intentional hypothermia must be documented.
SCIP CARD-2	*Surgery Patients on Beta-Blocker Therapy Prior to Arrival Who Received a Beta-Blocker During the Perioperative Period* The purpose is to ensure that patients with specific medical conditions

	receive beta-blocker therapy before surgery and continue the therapy in the immediate postoperative period. This evidence-based action has resulted in a significant reduction in coronary events, cardiovascular mortality, and overall mortality.
SCIP Venous thromboembolism-1 (SCIP VTE-1)	*Surgery Patients with Recommended Venous Thromboembolism Prophylaxis Ordered* The purpose is to reduce the complications from postoperative venous thromboembolism (VTE). Surgery is a major risk factor responsible for VTE formation and subsequent pulmonary embolism. Although VTE prophylaxis is effective, it is underused. Specific preoperative and postoperative VTE prophylaxis strategies are recommended on the basis of patient risk, type and duration of surgery, and extent of expected postoperative immobilization.
SCIP Venous thromboembolism-2 (SCIP VTE-2)	*Surgery Patients Who Received Appropriate Venous Thromboembolism Prophylaxis Within 24 Hours Prior to Surgery to 24 Hours After Surgery* The purpose is to reduce the complications from postoperative venous thromboembolism (VTE), particularly among patients undergoing the types of surgeries in which the risk is highest.

C. difficile, *Clostridium difficile*.

Data from The Joint Commission. (2014). *National Patient Safety Goals*. Retrieved April 2014, from www.jointcommission.org/surgical_care_improvement_project/.

NCLEX Examination Challenge

Safe and Effective Care Environment

Because of an unexpected emergency case, a client scheduled for colon surgery at 8 am has been rescheduled for 11 am. What is the nurse's best action related to preoperative prophylactic antibiotic administration according to the Surgical Care Improvement Project (SCIP) guidelines?

A Administer the preoperative antibiotic at 7 am as originally prescribed.

B Administer the antibiotic at the same time as the other prescribed preoperative drugs.

C Adjust the antibiotic administration time to be within 1 hour before the surgical incision.

D Hold the preoperative antibiotic until the client is actually in the operating room and has been anesthetized.

Overview

The preoperative period begins when the patient is scheduled for surgery and ends at the time of transfer to the surgical suite. As a nurse, you will function as an educator, an advocate, and a promoter of health. The surgical environment demands the use of knowledge, judgment, and skills based on the principles of nursing science. Perioperative nursing places special emphasis on safety, advocacy, and patient education, although ensuring a "culture of safety" is the responsibility of all health care team members.

The patient's readiness for surgery is critical to the outcome. Preoperative care focuses on preparing the patient for the surgery and ensuring patient safety. This care includes education and any intervention needed before surgery to reduce anxiety and complications and to promote patient cooperation in procedures after surgery. Use adult teaching and learning principles in teaching patients and families before surgery. Validate, clarify, and reinforce information the patient has received from the surgeon or other members of the surgical team. In addition, during the nursing assessment before surgery, problems may be identified that warrant further patient assessment or intervention before the procedure. As required by The Joint Commission's National Patient Safety Goals (NPSGs), communication and collaboration with the surgical team are essential so that correct actions are taken to achieve the desired outcome.

Categories and Purposes of Surgery

Surgical procedures are categorized by the purpose, body location, extent, and degree of urgency. Table 14-2 explains the categories and gives examples of surgical procedures.

TABLE 14-2

Selected Categories of Surgical Procedures

CATEGORY	DESCRIPTION	CONDITION OR SURGICAL PROCEDURE
Reasons for Surgery		
Diagnostic	Performed to determine the origin and cause of a disorder or the cell type for cancer	Breast biopsy Exploratory laparotomy Arthroscopy
Curative	Performed to resolve a health problem by repairing or removing the cause	Cholecystectomy Appendectomy Hysterectomy
Restorative	Performed to improve a patient's functional ability	Total knee replacement Finger reimplantation
Palliative	Performed to relieve symptoms of a disease process, but does not cure	Colostomy Nerve root resection Tumor debulking Ileostomy
Cosmetic	Performed primarily to alter or enhance personal appearance	Liposuction Revision of scars Rhinoplasty Blepharoplasty
Urgency of Surgery		
Elective	Planned for correction of a nonacute problem	Cataract removal Hernia repair Hemorrhoidectomy Total joint replacement
Urgent	Requires prompt intervention; may be life threatening if treatment is delayed more than 24 to 48 hr	Intestinal obstruction Bladder obstruction Kidney or ureteral stones Bone fracture Eye injury Acute cholecystitis
Emergent	Requires immediate intervention because of life-threatening consequences	Gunshot or stab wound Severe bleeding Abdominal aortic aneurysm Compound fracture Appendectomy
Degree of Risk of Surgery		
Minor	Procedure without significant risk; often done with local anesthesia	Incision and drainage (I&D) Implantation of a venous access device (VAD) Muscle biopsy
Major	Procedure of greater risk; usually longer and more extensive than a minor procedure	Mitral valve replacement Pancreas transplant Lymph node dissection
Extent of Surgery		
Simple	Only the most overtly affected areas involved in the surgery	Simple/partial mastectomy
Radical	Extensive surgery beyond the area obviously involved; is directed at finding a root cause	Radical prostatectomy Radical hysterectomy
Minimally invasive surgery (MIS)	Surgery performed in a body cavity or body area through one or more endoscopes; can correct problems, remove organs, take tissue for biopsy, re-route blood vessels and drainage systems; is a fast-growing and ever-changing type of surgery	Arthroscopy Tubal ligation Hysterectomy Lung lobectomy Coronary artery bypass Cholecystectomy

Surgical Settings

The term **inpatient** refers to a patient who is admitted to a hospital. The patient may be admitted the day before or, more often, the day of surgery (often termed *same-day admission [SDA]*), or the patient may already be an inpatient when surgery is needed. The terms **outpatient** and **ambulatory** refer to a patient who goes to the surgical area the day of the surgery and returns home on the same day (i.e., *same-day surgery [SDS]*). Hospital-based ambulatory surgical centers, freestanding surgical centers, physicians' offices, and ambulatory care centers are common. More than half of all surgical procedures in North America are performed in ambulatory centers (Ambulatory Surgery Center Association, 2013).

One advantage of outpatient surgery is that patients are not separated from the comfort and security of their home and family. Same-day surgery, however, places more responsibility on the patient and family, especially for care after surgery. Often a case manager is needed to coordinate post-discharge care for the patient.

Patient-Centered Collaborative Care

Assessment

History.

Data collection about the patient before surgery begins in various settings (e.g., the surgeon's office, the preadmission or admission office, the inpatient unit, the telephone, the Internet). Use privacy to increase the patient's comfort with the interview process. Anesthesia and surgery are both physical and emotional stressors. Collect these data:

- Age
- Use of tobacco, alcohol, or illicit substances, including marijuana
- Current drugs
- Use of complementary or alternative practices, such as herbal therapies, folk remedies, or acupuncture
- Medical history
- Prior surgical procedures and how these were tolerated
- Prior experience with anesthesia, pain control, and management of nausea or vomiting
- Autologous or directed blood donations
- Allergies, including sensitivity to latex products
- General health
- Family history
- Type of surgery planned

- Knowledge about and understanding of events during the perioperative period
- Adequacy of the patient's support system

When taking a history, screen the patient for problems that increase the risk for complications during and after surgery. Some problems that increase the surgical risk or increase the risk for complications after surgery are listed in Table 14-3.

TABLE 14-3

Selected Factors That Increase the Risk for Surgical Complications

Age

- Older than 65 years

Medications

- Antihypertensives
- Tricyclic antidepressants
- Anticoagulants
- Nonsteroidal anti-inflammatory drugs (NSAIDs)

Medical History

- Decreased immunity
- Diabetes
- Pulmonary disease
- Cardiac disease
- Hemodynamic instability
- Multi-system disease
- Coagulation defect or disorder
- Anemia
- Dehydration
- Infection
- Hypertension
- Hypotension
- Any chronic disease

Prior Surgical Experiences

- Less-than-optimal emotional reaction
- Anesthesia reactions or complications
- Postoperative complications

Health History

- Malnutrition or obesity
- Drug, tobacco, alcohol, or illicit substance use or abuse
- Altered coping ability

Family History

- Malignant hyperthermia
- Cancer
- Bleeding disorder

Type of Surgical Procedure Planned

- Neck, oral, or facial procedures (airway complications)
- Chest or high abdominal procedures (pulmonary complications)
- Abdominal surgery (paralytic ileus, venous thromboembolism)

Older patients are at increased risk for complications from both anesthesia and surgery (Doerflinger, 2009). The normal aging process decreases immune system functioning and delays wound healing. The frequency of chronic illness increases in older patients. Gas exchange is more profoundly affected by general anesthetic agents and by opioid analgesics. Age-related changes in kidney and liver function may delay the elimination of anesthetic and analgesic agents, increasing the risk for

adverse reactions. See Chart 14-1 for other changes in older adults that may alter the operative response or risk.

Chart 14-1 Nursing Focus on the Older Adult

Age-Related Changes as Surgical Risk Factors

PHYSIOLOGIC CHANGE	NURSING INTERVENTIONS	RATIONALES
Cardiovascular System		
Decreased cardiac output Increased blood pressure	Determine normal activity levels, and note when the patient tires.	Knowing limits helps prevent fatigue.
Decreased peripheral circulation	Monitor vital signs, peripheral pulses, and capillary refill.	Having baseline data helps detect deviations.
Respiratory System		
Reduced vital capacity Loss of lung elasticity	Teach coughing and deep-breathing exercises.	Pulmonary exercises help prevent pulmonary complications.
Decreased oxygenation of blood	Monitor respirations and breathing effort.	Having baseline data helps detect deviations.
Renal/Urinary System		
Decreased blood flow to kidneys Reduced ability to excrete waste Decline in glomerular filtration rate	Monitor intake and output. Assess overall hydration. Monitor electrolyte status.	Ongoing assessment helps detect fluid and electrolyte imbalances and decreased renal function.
Nocturia common	Assist frequently with toileting needs, especially at night.	Frequent toileting helps prevent incontinence and falls.
Neurologic System		
Sensory deficits Slower reaction time	Orient the patient to the surroundings. Allow extra time for teaching the patient.	An individualized preoperative teaching plan is developed based on the patient's orientation and any neurologic deficits.
Decreased ability to adjust to changes in the surroundings	Provide for the patient's safety.	Safety measures help prevent falls and injury.
Musculoskeletal System		
Increased incidence of deformities related to osteoporosis or arthritis	Assess the patient's mobility. Teach turning and positioning. Encourage ambulation.	Interventions help prevent complications of immobility.
	Place on falls precautions, if indicated.	Safety measures help prevent injury.
Skin		
Dry with less subcutaneous fat makes the skin at greater risk for damage; slower skin healing increases risk for infection	Assess the patient's skin before surgery for lesions, bruises, and areas of decreased circulation.	Having baseline data helps detect changes and evaluate interventions.
	Pad bony prominences.	Padding can protect at-risk areas.
	Use pressure-avoiding or pressure-reducing overlays.	Overlays can prevent pressure ulcer formation by redistributing body weight.
	Avoid applying tape to skin.	Tape removal damages thin skin.
	Teach the patient to change position at least every 2 hours.	Changing position frequently helps prevent reduced blood flow to an area and changes external pressure patterns.

Drugs and substance use may affect patient responses to surgery. Tobacco use increases the risk for pulmonary complications because of changes to the lungs, blood vessels, and chest cavity. Alcohol and illicit substance use can alter the patient's responses to anesthesia and pain medication. Withdrawal of alcohol before surgery may lead to delirium tremens. Prescription and over-the-counter drugs may also affect how the patient reacts to the operative experience. Adverse effects can occur with the use of some herbs. Thus asking about and documenting past and current use of herbs or botanicals are important.

Medical history is important to obtain because many chronic illnesses increase surgical risks and need to be considered when planning care.

For example, a patient with systemic lupus erythematosus may need additional drugs to offset the stress of the surgery. A patient with diabetes may need a more extensive bowel preparation because of decreased intestinal motility. An infection may need to be treated before surgery.

Ask the patient specifically about cardiac problems because complications from anesthesia occur more often in patients with cardiac problems (Johnson, 2011). A patient with a history of rheumatic heart disease may be prescribed antibiotics before surgery. Cardiac problems that increase surgical risks include coronary artery disease, angina, myocardial infarction (MI) within 6 months before surgery, heart failure, hypertension, and dysrhythmias. These problems impair the patient's ability to withstand hemodynamic changes and alter the response to anesthesia. The risk for an MI during surgery is higher in patients who have heart problems. Patients with cardiac disease may require perioperative therapy with beta-blocking drugs, as recommended by core measures for SCIP CARD-2 (see Table 14-1).

Pulmonary complications during or after surgery are more likely to occur in older patients, those with chronic respiratory problems, and smokers because of smoking- or age-related lung changes (Doerflinger, 2009). Increased chest rigidity and loss of lung elasticity reduce anesthetic excretion. Smoking increases the blood level of **carboxyhemoglobin** (carbon monoxide on oxygen-binding sites of the hemoglobin molecule), which decreases oxygen delivery to organs. Action of cilia in pulmonary mucous membranes decreases, which leads to retained secretions and predisposes the patient to infection (pneumonia) and **atelectasis** (collapse of alveoli). Atelectasis reduces gas exchange and causes intolerance of anesthesia. It is also a common problem after general anesthesia.

Chronic lung problems such as asthma, emphysema, and chronic bronchitis also reduce the elasticity of the lungs, which reduces gas exchange. As a result, patients with these problems have reduced tissue oxygenation.

Previous surgical procedures and anesthesia affect the patient's readiness for surgery. Previous experiences, especially with complications, may increase anxiety about the scheduled surgery. Ask about the patient's experience with anesthesia and all allergies. These data provide information about tolerance of and possible fears about the use of anesthesia. The family medical history and problems with anesthetics may indicate possible reactions to anesthesia, such as malignant hyperthermia (see Chapter 15).

An allergy to certain substances alerts you to a possible reaction to anesthetic agents or to substances that are used before or during surgery. For example, povidone-iodine (e.g., Betadine) used for skin cleansing contains the same allergens found in shellfish. Patients who are allergic to shellfish may have an adverse reaction to povidone-iodine. The patient with an allergy to avocados, bananas, strawberries, and other fruits may also have a latex sensitivity or allergy. Patients who have an egg, peanut, or soy allergy may have a reaction to propofol (Diprivan), which is an anesthetic agent often used in the induction and maintenance of anesthesia (MDConsult, 2012).

Blood donation for surgery can be made by the patient **(autologous donations)** a few weeks just before the scheduled surgery date. Then, if blood is needed during or after surgery, an autologous blood transfusion can be given. This practice eliminates transfusion reactions and reduces the risk for acquiring bloodborne disease. Specific patient criteria, which may vary by surgical type and patient health problem, must be met to qualify for autologous transfusion.

A special tag is placed on the blood bag when an autologous blood donation has been made. The blood donor center gives the patient a matching tag that he or she wears or brings to the surgical area before surgery as required by The Joint Commission's National Patient Safety Goals (NPSGs). This procedure helps ensure that patients receive only their own donated blood. Patients may wish to have family and friends donate blood exclusively for their use, if needed. This practice (called *directed blood donation*) is possible only if the blood types are compatible and the donor's blood is acceptable. Directed donation is not practiced in all blood donation centers. When directed blood donations are used, a special tag is attached to the blood bag. This tag notes the names of the patient and the donor and bears the patient's signature.

Ask whether autologous or directed blood donations have been made, and document this information in the chart. It is important to know the specific blood collection center where the donation was made and whether the blood has arrived before the patient goes into surgery. The hospital receives and stores the blood units until they are used or are no longer needed. Unused blood is returned to the collection center.

Increased use of "bloodless surgery" and minimally invasive surgery (MIS) provides alternatives for patients with religious or medical restrictions to blood transfusions. These programs reduce the need for transfusion during and after surgery. Some techniques used are limiting blood samples (the number of samples, as well as the volume of blood drawn per sample) before surgery and stimulating the patient's own red

blood cell production with epoetin alpha (e.g., Epogen, Procrit). Supplemental iron, folic acid, vitamin B_{12}, and vitamin C may be prescribed to help red blood cell formation. Newer equipment and surgical techniques cause less blood loss than older techniques. Such advances include recycling blood suctioned during surgery and immediately transfusing it back into the patient. Assess, monitor, teach, and support the patient during the bloodless surgery process.

Discharge planning is started before surgery. Assess the patient's home environment, self-care capabilities, and support systems and anticipate postoperative needs before surgery. *All patients, regardless of how minor the procedure or how often they have had surgery, should have discharge planning*. Older patients and dependent adults may need transportation referrals to and from the physician's office or the surgical setting. A home care nurse may be needed to monitor recovery and to provide instructions. Patients with few support systems may need follow-up care at home. Some patients need a planned direct admission to a rehabilitation facility or center for physical therapy after surgery, especially joint replacement surgery. Shortened hospital stays require adequate discharge planning to achieve the desired outcomes after surgery.

Physical Assessment/Clinical Manifestations.

The preoperative patient may be any age, with a health status that varies from well to debilitated. Perform a complete assessment before surgery to obtain baseline data. Use this information to identify current health problems, potential complications related to anesthesia, and risk for complications that may occur after surgery.

Begin the assessment by obtaining a complete set of vital signs. You may need to obtain vital signs several times at different time intervals for accurate baseline values. Previous vital signs from another admission (if available) are helpful to compare with current vital signs. Abnormal vital signs may require postponement of surgery until the problem is treated and the patient's condition is stable. Also assess for anxiety, which could increase blood pressure, pulse, and respiratory rate. Document these findings as part of the overall assessment.

Throughout the assessment, focus on problem areas identified from the patient's history and on all body systems affected by the surgical procedure. The older adult (Chart 14-2; see also Chapter 2) or chronically ill patient is at increased risk for complications during and after surgery. The number of serious problems **(morbidity)** and death **(mortality)** during or after surgery is higher in older and chronically ill patients

(Johnson, 2011).

Chart 14-2 Nursing Focus on the Older Adult

Specific Considerations When Planning Care for the Older Preoperative Patient

- Greater incidence of chronic illness
- Greater incidence of malnutrition
- More allergies
- Increased incidence of impaired self-care abilities
- Inadequate support systems
- Decreased ability to withstand the stress of surgery and anesthesia
- Increased risk for cardiopulmonary complications after surgery
- Risk for a change in mental status when admitted (e.g., related to unfamiliar surroundings, change in routine, drugs)
- Increased risk for a fall and resultant injury

Report any abnormal assessment findings to the surgeon and to anesthesia personnel, as required by The Joint Commission's NPSGs. In this way, you are a proactive patient advocate exercising professional legal responsibility. Often, established protocols or care maps identify what interventions are to be performed before surgery.

Cardiovascular status is critical to assess because cardiac problems are associated with many surgery-related deaths. Check the patient for hypertension, which is common, is often undiagnosed, and can affect the response to surgery. Cardiac assessment includes listening to heart sounds for rate, regularity, and abnormalities. Ask whether the patient has ever had a venous thromboembolism (VTE). Examine the patient's hands and feet for temperature, color, peripheral pulses, capillary refill, and edema. Report any problems (e.g., absent peripheral pulses, pitting edema, cardiac manifestations, chest pain, shortness of breath, and dyspnea) to the surgeon for further assessment and evaluation. (Cardiac assessment is discussed in Chapter 33.)

Respiratory status considers age, smoking history (including exposure to secondhand smoke), and any chronic illness (Doerflinger, 2009). Obese patients may have undiagnosed respiratory problems such as obstructive sleep apnea (OSA), which can lead to complications from anesthesia (Graham et al., 2011). Observe the patient's posture; respiratory rate, rhythm, and depth; overall respiratory effort; and lung expansion. Document any clubbing of the fingertips (swelling at the base of the nail

beds caused by a chronic lack of oxygen) or cyanosis. Auscultate the lungs to assess for any abnormal breath sounds (crackles, wheezes, rubs). (More information on respiratory assessment is found in Chapter 27.)

Kidney function affects the excretion of drugs and waste products, including anesthetic and analgesic agents. If kidney function is reduced, fluid and electrolyte balance can be altered, especially in older patients. Ask about problems such as urinary frequency, **dysuria** (painful urination), **nocturia** (awakening during nighttime sleep because of a need to void), difficulty starting urine flow, and **oliguria** (scant amount of urine). Ask the patient about the appearance and odor of the urine. Assess the patient's usual fluid intake and degree of continence. If the patient has kidney or urinary problems, consult with the physician about further workup. (Kidney/urinary assessment is discussed further in Chapter 65.)

Kidney impairment decreases the excretion of drugs and anesthetic agents. As a result, drug responses may be prolonged. Scopolamine (Buscopan), morphine, other opioids, benzodiazepines, and barbiturates often cause confusion, disorientation, apprehension, and restlessness when given to patients with decreased kidney function.

Neurologic status includes the patient's overall mental status, level of consciousness, orientation, and ability to follow commands. This information is needed before planning preoperative teaching and care after surgery. A problem in any of these areas affects the type of care needed during the surgical experience. Determine the patient's baseline neurologic status to be able to identify changes that may occur later. Also assess for any motor or sensory deficits. (See Chapter 41 for complete nervous system assessment.)

The usual neurologic status of a mentally impaired patient may be difficult to assess (Doerflinger, 2009). The patient who has been independent and oriented at home may become disoriented in the hospital setting. Family members can often provide information about what the patient was like at home.

The Joint Commission's NPSGs require that you ensure patient safety by assessing the patient's risk for falling, especially older patients. Evaluate factors such as mental status, muscle strength, steadiness of gait, and sense of independence to determine the patient's risk. Document the patient's ability to ambulate and the steadiness of gait as baseline data.

Musculoskeletal status problems may interfere with positioning during and after surgery. For example, patients with arthritis may be able to

assume surgical positions but have discomfort after surgery from prolonged joint immobilization. Other anatomic features, such as the shape and length of the neck and the shape of the chest cavity, may interfere with respiratory and cardiac function or require special positioning during surgery.

Nursing Safety Priority QSEN

Action Alert

Ask about a history of joint replacement, and document the exact location of any prostheses. Communicate this information to operating room personnel to ensure that electrocautery pads, which could cause an electrical burn, are not placed on or near the area of the prosthesis. Other areas to avoid electrocautery pad placement include on or near bony prominences, scar tissue, hair, tattoos, weight-bearing surfaces, pressure points, and metal piercings (Spruce & Braswell, 2012).

Nutrition status, especially malnutrition and obesity, can increase surgical risk. Surgery increases metabolic rate and depletes potassium, vitamin C, and B vitamins, all of which are needed for wound healing and blood clotting. In poorly nourished patients, decreased serum protein levels slow recovery. Negative nitrogen balance may result from depleted protein stores. This problem increases the risk for skin breakdown, delayed wound healing, possible dehiscence or evisceration (see Chapter 16), dehydration, and sepsis.

Some older patients may have poor nutrition because of chronic illness, diuretic or laxative use, poor dietary planning or habits, anorexia, lack of motivation, or financial limitations (Touhy & Jett, 2014). Indications of poor fluid or nutrition status include:

- Brittle nails
- Muscle wasting
- Dry or flaky skin, decreased skin turgor, and hair changes (e.g., dull, sparse, dry)
- Orthostatic (postural) hypotension
- Decreased serum protein levels and abnormal serum electrolyte values

The obese patient is often malnourished because of an imbalanced diet. Obesity increases the risk for poor wound healing because of excessive ***adipose*** (fatty) tissue. Fatty tissue has few blood vessels, little collagen, and decreased nutrients, all of which are needed for wound

healing. Obesity stresses the heart and reduces the lung volumes, which can affect the surgery and recovery. Obese patients may need larger drug doses and may retain them longer after surgery.

Skin assessment is important. Many insurers have denied coverage to hospitals for care provided to patients who develop skin breakdown or pressure ulcers during the perioperative period. Assess the patient's skin for signs of breakdown, open sores, or areas that may be exposed to excessive pressure during the surgical procedure, and document these findings. Communicate this information to the circulating nurse so that precautions can be taken to prevent injury.

NCLEX Examination Challenge

Safe and Effective Care Environment

An 81-year-old client, scheduled for a long orthopedic procedure, appears to have a low body mass index. In addition to the body mass index value, which additional client information is most important for the nurse to report to the surgeon and perioperative team as indicating an increased risk for skin breakdown?

A Negative nitrogen balance
B Previous abdominal surgery
C Allergy to latex products
D Change in mental status upon admission

Psychosocial Assessment.

Perform a psychosocial assessment to determine the patient's level of anxiety, coping ability, and support systems. Provide information and offer support as needed.

Most patients have some degree of anxiety or fear before surgery. The extent of these reactions varies according to the type of surgery, the perceived effects of the surgery and its potential outcome, and the patient's personality. Surgery may be seen as a threat to life, body image, self-esteem, self-concept, or lifestyle. Patients may fear death, pain, helplessness, a change in role or work status, a diagnosis of life-threatening conditions, possible disabling or crippling effects, or the unknown.

Anxiety or fear affects the patient's ability to learn, cope, and cooperate with teaching and operative procedures. Anxiety may also influence the amount and type of anesthetic needed and may slow recovery. In some cases, severe preoperative anxiety can increase the degree of pain after

surgery. Be aware of potential anxiety when interviewing the patient and planning teaching.

Assess coping mechanisms used by the patient under similar situations or in the past when confronted with a stressful situation. Ask open-ended questions about the patient's feelings about the entire surgical experience. Factors that influence coping include age, previous surgical or sick-role experiences, and physical discomfort. Manifestations of anxiety include anger, crying, restlessness, profuse sweating, increased pulse rate, palpitations, sleeplessness, diarrhea, and urinary frequency.

Laboratory Assessment.

Laboratory tests before surgery provide baseline data about the patient's health and help predict potential complications. The patient scheduled for surgery in an ambulatory surgical center or admitted to the hospital on the morning of or day before surgery may have preadmission testing (PAT) performed from 24 hours to 28 days before the scheduled surgery. These test results are usually valid unless there has been a change in the patient's condition that warrants repeated testing or the patient is taking drugs that can alter laboratory values (e.g., warfarin [Coumadin], aspirin, diuretics). Some facilities have time limits for tests, especially pregnancy testing or any other test results that would require altering the surgical plan.

The choice of laboratory testing before surgery varies among facilities and depends on the patient's age, medical history, and type of anesthesia planned (Rothrock, 2011). The most common tests include:

- Urinalysis
- Blood type and screen
- Complete blood count or hemoglobin level and hematocrit
- Clotting studies (prothrombin time [PT], international normalized ratio [INR], activated partial thromboplastin time [aPTT], platelet count)
- Electrolyte levels
- Serum creatinine and blood urea nitrogen levels
- Depending on a female patient's age and the nature of the planned procedure, a pregnancy test may also be needed

Urinalysis is performed to assess for abnormal substances in the urine such as protein, glucose, blood, and bacteria. If kidney disease is suspected or if the patient is older, the physician may request other tests to determine the type and degree of disease present.

Report electrolyte imbalances or other abnormal results to the anesthesia team and the surgeon before surgery. **Hypokalemia**

(decreased serum potassium level) increases the risk for toxicity if the patient is taking digoxin, slows recovery from anesthesia, and increases cardiac irritability. **Hyperkalemia** (increased serum potassium level) increases the risk for dysrhythmias, especially with the use of anesthesia.

Nursing Safety Priority QSEN

Critical Rescue

Any potassium imbalance—hypokalemia or hyperkalemia—must be corrected before surgery.

Other studies may be needed, depending on the patient's medical history. For example, baseline arterial blood gas (ABG) values are assessed before surgery for patients with chronic pulmonary problems. Chart 14-3 lists abnormal laboratory findings and their possible causes.

Chart 14-3

Laboratory Profile

Perioperative Assessment

TEST	NORMAL RANGE FOR ADULTS	SIGNIFICANCE OF ABNORMAL FINDINGS	
		INCREASED IN	DECREASED IN
Potassium (K^+)	3.5-5.0 mEq/L, or 3.5-5.0 mmol/L	Dehydration Kidney impairment Acidosis Cellular/tissue damage Hemolysis of the specimen	NPO status when potassium replacement is inadequate Excessive use of non–potassium-sparing diuretics Vomiting Malnutrition Diarrhea Alkalosis
Sodium (Na^+)	90 yr or younger: 136-145 mEq/L, or 136-145 mmol/L Older than 90 yr: 132-146 mEq/L, or 132-146 mmol/L	Cardiac failure or kidney impairment Hypertension Excessive amounts of IV fluids containing sodium chloride Edema Dehydration (hemoconcentration)	Nasogastric drainage Vomiting or diarrhea Excessive use of laxatives or diuretics Excessive amounts of IV fluids containing water Syndrome of inappropriate antidiuretic hormone (SIADH)
Chloride (Cl^-)	90 yr or younger: 98-106 mEq/L, or 98-106 mmol/L Older than 90 yr: 98-111 mEq/L, or 98-111 mmol/L	Respiratory alkalosis Dehydration Kidney impairment Excessive amounts of IV fluids containing sodium chloride (NaCl)	Excessive nasogastric drainage Vomiting Excessive use of diuretics Diarrhea
Carbon dioxide (CO_2)	60 yr or younger: 23-30 mEq/L, or 23-30 mmol/L 60-90 yr: 23-31 mEq/L, or 23-31 mmol/L Older than 90 yr: 20-29 mEq/L, or 20-29 mmol/L	Chronic pulmonary disease Intestinal obstruction Vomiting or nasogastric suctioning Metabolic alkalosis	Hyperventilation Diabetic ketoacidosis Diarrhea Lactic acidosis Renal failure Salicylate toxicity
Glucose (fasting)	60 yr or younger: 70-110 mg/dL, or 4.1-5.9 mmol/L 60-90 yr: 82-115 mg/dL, or 4.6-6.4 mmol/L Older than 90 yr: 75-121 mg/dL, or 4.2-6.7 mmol/L	Hyperglycemia Excessive amounts of IV fluids containing glucose Stress Steroid use Pancreatic or hepatic disease	Hypoglycemia Excess insulin
Creatinine	*Females:* 60 yr or younger: 0.5-1.1 mg/dL, or 44-97 μmol/L 60-90 yr: 0.6-1.2 mg/dL, or 53-106 μmol/L Older than 90 yr: 0.6-1.3 mg/dL, or 53-115 μmol/L *Males:* 60 yr or younger: 0.6-1.2 mg/dL, or 53-106 μmol/L 60-90 yr: 0.8-1.3 mg/dL, or 71-115 μmol/L Older than 90 yr: 1.0-1.7 mg/dL, or 88-150 μmol/L	Kidney damage with destruction of large number of nephrons Renal insufficiency Acute kidney injury Chronic kidney disease End-stage kidney disease (ESKD)	Atrophy of muscle tissue
Blood urea nitrogen (BUN)	Younger than 60 yr: 10-20 mg/dL, or 3.61-7.1 mmol/L 60-90 yr: 8-23 mg/dL, or 2.9-8.2 mmol/L Older than 90 yr: 10-31 mg/dL, or 3.6-11.1 mmol/L	Dehydration Kidney impairment Excessive protein in diet Liver failure	Overhydration Malnutrition
Prothrombin time (pro time, PT)	11-12.5 sec, 85%-100%, or 1 : 1.1 patient-control ratio	Coagulation defect (bleeding disorder) Vitamin K deficiency	Coagulation (clotting) disorder, such as thrombophlebitis or pulmonary embolus
International normalized ratio (INR)	0.7-1.8	Anticoagulant therapy (aspirin, warfarin)	Extensive cancer
Partial thromboplastin time, activated (aPTT)	30-40 sec	Coagulation defect (bleeding disorder) Anticoagulant therapy (heparin) Liver disease	Coagulation (clotting) disorder, such as thrombophlebitis or pulmonary embolus Extensive cancer
White blood cell (WBC) count (leukocyte count)	Total: 5,000-10,000/mm^3	Infection Inflammation Stress Tissue necrosis	Immune disorder Immunosuppressant therapy
Hemoglobin, total	*Females:* 18-44 yr: 12-16 g/dL, or 117-155 g/L 45-64 yr: 11.7-16.0 g/dL, or 117-160 g/L 65-74 yr: 11.7-16.1 g/dL, or 117-161 g/L *Males:* 18-44 yr: 14-18 g/dL, or 132-173 g/L 45-64 yr: 13.1-17.2 g/dL, or 131-172 g/L 65-74 yr: 12.6-17.4 g/dL, or 126-174 g/L	Dehydration Polycythemia Chronic pulmonary disease Congestive heart failure	Blood loss Anemia Renal failure

TEST	NORMAL RANGE FOR ADULTS	SIGNIFICANCE OF ABNORMAL FINDINGS	
		INCREASED IN	DECREASED IN
Hematocrit	*Females:* 18-44 yr: 35%-45% 45-74 yr: 37%-47% *Males:* 18-44 yr: 42%-52% 45-64 yr: 39%-50% 65-74 yr: 37%-51%	Dehydration Polycythemia High altitude	Blood loss Anemia Kidney failure

Imaging Assessment.

A chest x-ray may be requested before surgery. Often, healthy adults are not required to have a chest x-ray. A chest x-ray determines the size and shape of the heart, lungs, and major vessels and provides evidence of the presence of pneumonia or tuberculosis. It also provides baseline data in case of complications. Abnormal x-ray findings alert the surgeon to potential cardiac or pulmonary complications. Heart failure, cardiomyopathy, pneumonia, or infiltrates may cause cancellation or delay of elective surgery. For emergency surgery, x-ray results assist the anesthesia provider in selecting anesthesia type.

Other imaging studies are based on patient need, medical history, and the nature of the surgical procedure. For example, a patient with back pain may have CT scans or MRI examinations before spinal surgery to identify the exact location of the problem.

Other Diagnostic Assessment.

An electrocardiogram (ECG) may be required for patients older than a specific age who are to have general anesthesia. The age varies among facilities but is often 40 to 45 years. An ECG may also be required for patients with a history of cardiac disease or those at risk for cardiac complications. It provides baseline information on new or existing cardiac problems, such as an old myocardial infarction (MI). A patient with a known cardiac problem may need a cardiology consultation before surgery. Drugs for problem prevention, such as nitroglycerin, beta blockers, and antibiotics, may be needed throughout the surgical period to reduce or prevent stress on the heart. Abnormal or potentially life-threatening ECG results may cause the cancellation of surgery until the patient's cardiac status is stable.

A focused assessment of the preoperative patient is shown in Chart 14-4.

Chart 14-4 Focused Assessment

The Preoperative Patient

As part of the cardiopulmonary assessment, take and record vital signs; report:

- Hypotension or hypertension
- Heart rate less than 60 or more than 120 beats/min
- Irregular heart rate
- Chest pain
- Shortness of breath or dyspnea
- Tachypnea
- Pulse oximetry reading of less than 94%

Assess for and report any signs or symptoms of infection, including:

- Fever
- Purulent sputum
- Dysuria or cloudy, foul-smelling urine
- Any red, swollen, draining IV or wound site
- Increased white blood cell count

Assess for and report signs or symptoms that could contraindicate surgery, including:

- Increased prothrombin time (PT), international normalized ratio (INR), or activated partial thromboplastin time (aPTT)
- Hypokalemia or hyperkalemia
- Patient report of possible pregnancy or positive pregnancy test

Assess for and report other clinical conditions that may need to be evaluated by a physician or advanced practice nurse before proceeding with the surgical plans, including:

- Change in mental status
- Vomiting
- Rash
- Recent administration of an anticoagulant drug

NCLEX Examination Challenge

Physiological Integrity

The preoperative admitting nurse notices that the client scheduled for total joint replacement surgery in 2 hours has a smell of alcohol on his breath even though he has just stated that he has fasted completely for the past 10 hours. What is the nurse's best first action?

A Accept the client's statement and continue the preoperative

preparation.
B Report the discrepancy to the surgeon and anesthesiologist immediately.
C Tell the client the observation and provide the opportunity for him to explain.
D Remind the client that alcohol consumption may require changes in anesthesia procedure.

Analysis

The priority NANDA-I nursing diagnoses and collaborative problems for preoperative patients include:
1. Deficient Knowledge related to unfamiliarity with surgical procedures and preparation (NANDA-I)
2. Anxiety related to new or unknown experience, possibility of pain, and possible surgical outcomes (NANDA-I)

Planning and Implementation

As the nurse, your role is to ensure coordination of care for the patient before surgery. This responsibility continues until the patient is transferred to the operating room (OR).

Providing Information

Planning: Expected Outcomes.

The patient needs to know what to expect during and after surgery and participate in his or her recovery as indicated by consistently demonstrating these behaviors:

- Explaining in his or her own words the purpose and expected results of the planned surgery
- Asking questions when a term or procedure is not known
- Adhering to the NPO requirements
- Stating an understanding of preoperative preparations (e.g., skin preparation, bowel preparation)
- Demonstrating correct use of exercises and techniques to be used after surgery for the prevention of complications (e.g., splinting the incision, using an incentive spirometer, performing leg exercises, ambulating as early as permitted)

Interventions.

Because the surgical experience is foreign to many people, focus on

teaching the patient and family members. Teaching may begin in the surgeon's office for planned or elective surgery. Pamphlets, written instructions, approved websites, and video recordings or DVDs may be given or sent to the patient. More teaching may occur when the patient has preadmission testing. Some facilities hold classes before surgery for groups of patients or show videos for those who are having the same or similar surgical procedures. A tour of the operating suite and the postanesthesia care unit (PACU) may be included.

Explore the patient's level of knowledge and understanding. Increased access to information via the Internet may be helpful but is also a concern. Some Internet information may not be accurate or may not apply to a specific patient's plan of care.

The Joint Commission's NPSGs require that you provide information about informed consent, dietary restrictions, specific preparation for surgery (bowel and skin preparations), exercises after surgery, and plans for pain management to promote patients' participation and help achieve the expected outcome. A sample educational checklist is shown in Table 14-4. Because education occurs in a variety of settings, coordination of patient teaching efforts is challenging. When you care for the patient just before surgery (same-day, ambulatory surgery [outpatient] unit, inpatient hospital unit), assess the patient's and family members' knowledge and provide additional information as needed. If the patient is receiving sedation or general anesthesia, stress the importance of having another person drive the patient home after the procedure. Document in the patient record information about who was involved in teaching, what specifically was taught, and what education materials were given to the patient and family.

TABLE 14-4

Preoperative Teaching Checklist

Consider these items when planning individualized preoperative teaching for patients and families:

- Fears and anxieties
- Surgical procedure
- Preoperative routines (e.g., NPO, blood samples, showering)
- Invasive procedures (e.g., lines, catheters)
- Coughing, turning, deep breathing
- Incentive spirometer
  - How to use
  - How to tell when used correctly
- Lower extremity exercises
- Stockings and pneumatic compression devices
- Early ambulation
- Splinting
- Pain management

Ensuring Informed Consent.

Surgery of any type involves invasion of the body and requires informed consent from the patient or legal guardian (Fig. 14-2). The Joint Commission's NPSGs state that patients deserve to be informed and involved in decisions affecting their health care. Consent implies that the patient has sufficient information to understand:

GENERAL REQUEST AND CONSENT

FOR OFFICE USE ONLY:
Patient Name: _____
Date of Birth: _____
Date of Procedure: _____

I _____ request and give consent to _____
(Type or print patient name) (Type or print Doctor or Practitioner Name(s))

to perform the following procedure(s) _____
(Please list site and side if appropriate)

_____

_____

The benefits, risks, complications, and alternatives to the above procedure(s) have been explained to me.

I understand that the procedure(s) will be performed at Christiana Care by and under supervision of my doctor or practitioner. My doctor or practitioner may use the services of other doctors or practitioners, or members of the resident staff as he or she deems necessary or advisable.

I authorize my doctor or practitioner and his or her associates and assistants to perform such additional procedures, which in their judgment are necessary and appropriate to carry out my diagnosis or treatment.

I authorize the hospital to retain, preserve and use for scientific, teaching or transplant purposes, or to make other dispositions of, at their convenience, any specimens, tissues, or parts taken from my body during the course of this operation.

I consent to observers in the operating room in accordance with hospital policy. I consent to photography or video taping of my surgical procedure for educational purposes, provided my identity remains anonymous and confidential.

I agree to being given blood or blood products as deemed advisable during the course of my procedure. The risks, benefits, and alternatives to receiving blood or blood products have been explained to me.

I consent to the administration of sedation or analgesia during my procedure. The risks, benefits, and alternatives to receiving sedation or analgesia have been explained to me.

If anesthesia is required, I consent to the administration of anesthesia by members of the Department of Anesthesiology. I also consent to the use of non-invasive and invasive monitoring techniques as deemed necessary. I understand that anesthesia involves risks that are in addition to those resulting from the operation itself including, but not limited to, dental injury, hoarseness, vocal cord injury, infection, nerve injury, corneal abrasion, seizures, heart attack, stroke and even death.

Please initial one of the following statements (females only):

_____ To the best of my knowledge I am not pregnant. _____ I believe I am pregnant.

I certify that I have read and understand the above consent statements. In addition, I have been offered the opportunity to ask my doctor or practitioner any questions I have regarding the procedure(s) to be performed and they have been answered to my satisfaction. I acknowledge that I have been given no guarantee or assurance as to the results that may be obtained from the procedure(s).

Signature of Patient or Decision Maker — Date and Time

Relationship to Patient if Decision Maker

Witness Signature — Date and Time

Witness Print Name

Doctor or Practitioner Signature — Date and Time

Doctor ID # or Print Name

Practitioner Print Name/Title

Telephone Consent: _____
Name of person obtained from/Relationship to Patient

Witness's (es') Signature(s) — Date and Time

Witness's (es') Print Name(s)

Witness's (es') Signature(s) — Date and Time

Witness's (es') Print Name(s)

FIG. 14-2 A surgical consent form.

- The nature of and reason for surgery
- Who will be performing the surgery and whether others will be present during the procedure (e.g., students)
- All available options and the risks associated with each option
- The risks associated with the surgical procedure and its potential outcomes
- The risks associated with the use of anesthesia

Informed consent is one way to help ensure patient safety. It helps

protect the patient from any unwanted procedures and protects the surgeon and the facility from lawsuit claims related to unauthorized surgery or uninformed patients. Written record of informed consent is documented on a "consent form" but can also be documented in the surgeon's notes. The consent form documents the patient's consent and signature for the procedure listed.

As a competent adult, it is the patient's right to refuse treatment for any reason, even when refusal might lead to death. For example, in the case of Jehovah's Witnesses, some patients will not accept blood transfusions because of their religious convictions.

The surgeon is responsible for having the consent form signed before sedation is given and before surgery is performed. *You, as a nurse, are not responsible for providing detailed information about the surgical procedure. Rather, your role is to clarify facts that have been presented by the surgeon and dispel myths that the patient or family may have about the surgical experience. You verify that the consent form is signed, and you serve as a witness to the signature, not to the fact that the patient is informed (Rock & Hoebeke, 2014).*

Nursing Safety Priority QSEN

Action Alert

If you believe that the patient has not been adequately informed, contact the surgeon and request that he or she see the patient for further clarification. Document this action in the medical record.

Patients who cannot write may sign with an X, which must be witnessed by two people. In an emergency, telephone or telegram authorization is acceptable and should be followed up with written consent as soon as possible. The number of witnesses (usually two) and the type of documentation vary according to the facility's policy. For a life-threatening situation in which every effort has been made to contact the person with medical power of attorney, consent is desired but not essential. In place of written or oral consent, written consultation by at least two physicians who are not associated with the case may be requested by the surgeon. This formal consultation legally supports the decision for surgery until the appropriate person can sign a consent form. If the patient is not capable of giving consent and has no family, the court can appoint a legal guardian to represent the patient's best interests.

A blind patient may sign his or her own consent form, which usually

needs to be witnessed by two persons. Patients who do not speak the general language of the facility or who are hearing impaired may require a qualified translator and a second witness. Many facilities have consent forms written in more than one language and also have health care professionals who are proficient with American Sign Language. Qualified translators may be health care professionals, other types of hospital employee, or family members. They are required to keep patient information confidential.

Some surgical procedures, such as sterilization and experimental procedures, may require a special permit in addition to the standard consent. National and local governing bodies and the individual facility determine which procedures require a separate permit. Separate consents for anesthesia and blood products may be required.

Surgical procedures that are site-specific, such as left, right, or bilateral, require patient identification before surgery. As required by The Joint Commission's NPSGs, to ensure the correct site is selected and the wrong site is avoided, the site is marked by a licensed independent practitioner and, whenever possible, involves the patient. The surgeon is accountable and should be present during the procedure. The nurse is an important part of this safety measure. Before starting the operative procedure, facilities use a "time-out" procedure to verify the correct site, patient, and procedure. The perioperative nurse is in a position of ensuring these safety measures are implemented immediately before the procedure is started (Association of periOperative Registered Nurses [AORN], 2014c). The "time-out" involves the participation of all members of the procedure team including the surgeon, anesthesia provider, circulating nurse, scrub person, and any other active participants.

Nursing Safety Priority QSEN

Critical Rescue

At a minimum, the patient's identity, correct side and site, correct patient position, and agreement on the proposed procedure must be verified by all members of the surgical team.

Clinical Judgment Challenge

Safety QSEN

The patient states the surgeon discussed the addition of a second

procedure to the one indicated on the consent. The patient is visibly upset that the consent he is asked to sign with the surgical resident reflects only one procedure and cannot understand why the nurse and resident do not have the authority to "fix" the consent. In addition, he states he will not take his wedding ring off because it has never left his hand since his wife put it there 30 years ago.

1. How would you address the patient's immediate concern regarding the consent?
2. Under what conditions could the second procedure be performed?
3. What remedy would you propose to prevent such occurrences in the future?
4. How will you respond to the patient's unwillingness to remove his wedding ring?

Patient Self-Determination.

Patients receiving medical care have the right to have or to initiate advance directives, such as a living will or durable power of attorney, as mandated by the Patient Self-Determination Act. Advance directives provide legal instructions to the health care providers about the patient's wishes and are to be followed. *Surgery does not provide an exception to a patient's advance directives or living will* (AORN, 2014b). Chapter 7 discusses advance directives in more detail.

Implementing Dietary Restrictions.

Regardless of the type of surgery and anesthesia planned, the patient is restricted to NPO status before surgery. **NPO** means no eating, drinking (including water), or smoking (nicotine stimulates gastric secretions). The exact amount of time a patient must be NPO before surgery is controversial. Patients, especially older adults, who fast for 8 or more hours may have imbalances of fluids, electrolytes, and blood glucose levels. The American Society of Anesthesiologists (ASA) recommends a reduced NPO time—6 or more hours for easily digested solid food and 2 hours for clear liquids (Crenshaw, 2011; Sendelbach, 2010). A major problem is that these guidelines for duration of fasting have not been implemented universally.

NPO status ensures that the stomach contains a limited volume of gastric secretions, which decreases the risk for aspiration. Outpatients and patients who are scheduled for admission to the hospital on the same day that surgery is performed must receive written and oral instructions about when to begin NPO status.

Nursing Safety Priority QSEN

Action Alert

Emphasize the importance of adhering to the prescribed NPO restriction. Failure to adhere can result in cancellation of surgery or increase the risk for aspiration during or after surgery.

Administering Regularly Scheduled Drugs.

On the day of surgery, the patient's usual drug schedule may need to be altered. Consult the medical health care provider and the anesthesia provider for instructions about drugs such as those taken for diabetes, cardiac disease, or glaucoma, as well as regularly scheduled anticonvulsants, antihypertensives, anticoagulants, antidepressants, and corticosteroids. The surgeon may prescribe some drugs, including over-the-counter drugs such as aspirin, other NSAIDs, and herbal supplements, to be stopped until after surgery. Other drugs may be given IV to maintain the drug level in the blood. *Drugs for cardiac disease, respiratory disease, seizures, and hypertension are commonly allowed with a sip of water before surgery.* Some antihypertensive or antidepressant drugs are withheld on the day of surgery to reduce adverse effects on blood pressure during surgery. Even when beta blockers are not part of a patient's usual medications, they may be prescribed for some patients who are at risk for cardiac problems. Check with the health care provider, surgeon, or anesthesia provider to determine whether a specific patient requires perioperative therapy with beta-blocking drugs, as recommended by core measures for SCIP CARD-2 (see Table 14-1).

The patient who takes insulin for diabetes may be given a reduced dose of intermediate- or long-acting insulin based on the blood glucose level or may be given regular (fast-acting) insulin in divided doses on the day of surgery. As an alternative, an IV infusion of 5% dextrose in water may be given with the insulin to prevent low blood sugar during surgery. Because of the many treatment approaches to diabetes, clarify drug and IV prescriptions with the health care provider. (See Chapter 64 for more information about diabetes.)

Intestinal Preparation.

Bowel or intestinal preparations are performed to prevent injury to the colon and to reduce the number of intestinal bacteria. Bowel evacuation is needed when a patient is having major abdominal, pelvic, perineal, or perianal surgery. In addition, colonoscopy procedures, routinely

performed in outpatient ambulatory care facilities, require the patient to follow a strict preoperative protocol for bowel evacuation. The surgeon's preference and the type of surgical procedure determine the type of bowel preparation. Enemas ordered to be given until return flow is clear is a stressful procedure, especially for the older patient. Repeated enemas can cause electrolyte imbalance, fluid volume imbalances, vagal stimulation, and postural (orthostatic) hypotension. Enemas cause severe anal discomfort in patients with hemorrhoids. Some physicians prescribe potent laxatives instead of enemas, especially for older patients. Bowel preparations can exhaust the patient, and you must take safety precautions to prevent falls.

Skin Preparation.

The skin is the body's first line of defense against infection. A break in this barrier increases the risk for infection, especially for older patients. Skin preparation before surgery is the first step to reduce the risk for surgical site infection (AORN, 2014d).

One or two days before the scheduled surgery, the surgeon may ask the patient to shower using an antiseptic solution. Instruct the patient to be especially careful to clean well around the proposed surgical site. If the patient is hospitalized before surgery, showering and cleaning are repeated the night before surgery or in the morning before transfer to the surgical suite. This cleaning reduces contamination of the surgical field and reduces the number of organisms at the site. Remove any soil or debris from the surgical site and surrounding areas.

Factors that predispose to wound contamination and surgical site infection (SSI) include bacteria found in hair follicles, disruption of the normal protective mechanisms of the skin, and nicks in the skin. Shaving of hair creates the potential for infection. Hair clipping with electrical clippers and depilatories are to be used for hair removal as required by The Joint Commission's NPSGs (Tanner et al., 2011). This type of skin preparation is part of the Surgical Care Improvement Project's (SCIP) core measures for SCIP Inf-6 (see Table 14-1).

The Centers for Disease Control and Prevention (CDC) recommends that if shaving is necessary, the hair should be removed using disposable sterile supplies and aseptic principles *immediately* before the start of the surgical procedure. If needed, shaving is performed in the treatment room, the holding area of the operating suite, or the operating room (OR). Fig. 14-3 shows areas of hair removal for various surgical procedures.

FIG. 14-3 Skin preparation of common surgical sites. *Shaded areas* indicate preparation areas.

Preparing the Patient for Tubes, Drains, and Vascular Access.

Prepare the patient for possible placement of tubes, drains, and vascular access devices. Preparation reduces the patient's anxiety and fear and the family's negative reaction. Be careful not to scare the patient while providing information about the purpose of each tube.

Tubes of all sorts are common after surgery. A nasogastric (NG) tube

may be inserted before abdominal surgery to decompress or empty the stomach and the upper bowel. Usually the tube is placed after the induction of anesthesia, when insertion is less disturbing to the patient and is easier to perform. The patient may need an indwelling urinary (Foley) catheter before, during, or after surgery to keep the bladder empty and to monitor kidney function.

Drains are often placed during surgery to help remove fluid from the surgical site. Some drains are under the dressing; others are visible and require emptying. Drains come in various shapes and sizes (see Chapter 16). Inform the patient that drains are often used routinely and that generally they are not painful but may cause some discomfort. Discuss the reasons drains should not be kinked or pulled.

Vascular access is placed for patients receiving a general anesthetic and for most patients receiving other types of anesthetics. Access is needed to give drugs and fluids before, during, and after surgery. Patients who are dehydrated or are at risk for dehydration may receive fluids before surgery.

Considerations for Older Adults

Patient-Centered Care QSEN

Older adult patients are at greater risk for dehydration because their fluid reserves are lower than those of young or middle-aged adults. Carefully monitor older adult patients and patients with cardiac disease receiving IV fluids. (See Chapter 13 for more information on IV therapy.)

The IV access is usually placed in the arm using a large-bore, short catheter (e.g., 18-gauge, 1-inch catheter) or placed in the back of the hand using a smaller-bore (20-gauge) catheter. A larger vein provides the least resistance to fluid or blood infusion, especially in an emergency when rapid infusions may be needed. Depending on the patient's needs and the facility's policies, the IV access can be placed before surgery when the patient is in the hospital room, in the holding or admission area of the surgical suite, or in the OR.

Postoperative Procedures and Exercises.

Teach the patient and family members about exercises and procedures (e.g., checking dressings, obtaining vital signs frequently) to be performed after surgery. Family members can be helpful in reminding patients to perform the exercises. Teaching before surgery reduces apprehension and fear, increases cooperation and participation in care

after surgery, and decreases respiratory and vascular complications. When the fear or anxiety level is high, explore the patient's feelings before discussing procedures.

Discussion, demonstration with return demonstration, and practice by the patient aid in the ability to perform various breathing (Chart 14-5) and leg (Chart 14-6) exercises after surgery. Stress the need to begin exercises early in the recovery phase and to continue them, with 5 to 10 repetitions each, every 1 to 2 hours after surgery for at least the first 48 hours. Explain that the patient may need to be awakened for these activities.

Chart 14-5 Patient and Family Education: Preparing for Self-Management

Perioperative Respiratory Care

Deep (Diaphragmatic) Breathing

1. Sit upright on the edge of the bed or in a chair, being sure that your feet are placed firmly on the floor or a stool. (After surgery, deep breathing is done with the patient in Fowler's position or in semi-Fowler's position.)
2. Take a gentle breath through your mouth.
3. Breathe out gently and completely.
4. Then take a deep breath through your nose and mouth, and hold this breath to the count of five.
5. Exhale through your nose and mouth.

Expansion Breathing

1. Find a comfortable upright position, with your knees slightly bent. (Bending the knees decreases tension on the abdominal muscles and decreases respiratory resistance and discomfort.)
2. Place your hands on each side of your lower rib cage, just above your waist.
3. Take a deep breath through your nose, using your shoulder muscles to expand your lower rib cage outward during inhalation.
4. Exhale, concentrating first on moving your chest, then on moving your lower ribs inward, while gently squeezing the rib cage and forcing air out of the base of your lungs.

Splinting of the Surgical Incision

1. Unless coughing is contraindicated, place a pillow, towel, or folded

blanket over your surgical incision and hold the item firmly in place.
2. Take three slow, deep breaths to stimulate your cough reflex.
3. Inhale through your nose, and then exhale through your mouth.
4. On your third deep breath, cough to clear secretions from your lungs while firmly holding the pillow, towel, or folded blanket against your incision.

Chart 14-6 Patient and Family Education: Preparing for Self-Management

Postoperative Leg Exercises

Exercise No. 1 1. Lie in bed with the head of your bed elevated to about 45 degrees. 2. Beginning with your right leg, bend your knee, raise your foot off the bed, and hold this position for a few seconds. 3. Extend your leg by unbending your knee, and lower the leg to the bed. 4. Repeat this sequence four more times with your right leg; then perform this same exercise five times with your left leg.	
Exercise No. 2 1. Beginning with your right leg, point your toes toward the bottom of the bed. 2. With the same leg, point your toes up toward your face. 3. Repeat this exercise several times with your right leg; then perform this same exercise with your left leg.	Exercise No. 3 1. Beginning with your right leg, make circles with your ankle, first to the left and then to the right. 2. Repeat this exercise several times with your right leg; then perform this same exercise with your left leg.	Exercise No. 4 1. Beginning with your right leg, bend your knee and *push* the ball of your foot into the bed or floor until you feel your calf and thigh muscles contracting. 2. Repeat this exercise several times with your right leg; then perform this same exercise with your left leg.	

Procedures and Exercises to Prevent Respiratory Complications.

Breathing exercises include deep, or diaphragmatic, breathing to enlarge the chest cavity and expand the lungs. After you demonstrate and explain the technique, urge the patient to practice deep breathing.

For patients with chronic lung disease or limited chest expansion, as seen in older patients because of the aging process, expansion breathing exercises are useful. For the patient having chest surgery, expansion breathing exercises strengthen accessory muscles and are started before

surgery. Expansion breathing after surgery during chest physiotherapy (percussion, vibration, postural drainage) may help loosen secretions and maintain an adequate air exchange.

Incentive spirometry is another way to encourage the patient to take deep breaths. Its purpose is to promote complete lung expansion and to prevent pulmonary problems. Various types of incentive spirometers are available; Fig. 14-4 shows a patient using one type. With all types, the patient must be able to seal the lips tightly around the mouthpiece, inhale spontaneously, and hold his or her breath for 3 to 5 seconds for effective lung expansion. Goals (e.g., attaining specific volumes) can be set according to the patient's ability and the type of incentive spirometer. Seeing a ball move up a column or a bellows expanding reinforces and motivates the patient to continue performance.

FIG. 14-4 A patient using an incentive spirometer.

Coughing and splinting may be performed along with deep breathing every 1 to 2 hours after surgery. The purposes of coughing are to expel secretions, keep the lungs clear, allow full aeration, and prevent pneumonia and atelectasis. Coughing may be uncomfortable for the patient, but when performed correctly, it should not harm the incision. Splinting (i.e., holding) the incision area provides support, promotes a feeling of security, and reduces pain during coughing. The proper technique for splinting the incision site and coughing is described in Chart 14-5. A folded bath blanket or pillow is helpful to use as a splint. Cardiac surgery patients may receive their own heart-shaped pillow for

splint use.

The use of routine coughing exercises after surgery is controversial. Some surgeons believe coughing may harm the surgical wound and that it would be better to use other, safer measures for lung hygiene, such as deep breathing and incentive spirometer exercises. When routine coughing exercises should be avoided for a specific patient, such as after a hernia repair or craniotomy, the surgeon usually writes a "do not cough" prescription.

Procedures and Exercises to Prevent Cardiovascular Complications.

Venous stasis and venous thromboembolism (VTE) (a group of vascular disorders that includes deep vein thrombosis [DVT] and pulmonary embolism [PE]) are potential but often avoidable complications of surgery. VTE or DVT can lead to a PE if the blood clot breaks off and travels to the lungs. Patients at greater risk for VTE:

- Are obese
- Are older than 40 years
- Have cancer
- Have decreased mobility or are immobile
- Have a spinal cord injury
- Have a history of VTE, DVT, PE, varicose veins, or edema
- Are taking oral contraceptives
- Smoke
- Have decreased cardiac output
- Have hip fracture or total hip or total knee surgery

Always assess for VTE before surgery. Sudden swelling in one leg is a common physical finding of VTE caused by DVT. A patient may feel a dull ache in the calf area that becomes worse with ambulation. A careful assessment and timely intervention may prevent the potentially fatal complication of pulmonary embolism.

Because surgical-related VTE can be prevented, prophylaxis is required by the Surgical Care Improvement Project (SCIP) core measures (see Table 14-1). All patients should be evaluated for VTE risk based on history, type and duration of surgery, and expected time of immobilization after surgery. VTE prophylaxis may involve devices and drug therapy, depending on a specific patient's evaluated risk. Devices may be used during and after surgery along with leg exercises and early ambulation to promote venous return. Specific interventions depend on the patient's risk factors (Larkin et al., 2012). (See the Evidence-Based Practice box.)

VTE Prevention Beyond the Surgical Care Improvement Project (SCIP): What Works?

Larkin, B., Mitchell, K., & Petrie, K. (2012). Translating evidence to practice for mechanical venous thromboembolism prophylaxis. *AORN Journal*, *96*(5), 513-527.

Both pharmacologic and mechanical prophylaxis for prevention of venous thromboembolism (VTE) are being used extensively to prevent VTE after surgery. Many health care professionals, including nurses, believe that pharmacologic prophylaxis is more effective and more important than mechanical prophylaxis. However, some patients cannot use pharmacologic prophylaxis. This integrative review of the literature sought to determine the evidence for best practices related to mechanical prophylaxis to prevent surgical-related venous thromboembolism (VTE) events. Variables compared included the types of mechanical prophylaxis, timing of application, the effects of combining prophylaxis methods, and the use of unilateral prophylaxis for some orthopedic procedures.

A variety of research reports and previous meta-analyses from appropriate sources were reviewed. The criteria and need for mechanical prophylaxis and its optimal initiation varied by institution and profession. Most surgeons followed the SCIP guidelines, whereas experienced perioperative nurses expanded the risk factors to include history of VTE events, level of general immobility, and presence of varicosities. Also examined were issues related to availability of prescribed devices and the timing of their application.

Results of the study indicated that use of mechanical prophylaxis for VTE is increasing, although the timing and duration of application is not consistent. Overall, the best outcomes were obtained when devices, whether they were graduated compression stockings or intermittent pneumatic compression devices, were applied correctly in the preoperative period rather than intraoperatively or postoperatively. No evidence supports the combination of devices to be more effective than either type of device alone. In addition, patients with issues not listed in the SCIP guidelines were also at risk for VTE and could benefit from perioperative mechanical prophylaxis. These include older age, decreased general mobility, irritable bowel syndrome, oral contraceptive use, malignant disease, severe infection, and presence of varicose veins.

Level of Evidence: 1

The study is an analysis of previous research studies on the use of mechanical prophylaxis for perioperative prevention of VTE, examining practices and specific devices. The methods used were appropriate to answer the question posed, and the large numbers of human subjects resulted in credible evidence to support the need for practice consistency.

Commentary: Implications for Practice and Research

The current SCIP criteria for VTE mechanical prophylaxis are beginning points, not end points, for this evolving prevention strategy. Nurses can contribute to the desired outcome of reducing surgical-related VTE events by identifying patients who have other risk factors for VTE that may be less obvious or are not included in the SCIP criteria. By partnering with surgeons to ensure that such patients are prescribed mechanical prophylaxis and that the devices are applied correctly during the preoperative period, the goal of VTE as a "never" event is closer to being achieved.

Antiembolism stockings (TED or Jobst stockings) and elastic (Ace) wraps provide graduated compression of the legs, starting at the end of the foot and ankle. Measure the patient's leg length and circumference before ordering the stocking size. Elastic wraps are used when the legs are too large or too small for the stockings. Assist the patient in applying the stockings or wraps, and ensure that they are neither too loose (are ineffective) nor too tight (inhibit blood flow). They need to be worn properly and should be removed 1 to 3 times per day for 30 minutes for skin inspection and skin care.

Pneumatic compression devices enhance venous blood flow by providing intermittent periods of compression on the legs. Measure the patient's legs, and order the correct size. Place the boots on the patient's legs, and then set and check the compression pressures (usually 35-55 mm Hg). *Unless these devices are applied properly, there is no benefit (Elpern et al., 2013).* Fig. 14-5 shows various types of sequential compression devices. Antiembolism stockings may be worn in addition to the boots and may reduce some of the uncomfortable sensations of the boots (e.g., itching, sweating, heat).

FIG. 14-5 An external pneumatic compression device used to promote venous return and prevent deep vein thrombosis (DVT).

Leg exercises also promote venous return. Teach the leg exercises outlined in Chart 14-6, and then urge the patient to practice these exercises before surgery. The exercises are important, even when other devices are used.

Mobility soon after surgery (early ambulation) has many cardiovascular and other benefits. It stimulates intestinal motility, enhances lung expansion, mobilizes secretions, promotes venous return, prevents joint rigidity, and relieves pressure. For most types of surgery, teach the patient to turn at least every 2 hours after surgery while confined to bed. Teach patients how to use the bed siderails safely for turning and how to protect the surgical wound by splinting when turning. Assure patients that assistance and pain drugs will be given as needed to reduce any anxiety and pain they may have with this activity.

For certain surgical procedures, such as some brain, spinal, and orthopedic procedures, the surgeon may prescribe turning restrictions. Ask the surgeon about other interventions to prevent complications of immobility in patients with turning restrictions. During teaching before surgery, inform the patient of anticipated turning restrictions.

Most patients are allowed and encouraged to get out of bed the day of or the day after surgery. Assist the patient into a chair or with ambulation after the surgery, the next day, or when the surgeon specifies. If a patient must remain in bed, help him or her turn, deep breathe, and perform leg exercises at least every 2 hours to prevent complications from immobility.

Minimizing Anxiety

Planning: Expected Outcomes.

Before surgery, the patient is expected to have manageable anxiety as indicated by consistently demonstrating these behaviors:

- Expressing a reduced level of anxiety
- Showing an absence of body language indicators of anxiety (e.g., hand wringing, facial tension, restlessness, dilated pupils, sweating, elevated blood pressure, elevated pulse rate)

Interventions.

Anxiety often causes restlessness and sleeplessness. The patient may perceive the surgical experience as a threat to life and function. Assess the patient's level of anxiety, as discussed on p. 222 in the Psychosocial Assessment section. Interventions such as teaching and communicating with the patient before surgery, enabling the patient to use previously successful coping mechanisms, and giving antianxiety drugs help reduce the anxiety. Incorporate available support systems into the plan of care.

Preoperative teaching involves first assessing the patient's knowledge about the surgical experience (see p. 225 in the Providing Information section) and then providing factual information to promote his or her understanding. Allow ample time for questions. Respond to the questions accurately, and refer unanswered questions to the proper professional. During the discussion, continually assess the patient's responses and anxiety level. Be careful not to provide information that might increase anxiety. The informed, educated patient is better able to anticipate events and maintain self-control and is thus less anxious.

Encouraging communication by having the patient state feelings, fears, and concerns can help reduce anxiety. Use an honest and open approach so that the patient can express feelings freely without fear of ridicule or judgment. Keep the patient informed by clarifying information, answering questions, and allaying fears about the surgery.

Promoting rest is helpful because the stress and anxiety of impending surgery often interfere with the patient's ability to sleep and rest the night before surgery. The period before surgery is physically and emotionally stressful. To help the patient relax, determine what he or she usually does to relax and fall asleep. If the patient is able, urge him or her to continue these methods of relaxation. A back rub is relaxing and can be performed by a nurse, unlicensed assistive personnel (UAP), or family member. The surgeon may prescribe a sedative or hypnotic drug to help the patient be well rested for surgery.

Distraction may be used as an intervention for anxiety, especially in the 24 hours immediately before surgery. Listening to music may decrease

anxiety, as may watching television, reading, or visiting with friends and family members.

Teaching family members helps reduce anxiety by increasing the likelihood of support and involvement in the patient's care. Assess the readiness and desire of the family to take an active part in the patient's care. A positive sign of family interest is that of members asking questions about the surgical experience. After family readiness is determined, keep family members informed and encourage their involvement in all aspects of education. Emphasize the important role of the family before surgery, but guide discussions and practice sessions so that the patient is the focus of the discussion. Family members can encourage and help the patient practice exercises to be performed after surgery.

Inform the family of the time for surgery, if known, and of any schedule changes. If the patient is an outpatient, provide clear directions to the patient and family regarding any specific night-before procedures, what time and where to report, and what to bring with them. Encourage the family to stay with the patient before surgery for support.

Most families are anxious about the surgery planned for their loved one. To reduce their anxiety, explain the routines expected before, during, and after surgery. Tell the family that after the patient leaves the hospital room or admission area, there is usually a 30- to 60-minute preparation period in the operating area (holding room, treatment area) before the surgery actually begins. After surgery, the patient is taken to the postanesthesia care unit (PACU) usually for 1 to 2 hours before returning to the hospital room or discharge area. The length of stay in the PACU depends on the type of surgery, the type of anesthesia, any complications, and the patient's responses. Tell the family about the best place to wait for the patient or surgeon according to the facility's policy and the surgeon's preference. Many hospitals and surgical centers have surgical waiting areas so that families can wait in comfortable surroundings and be easily located when the procedure is completed. Often families are provided with a beeper to let them know when to report to a specific area to receive updates about the patient's status, meet with the surgeon, or see the patient.

Preoperative Chart Review.

Review the patient's chart to ensure that all documentation, preoperative procedures, and orders are completed. Check the surgical informed consent form and, if indicated, any other special consent forms to see that they are signed and dated and that they contain the witnesses'

signatures. Confirm that the scheduled procedure, including the identification of left versus right when necessary, is what is listed on the consent form. Even though it might be obvious, inform the patient that the site for surgery will be marked before the procedure begins. If possible, encourage the patient to assist with the marking, as suggested by The Joint Commission's NPSGs. Document allergies according to facility policy. Accurate measuring and recording of height and weight are important for proper dosage of the anesthetic agents. Ensure that the results of all laboratory, radiographic, and diagnostic tests are on the chart. Document any abnormal results, and report them to the surgeon and the anesthesia provider. If the patient is an autologous blood donor or has had directed blood donations made, those special slips must be included in the chart. Record a current set of vital signs (within 1 to 2 hours of the scheduled surgery time), and document any significant physical or psychosocial observations.

Report special needs, concerns, and instructions (including advance directives) to the surgical team, as required by The Joint Commission's NPSGs. For example, advise the surgical team if the patient is a member of Jehovah's Witnesses and does not accept blood products or if the patient is hard of hearing and does not have his or her hearing aid. This information assists the surgical team in providing personalized care while the patient is in the surgical area.

Preoperative Patient Preparation.

Facilities usually require the patient to remove most clothing and wear a hospital gown into the OR; however, underpants may be worn in above-the-waist surgery and socks may be worn, except in foot or leg surgery. If prescribed by the surgeon, apply antiembolism stockings or pneumatic compression devices before surgery. In some ambulatory settings, such as for cataract surgery, no or minimal clothes are removed.

Patients are advised to leave all valuables at home. If he or she has valuables, including jewelry, money, or clothes, they are given to a family member or locked in a safe place, according to the facility's policy. If rings cannot be removed, tape them in place. Depending on the type and location of surgery, pierced jewelry may need to be removed. Religious emblems may be pinned or fastened securely to the patient's gown. Some facilities have paper emblems from a religious leader.

The patient wears an identification band that clearly gives the first and last name, hospital number, surgeon, and birth date. An additional bracelet, usually red, identifies any allergies. A bracelet indicating that a blood sample for type and screen has been drawn may be worn,

depending on the facility's policy.

If dentures are to be removed, including partial dental plates, place them in a labeled denture cup. Denture removal is a safety measure to prevent aspiration and obstruction of the airway. If a patient has any capped teeth, document this finding on the checklist.

All prosthetic devices, such as artificial eyes and limbs, are removed and given to a family member or safely stored, as are contact lenses, glasses, wigs, and toupees. Check and remove hairpins and clips, which can conduct electrical current used during surgery and cause scalp burns.

Some facilities allow hearing aids in the surgical suite to help communication before and after surgery. If the patient is sent to surgery with a hearing aid, communicate this to the surgical nurse to prevent accidental loss of or damage to the device. Some facilities allow dentures, wigs, and glasses to be worn into the operating suite to prevent embarrassment to the patient. These items are removed when absolutely necessary.

The removal of fingernail polish or artificial nails is controversial. Polish and artificial nails have been thought to affect the accuracy of pulse oximetry readings. Recent studies have indicated that pulse oximetry readings taken on fingers are affected by brown or blue polish but not by red or lighter color polish. In addition, pulse oximetry does not have to be measured on fingers only. Some facilities still require that at least one artificial nail must be removed to monitor oxygen saturation by pulse oximetry.

After the patient is prepared for surgery and the operating suite is ready to receive him or her, ask him or her to empty the bladder. This action prevents incontinence or overdistention and is a starting point for intake and output measurement. A full bladder may hinder access to the surgical site. Answer questions, offer reassurance as needed, and give prescribed drugs.

Preoperative Drugs.

Preoperative drugs may be prescribed regardless of the type of planned anesthesia. Various drugs reduce anxiety, promote relaxation, prevent laryngospasm, reduce vagal-induced bradycardia, inhibit oral and gastric secretions, and decrease the amount of anesthetic needed for the induction and maintenance of anesthesia. Drug selection is based on the patient's age, physical and psychological condition, medical history, and height and weight; other drugs the patient takes routinely; test results; and the type and extent of the planned surgical procedure. If more than one response is required, combination therapy may be prescribed.

Drug types for preoperative purposes may include sedatives (e.g., hydroxyzine [Atarax, Vistaril]); hypnotics (e.g., lorazepam [Ativan]); anxiolytics (e.g., midazolam [Versed]); opioid analgesics (e.g., morphine, hydromorphone); and an anticholinergic agent (e.g., atropine). Other specific-purpose drugs also may be added. For example, if rapid emptying of the stomach is needed, metoclopramide (Reglan) may be prescribed. When procedures are long or stress ulcers are likely, an H_2 histamine blocker (e.g., cimetidine [Tagamet]; ranitidine [Zantac]) is used.

Preoperative drugs may be given when the patient is "on call" to the surgical suite. After positively identifying the patient as required by The Joint Commission's NPSGs (using the armband and asking the patient to state his or her name and birth date) and making sure the operative permit is signed, give the correct drugs in the correct doses. Then raise the siderails, place the call light within easy reach of the patient, and remind him or her not to try to get out of bed. Place the bed in a low position. Tell the patient that he or she may become drowsy and have a dry mouth as a result of the drugs.

A more common practice is for the preoperative drugs to be given *after* the patient is transferred to the preoperative area. This practice permits the surgical team and anesthesia personnel to make more accurate assessments and have last-minute discussions with a patient not yet affected by drugs. In addition, after the patient is in the preoperative area, drugs can be given by the IV route. Monitoring equipment such as continuous pulse oximetry and ECG are more readily available in this area. The oral or IM route is used less often because of variable absorption rates. The surgeon may order a prophylactic antibiotic to be given right before or during surgery to reduce the risk for a surgical site infection (SSI), as suggested by The Joint Commission's NPSGs. When needed, the antibiotic is given within 60 minutes before the incision is made, as mandated by the Surgical Care Improvement Project (SCIP) core measures, SCIP Inf-1 (see Table 14-1).

Patient Transfer to the Surgical Suite.

In the immediate preoperative period, review and update the patient's chart, reinforce teaching, ensure that the patient is correctly dressed for surgery, and give prescribed preoperative drugs. Use an electronic or hardcopy preoperative checklist for a smooth, efficient transfer to the surgical suite (Fig. 14-6). The patient, along with the signed consent form, the completed preoperative checklist, the chart, and the patient identification card, is transported to the surgical suite.

PREOPERATIVE CHECKLIST **PATIENT INFORMATION**

Date and Time of Arrival to Presurgical Holding Area: _____

INITIAL APPROPRIATELY

1. Hospital identification band intact and legible including patient name, date of birth, medical record number ____ Yes ____ No
A. If yes, which arm? _____
B. If no, make and apply arm band
C. Is the extremity involved in the surgery? ____ Yes ____ No
D. If yes, change to another extremity ____ Yes ____ No

FIG. 14-6 A preoperative checklist.

Most patients in the hospital setting are transferred to the surgical suite on a stretcher with the siderails up. In special circumstances (e.g., patients requiring traction, those having some types of orthopedic surgery, those who should be moved as little as possible), the patient is transferred in the hospital bed. Other factors that influence the decision to transfer in a bed are the patient's age, size, and physical condition. In ambulatory settings, patients either walk or are transferred to the surgical suite on a stretcher or in a wheelchair.

Evaluation: Outcomes

Evaluate the care of the preoperative patient based on the identified patient problems. The expected outcomes include that the patient:

- States understanding of the informed consent and preoperative procedures
- Demonstrates postoperative exercises and techniques for prevention of complications
- Has reduced anxiety

Specific indicators for these outcomes are listed for each patient problem in the Planning and Implementation section (see earlier).

Nursing Concepts and Clinical Judgment Review

What might you NOTICE in a patient who is preparing for surgery and has adequate body defenses related to infection?

Vital signs:

- Body temperature within normal range
- No sweating or chills

Physical assessment:

- Skin intact (no rashes, abnormal lesions, open areas, or drainage)
- Skin color normal for ethnicity
- Lymph nodes normal, no enlargement or pain
- Absence of sore throat, pain or burning on urination, productive cough
- Lung sounds clear to auscultation

Psychological assessment:

- Oriented, not confused

Laboratory assessment:

- White blood cell levels within normal limits for age and gender
- All cultures negative for pathogenic organisms
- Urinalysis result shows clear urine, no bacteria, white blood cells, or nitrates present
- Chest x-ray clear

Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Determine the purpose of surgery for each patient in your care.
- Assess each patient's personal factors for threats to safety.
- Ensure that the patient is wearing proper identification.
- Use at least two appropriate identifiers (e.g., hospital number, the identification band, asking the patient to state his or her name and birthdate) to identify the patient when providing instruction, administering drugs, marking surgical sites, and performing any procedure. *Do not use room number or bed number to identify the patient.* **Safety** QSEN
- Check that the informed consent has been properly signed by the patient and witness and that the presurgical checklist is complete and accurate. **Safety** QSEN
- Ask the patient to explain in his or her own words what surgical procedure is being done and why.
- Check that documentation for any procedure to be performed on one of a paired organ or extremity clearly indicates which organ or extremity is involved. **Safety** QSEN
- If the patient's explanation of the scheduled surgery is not consistent with the documentation, notify the surgeon and request that he or she speak to the patient. **Safety** QSEN
- Ensure that the patient is not asked to sign an operative permit or any other legal document after the preoperative drugs have been given.
- After the patient has received preoperative drugs, keep the siderails up and the bed in the low position.
- Communicate during hand-off to the operating room personnel all care that has been provided and what care may still be needed.

Health Promotion and Maintenance

- Teach patients about dietary restrictions, preoperative preparations, and specific interventions to perform after surgery to prevent complications (incision splinting, deep-breathing exercises, range-of-motion exercises—as described in Charts 14-5 and 14-6). **Patient-Centered Care** QSEN

Psychosocial Integrity

- Assess the extent of the patient's and family members' knowledge about the scheduled surgical procedure to identify learning needs. **Patient-Centered Care** QSEN
- Encourage the patient to express his or her feelings regarding the surgical procedure or its possible outcome.
- Explain and provide written information for all diagnostic procedures, restrictions, and follow-up care to the patient and his or her family.
- Communicate to the surgeon and anesthesia personnel any concerns, fears, or preferences the patient has. **Patient-Centered Care** QSEN
- Apply appropriate interventions to reduce patient anxiety.

Physiological Integrity

- Perform a complete and accurate preoperative assessment.
- If required, ensure that dentures and any other personal items are removed from the patient before he or she is transferred to the surgical suite.
- Apply prescribed antiembolic stockings, sequential compression boots, or other devices to reduce or prevent vascular complications. **Evidence-Based Practice** QSEN
- Communicate to the surgeon and anesthesia personnel any physical or laboratory change that may alter the patient's response to drugs, anesthesia, or surgery.

CHAPTER 15

Care of Intraoperative Patients

Robin Chard

PRIORITY CONCEPTS

- Infection
- Gas Exchange
- Sensory Perception
- Clotting
- Thermoregulation

Learning Outcomes

Safe and Effective Care Environment

1. Differentiate the roles and responsibilities of various intraoperative personnel.
2. Use appropriate patient identifiers when administering drugs, ensuring informed consent, and verifying surgical sites during the intraoperative period.
3. Protect the patient from injury, poor thermoregulation, and infection during the intraoperative period.
4. Communicate care provided and needed at each transition in care during the intraoperative period.

Psychosocial Integrity

5. Reduce the psychological impact for the patient and family regarding the intraoperative experience.
6. Ensure patient concerns and needs are communicated to other members of the health care team during the intraoperative period.

Physiological Integrity

7. Use knowledge of anatomy, physiology, and principles of aging to modify and prioritize patient care during the intraoperative period to prevent skin breakdown and positioning injury.
8. Coordinate appropriate care for the patient with malignant hyperthermia.

 http://evolve.elsevier.com/Iggy/

The *intraoperative period* begins when the patient enters the surgical suite and ends at the time of transfer to the postanesthesia recovery area, same-day surgery unit, or the intensive care unit. The main concerns of perioperative nurses are safety and patient advocacy by preventing, reducing, controlling, and managing many hazards. In the operating room (OR) the patient is at risk for infection, impaired skin integrity, increased anxiety, poor thermoregulation and altered body temperature, and injury related to positioning and other hazards. The surgical phase is filled with unfamiliar experiences and uncertain outcomes. Nursing care during this period affects the patient's physical needs, spiritual needs, comfort, safety, dignity, and psychological status. Specific procedures and policies may differ among agencies but should all reflect the standards and recommended practices as published by the Association of periOperative Registered Nurses (AORN) (2014a). Perioperative nurses practice within a specific, patient-focused model that incorporates professional practice with attainable, measurable outcomes.

Overview

Members of the Surgical Team

The surgical team usually consists of the surgeon, one or more surgical assistants, the anesthesia provider, and the OR nursing staff. Perioperative, or OR, nurses include the holding area nurse, circulating nurse, scrub nurse or a non-nurse "scrub person," and specialty nurse. The number of assistants, circulating nurses, and scrub nurses depends on the complexity and length of the surgical procedure. For some minor procedures, only a circulating nurse and scrub person may be needed in addition to the surgeon. More complex procedures may require additional nursing staff to either circulate or scrub.

Surgeon and Surgical Assistant

The *surgeon* is a physician who is responsible for the surgical procedure and any surgical judgments about the patient. The *surgical assistant* might be another surgeon (or physician, such as a resident or intern) or an advanced practice nurse, physician assistant, certified registered nurse first assistant (CRNFA), or surgical technologist. Under the direction of the surgeon and within the legal scope of practice for each state, the assistant may hold retractors, suction the wound (to improve viewing of the operative site), cut tissue, suture, and dress wounds.

Anesthesia Providers

The *anesthesiologist* is a physician who specializes in giving anesthetic agents. A *certified registered nurse anesthetist (CRNA)* is an advanced practice registered nurse with additional education and credentials who delivers anesthetic agents under the supervision of an anesthesiologist, surgeon, dentist, or podiatrist. The anesthesia provider gives anesthetic drugs to induce and maintain anesthesia and delivers other drugs to support the patient during surgery.

The anesthesia provider monitors the patient during surgery by assessing and monitoring:

- The level of anesthesia (i.e., by using a peripheral nerve stimulator or electroencephalogram [EEG] bispectral analysis)
- Cardiopulmonary function (using electrocardiographic [ECG] monitoring, pulse oximetry, end-tidal carbon dioxide monitoring, arterial blood gases [ABGs], and hemodynamic monitoring via arterial lines and/or pulmonary artery catheters)
- Capnography (monitors ventilation for non-intubated patients)

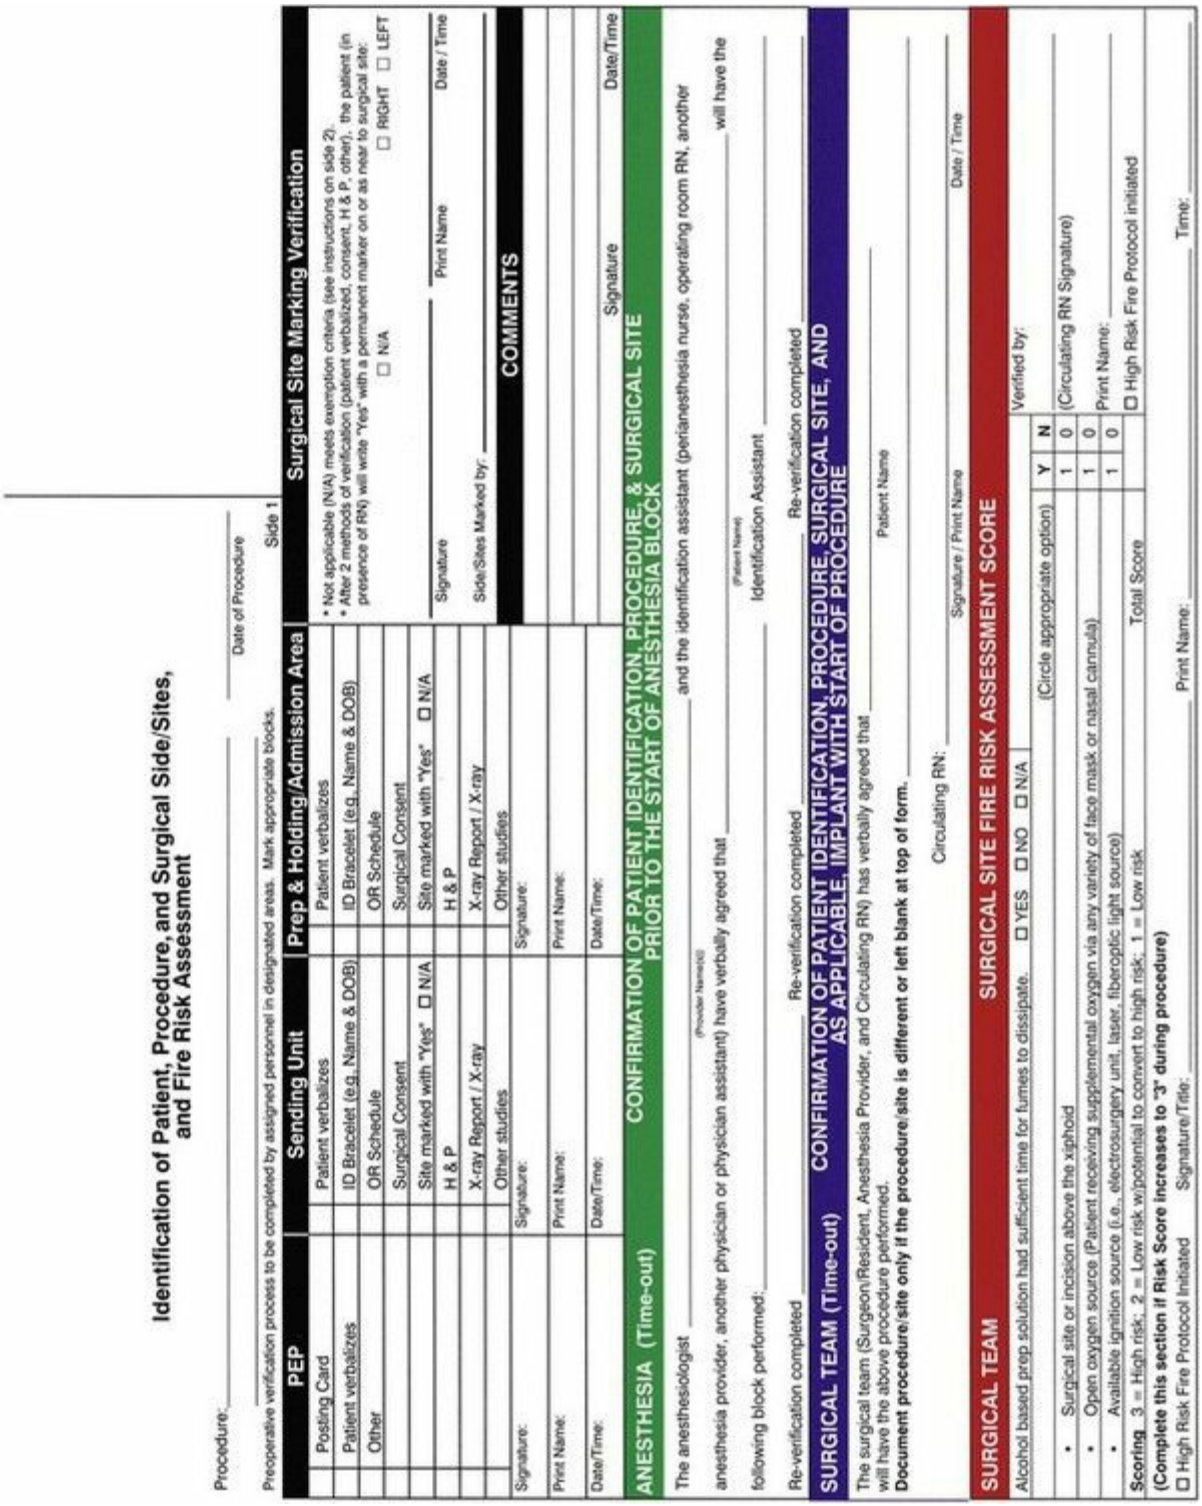
- Vital signs
- Intake and output

Depending on the patient's needs, anesthesia personnel give IV fluids, including blood products.

Perioperative Nursing Staff

Perioperative nursing staff have several roles during surgery, depending on their education, experience, skill, and job responsibilities. Regardless of their role, the OR nurse uses clinical decision-making skills, develops a plan of nursing care, and coordinates care delivery to patients and their family members.

Holding area nurses work in those operating suites that have a presurgical holding area next to the main ORs. The holding area nurse coordinates and manages the care while the patient waits in this area until the OR is ready. Responsibilities include greeting the patient on arrival, reviewing the medical record and preoperative checklist, verifying that the operative consent forms are signed, and documenting the risk assessment (Fig. 15-1). This nurse also assesses the patient's physical and emotional status, gives emotional support, answers questions, and provides additional education as needed.



Identification of Patient, Procedure, and Surgical Side/Sites, and Fire Risk Assessment

Signature _____ Date/Time

FIG. 15-1 Identification of patient, procedure, and surgical side/sites, and fire risk assessment.

The holding area is busy, with many staff members performing different procedures before surgery (e.g., starting IV lines, inserting catheters). The nurse promotes comfort, privacy, and confidentiality. In some facilities, family members may wait here with the patient.

Circulating nurses, or "circulators," are registered nurses who coordinate, oversee, and are involved in the patient's nursing care in the OR. This nurse's actions are vital to the smooth flow of events before,

during, and after surgery. He or she coordinates all activities within that particular OR. The circulator sets up the OR and ensures that needed supplies, including blood products and diagnostic support, are available. All anticipated equipment is gathered and inspected by the circulator to ensure safety and function before surgery. Depending on the procedure and position required, the circulator makes up the operating bed (OR table) with gel pads (to prevent pressure ulcers), safety straps and armboards, and either heating pads under the sheets or disposable warming blankets placed over the patient as needed to prevent hypothermia.

If there is no holding area nurse, the circulator also assumes the responsibilities of that role. Even when there is a holding area nurse, the circulator also greets the patient and reviews findings with the holding area nurse.

Once the patient is moved into the OR, the circulating nurse, along with the OR team, assists the patient in transferring to the OR table. The nurse positions the patient, protecting bony areas with padding while providing comfort and reassurance. While observing the patient, the circulating nurse also assists the anesthesia provider with the induction of anesthesia by positioning the patient and applying cricoid pressure, when requested. The circulator then may assist with additional positioning, insert a Foley catheter if needed, apply the grounding pad, test equipment, and "prep" (scrub) the surgical site before the patient is draped with sterile drapes.

Throughout the surgery, the circulating nurse:

- Protects the patient's privacy
- Ensures the patient's safety
- Monitors traffic in the room
- Assesses the amount of urine and blood loss
- Reports findings to the surgeon and anesthesia provider
- Ensures that the surgical team maintains sterile technique and a sterile field
- Anticipates the patient's and surgical team's needs, providing supplies and equipment
- Communicates information about the patient's status to family members during long or unique procedures
- Documents care, events, interventions, and findings

Depending on facility policy, the circulating nurse may record drugs, blood, and blood components given. (This also may be a function of the anesthesia provider.)

Before the procedure is over, the circulating nurse completes

documentation in the OR and nursing records, including the presence of drains or catheters, the length of the surgery, and a count of all sponges, "sharps" (needles, blades), and instruments. He or she notifies the postanesthesia care unit (PACU) of the patient's estimated time of arrival and any special needs.

Scrub nurses or scrub persons set up the sterile table (Fig. 15-2), drape the patient, and hand sterile supplies, sterile equipment, and instruments to the surgeon and the assistant. Knowledge of the surgical procedure allows the scrub person to anticipate which instruments and types of sutures the surgeon will need, which reduces the duration of anesthesia. Collaboration and coordination of activities between the surgeon and the scrub person help promote the best surgical outcome for the patient. Throughout the procedure, the scrub person (with the circulating nurse) maintains an accurate count of sponges, sharps, and instruments and amounts of irrigation fluid and drugs used.

FIG. 15-2 Setting up the sterile table.

A specially trained person who is not a nurse may perform the scrub role. Such people are called *operating room technicians (ORTs)* or *surgical technologists*. Often certified surgical technologists (CSTs) are used in the OR.

Specialty nurses may be in charge during some types of specialty

surgery (e.g., orthopedic, cardiac, ophthalmologic) and provide specific nursing care during surgery. This nurse assesses, maintains, and recommends equipment, instruments, and supplies used in that specialty.

If the facility uses laser technology, a nurse specially trained in the use, care, and maintenance of the laser is needed (laser specialty nurse or a laser nurse coordinator). (**Laser** is an acronym for **l**ight **a**mplification by the **s**timulated **e**mission of **r**adiation.) A laser creates intense heat, rapidly clots blood vessels or tissue, and turns target tissue (e.g., a tumor) into vapor. All personnel must observe safety measures (e.g., wear eye shields, read door signs) during laser procedures to prevent injury to the patient and staff (AORN, 2014h).

Preparation of the Surgical Suite and Team Safety

The patient is unable to protect himself or herself during surgery; protection is provided by all members of the surgical team. The OR layout helps prevent infection by reducing contaminants through air exchanges in the room, maintaining recommended temperature and humidity levels, and limiting the traffic and activities in the OR. Safety straps are used for the patient, and the OR bed is locked in place. Blankets or warming units are used to prevent hypothermia from poor thermoregulation, and interventions are used to prevent skin breakdown.

The nurse ensures electrical safety through proper placement of grounding pads and use of electrical equipment that meets safety standards. All equipment used during surgery must be functional and in proper working condition as determined by the safety procedure of that facility. Equipment is cleaned and, when required, sterilized before use. The scrub and circulating nurses together ensure a correct count of surgical instruments, sharps, and sponges. Counts are performed before the procedure, during the procedure as items are added or when personnel are relieved from that assignment, at closure of the first layer of the surgical wound, and immediately before complete skin closure (AORN, 2014l).

All OR personnel work to prevent fire and complications from the use of hazardous or toxic substances. Ignition sources, oxidizers, and fuels are present in the OR and increase the risk for fires. Such events are rare but can occur during any procedure. A cool room temperature (between 68° and 73° F [20° and 23° C]) with low humidity (30% to 60%) is optimal. The nurse is aware of emergency measures to take in the event of a fire or spill.

Layout

The surgical suite is located out of the mainstream of the hospital and near the PACU and support services (e.g., blood bank, pathology, and laboratory departments). Traffic flow is patterned to reduce contamination from outside the suite. Within the suite, clean and contaminated areas are separate. The surgical area is divided into three zones—unrestricted, semirestricted, and restricted—to ensure proper movement of patients and personnel.

Most suites contain staff areas as well as areas related to patient care, surgery, and surgical support. Staff areas include locker rooms and staff lounges. Patient care areas include an admission or holding area and operating rooms (ORs). Support areas include ORs, cabinets for sterile supplies, separate utility rooms for clean and soiled equipment, and a clean linen room.

Fig. 15-3 shows a typical OR. The number of tables and equipment in a room is based on the needs of each patient. A communication system links the OR with the main desk of the surgical suite and includes an intercom with separate systems for routine and emergency calls.

FIG. 15-3 **A,** A typical operating room. **B,** A typical anesthesia station with an anesthesia machine.

New OR designs use computers with the surgical equipment, lights, OR bed, and communications. These "hi-tech" rooms are similar to traditional ORs but larger with the addition of computer equipment. Many have voice-activated command systems to operate some equipment instead of manual operation.

Minimally Invasive and Robotic Surgery

Minimally invasive surgery (MIS) is a common practice and now is the preferred technique for many types of surgery, including cholecystectomy, cardiac surgery, splenectomy, and spinal surgery. It is even being used for cancer surgeries, such as the removal of a lung lobe (lobectomy) or even the entire lung (pneumonectomy) and colectomy. Benefits of MIS include reduced surgery time for some surgeries, smaller incisions, reduced blood loss, faster recovery time, and less pain after surgery.

During MIS, one or more small incisions is made in the surgical area and an **endoscope** (a tube that allows viewing and manipulation of internal body areas) is placed through the opening (Fig. 15-4). These instruments may be rigid, semirigid, or flexible and may have self-contained light sources. Endoscopes have different names and shapes for different surgical purposes. For example, laparoscopes are used for abdominal surgery, arthroscopes are used for joint surgery, and ureteroscopes are used for urinary tract surgery.

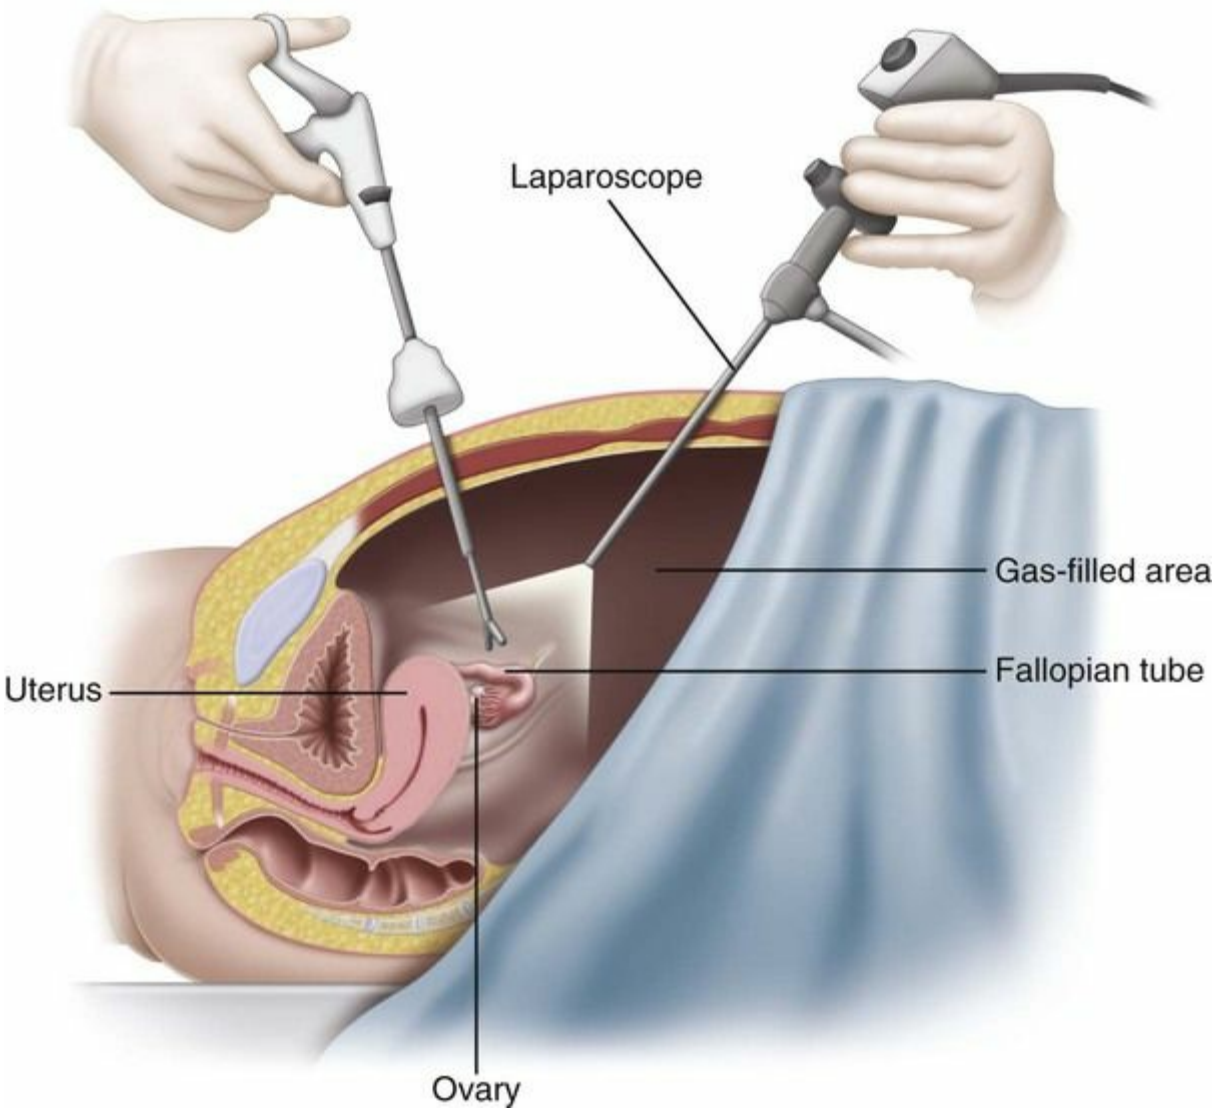

FIG. 15-4 How an operative laparoscope is used.

In addition to being used for examination and obtaining specimens for biopsy, endoscopes can be used for organ removal, reconstruction, blood vessel grafting, and many other procedures. Cutting, suturing, stapling, cautery, and laser surgery can all be performed through or with endoscopes. An important part of MIS for abdominal surgery, pelvic surgery, and surgery in some other body cavity areas is injecting gas or air into the cavity before the surgery to separate organs and improve visualization. This injection is known as **insufflation** and may contribute to complications and patient discomfort. This factor is considered when deciding whether to perform a procedure by traditional surgery or by endoscopy.

Patient preparation for endoscopic surgery is similar to the preparation for the same procedure when performed by open surgical methods. An endoscopic surgical procedure has a chance for becoming an open surgical procedure depending on what patient-related or procedure-related variables are discovered or develop during the surgery.

Robotic technology takes MIS to a new level and is changing how surgery is performed and how the OR is organized. Many gynecologic, urologic, and cardiovascular procedures are being performed by using robotics. The robotic system consists of a console, surgical arm cart, and video cart (Fig. 15-5). The surgeon first inserts the required instruments and positions the articulating arms; he or she then breaks scrub and performs the surgery while sitting at the console. A three-dimensional (3-D) view of the patient's anatomy allows precise control and dexterity. The vision cart holds the monitors, cameras, and recorder equipment. This new technology requires a perioperative robotics nurse specialist who teaches patients and family and trains members of the surgical team.

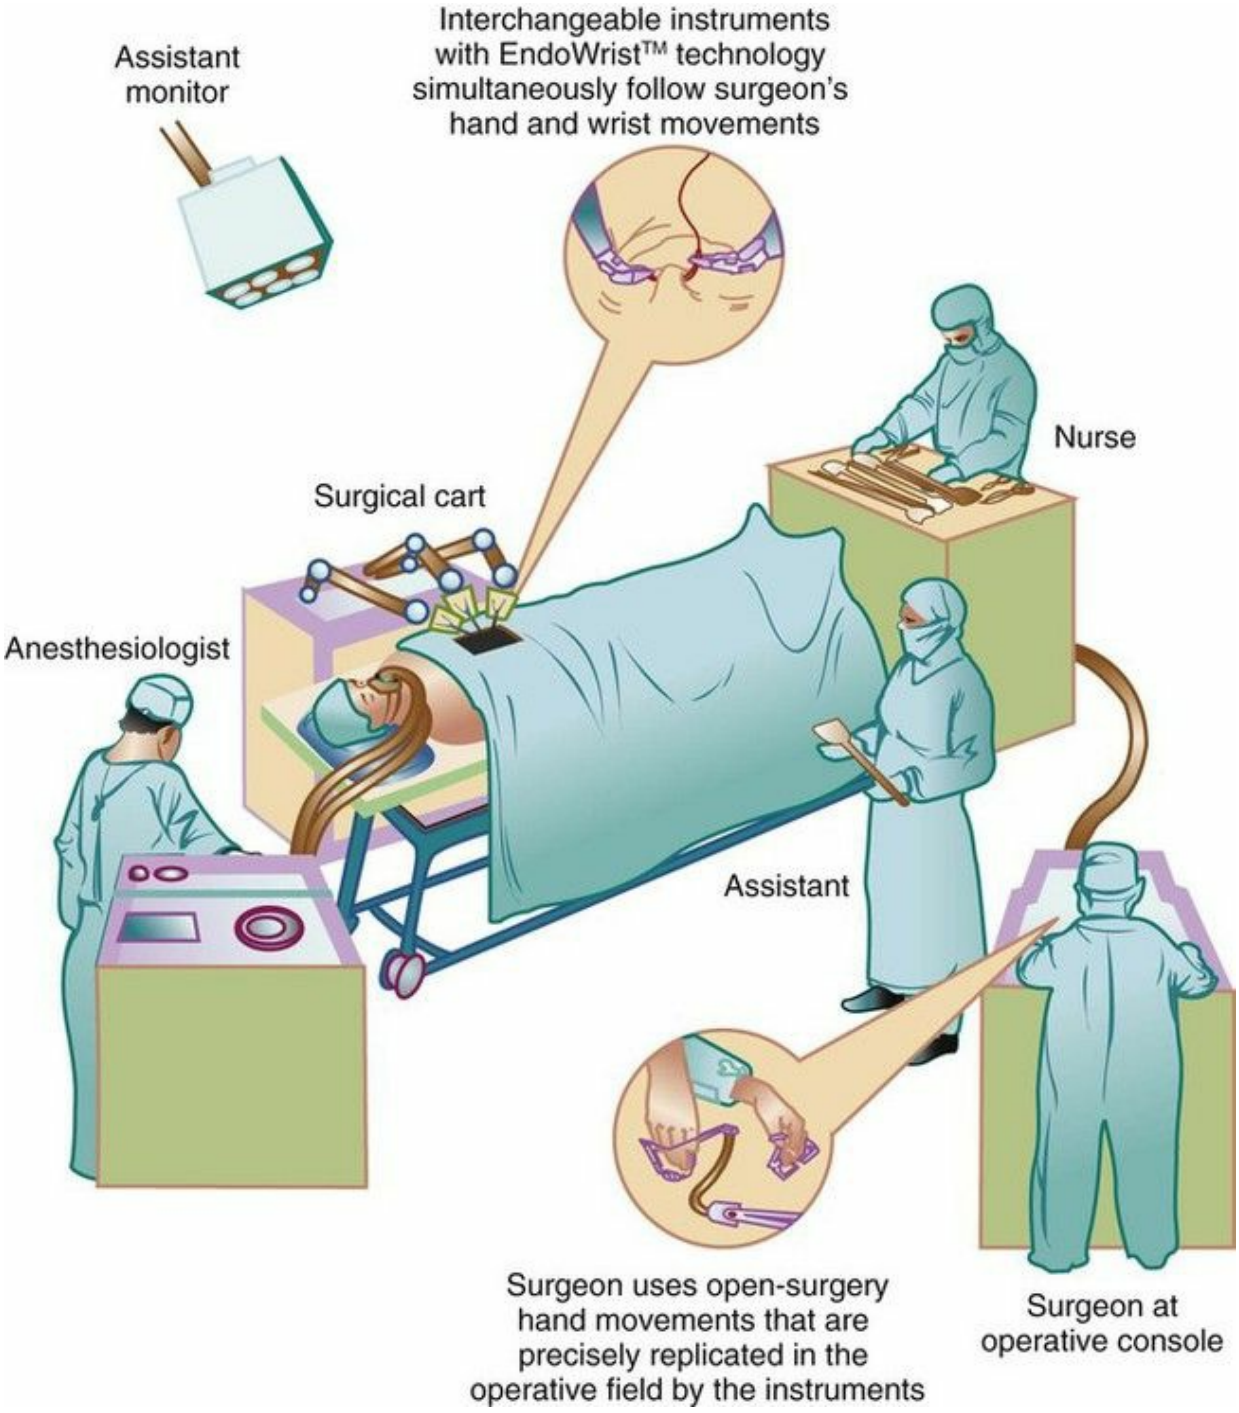

FIG. 15-5 The operating room layout for robotic surgery with the da Vinci Surgery System.

Mechanical trauma and thermal injury are two types of injury that a patient can incur during MIS and robotic surgery (Ulmer, 2010). Both MIS and robotic surgery are limited by the cost of special equipment, OR settings, and the lengthy training and practice periods for the surgeon to become proficient in even one procedure using these methods.

Health and Hygiene of the Surgical Team

People are a source of contamination in the surgical setting from the

bacteria on the skin and the hair and in the airways. To avoid transmitting these organisms to the patient, policies and procedures for special health standards and dress must be followed. All members of the surgical team and support personnel in the surgical suite must be free of communicable diseases. No one who has an open wound, cold, or any infection should participate in surgery.

Good personal hygiene and frequent handwashing help prevent and control infection. Jewelry carries many organisms and should be minimal. All personnel must wash their hands between touching patients and performing procedures. Hands of surgical personnel may be cultured on a regular basis to assess for potential **nosocomial** (health care–acquired) infections and to identify sources of pathogens. Further interventions or cultures are needed if quality reports indicate a problem. Routine cultures are usually obtained every 3 to 6 months. Surgical attire and the surgical scrub help prevent contaminations.

Surgical Attire

All members of the surgical team and all OR personnel must wear scrub attire while in the surgical suite. Scrub attire, provided by the hospital, is clean (not sterile) and is worn to reduce contamination and risk for infection from areas outside of the surgical setting. Basic surgical attire is a shirt and pants and a cap or hood (Fig. 15-6). Shoe coverings may be worn only to protect the shoes. *Staff change into clean surgical attire in the OR suite locker rooms, not at home* (AORN, 2014o). All members of the surgical team must cover their hair, including any facial hair.

FIG. 15-6 Typical attire for all scrubbed personnel. Note complete hair covering, eye shields, mask, sterile gloves over the sleeves of the sterile gown, and shoe coverings. Note that when not in use, the hands are typically folded in front of the body, never below the waist.

In addition to basic attire, everyone must wear protective attire (mask, eyewear, gloves, and gown). Everyone who enters an OR where a sterile field is present must wear a mask. Surgical team members who are scrubbed and at the bedside during the surgery must also wear a sterile fluid-resistant gown, sterile gloves, and eye protectors or face shields. Team members who are *not* scrubbed (e.g., anesthesia provider, circulator) may wear cover scrub jackets that are snapped or buttoned closed and eyewear, as warranted. For some procedures, the surgical

team wears what amounts to surgical “space suits” to prevent wound contamination.

Surgical Scrub

The surgeon, assistants, and the scrub nurse perform a surgical scrub after putting on a mask and before putting on a sterile gown and gloves (Fig. 15-7). *The scrub does not make the skin sterile*. Correctly performed, the scrub reduces the number of organisms from the hands, arms, and nails. Rings, watches, and bracelets are removed before scrubbing. Fingernails are kept short, clean, and healthy. Artificial nails, which have been proven to harbor organisms even after appropriate scrub techniques are used, are not worn (World Health Organization, 2014).

FIG. 15-7 The scrubbing, gowning, and gloving process. **A,** The surgical scrub. **B,** Rinsing. Note the water falling off the hands and arms. Also note the foot-operated handle that controls the water flow. (After scrubbing and rinsing, the scrub nurse dries his hands and arms with a sterile towel inside the operating room and then is assisted into a sterile gown.) **C,** The scrub nurse prepares sterile gloves. Note that the scrub nurse's hands are *inside* the sleeve of the gown and that he is touching the sterile gloves only with the sterile sleeve. **D,** The scrub nurse puts on his first sterile glove while the sterile gown is being tied in the back. Note again that his hand never emerges from under the sterile sleeve. **E,** The scrub nurse puts on his second sterile glove.

A surgical antimicrobial solution is used for the surgical scrub. Plain or antimicrobial soap is used for washing hands immediately before the surgical scrub. Vigorous rubbing that creates friction is used from the fingertips to the elbow. The scrub continues for 3 to 5 minutes, followed by a rinse. For rinsing, hands and arms are positioned so that water runs off, rather than up or down, the arms (AORN, 2014p). After scrubbing, personnel enter the OR with their hands held higher than the elbows and thoroughly dry their hands and forearms with a sterile towel. This person is then assisted into a sterile gown *("gowning")* and puts on sterile gloves *("gloving")*. Newer, alcohol-based surgical scrub agents may or may not require the use of water. Operating room personnel wash and dry their hands with soap and water before applying the agent to their hands and

forearms, rubbing thoroughly until dry.

Gowns, gloves, and materials used at the operative field must be sterile. These items are changed between procedures and as they become contaminated. The surgical gown is considered sterile only on the front from the chest to the level of the sterile field. The entire sleeves of the gown are considered sterile from 2 inches above the elbow to the cuff. The back of the gown is not considered sterile because it cannot be seen by the wearer. Only when they are properly scrubbed and attired do members of the surgical team handle sterile drapes and equipment.

NCLEX Examination Challenge

Safe and Effective Care Environment

While at the scrub sink, the scrub person informs the circulating nurse that she now wears artificial nails because her own nails break frequently posing a risk for a glove puncture. What is the nurse's best response?

A Ask the scrub person to wear double-gloves to prevent puncture or contamination.

B Confirm with the scrub person that artificial nails are acceptable and do not affect hand hygiene.

C Support the scrub person's rationale that broken nails are a serious source of cross-contamination.

D Remind the scrub person that artificial nails alter skin flora, impede hand hygiene, and are not permitted.

Anesthesia

Anesthesia reduces or temporarily eliminates sensory perception. Anesthesia delivery is a precise science. It requires the skill of an anesthesiologist, a certified registered nurse anesthetist (CRNA) working under the direction of an anesthesiologist or another physician, or an anesthesiologist assistant (AA—similar to a physician assistant working under the direction of an anesthesiologist).

Anesthesia is an induced state of partial or total loss of sensory perception, with or without loss of consciousness. The purpose of anesthesia is to block nerve impulse transmission, suppress reflexes, promote muscle relaxation, and, in some cases, achieve a controlled level of unconsciousness. Anesthesia providers use a separate anesthesia record for documentation.

Usually the anesthesia provider selects the type of anesthesia to be

used after consulting with the patient and surgeon and after considering specific patient factors. The nurse and patient communicate preferences and fears about anesthesia to the anesthesia provider. Patient health problems are factors in the selection and dose of anesthetic. Selection is also influenced by:

- Type and duration of the procedure
- Area of the body having surgery
- Safety issues to reduce injury, such as airway management
- Whether the procedure is an emergency
- Options for management of pain after surgery
- How long it has been since the patient ate, had any liquids, or had any drugs
- Patient position needed for the surgical procedure
- Whether the patient must be alert enough to follow instructions during surgery
- The patient's previous responses and reactions to anesthesia

The physical status of a patient is ranked according to a classification system developed by the American Society of Anesthesiologists (ASA). The anesthesiologist assesses the patient and assigns him or her to one of six categories based on current health and the presence of diseases and disorders. The categories rank patients in a range from a totally healthy patient (P1 ranking) to a patient who is brain dead (P6 ranking) (Johnson, 2011). This system is used to estimate potential risks during surgery and patient outcomes.

Anesthesia delivery begins with selecting and giving preoperative drugs (see Chapter 14). The nurse must know the actions of the drugs used and their effects during and after surgery. Anesthetic agents affect many systems and can worsen other health problems. For example, most anesthetics are metabolized by the liver and excreted by the kidneys. Liver or kidney impairment increases anesthetic effects and the risk for toxicity. In addition, interactions may occur between the anesthetics and other drugs the patient has received.

Anesthesia can be induced in many ways. The most common forms of anesthesia used in North America include general, regional, and local anesthesia (Table 15-1). Less commonly used forms include hypnosis, cryothermia (use of cold), and acupuncture.

TABLE 15-1

Features of Various Types of Anesthesia

TYPE	FEATURES
Inhalation	Most controllable method
	Induction and reversal accomplished with pulmonary ventilation
	Must be used in combination with other agents for painful or prolonged procedures
	Limited muscle relaxant effects
	Postoperative nausea and shivering common
Intravenous	Rapid and pleasant induction
	Low incidence of postoperative nausea and vomiting
	Must be metabolized and excreted from the body for complete reversal
	Contraindicated in presence of liver or kidney disease
	Increased cardiac and respiratory depression
Balanced	Minimal disturbance to physiologic function
	Can be used with older and high-risk patients
	Drug interactions can occur
Regional or Local	Gag and cough reflexes stay intact
	Allows participation and cooperation by the patient
	Less disruption of physical and emotional body functions
	No way to control agent after administration
	Increased nervous system stimulation (overdose)
	Not practical for extensive procedures because of the amount of drug that would be required to maintain anesthesia

General Anesthesia

General anesthesia is a reversible loss of consciousness induced by inhibiting neuronal impulses in several areas of the central nervous system (CNS). This state can be achieved with a single agent or a combination of agents. General anesthesia depresses the CNS, resulting in **analgesia** (pain relief or pain suppression), **amnesia** (memory loss of the surgery), and unconsciousness, with loss of muscle tone and reflexes. The patient is unconscious and has no sensory perception. General anesthesia is used most often in surgery of the head, neck, upper torso, and abdomen.

Stages of General Anesthesia.

Induction of general anesthesia involves four stages. Table 15-2 lists the expected patient responses and nursing care for each stage. The speed of **emergence** (recovery from the anesthesia) depends on the anesthetic agent, the duration of anesthesia administration, and whether a reversal agent is used. Retching, vomiting, and restlessness may occur during

emergence, although not all patients have these responses. Suction equipment must be available to prevent aspiration. During recovery, shivering, rigidity, and slight cyanosis may occur. These responses are caused by a temporary change in the body's thermoregulation. The nurse provides warm blankets, radiant heat, and oxygen to decrease the effects of emergence.

TABLE 15-2

The Four Stages of General Anesthesia and Related Nursing Interventions

DESCRIPTION	NURSING INTERVENTIONS	RATIONALES
Stage 1 (Analgesia and Sedation, Relaxation)		
Begins with induction and ends with loss of consciousness.	Close operating room doors, dim the lights, and control traffic in the operating room.	Avoiding external stimuli in the environment promotes relaxation.
Patient feels drowsy and dizzy, has a reduced sensation to pain, and is amnesic.	Position patient securely with safety belts.	Using safety measures in stage 1 prepares for stage 2.
Hearing is exaggerated.	Keep discussions about the patient to a minimum.	Being sensitive to the patient maintains his or her dignity.
Stage 2 (Excitement, Delirium)		
Begins with loss of consciousness and ends with relaxation, regular breathing, and loss of the eyelid reflex.	Avoid auditory and physical stimuli.	Sensory stimuli can contribute to the patient's response.
Patient may have irregular breathing, increased muscle tone, and involuntary movement of the extremities.	Protect the extremities.	Safety measures help prevent injury.
Laryngospasm or vomiting may occur.	Assist the anesthesiologist or CRNA with suctioning as needed.	Adequate suctioning of vomitus can prevent aspiration.
Patient is susceptible to external stimuli.	Stay with patient.	Staying with the patient is emotionally supportive.
Stage 3 (Operative Anesthesia, Surgical Anesthesia)		
Begins with generalized muscle relaxation and ends with loss of reflexes and depression of vital functions. The jaw is relaxed, and breathing is quiet and regular. The patient cannot hear. Sensations (i.e., to pain) are lost.	Assist the anesthesiologist or CRNA with intubation. Place patient into operative position. Prep (scrub) the patient's skin over the operative site as directed.	Providing assistance helps promote smooth intubation and prevent injury. Performing procedures as soon as possible promotes time management to minimize total anesthesia time for the patient.
Stage 4 (Danger)		
Begins with depression of vital functions and ends with respiratory failure, cardiac arrest, and possible death. Respiratory muscles are paralyzed; apnea occurs. Pupils are fixed and dilated.	Prepare for and assist in treatment of cardiac and/or pulmonary arrest. Document occurrence in the patient's chart.	Teamwork and preparedness help decrease injuries and complications and promote the possibility of a desired outcome for the patient.

CRNA, Certified registered nurse anesthetist.

Administration of General Anesthesia.

General anesthesia agents are administered by inhalation and IV injection. A combination of types of agents (balanced anesthesia) is used to provide hypnosis, amnesia, analgesia, muscle relaxation, and reduced reflexes with minimal disturbance of physiologic function. This method provides safe and controlled anesthetic delivery, especially for older and high-risk patients. An example of balanced anesthesia is the use of thiopental or propofol for induction, morphine for analgesia, and pancuronium for muscle relaxation. Agent selection is based on the individual patient and the specific surgical procedure.

Other drugs, such as hypnotics, opioid analgesics, and neuromuscular blocking agents, may be used as part of the anesthesia regimen. Hypnotics and opioid analgesics can be used for sedation before surgery, for IV moderate sedation for short procedures, and as an adjunct to general anesthesia during surgery. The neuromuscular blocking agents are used to relax the jaw and vocal cords immediately after induction so that the endotracheal tube can be placed. These drugs also may be used during surgery to provide continued muscle relaxation.

Complications of General Anesthesia.

Complications can range from minor (e.g., sore throat) to death. Improvement in anesthesia delivery and surgical techniques has resulted in a decline in anesthesia-related deaths, even among higher-risk patients. Although the anesthesia provider has the main responsibility for monitoring patient responses during surgery, the circulating nurse also remains alert for changes in the patient's condition.

Malignant hyperthermia (MH), an inherited muscle disorder, is an acute, life-threatening complication of certain drugs used for general anesthesia. It is characterized by many problems, including poor thermoregulation. The reaction begins in skeletal muscle exposed to the drugs, causing increased calcium levels in muscle cells and increased muscle metabolism. Serum calcium and potassium levels are increased, as is the metabolic rate, leading to acidosis, cardiac dysrhythmias, and a high body temperature.

Onset of MH may occur immediately after anesthesia induction, several hours into the procedure, or even after the anesthetic has been terminated. Manifestations are caused by increased muscle calcium level and the greatly increased body metabolism. These include tachycardia, dysrhythmias, muscle rigidity (especially of the jaw and upper chest), hypotension, tachypnea, skin mottling, cyanosis, and **myoglobinuria** (presence of muscle proteins in the urine). *The most sensitive indication is an unexpected rise in the end-tidal carbon dioxide level with a decrease in oxygen saturation and tachycardia. Extremely elevated temperature, as high as 111.2° F (44° C), is a late sign of MH.* Survival depends on early diagnosis and the immediate actions of the entire surgical team. Dantrolene sodium, a skeletal muscle relaxant, is the drug of choice along with other interventions (Mitchell-Brown, 2012).

Nursing Safety Priority QSEN

Critical Rescue

Monitor patients for the cluster of elevated end-tidal carbon dioxide level, decreased oxygen saturation, and tachycardia related to malignant hyperthermia. If these changes begin, alert the surgeon and anesthesia provider immediately.

When the patient has a known history or risk for MH, treatment with dantrolene can begin before, during, and after surgery to prevent it. Chart 15-1 lists best practices for care of the patient with MH. The AORN recommends that all operating rooms have a dedicated MH cart containing drugs for management (normal saline, dantrolene, sodium bicarbonate, insulin, 50% dextrose, lidocaine, and calcium chloride), a protocol card listing interventions, and the MH hotline number. Additional nursing support is needed during this true perioperative emergency.

Chart 15-1

Best Practice for Patient Safety & Quality Care QSEN

Emergency Care of the Patient with Malignant Hyperthermia

- Stop all inhalation anesthetic agents and succinylcholine.
- If an endotracheal tube (ET) is not already in place, intubate immediately.
- Ventilate the patient with 100% oxygen, using the highest possible flow rate.
- Administer dantrolene sodium (Dantrium) IV at a dose of 2 to 3 mg/kg.
- If possible, terminate surgery. If termination is not possible, continue surgery using anesthetic agents that do not trigger malignant hyperthermia (MH).
- Assess arterial blood gases (ABGs) and serum chemistries for metabolic acidosis and hyperkalemia.
- If metabolic acidosis is evident by ABG analysis, administer sodium bicarbonate IV.
- If hyperkalemia is present, administer 10 units of regular insulin in 50 mL of 50% dextrose IV.
- Use active cooling techniques:
  - Administer iced saline (0.9% NaCl) IV at a rate of 15 mL/kg every 15 minutes as needed.
  - Apply a cooling blanket over the torso.
  - Pack bags of ice around the patient's axillae, groin, neck, and head.

- Lavage the stomach, bladder, rectum, and open body cavities with sterile iced normal saline.
- Insert a nasogastric tube and a rectal tube.
- Monitor core body temperature to assess effectiveness of interventions and to avoid hypothermia.
- Monitor cardiac rhythm by electrocardiography (ECG) to assess for dysrhythmias.
- Insert a Foley catheter to monitor urine output.
- Treat any dysrhythmias that do not resolve on correction of hyperthermia and hyperkalemia with antidysrhythmic agents *other than calcium channel blockers*.
- Administer IV fluids at a rate and volume sufficient to maintain urine output above 2 mL/kg/hr.
- Monitor urine for presence of blood or myoglobin.
- If urine output falls below 2 mL/kg/hr, consider using osmotic or loop diuretics, depending on the patient's cardiac and kidney status.
- Contact the Malignant Hyperthermia Association of the United States (MHAUS) hotline for more information regarding treatment: (800) 644-9737.
- Transfer the patient to the intensive care unit (ICU) when stable.
- Continue to monitor the patient's temperature, ECG, ABGs, electrolytes, creatine kinase, coagulation studies, and serum and urine myoglobin levels until they have remained normal for 24 hours.
- Instruct the patient and family about testing for MH risk.
- Refer the patient and family to the Malignant Hyperthermia Association of the United States at (800) 986-4287 or www.mhaus.org.
- Report the incident to the North American Malignant Hyperthermia Registry at the Malignant Hyperthemia Association of the United States: (800) 644-9737.

Data from Malignant Hyperthermia Association of the United States. (2014). *Emergency therapy for MH acute phase treatment.* Retrieved April 2014, from www.mhaus.org/healthcare-professionals/#.UPGIEGeN58F

Genetic/Genomic Considerations

Patient-Centered Care QSEN

MH is a genetic disorder with an autosomal dominant pattern of inheritance. The patient with a genetic predisposition for MH is at risk for this complication from halothane, enflurane, isoflurane, desflurane, sevoflurane, and succinylcholine. This rare problem is most common in

young adults. Males are affected more often than females (despite the autosomal dominant pattern of inheritance) because of gender differences in muscle mass. The muscle biopsy tested with the caffeine halothane contracture test (CHCT) is still considered the most commonly used MH testing even though this disorder is inherited and only five centers are approved to perform the test (Online Mendelian Inheritance in Man [OMIM], 2013). There is also a genetic test that is performed on blood to assess whether a mutation in the *RYR1* gene is present. Usually, the cost of the genetic test is not covered by insurance. Always ask the patient about any previous problems or difficulties with anesthesia.

Overdose of anesthetic can occur if the patient's metabolism and drug elimination are slower than expected, such as with patients who are older or who have liver or kidney problems. Other drugs (e.g., antihypertensives) also alter metabolism, and interactions can occur between the anesthetic and the patient's regular drugs. Accurate information about the patient's height, weight, and medical history, especially liver and kidney function, is vital in determining the anesthetic type and dosage.

Unrecognized hypoventilation is an anesthesia-induced complication. Failure of adequate gas exchange can lead to cardiac arrest, permanent brain damage, and death. Monitoring standards include the use of an end-tidal carbon dioxide monitor to confirm carbon dioxide levels in the patient's expired gas and a breathing system disconnect monitor to detect any break in the breathing circuit equipment.

Intubation complications can include many problems (e.g., broken teeth and caps, swollen lip, vocal cord trauma). Difficult intubation may be caused by anatomic issues or disease presence (e.g., small oral cavity, tight jaw joint, tumor). Improper neck extension during intubation may cause injury. The surgeon should be in the OR during the intubation process in case a tracheotomy is needed when the endotracheal tube (ET) is placed. Intubation causes tracheal irritation and edema. Often the patient has a sore throat after surgery.

NCLEX Examination Challenge

Safe and Effective Care Environment

Which change in the anesthetized client alerts the nurse to the possibility of malignant hyperthermia?

A Widening pulse pressure
B Increasing output of dilute urine
C Increasing end-tidal carbon dioxide level
D Ascending flaccid paralysis of skeletal muscles

Local or Regional Anesthesia

Local or regional anesthesia briefly disrupts sensory nerve impulse transmission from a specific body area or region, thus reducing sensory perception in a limited area. Motor function may or may not be affected. The patient remains conscious and can follow instructions. The gag and cough reflexes remain intact, and the risk for aspiration is low. This type of anesthesia may be supplemented with sedatives, opioid analgesics, or hypnotics to reduce anxiety and increase comfort. The OR nurse provides the patient with information, directions, and emotional support before, during, and after the procedure.

Local Anesthesia.

Local anesthesia is delivered topically (applied to the skin or mucous membranes of the area to be anesthetized) and by local infiltration (injected directly *into* the tissue around an incision, wound, or lesion). Sometimes when the term *local* is used, it means *any* form of anesthesia that is not general or monitored anesthesia.

Regional Anesthesia.

Regional anesthesia is a type of local anesthesia that blocks multiple peripheral nerves and reduces sensory perception in a specific body region. It can be used under a variety of conditions and surgeon and patient preferences. It is often used when pain management after surgery is enhanced by regional anesthesia, such as after a total knee replacement. If the patient has eaten and the surgery is an emergency, it may be possible to perform surgery with the patient under regional anesthesia to decrease the risk for aspiration. Regional anesthesia includes field block, nerve block, spinal, and epidural (Table 15-3). Figs. 15-8 and 15-9 show common sites of nerve blocks, spinal anesthesia, and epidural anesthesia.

TABLE 15-3
Types of Regional Anesthesia

ANESTHESIA TYPE	DEFINITION AND COMMON USE
Field block	A series of injections *around* the operative field
	Most commonly used for chest procedures, hernia repair, dental surgery, and some plastic surgeries
Nerve block	Injection of the local anesthetic agent *into or around* one nerve or group of nerves in the involved area
	Most commonly used for limb surgery or to relieve chronic pain
Spinal anesthesia	Injection of an anesthetic agent into the cerebrospinal fluid in the subarachnoid space (see Fig. 15-9)
	Most commonly used for lower abdominal, pelvic, hip, and knee surgery
Epidural anesthesia	Injection of an agent into the epidural space (see Fig. 15-9)
	Most commonly used for anorectal, vaginal, perineal, hip, and lower extremity surgeries

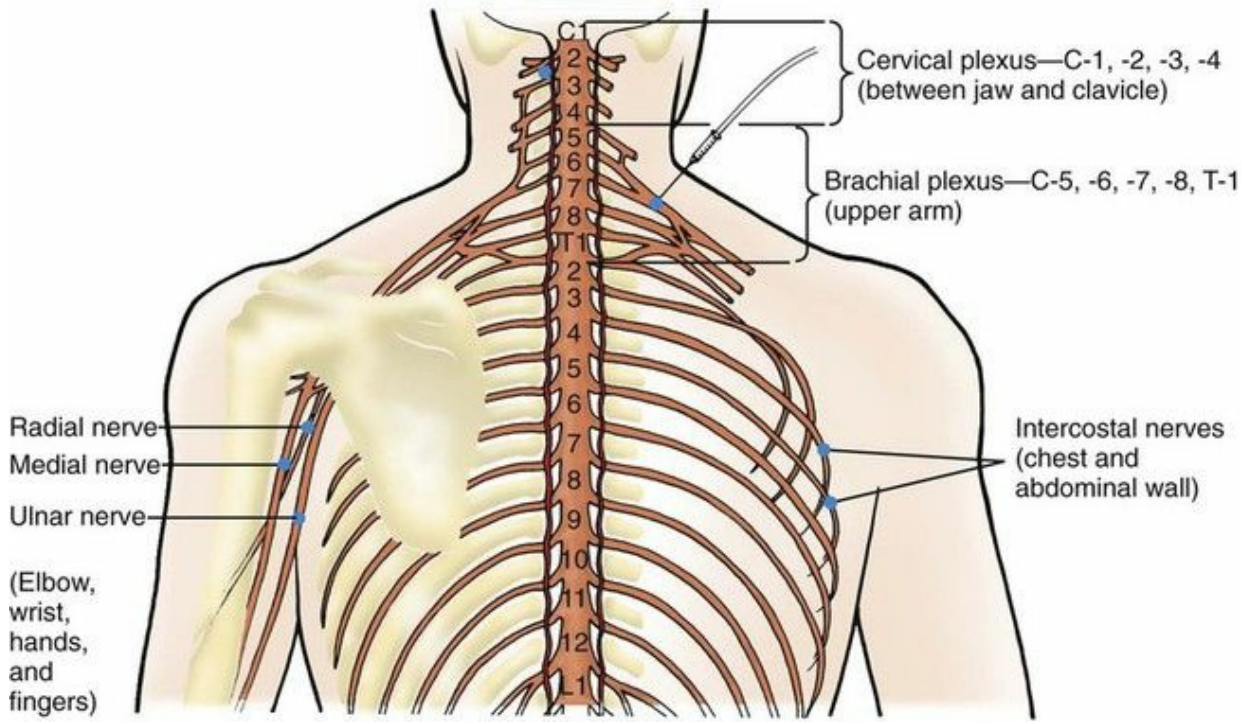

FIG. 15-8 Nerve block sites.

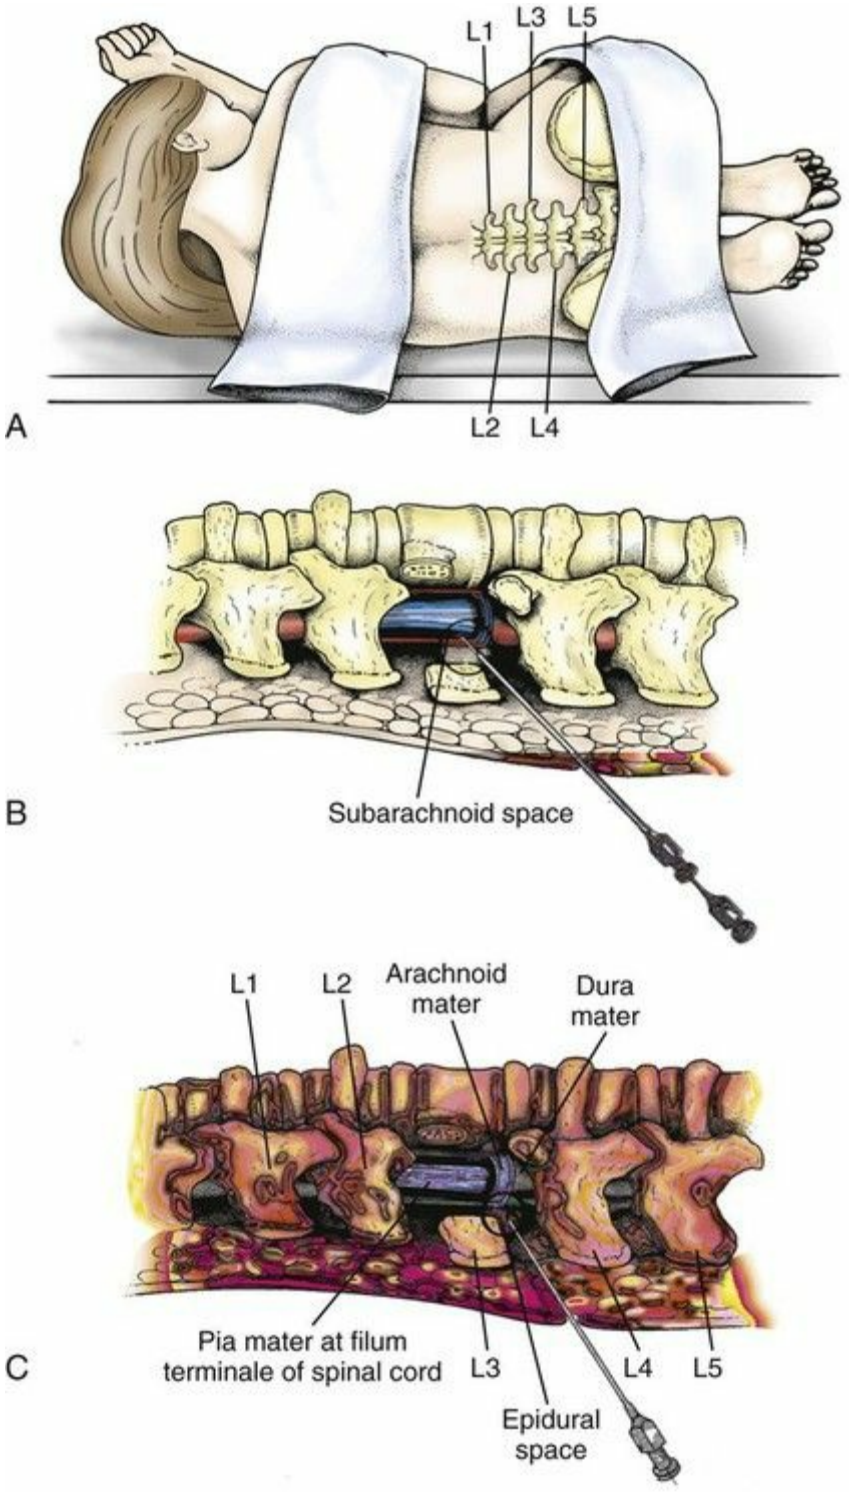

FIG. 15-9 Administration of spinal and epidural anesthesia. **A,** Spinal or epidural anesthesia is administered by inserting a spinal needle between the second and third or the third and fourth lumbar vertebrae (L2-3 or L3-4). The patient is placed in the flexed lateral (fetal) position *(shown here)* or seated on the edge of the operating bed with the back arched and the chin tucked to the chest. **B,** Spinal anesthesia *(viewed from the side).* A large needle is inserted to the surface of the dura mater, and a second, smaller needle is passed through the first to penetrate the dura mater and arachnoid mater. An anesthetic is injected, sometimes through an indwelling

catheter, directly into the cerebrospinal fluid in the subarachnoid space. **C,** Epidural anesthesia *(viewed from the side).* The needle is inserted to the surface of the dura mater, and the anesthetic is injected, usually through an indwelling catheter, into the epidural space.

The nurse's role in the delivery of regional anesthesia consists of:

- Assisting the anesthesia provider
- Observing for breaks in sterile technique
- Providing emotional support for the patient
- Staying with the patient
- Offering information and reassurance
- Positioning the patient comfortably and safely

Complications of Local or Regional Anesthesia.

Complications of local or regional anesthesia are related to patient sensitivity to the anesthetic agent (anaphylaxis), incorrect delivery technique, systemic absorption, and overdose. The nurse observes for central nervous system (CNS) stimulation followed by CNS and cardiac depression, which are indications of a systemic toxic reaction. The nurse also assesses for restlessness, excitement, incoherent speech, headache, blurred vision, metallic taste, nausea, tremors, seizures, and increased pulse, respiration, and blood pressure. Interventions include establishing an open airway, giving oxygen, and notifying the surgeon. Usually a fast-acting barbiturate is needed for treatment. If the toxic reaction is untreated, unconsciousness, hypotension, apnea, cardiac arrest, and death may result.

Cardiac arrest may occur as a rare complication of spinal anesthesia. Epinephrine is given to prevent cardiac arrest in patients who develop sudden, unexplained bradycardia.

Local early complications include edema and inflammation. Abscess formation, tissue necrosis, and/or gangrene may occur later. Abscesses result from contamination during injection of the agent. Necrosis and gangrene may occur as a result of prolonged blood vessel constriction in the injected area.

Moderate Sedation

Moderate sedation (conscious sedation) is the IV delivery of sedative, hypnotic, and opioid drugs to reduce sensory perception but allow the patient to maintain a patent airway. The amnesia action is short, and the patient has a rapid return to ADLs. Etomidate (Amidate), diazepam (Valium,

Vivol, Novo-Dipam), midazolam (Versed), fentanyl (Sublimaze), alfentanil (Alfenta), propofol (Diprivan), and morphine sulfate are the most commonly used drugs. Moderate sedation is used to reduce the level of consciousness during endoscopy, cardiac catheterization, closed fracture reduction, cardioversion, and other short procedures.

Selection of patients for moderate sedation is based on specific criteria. The physician determines whether the patient is a candidate. In most states, a credentialed registered nurse may deliver moderate sedation under physician supervision and within the state-defined scope of nursing practice. Credentialing includes advanced training in IV drug delivery, airway management, and advanced cardiac life support (ACLS).

The nurse monitors the patient during and after the procedure for response to the procedure and the drugs. The airway, level of consciousness, oxygen saturation, capnography (measure of carbon dioxide level), ECG status, and vital signs are monitored every 15 to 30 minutes until the patient is awake and oriented and vital signs have returned to baseline levels (AORN, 2014i).

Evaluation of consciousness for recovery sedation is performed using a sedation scale. The Ramsay Sedation Scale (RSS) lists specific patient responses or behaviors to a continuum of environmental stimulation demonstrating degree of arousal from sedation (Table 15-4).

TABLE 15-4

Ramsay Sedation Scale for Assessing Post-Sedation Consciousness

RAMSAY SCORE	RESPONSE DESCRIPTORS
RSS 1	Patient is anxious and agitated or restless, or both.
RSS 2	Patient is cooperative, oriented, and tranquil (calm, not agitated).
RSS 3	Patient responds quickly, but only to commands.
RSS 4	Patient exhibits brisk response to stimulus.
RSS 5	Patient exhibits a sluggish response to stimulus.
RSS 6	Patient exhibits no response to stimulus. The RSS must be reapplied at intervals until full consciousness is achieved.

RSS, Ramsay Sedation Scale.

Data from Dawson, R., von Fintel, N., & Naim, S. (2010). Sedation assessment using the Ramsay scale. *Emergency Nurse, 18*(3), 18-20.

The patient receiving IV moderate sedation can be discharged to go home with a responsible adult if capnography indicates gas exchange is adequate and arousal from sedation is at an RSS 2 level. If the patient returns to the general medical-surgical nursing unit, the unit nurses continue monitoring. The patient is expected to be sleepy but arousable

for several hours after the procedure. Oral intake is not permitted until 30 minutes after the patient has received the sedation or according to the physician's prescription. If the patient was intubated or had oral endoscopy, return of the gag reflex is required before oral intake. When fluids are permitted, the nurse makes sure that the patient is awake and positioned to avoid aspiration.

Patient-Centered Collaborative Care

Assessment

History.

On arrival in the surgical suite, the patient is taken to the holding area or directly into the operating suite. The holding area nurse or the circulating nurse greets the patient on arrival. As indicated in The Joint Commission's National Patient Safety Goals (NPSGs), *correct identification of the patient is the responsibility of every member of the health care team.* Check the patient's identification bracelet and ask, "What is your name and birth date?" This practice prevents errors by drowsy or confused patients. For example, if a patient is asked "Are you Mr. Gates?," he may respond inappropriately if he is anxious or sedated. The nurse always validates identification using the medical record and identification bracelet and by asking the patient or family.

Nursing Safety Priority QSEN

Critical Rescue

The Joint Commission's NPSGs require that you verify the patient's identity with two types of identifiers (name, medical record number, telephone number, or other person-specific identifier). Ask the patient to tell you his or her name.

After completing the identification process, the nurse validates that the surgical consent form has been signed and witnessed. The nurse asks "What kind of operation are you having today?" to ascertain that the patient's perception of the procedure, the surgical consent, the surgeon's order, and the operative schedule are the same. *When the procedure involves a specific site, validating the side on which a procedure is to be performed (e.g., for amputation, cataract removal, hernia repair) is the responsibility of each health care professional before and at the time of surgery.*

The Joint Commission now recommends that the patient and the licensed independent practitioner who is ultimately accountable for the procedure and will be present during the procedure (usually the surgeon performing the surgery) mark the surgical site (The Joint Commission [TJC], 2014). Before proceeding, each health care professional thoroughly investigates *any* discrepancy and notifies the surgeon and anesthesia provider. The Joint Commission (TJC) has developed a Universal Protocol for Preventing Wrong Site, Wrong Procedure, Wrong Person Surgery, and the Association of periOperative Registered Nurses has developed recommendations based on this protocol (AORN, 2014r). The nurse asks the patient about any allergies and determines whether autologous blood was donated. A special allergy bracelet on the patient's wrist and the medical record must be verified with what has been communicated.

Nursing Safety Priority QSEN

Critical Rescue

If the patient's description of the surgical site is different from that listed on the informed consent, form a time-out with the patient, yourself, and the surgeon to ascertain and mark the correct site.

The nurse checks the patient's attire to ensure adherence with facility policy. Dentures and dental prostheses, jewelry (including body piercing), eyeglasses, contact lenses, hearing aids, wigs, and other prostheses are removed. Denture removal before anesthesia is controversial because, although the denture plate may come loose and obstruct the airway, the anesthesia provider may request that dentures be left in place to ensure a snug fit of the bag-mask. In some facilities, patients may wear eyeglasses and hearing aids until after anesthesia induction.

Medical Record Review.

The circulating nurse and anesthesia provider review the patient's medical record in the holding area or the operating room (OR). This record provides information to identify patient needs during surgery and allows the nurse to assess and plan specific care during and after surgery. It is the main source of information on the type and location of the planned surgery. The nurse checks the medical record to ensure required data are present before surgery is started.

Advance Directives and Do-Not-Resuscitate Orders.

Ethical dilemmas may occur during or after surgery. As a patient advocate, the nurse may have to intervene on behalf of the patient's rights and wishes. The nurse must be familiar with the advance directives and do-not-resuscitate (DNR) orders for each patient. It is difficult for some health care providers to not treat the patient in the OR for an emergency situation, and they may ignore an advance directive or living will. Some agencies suspend DNR orders while a patient is undergoing a surgical procedure. The position statement of the Association of periOperative Registered Nurses regarding the care of patients with DNR orders states that automatically suspending a DNR or allow-natural-death order during surgery undermines a patient's right to self-determination (AORN, 2014c).

Nursing Safety Priority QSEN

Action Alert

Advance directives are to be honored in the surgical environment regardless of the situation.

Allergies and Previous Reactions to Anesthesia or Transfusions.

The nurse asks about allergies and previous reactions to anesthesia or blood transfusions. Allergies to iodine products or shellfish indicate a risk for a reaction to the agents used to clean the surgical area. Latex allergies are assessed with all patients because anaphylaxis can occur with latex contact during surgery. Latex-free equipment and supplies are used when there is a latex allergy. The nurse documents the allergy in the medical record and notifies the OR team.

The patient's previous experience with anesthesia helps the nurse and anesthesia provider anticipate needs and plan interventions. For example, if a patient is restless or agitated as a reaction to anesthesia, the nurse can have padding for the siderails and protective restraints available. The use of blood products during surgery may be influenced by the patient's history, religious beliefs, preferences, and past transfusion reactions.

Autologous Blood Transfusion.

Autologous blood transfusion (reinfusing the patient's own blood) may be used for surgery. Chapters 14 and 40 discuss autologous transfusion in more detail. Chart 15-2 outlines best practices for autologous blood

transfusion using blood salvage techniques during surgery.

Chart 15-2 Best Practice for Patient Safety & Quality Care QSEN

Intraoperative Autologous Blood Salvage and Transfusion

- Be aware of the cell-processing method to be used.
- Make sure that collection containers are labeled for the patient.
- Assist with sterile setup as necessary.
- Assist with processing and reinfusing procedures as needed.
- Document the transfusion process.
- Monitor the patient's vital signs during the transfusion procedure.

Laboratory and Diagnostic Test Results.

The OR nurse reviews the most recent laboratory findings and test results to inform the surgical team about the patient's health and to alert them for potential problems. These results are usually obtained within 24 to 48 hours before surgery for hospitalized patients and within 4 weeks for ambulatory surgery patients. The nurse reports all abnormal findings or results to the surgeon and anesthesia provider. Laboratory values greater than or less than the normal range are potentially life threatening during surgery (see Chapter 14). For example, if the hemoglobin level is less than 10 g/dL, oxygen transport and gas exchange are reduced, affecting the amount and type of anesthesia used.

Medical History and Physical Examination Findings.

The nurse performs a final assessment for threats to patient safety, starting with the patient's age and general physical condition. Older patients and those who are thin or overweight are at greater risk for skin injury. Assessing mental status is important because confused patients and those who are unable to either follow instructions or communicate may not be able to tell you when a problem exists. Patients who have impaired sensory perception of any type are at increased risk for injury. Specific drugs, such as long-term steroid use (which increases capillary fragility and thins the skin), as well as limitations of range or motion, require modification during positioning and threaten patient safety.

The OR nurse checks that the medical history and examination findings, including usual pulse and blood pressure, are recorded. This information provides baseline data to assess the patient's reaction to the surgery and anesthesia. Drugs taken before surgery may affect the

patient's reaction to surgery and wound healing. For example, aspirin and other NSAIDs that can increase clotting time and the risk for hemorrhage.

Knowing the patient's medical history and age allows the nurse to plan interventions for the care and safety of high-risk patients (Chart 15-3). The nurse carefully monitors older patients and those with cardiac disease for potential fluid overload.

Chart 15-3

Nursing Focus on the Older Adult

Intraoperative Nursing Interventions

- Allow patients to retain eyeglasses, dentures, and hearing aids until anesthesia has begun.
- Use a small pillow under the patient's head if his or her head and neck are normally bent slightly forward.
- Lift patients into position to prevent shearing forces on fragile skin.
- Position arthritic and artificial joints carefully to prevent postoperative pain and discomfort from strain on those joints.
- Pad bony prominences to prevent pressure sores.
- Provide extra padding for those patients with decreased peripheral circulation.
- Use warming devices to prevent hypothermia.
- Cover the patient's head and feet.
- Warm IV and irrigation fluids as indicated by agency policy and manufacturer's recommendations.
- Follow strict aseptic technique.
- Carefully monitor intake and output, including blood loss.

Data from Clayton, J. (2008). Special needs of older adults undergoing surgery. *AORN Journal*, *88*(3), 557-570.

After completing the medical record review, the nurse may insert an IV catheter and perform a surgical skin preparation. He or she provides emotional support and explains procedures to the patient. If the patient is in the holding area, he or she is moved to the OR after the preoperative routine is completed.

Nursing Safety Priority QSEN

Action Alert

Once the patient has been moved into the holding area or the OR, do not leave him or her alone.

Clinical Judgment Challenge

Ethical/Legal; Safety; Teamwork and Collaboration; Quality Improvement QSEN

A patient scheduled for a palliative, pain-relieving procedure has a do-not-resuscitate (DNR) order confirmed in the medical record. However, after being premedicated, the patient requests the order be suspended during the procedure and that a family member be contacted.

1. Is the patient permitted to suspend the DNR order in light of the fact that he has already received premedication?
2. What principle of ethical behavior guides your response? (You may need to review the ethical principles in Chapter 1.)
3. How should the OR nurse proceed with the patient request?
4. What steps could be taken to ensure that patient requests and revisions of requests can be handled appropriately in the future?

Analysis

The priority NANDA-I nursing diagnoses and collaborative problems for patients during surgery include:

1. Risk for Perioperative Positioning Injury related to improper positioning (NANDA-I)
2. Risk for Infection related to invasive procedures (NANDA-I)
3. Impaired Gas Exchange related to anesthesia, pain, reduced respiratory effort (NANDA-I)

Planning and Implementation

Preventing Injury

Planning: Expected Outcomes.

The patient is expected to be free of injury as indicated by:

- Adequate capillary refill and peripheral pulses in all extremities
- Sensory perception and motor function after surgery at the same level as before surgery
- Absence of skin redness or open skin areas
- Absence of bruising

Interventions.

Interventions are needed to prevent injury from positioning because of anesthesia and the narrow OR bed. The patient cannot guard against nerve or joint damage and muscle stretch or strain. In addition, pressure ulcers often start to develop during surgery. Thus proper positioning is important. The circulating nurse pads the operating bed with foam and/or silicone gel pads and properly places the grounding pads. He or she coordinates the transfer to the operating bed and helps the patient to a comfortable position. The skin is assessed, especially of older patients, for bruising or injury, and extra padding is placed as indicated.

The patient is usually in a supine position after transfer to the operating bed. Anesthesia may be initiated with the patient supine, and the patient then may be repositioned for surgery (Fig. 15-10).

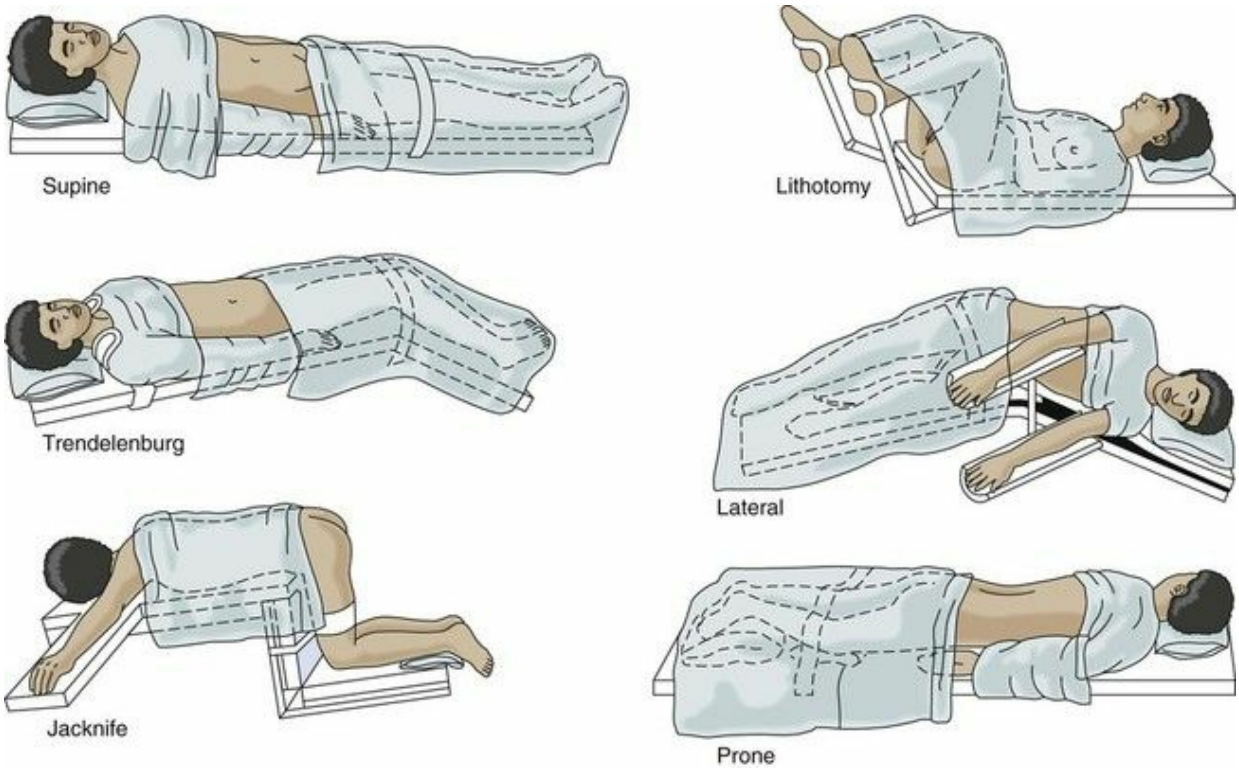

FIG. 15-10 Common surgical positions.

The circulating nurse coordinates positioning of the patient for surgery and modifies the position according to the patient's safety and special needs. The OR nurse ensures that there is an adequate number of personnel to assist in positioning the patient.

Factors influencing the *timing* of repositioning include:

- The surgical site
- The age and size of the patient
- The anesthetic delivery technique

- Pain on movement (conscious patient)

Factors influencing the actual *position* include:

- The specific procedure being performed
- The surgeon's preference
- The patient's age, size, and weight
- Any pulmonary, skeletal, or muscular limitations, such as arthritis, joint replacements, emphysema, or implanted devices

Chart 15-4 lists best practices to prevent complications related to prolonged immobility during surgery.

Chart 15-4

Best Practice for Patient Safety & Quality Care QSEN

Prevention of Complications Related to Intraoperative Positioning

Prevention of Brachial Plexus Complications (Paralysis, Loss of Sensation in Arm and Shoulder)

- Pad the elbow if tucked at the side.
- Avoid excessive abduction.
- Secure the arm firmly on a padded armboard, positioned at shoulder level, and extended less than 90 degrees.

Prevention of Radial Nerve Complications (Wrist Drop)

- Support the wrist with padding.
- Be careful not to overtighten wrist straps.

Prevention of Medial or Ulnar Nerve Complications (Hand Weakness, Claw Hand)

- Place the safety strap above or below the nerve locations.

Prevention of Peroneal Nerve Complications (Foot Drop)

- Pad knees and ankles.
- Maintain minimal external rotation of the hips.
- Support the lower extremities.
- Be careful not to overtighten leg straps.

Prevention of Tibial Nerve Complications (Loss of Sensation on the Plantar Surface of the Foot)

- Place the safety strap above the ankle.
- Do not place equipment on lower extremities.

- Urge operating room (OR) personnel to avoid leaning on the patient's lower extremities.

Prevention of Joint Complications (Stiffness, Pain, Inflammation, Limited Motion)

- Place a pillow or foam padding under bony prominences.
- Maintain the patient's extremities in good anatomic alignment.
- Slightly flex joints and support with pillows, trochanter rolls, or pads.

Data from Association of periOperative Registered Nurses. (2010). Recommended practices for positioning the patient in the perioperative practice setting. In *Perioperative standards and recommended practices* (pp. 327-350). Denver: Author.

The dorsal recumbent (supine), prone, lithotomy, and lateral positions are most often used for surgery. Fig. 15-10 shows many surgical positions and the use of protective padding. When general anesthesia is used, the nurse positions the patient slowly to prevent hypotension from blood vessel dilation. Proper positioning is ensured by assessing for:

- Anatomic alignment
- Interference with circulation and breathing
- Protection of skeletal and neuromuscular structures
- Optimal exposure of the operative site and IV line
- Adequate access to the patient for the anesthesia provider
- The patient's comfort, safety, and dignity

Care is modified to reduce the potential complications from specific positions. For example, patients in the lithotomy position may develop leg swelling, pain in the legs or back, reduced foot pulses, or reduced sensory perception from compression of the peroneal nerve. The nurse ensures proper padding and position changes at regular intervals. He or she continually assesses circulation adequacy by checking pulses and capillary refill below pressure points. Throughout surgery, the nurse prevents obstruction of circulation, respiration, or nerve conduction caused by tight straps, poorly placed pads and pillows, or the position of the bed.

Preventing Infection

Planning: Expected Outcomes.

The patient is expected to have an uninfected surgical wound or wounds. Indicators include:

- Wound edges are closed and not excessively red or swollen
- Wound is free from purulent drainage

- White blood cell counts remain at expected levels after surgery
- Patient is afebrile

Interventions.

Surgical wound infections interfere with recovery, delay wound healing, contribute to rising health care costs, and are a source of nosocomial infections. The Centers for Disease Control and Prevention (CDC) defines surgical site infections as occurring 30 days post-surgery (CDC, 2014). Aseptic technique must be strictly practiced by all OR personnel to ensure that the patient is free from infection, as required by The Joint Commission's NPSGs. The Surgical Care Improvement Project (SCIP), as described in Table 14-1 of Chapter 14, has core measures related for the prevention of surgical site infections.

Assess the risk for infection by identifying patients with health problems such as diabetes mellitus, immunodeficiency, obesity, and kidney disease. The nurse performs the prescribed skin preparation, protects against cross-contamination, keeps traffic to a minimum, and administers prescribed antimicrobial prophylaxis. Surgery increases risk for wound complications (e.g., incisional tears, lacerations), infection, and loss of body fluids. Sterile surgical technique and the use of protective drapes, skin closures, and dressings reduce complications and promote wound healing. When a wound is already infected or is at high risk for infection, antibiotics may be used directly in the wound before wound closure.

Skin and tissue closures include sutures, staples, special tape, and tissue adhesive (surgical "glue"). Fig. 15-11 shows commonly used wound closures. They are used to:

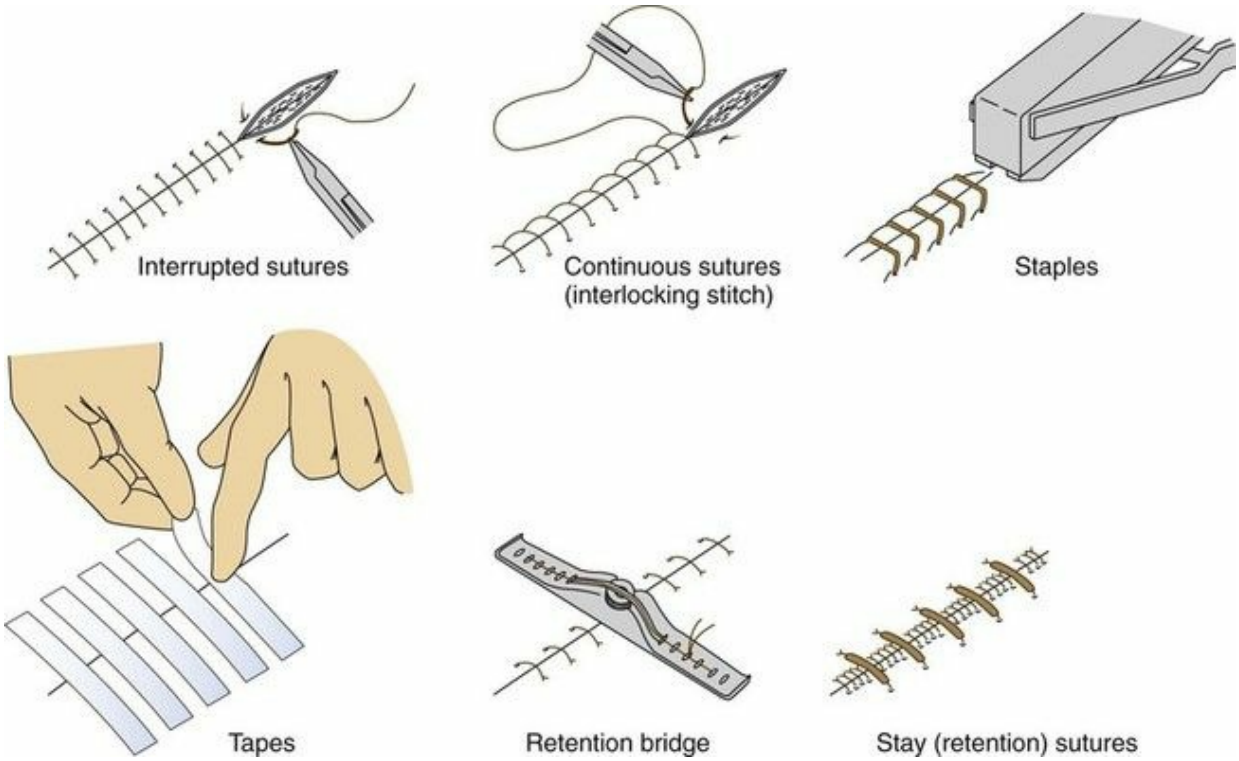

FIG. 15-11 Common skin closures.

- Hold wound edges in place until wound healing is complete
- Occlude blood vessels, preventing poor clotting and hemorrhage
- Prevent wound contamination and infection

Sutures are absorbable or nonabsorbable. *Absorbable sutures* are digested over time by body enzymes. *Nonabsorbable sutures* become encapsulated in the tissue during the healing process and remain in the tissue unless they are removed. Body enzymes do not affect nonabsorbable sutures. Retention (stay) sutures (see Fig. 15-11) may be used in addition to standard sutures for patients at high risk for impaired wound healing (obese patients, patients with diabetes, and those taking steroids).

After the incision is closed, the surgeon may inject a local anesthetic or instill an antibiotic into the wound. A gauze or spray dressing may be applied to protect the incision from contamination. A variety of dressings are used to absorb drainage and support the incision. A pressure dressing may be applied to prevent poor clotting and bleeding. One or more drains (see Chapter 16) may be inserted to remove secretions and fluids around the surgical area. These secretions, if not drained, slow healing and promote bacterial growth, which could result in wound infection.

The nurse coordinates the surgical team in positioning and transferring the patient. When needed, a roller board or a lift sheet is used to move the patient from the operating bed to a stretcher or bed.

The circulating nurse and anesthesia provider go with the patient to the PACU and report his or her surgical experience to the PACU nurse (see Chapter 16).

Preventing Hypoventilation

Planning: Expected Outcomes.

The patient is expected to be free of damaging events related to impaired gas exchange and hypoventilation as indicated by:

- Maintenance of Sa_{o_2}, Pa_{o_2}, and blood pH within normal limits
- Vital signs within normal limits
- Return to presurgical level of cognitive function

Interventions.

The purpose of interventions is to prevent injury resulting from the anesthesia effect on breathing and gas exchange. The nurse, surgeon, and anesthesia provider monitor the patient according to official standards. These standards, adopted by both the American Society of Anesthesiologists and the American Association of Nurse Anesthetists, include continuous monitoring of breathing, circulation, and cardiac rhythms; blood pressure and heart rate recordings every 5 minutes; and the constant presence of an anesthesia provider during the case.

Evaluation: Outcomes

The nurse evaluates the care of the patient during surgery based on the identified priority patient problems. The expected outcomes are that the patient:

- Is safely anesthetized without complications
- Does not experience any injury related to surgical positioning or equipment
- Is free of skin or tissue contamination and infection during surgery
- Is free of skin tears, bruises, redness, or other injury over pressure points and elsewhere
- Maintains normal thermoregulation and body temperature

Specific indicators for these outcomes are listed for each priority patient problem under the Planning and Implementation section (see earlier).

Nursing Concepts and Clinical Judgment Review

What might you NOTICE in a patient during surgery who has adequate body defenses related to infection?

Vital signs:

- Body temperature within normal range
- No sweating or chills

Physical assessment:

- Skin color normal for ethnicity
- Any drainage is not purulent
- Urine is clear

Safe and Effective Care Environment

- Review preoperative checklist and informed consent forms, including any allergies.
- Highlight any known allergies. **Safety** QSEN
- Ensure that all personnel entering the OR are wearing proper OR attire for their role.
- Observe for and inform OR personnel of any break in sterile field or sterile technique. **Safety** QSEN
- Use appropriate patient identifiers when administering drugs or marking surgical sites. **Safety** QSEN
- Report to the surgeon any discrepancy between what type of surgery the patient says is going to be performed and what the informed consent form indicates. **Safety** QSEN
- Apply grounding pads as needed. **Safety** QSEN
- Complete any needed skin preparation.
- Perform an accurate "sharps," sponge, and instrument count with the scrub nurse or surgical technologist. **Safety** QSEN

Psychosocial Integrity

- Communicate patient preferences or fears about anesthesia to the anesthesia provider. **Patient-Centered Care** QSEN
- Preserve the patient's privacy and dignity by keeping body exposure to a minimum.
- Stay with the patient during induction of anesthesia.
- Communicate information about the patient's status to waiting family members.
- Ensure that the patient's wishes, as expressed in the advance directives statement, are honored in the surgical setting. **Patient-Centered Care** QSEN

Physiological Integrity

- Apply padding to the OR bed to maintain the patient's skin integrity. **Evidence-Based Practice** QSEN
- Position the patient comfortably and safely.

- Maintain the malignant hyperthermia cart.
- Monitor the patient's airway, level of consciousness, oxygen saturation, ECG, and vital signs during and immediately after moderate sedation.
- Assess the patient for tachycardia, increased end-tidal carbon dioxide level, and increased body temperature as indicators of malignant hyperthermia.
- Assess all skin areas and document findings before transferring the patient to the postanesthesia care unit.
- Communicate clearly and accurately information about the patient's surgical experience when handing off the patient to the postanesthesia care nurse. **Teamwork and Collaboration** QSEN

CHAPTER 16

Care of Postoperative Patients

Robin Chard

PRIORITY CONCEPTS

- Gas Exchange
- Pain
- Clotting
- Infection
- Tissue Integrity

Learning Outcomes

Safe and Effective Care Environment

1. Protect the patient from injury and infection during the postoperative period.
2. Communicate care provided and needed at each transition in care during the postoperative period.

Health Promotion and Maintenance

3. Evaluate patient risk for complications of wound healing, infection, and development of venous thromboembolism.
4. Continue to provide perioperative education for patients and family members after surgery.

Psychosocial Integrity

5. Reduce the psychological impact for the patient and family regarding the postoperative experience.

Physiological Integrity

6. Perform an ongoing head-to-toe assessment of the postoperative patient.
7. Implement appropriate pain relief strategies for the postoperative patient.
8. Apply knowledge of anatomy, physiology, and pathophysiology to monitor the patient for the complications of shock, respiratory depression, and impaired wound healing.
9. Prioritize nursing interventions for the patient during the postoperative period.
10. Collaborate with health care team members to perform emergency procedures for surgical wound dehiscence or wound evisceration.

 http://evolve.elsevier.com/Iggy/

The **postoperative period** starts with completion of surgery and transfer of the patient to a specialized area for monitoring such as the postanesthesia care unit (PACU) and may continue after discharge from the hospital until all activity restrictions have been lifted. The period of postanesthesia care is divided into three phases that are based on the level of care needed, not the physical place of care. Not every patient will need all three phases.

Phase I care occurs immediately after surgery, most often in a PACU, although care in an ambulatory care unit is becoming common. For those patients who have very complicated procedures or many serious health problems, phase I care may occur in an intensive care unit (ICU). The length of time the patient remains at a phase I level of observation depends on his or her health status, the surgical procedure, anesthesia type, and rate of progression to complete alertness and hemodynamic stability. It can range from less than 1 hour to days. This level features very close monitoring of the airway, vital signs, and indicators of recovery that varies from every 5 to 15 minutes initially. The time between assessments gradually increases as the patient progresses toward recovery.

Phase II postoperative recovery focuses on preparing the patient for care in an extended care environment, such as a medical-surgical unit, step-down unit, skilled nursing facility, or home. This phase can occur in a PACU, on a medical-surgical unit, or in the same-day surgery (SDS) unit (ambulatory care unit) and may last only 15 to 30 minutes, although 1 to 2 hours is more typical. Patients are discharged from this phase

when presurgery level of consciousness has returned, oxygen saturation is at baseline, and vital signs are stable. Some patients achieve this level of recovery in phase I and can be discharged directly to home. Others may require further observation.

The third phase of postoperative recovery, known as the *extended-care environment*, most often occurs on a hospital unit or in the home. For patients who have continuing care needs that cannot be met at home, discharge may be from the hospital unit to an extended-care facility. Although vital signs continue to be monitored in this type of environment, the frequency ranges from several times daily to just once daily.

The actual time spent away from home after surgery varies according to age, physical health, self-care ability, support systems, type and length of surgical procedure, anesthesia, any complications, home environmental conditions, and community resources. The core measures recommended by the Surgical Care Improvement Project (SCIP) that were initiated during the preoperative period to prevent certain surgical complications are continued or re-evaluated during the postoperative period. (See Chapter 14 and Table 14-1 for an explanation of these measures.)

Overview

The purpose of a **postanesthesia care unit (PACU)** (recovery room) is the ongoing evaluation and stabilization of patients to anticipate, prevent, and manage complications after surgery. The PACU is usually located close to the surgical suite for ease of access and patient transfer. The unit is usually a large and open room to provide direct observation of all patients and easy access to supplies and emergency equipment. The patient area may be divided into individual cubicles. So that each patient can be observed continuously, privacy curtains or screens are partially open and are fully closed only during bedside procedures. Each cubicle has equipment to monitor and care for the patient, such as oxygen, suction equipment, cardiac monitors, pulse oximetry, airway equipment, and emergency drugs.

After the surgery is completed, the circulating nurse and the anesthesia provider accompany the patient to the PACU. For patients in critical condition, transfer may be directly from the operating room (OR) to the ICU. On arrival, the anesthesia provider and the circulating nurse give the PACU nurse a verbal "hand-off" report to communicate the patient's condition and care needs.

A hand-off report that meets The Joint Commission's National Patient Safety Goals requires effective communication between health care professionals. It is at least a two-way verbal interaction between the health care professional giving the report and the nurse receiving it. The language used to give the report is clear and cannot be interpreted in more than one way. The nurse receiving the report focuses on the report and is not distracted by the environment or other responsibilities. Standardizing the information reported helps prevent omission of critical patient-centered information and helps avoid irrelevant details (Association of periOperative Registered Nurses [AORN], 2014). The receiving nurse takes the time to restate (report back) the information to verify what was said and to make certain he or she has the same understanding as the reporting person. The receiving nurse takes the time to ask questions and the reporting professional must respond to the questions until a common understanding is established. Chart 16-1 gives an example of critical information to include in a standard hand-off report.

Chart 16-1 Best Practice for Patient Safety & Quality Care QSEN

Postoperative Hand-off Report

- Type and extent of the surgical procedure
- Type of anesthesia and length of time the patient was under anesthesia
- Allergies (especially to latex or drugs)
- Any health problems or pathologic conditions
- Status of vital signs, including temperature and oxygen saturation
- Type and amount of IV fluids and drugs administered
- Estimated blood loss (EBL)
- Any intraoperative complications, such as a traumatic intubation
- Primary language, any sensory impairments, any communication difficulties
- Special requests that were verbalized by the patient preoperatively
- Preoperative and intraoperative respiratory function and dysfunction
- Location and type of incisions, dressings, catheters, tubes, drains, or packing
- Intake and output, including current IV fluid administration and estimated blood loss
- Prosthetic devices
- Joint or limb immobility while in the operating room, especially in the older patient
- Other intraoperative positioning that may be relevant in the postoperative phase
- Intraoperative complications, how managed, patient responses (e.g., laboratory values)

The PACU nurse is skilled in the care of patients with multiple medical and surgical problems immediately after a surgical procedure. This area requires in-depth knowledge of anatomy and physiology, anesthetic agents, pharmacology, pain management, extubation, surgical procedures, and advanced cardiac life support (ACLS). The PACU nurse is skilled in assessment and can make knowledgeable, quick decisions if emergencies or complications occur. The patient is monitored closely. The anesthesia provider and surgeon are consulted as needed.

❖ Patient-Centered Collaborative Care

◆ Assessment

History.

Use the surgical team's report to plan the care for an individual patient. After receiving the report and assessing the patient, review the medical

record for information about the patient's history, physical condition, and emotional status. If the patient remains as an inpatient, the surgical and anesthesia information is incorporated into the postoperative plan of care. Chapter 14 identifies factors that increase the risk for the potential complications listed in Table 16-1.

TABLE 16-1

General Potential Complications of Surgery

Respiratory System Complications

- Atelectasis
- Pneumonia
- Pulmonary embolism (PE)
- Laryngeal edema
- Ventilator dependence
- Pulmonary edema

Cardiovascular Complications

- Hypertension
- Hypotension
- Hypovolemic shock
- Dysrhythmias
- Venous thromboembolism (VTE), especially deep vein thrombosis (DVT)
- Heart failure
- Sepsis
- Disseminated intravascular coagulation (DIC)
- Anemia
- Anaphylaxis

Skin Complications

- Pressure ulcers
- Wound infection
- Wound dehiscence
- Wound evisceration
- Skin rashes or contact allergies

Gastrointestinal Complications

- Paralytic ileus
- Gastrointestinal ulcers and bleeding

Neuromuscular Complications

- Hypothermia
- Hyperthermia
- Nerve damage and paralysis
- Joint contractures

Kidney/Urinary Complications

- Urinary tract infection
- Acute urinary retention
- Electrolyte imbalances
- Acute kidney injury (AKI)
- Stone formation

Physical Assessment/Clinical Manifestations.

Assess the patient, and record data on a PACU flow chart record (Fig. 16-1). Assessment data include level of consciousness, temperature, pulse, respiration, oxygen saturation, and blood pressure. Examine the surgical area for bleeding. Monitor vital signs as often as your facility's policy states, the patient's condition warrants, and the surgeon prescribes. Once the patient is discharged from the PACU, vital signs are measured as

prescribed or as often as the patient's condition indicates.

FIG. 16-1 Example of a postanesthesia care unit record.

Nursing Safety Priority QSEN

Action Alert

Respiratory assessment is the most critical assessment to perform after surgery for any patient who has undergone general anesthesia or

moderate sedation or has received sedative or opioid drugs.

The health care team determines the patient's readiness for discharge from the PACU by the presence of a recovery score rating of 9 to 10 on the recovery scale (see Fig. 16-1). Other criteria for discharge (e.g., stable vital signs; normal body temperature; no overt bleeding; return of gag, cough, and swallow reflexes; the ability to take liquids; and adequate urine output) may be specific to the facility. After you determine that all criteria have been met, the patient is discharged by the anesthesia provider to the hospital unit or to home. If an anesthesia provider has not been involved, which may be the case with local anesthesia or moderate sedation, the surgeon or nurse discharges the patient once the discharge criteria have been met.

Assessment continues from the PACU to the intensive care or medical-surgical nursing unit. If the patient is to be discharged from the PACU to home, assessment and any needed nursing care are continued by home care nurses or by the patient or family members after health teaching. When the patient is transferred to an inpatient unit, complete an initial assessment on arrival (Chart 16-2).

Chart 16-2 Focused Assessment

The Patient on Arrival at the Medical-Surgical Unit After Discharge from the Postanesthesia Care Unit

Airway

- Is it patent?
- Is the neck in proper alignment?

Breathing

- What is the quality and pattern of the breathing?
- What is the respiratory rate and depth?
- Is the patient using accessory muscles to breathe?
- Is the patient receiving oxygen? At what setting? What is the pulse oximetry reading?

Mental Status

- Is the patient awake, able to be aroused, oriented, and aware?
- Does the patient respond to verbal stimuli?

Surgical Incision Site

- How is it dressed?
- Review the amount of drainage on the dressing immediately.
- Is there any bleeding or drainage under the patient?
- Are any drains present?
- Are the drains set properly (e.g., compressed if they should be compressed, not kinked, patient not lying on them)?
- How much drainage is present in the drainage container?

Temperature, Pulse, and Blood Pressure

- Are these values within the patient's baseline range?
- Are these values significantly different from when the patient was in the postanesthesia care unit (PACU)?

Intravenous Fluids

- What type of solution is infusing and with what additives?
- How much solution was remaining on arrival?
- How much solution infused in the transport time from PACU?
- At what rate is the infusion supposed to be set? Is it?

Other Tubes

- Is there a nasogastric or intestinal tube?
- What is the color, consistency, and amount of drainage?
- Is suction applied to the tube if ordered? Is the suction setting correct?
- Is there a Foley catheter?
- Is the Foley draining properly?
- What is the color, clarity, and volume of urine output?

During the postoperative period, all patients remain at risk for pneumonia, shock, cardiac arrest, respiratory arrest, clotting and venous thromboembolism (VTE), and GI bleeding. These serious complications can be prevented or the consequences reduced with collaborative care. Nursing observations and interventions are part of critical rescue management for patient safety and quality care.

Respiratory System.

When the patient is admitted to the PACU, immediately assess for a patent airway and adequate gas exchange. Although some patients may be awake and able to speak, talking is not a good indicator of adequate gas exchange. An artificial airway, such as an endotracheal tube (ET), a nasal trumpet, or an oral airway, may be in place. If the patient is receiving oxygen, document the type of delivery device and the concentration or liter flow of the

oxygen. Continuously monitor pulse oximetry for oxygen saturation (Spo_2) while the patient is in the PACU. The Spo_2 should be above 95% (or at the patient's presurgery baseline).

Nursing Safety Priority QSEN

Critical Rescue

If the oxygen saturation drops below 95% (or below the patient's presurgery baseline), notify the surgeon or anesthesia provider. If it drops by 10 percentage points and you are certain it is an accurate measure, call the Rapid Response Team.

Assess the rate, pattern, and depth of breathing to determine adequacy of gas exchange. A respiratory rate of less than 10 breaths per minute may indicate anesthetic- or opioid analgesic–induced respiratory depression. Rapid, shallow respirations may signal shock, cardiac problems, increased metabolic rate, or pain.

Listen to the lungs over all lung fields to assess breath sounds. Also check symmetry of breath sounds and chest wall movement. If, for example, the patient has an ET tube, it could move down into the right bronchus and prevent left lung expansion. In this case, lung sounds on the left are absent or decreased and only the right chest wall rises and falls with breathing.

Perform ongoing inspection of the chest wall for accessory muscle use, sternal retraction, and diaphragmatic breathing. These manifestations may indicate an excessive anesthetic effect, airway obstruction, or paralysis, which could result in hypoxia. Listen for snoring and **stridor** (a high-pitched crowing sound). Snoring and stridor occur with airway obstruction resulting from tracheal or laryngeal spasm or edema, mucus in the airway, or blockage of the airway from edema or tongue relaxation. When neuromuscular blocking agents are retained, the patient has muscle weakness, which could impair gas exchange. Indicators of muscle weakness include the inability to maintain a head lift, weak hand grasps, and an abdominal breathing pattern.

If the patient returns to an inpatient unit, complete an initial assessment on arrival (see Chart 16-2) and then continue to assess for respiratory depression or hypoxemia. Listen to the lungs to check for effective expansion and for abnormal breath sounds. Check the lungs at least every 4 hours during the first 24 hours after surgery and then every 8 hours, or more often, as indicated. Older patients, smokers, and

patients with a history of lung disease are at greater risk for respiratory complications after surgery and need more frequent assessment (Sullivan, 2011). Obese patients are also at high risk for respiratory complications.

Cardiovascular System.

Vital signs and heart sounds are assessed on admission to the PACU and then at least every 15 minutes until the patient's condition is stable. Automated blood pressure cuffs and cardiac monitoring assist in continuous assessment.

Review vital signs after surgery for trends, and compare them with those taken before surgery. Report blood pressure changes that are 25% higher or lower than values obtained before surgery (or a 15- to 20-point difference, systolic or diastolic) to the anesthesia provider or the surgeon. Decreased blood pressure and pulse pressure and abnormal heart sounds indicate possible cardiac depression, fluid volume deficit, shock, hemorrhage, or the effects of drugs (see Chapters 11 and 37). Bradycardia could indicate an anesthesia effect or hypothermia. Older patients are at risk for hypothermia because of age-related changes in the hypothalamus (the temperature regulation center), low levels of body fat, and coolness of the OR suite (Sullivan, 2011; Touhy & Jett, 2014). An increased pulse rate could indicate hemorrhage, shock, or pain.

Cardiac monitoring is maintained until the patient is discharged from the PACU. For patients at risk for dysrhythmias, monitoring may continue either on telemetry units or on general medical-surgical units. In assessing the vital signs of a patient who is not being monitored continuously, compare the rate, rhythm, and quality of the apical pulse with the rate, rhythm, and quality of a peripheral pulse, such as the radial pulse. A **pulse deficit** (a difference between the apical and peripheral pulses) could indicate a dysrhythmia.

Peripheral vascular assessment needs to be performed because anesthesia and positioning during surgery (e.g., the lithotomy position for genitourinary procedures) may impair the peripheral circulation and contribute to clotting and venous thromboembolism (VTE), especially deep vein thrombosis (DVT). Compare distal pulses on both feet for pulse quality, observe the color and temperature of extremities, evaluate sensation and motion, and determine the speed of capillary refill. Palpable pedal pulses indicate adequate circulation and perfusion of the legs.

In adherence with The Joint Commission's Surgical Care Improvement Project (SCIP) core measures for prevention of inappropriate clotting and

VTE, continue the prophylactic measures initiated before surgery (Myles, 2012). Although these measures vary in type (e.g., drug therapy with anticoagulants or antiplatelet drugs, sequential compression devices, antiembolic stockings or elastic wraps, early ambulation) depending on the patient's specific risk factors and the type and extent of surgery, any preventive strategies started before surgery are usually needed for at least the first 24 hours after surgery. Reassess the patient's risk for clotting and VTE and the effectiveness of the preventive strategies daily. Assess the feet and legs for redness, pain, warmth, and swelling, which may occur with DVT. Foot and leg assessment may be performed once during a nursing shift or once daily depending on the patient's risk for complications and the facility's or agency's policy. (See Chapters 14 and 36 for more information on prevention of inappropriate clotting and VTE.)

Neurologic System.

Cerebral functioning and the level of consciousness or awareness must be assessed in *all* patients who have received general anesthesia (Table 16-2) or any type of sedation. Observe for lethargy, restlessness, or irritability, and test coherence and orientation. Determine awareness by observing responses to calling the patient's name, touching the patient, and giving simple commands such as "Open your eyes" and "Take a deep breath." Eye opening in response to a command indicates wakefulness or arousability but not necessarily awareness. Determine the degree of orientation to person, place, and time by asking the conscious patient to answer questions such as "What is your name?" (person), "Where are you?" (place), and "What day is it?" (time).

TABLE 16-2

Immediate Postoperative Neurologic Assessment: Return to Preoperative Level

Order of Return to Consciousness After General Anesthesia
1. Muscular irritability
2. Restlessness and delirium
3. Recognition of pain
4. Ability to reason and control behavior
Order of Return of Motor and Sensory Functioning After Local or Regional Anesthesia
1. Sense of touch
2. Sense of pain
3. Sense of warmth
4. Sense of cold
5. Ability to move

Clinical Judgment Challenge

Patient-Centered Care QSEN

The patient is a 71-year-old woman who came from the operating room to the postanesthesia recovery unit about an hour ago after a short procedure (dilation and curettage) under general anesthesia for dysfunctional uterine bleeding. She awakens when her name is called, but she does not know where she is or why. In addition, she has pulled off her oxygen cannula and keeps trying to pull out her IV. Her last vital signs, taken 15 minutes ago, were BP, 140/92; pulse, 88; respirations, 18. When you check her vital signs now, they are BP, 128/102; pulse 110; respirations 24. She is saying she is thirsty and wants some water.

1. Are any of the changes in vital signs a cause for concern? If so which ones?
2. Given her surgery, where should you look for bleeding? (Check Chapter 71 for information about this procedure.)
3. Should you apply oxygen? Why or why not?
4. Should you give her sips of water? Why or why not?
5. Should you notify the surgeon or anesthesia provider? Why or why not?

Considerations for Older Adults

Patient-Centered Care QSEN

For an older adult, a rapid return to his or her level of orientation before surgery may not be realistic. Preoperative drugs and anesthetics may delay the older patient's return of orientation.

Reassure family members that most episodes of postoperative confusion or delirium resolve within a day or two (Brooks, 2012).

Compare the patient's baseline neurologic status (obtained before surgery) with the findings after surgery. Patients who had altered cerebral functioning before surgery because of another condition usually continue to have that alteration after surgery. After the patient is alert (and all other criteria have been met), he or she is discharged from the PACU. On the medical-surgical nursing unit, assess the level of consciousness every 4 to 8 hours or as indicated by the patient's condition and the facility's policy.

Motor function and sensory function after general anesthesia are altered and must be assessed. General anesthesia depresses all voluntary motor

function. Regional anesthesia alters the motor and sensory function of only part of the body. (See Chapter 15 for more information on anesthesia.)

Motor and sensory function after spinal and epidural anesthesia are profoundly affected and critical to assess. Assess the level of sensation loss remaining by lightly pricking the patient's skin with a needle or pin and having the patient indicate when the sensation feels sharp rather than dull (just pressure). Evaluate motor function by asking the patient to move each extremity. The patient who had epidural or spinal anesthesia remains in the PACU until sensory function (feeling) and voluntary motor movement of the legs have returned (see Table 16-2). Also assess the strength of each limb, and compare the results on both sides. Test for the return of sympathetic nervous system tone by gradually elevating the patient's head and monitoring for hypotension. Begin this evaluation after the patient's sensation has returned to at least the spinal dermatome level of T10.

Specific assessment findings for complications of spinal and epidural anesthesia are listed in Chart 16-3. After the patient is transferred to the nursing unit, continue neurologic assessment as indicated.

Chart 16-3 Best Practice for Patient Safety & Quality Care QSEN

Recognizing Serious Complications of Spinal and Epidural Anesthesia

Respiratory Depression (can occur if the anesthetic agent moves higher in the epidural or subarachnoid space)

- What is the quality and pattern of the breathing?
- What is the respiratory rate and depth?
- Is the patient receiving oxygen? At what setting? What is the pulse oximetry result?
- Notify the anesthesia provider if pulse oximetry drops or if the patient is unable to increase the depth of respiration.

Hypotension (can occur when regional anesthesia causes widespread vasodilation)

- What is the patient's blood pressure?
- Is the blood pressure now lower than in the preoperative or operative period?

- Has the pulse pressure widened?
- Notify the anesthesia provider if systolic blood pressure remains more than 10 mm Hg below the patient's baseline or if other manifestations of shock are present.
- Notify the anesthesia provider if hypotension is accompanied by other manifestations of autonomic nervous system blockade (bradycardia, nausea, vomiting).

Epidural Hematoma

- Assess for delayed or regressing return of sensory and motor function.
- If return is delayed or is taking longer than usual, alert the anesthesia provider.
- Determine whether sensory or motor deficits are improving, remaining the same, or worsening.
- If motor deficits are worsening or decreasing after brief improvement, notify the anesthesia provider immediately.
- Assess for return of deep tendon reflexes of extremities on both sides.
- Compare reflexes from one side of the body with the other.
- If reflexes regress, notify the anesthesia provider immediately.
- Assess pain level in the back.
- If the patient feels pressure or increasing back pain while coughing or straining, notify the anesthesia provider immediately.

Infection (Meningitis)

- Assess for mental status changes.
- Assess for increasing temperature.
- Assess for ability to turn the neck.
- Notify the anesthesia provider immediately for temperature elevations above 101° F (38.3° C), inability to move the neck, acute confusion.

Postdural Puncture Headache

- Assess for report of headache in the occipital region, especially when the patient is permitted to sit upright.

NCLEX Examination Challenge

Physiological Integrity

Which assessment parameter is most important for the nurse to employ for the client admitted to the postanesthesia care unit (PACU) for recovery after surgery under epidural anesthesia?

A Determining the client's level of consciousness

B Checking for pain on dorsi and plantar flexion of the foot
C Assessing the response to pinprick stimulation from feet to mid-chest level
D Comparing blood pressure taken in the right arm with blood pressure taken in the left arm

Fluid, Electrolyte, and Acid-Base Balance.

Fasting before and during surgery, the loss of fluid during the procedure, and the type and amount of blood or fluid given affect the patient's fluid and electrolyte balance after surgery. Fluid volume deficit or fluid volume overload may occur after surgery. Sodium, potassium, chloride, and calcium imbalances also may result, as may changes in other electrolyte levels. Fluid and electrolyte imbalances occur more often in older or debilitated patients and in those with health problems such as diabetes mellitus, Crohn's disease, or heart failure.

Intake and output measurement is part of the operative record and is reported by the circulating nurse to the PACU nurse. Record any intake or output, including IV fluid intake, vomitus, urine, wound drainage, and nasogastric (NG) tube drainage. You must know the total intake and output from both the OR and the PACU to assess fluid balance accurately and to complete the 24-hour intake and output record.

Hydration status is assessed in the PACU and the medical-surgical unit. To determine hydration status, inspect the color and moisture of mucous membranes; the turgor, texture, and "tenting" of the skin (test over the sternum or forehead of an older patient); the amount of drainage on dressings; and the presence of axillary sweat. Measure and compare total output (e.g., NG tube drainage, urine output, wound drainage) with total intake to identify a possible fluid imbalance. Consider insensible fluid loss, such as sweat, when reviewing total output. Continue to assess intake and output as long as the patient is at risk for fluid imbalances. Some facilities require intake and output to be measured if the patient receives IV fluids or has a catheter, drains, or an NG tube. In addition, patients who have heart disease or kidney disease may need a longer period of intake and output measurement.

IV fluids are closely monitored to promote fluid and electrolyte balance. Isotonic solutions such as lactated Ringer's (LR), 0.9% sodium chloride (normal saline), and 5% dextrose with lactated Ringer's (D_5/LR) are used for IV fluid replacement in the PACU. After the patient returns to the medical-surgical unit, the type and rate of IV infusions are based on need.

Acid-base balance is affected by the patient's respiratory status; metabolic changes during surgery; and losses of acids or bases in drainage. For example, NG tube drainage or vomitus causes a loss of hydrochloric acid and leads to metabolic alkalosis. Examine arterial blood gas (ABG) values and other laboratory values. (See Chapter 12 for more detailed information on acid-base imbalances.)

Kidney/Urinary System.

Control of urination may return immediately after surgery or may not return for hours after general or regional anesthesia. The effects of preoperative drugs (especially atropine), anesthetic agents, or manipulation during surgery can cause urine retention. Assess for urine retention by inspection, palpation, and percussion of the lower abdomen for bladder distention or by the use of a bladder scanner (see Chapter 65). Assessment may be difficult to perform after lower abdominal surgery. Urine retention is common early after surgery and requires intervention, such as intermittent (straight) catheterization, to empty the bladder.

When the patient has an indwelling urinary (Foley) catheter, assess the urine for color, clarity, and amount. If the patient is voiding, assess the frequency, amount per void, and any manifestations. Urine output should be close to the total intake for a 24-hour period. Consider sweat, vomitus, or diarrhea stools as sources of output. Report a urine output of less than 30 mL/hr (240 mL per 8-hour nursing shift) to the surgeon. Decreased urine output may indicate hypovolemia or renal complications. (See Chapter 65 for kidney/urinary assessment.)

Gastrointestinal System.

Postoperative nausea and vomiting (PONV) are among the most common reactions after surgery. Many patients who receive general anesthesia have some form of GI upset within the first 24 hours after surgery; however, some patients are more at risk than others (Tinsley & Barone, 2013). Patients with a history of motion sickness are more likely to develop nausea and vomiting after surgery. Obese patients may be at risk because many anesthetics are retained by fat cells and remain in the body longer. Abdominal surgery and the use of opioid analgesics reduce intestinal peristalsis after surgery. These problems increase the risk for prolonged nausea and vomiting after surgery. Preventive drug therapy, often started in the preoperative period, is effective in reducing the incidence. Drugs often used are a serotonin antagonist such as

ondansetron (Zofran), a sedating H_1 histamine antagonist such as dimenhydrinate (Dramamine), and an anticholinergic agent such as scopolamine.

PONV can stress and irritate abdominal and GI wounds, increase intracranial pressure in patients who had head and neck surgery, elevate intraocular pressure in patients who had eye surgery, and increase the risk for aspiration. Assess the patient continuously for PONV. Often patients have nausea as the head of the bed is raised early after surgery. Help reduce this distressing symptom by having the patient in a side-lying position before raising the head slowly.

Intestinal peristalsis may be delayed because of prolonged anesthesia time, the amount of bowel handling during surgery, and opioid analgesic use. In the PACU and later on the medical-surgical unit, assess for the return of peristalsis. *Patients who are recovering from abdominal surgery often have decreased or no peristalsis for at least 24 hours.* This problem may persist for several days for those who have GI surgery.

Listen for bowel sounds in all four abdominal quadrants and at the umbilicus. If NG suction is being used, turn off the suction before listening to prevent mistaking the sound of the suction for bowel sounds. *The presence of active bowel sounds usually indicates return of peristalsis; however, the absence of bowel sounds does not confirm a lack of peristalsis. The best indicator of intestinal activity is the passage of flatus or stool (Massey, 2012).* Abdominal cramping along with distention denotes trapped, nonmoving gas—not peristalsis.

Decreased peristalsis occurs in patients who have a paralytic ileus. The abdominal wall is distended with no visible intestinal movement. Assess for the manifestations of paralytic ileus (distended abdomen, abdominal discomfort, vomiting, no passage of flatus or stool). In some patients, bowels sounds can be heard even when a true paralytic ileus is present. The passage of flatus or stool is the best indicator of resolution of a paralytic ileus. See the Evidence-Based Practice box.

Evidence-Based Practice QSEN

Evidence-Based Practice or Sacred Cow?

Massey, R. (2012). Return of bowel sounds indicating an end of postoperative ileus: Is it time to cease this long-standing nursing tradition? *MEDSURG Nursing, 21*(3), 146-150.

Abdominal surgery, especially surgery involving bowel anastomosis, is known to reduce or stop intestinal peristalsis and result in postoperative

ileus (POI) with a duration of 3 to 5 days. POI causes a cluster of patient symptoms, which include abdominal pain, distention, nausea, and vomiting. In addition, POI delays nutrition and lengthens hospital stay. For more than a century, the classic indicator for return of bowel function after POI was the presence of bowel sounds. Recommended assessment is auscultation of the four abdominal quadrants for 5 minutes each, a total time task of 20 minutes. A variety of previous research suggests that assessment of bowel sounds for return of function after POI is an unreliable "tradition" that wastes nursing care time and may, in fact, cause harm.

Problems associated with assessment of bowel sounds as an indicator of bowel function return include the fact that the small intestine usually recovers bowel sounds ahead of the colon but that the sounds do not always correlate to peristaltic movement of retained gas and fluids. This means that positive bowel sounds in some quadrants may result in early enteral feeding of a patient before true peristalsis returns. Also, some patients have no loss of bowel sounds after abdominal surgery but do experience the symptom cluster associated with POI, again making the presence of bowel sounds an unreliable indicator of peristalsis. Moreover, studies indicate that most nurses auscultate the abdomen for only 30 to 60 seconds in each quadrant, not the recommended but unvalidated time of 5 minutes per quadrant. Even this smaller amount of time represents unproductive nursing activity.

The current study examined the return of bowel sounds and other manifestations as indicators for resolution of POI among 66 patients who all had intestinal surgery with anastomosis for cancer. The average return of bowel sounds among these 66 patients was 2.23 days and was not related to the average time to first passage of flatus.

Level of Evidence: 3

This quasi-experimental study with a two-group, post-test only design was randomized and had sufficient subjects to provide result validity. The use of objective measurements added to study strength.

Commentary: Implications for Practice and Research

This study provides evidence for the rational elimination of 20 minutes of nursing time spent in auscultation of bowel sounds several times daily after abdominal surgery. The findings of this study support other studies that recommend using the practice of using passage of flatus or stool as the marker for the end of POI rather than the time-honored but unsupported practice of auscultating bowel sounds for 20 minutes.

Actual passage of flatus or stool demonstrates an end of POI and complete return of peristalsis with forward propulsion of intestinal contents for the entire GI tract. Additional positive indicators for evidence of an end to POI include elimination of abdominal distention, nausea, and vomiting and the tolerance of oral intake. Nurses need to understand the physiologic basis for why return of bowel sounds may be an unreliable indicator of an end to POI and may result in inappropriate initiation of dietary intake.

A nasogastric (NG) tube may be inserted during surgery to decompress and drain the stomach, to promote GI rest, and to allow the lower GI tract to heal. It may also be used to monitor any gastric bleeding and to prevent intestinal obstruction. Usually low suction is applied to promote drainage. Suction is either continuous or intermittent.

Record the color, consistency, and amount of the NG drainage every 8 hours (Table 16-3). In some instances, an occult blood test (Gastroccult) may be performed. Normal NG drainage fluid is greenish yellow. Red or pink drainage fluid indicates active bleeding, and brown liquid or drainage with a "coffee-ground" appearance indicates old bleeding. Assess that the NG tube is securely taped to the nose, and note any skin irritation.

TABLE 16-3

Calculating Nasogastric Tube Drainage

Formula

$$\text{Drainage in collection device} - \text{Amount of irrigant} = \text{True (actual) amount of drainage}$$

Example

A patient's drainage container was marked at 150 mL at 7 am. At 3 pm, there was 525 mL in the container. During the nursing shift, the nurse instilled 30 mL of saline as an irrigant into the tube four times, as prescribed by the physician.

525 mL – 150 mL = 375 mL of drainage

30 mL × 4 = 120 mL of irrigant

375 mL – 120 mL = 255 mL of actual drainage

Assess the patient for complications related to NG tube use, such as fluid and electrolyte imbalances, aspiration, and nares discomfort. To prevent aspiration, check the tube placement every 4 to 8 hours and before instilling any liquid, including drugs, into the tube. (See Chapter 55 for information on tube placement and care.) Electrolyte imbalances can result from NG drainage and tube irrigation with water instead of saline. Imbalances include fluid volume deficit, hypokalemia and hyponatremia (see Chapter 11), hypochloremia, and metabolic alkalosis (see Chapter 12).

Nursing Safety Priority QSEN

Action Alert

After gastric surgery, do not move or irrigate the NG tube unless prescribed by the surgeon.

Constipation may occur after surgery as a result of anesthesia, analgesia (especially opioids), decreased activity, and decreased oral intake. Assess the abdomen by inspection, auscultation, palpation, and percussion and record the elimination pattern to determine whether intervention is needed. *Auscultate before palpation or percussion because these two maneuvers can affect peristalsis.* Increased dietary fiber intake, the use of mild laxatives or bulk-forming agents, or the use of enemas may be needed.

NCLEX Examination Challenge

Safe and Effective Care Environment

The assessment findings for the nasogastric tube drainage of a client recently transferred from the PACU include the presence of 140 mL of greenish yellow drainage. What is the nurse's best action?
A Instruct the client to drink water until the drainage is clear.
B Reposition the tube to increase the drainage.
C Call and report this finding to the surgeon.
D Document the finding as the only action.

Skin Assessment.

The clean surgical wound regains tissue integrity *(heals) at skin level in about 2 weeks in the absence of trauma, connective tissue disease, malnutrition, or the use of some drugs, such as steroids. Smokers and patients who are older, obese, or have diabetes or whose immunity is reduced have delayed wound healing. Complete tissue integrity (healing) of all layers within the surgical wound may take 6 months to 2 years. The physical health and age of the patient, size and location of the wound, and stress on the wound all affect healing time. Head and facial wounds heal more quickly than abdominal and leg wounds because of the better blood flow to the head and neck.*

Normal Wound Healing.

During the first few days of normal wound healing, the incised tissue regains blood supply and begins to bind together. Fibrin and a thin layer of epithelial cells seal the incision. After 1 to 4 days, epithelial cells continue growing in the fibrin and strands of collagen begin to fill in the wound gaps. *This process continues for 2 to 3 weeks. At that time,* tissue integrity *appears regained; however, healing is not complete for up to 2 years, until the scar is strengthened.* (See Chapters 24 and 25 for discussion of wound healing and wound infection.)

When the patient is an inpatient, the surgeon usually removes the original dressing on the first or second day after surgery. Assess the tissue integrity of the incision on a regular basis, at least every 8 hours, for redness, increased warmth, swelling, tenderness or pain, and the type and amount of drainage. Some drainage, changing from **sanguineous** (bloody) to serosanguineous to **serous** (serum-like, or yellow), is normal during the first few days. Serosanguineous drainage continuing beyond the fifth day after surgery or increasing in amount instead of decreasing alerts you to the possibility of dehiscence (discussed below), and the

surgeon should be notified. Crusting on the incision line is normal, as is a pink color to the line itself, which is caused by inflammation from the surgical procedure. Slight swelling under the sutures or staples is also normal. Redness or swelling of or around the incision line, excessive tenderness or pain on palpation, and purulent or odorous drainage indicate wound infection and must be reported to the surgeon.

Impaired Wound Healing.

Impaired wound healing with loss of tissue integrity may be caused by infection, distention, stress at the surgical site, and health problems that cause delayed wound healing (e.g., diabetes). Wound **dehiscence** is a partial or complete separation of the outer wound layers, sometimes described as a "splitting open of the wound." **Evisceration** is the total separation of all wound layers and protrusion of internal organs through the open wound (Fig. 16-2). Both of these problems occur most often between the fifth and tenth days after surgery. Wound separation occurs more often in obese patients and those with diabetes, immune deficiency, or malnutrition or who are using steroids. Dehiscence or evisceration may follow forceful coughing, vomiting, or straining and when not splinting the surgical site during movement. The patient may state, "Something popped" or "I feel as if I just split open."

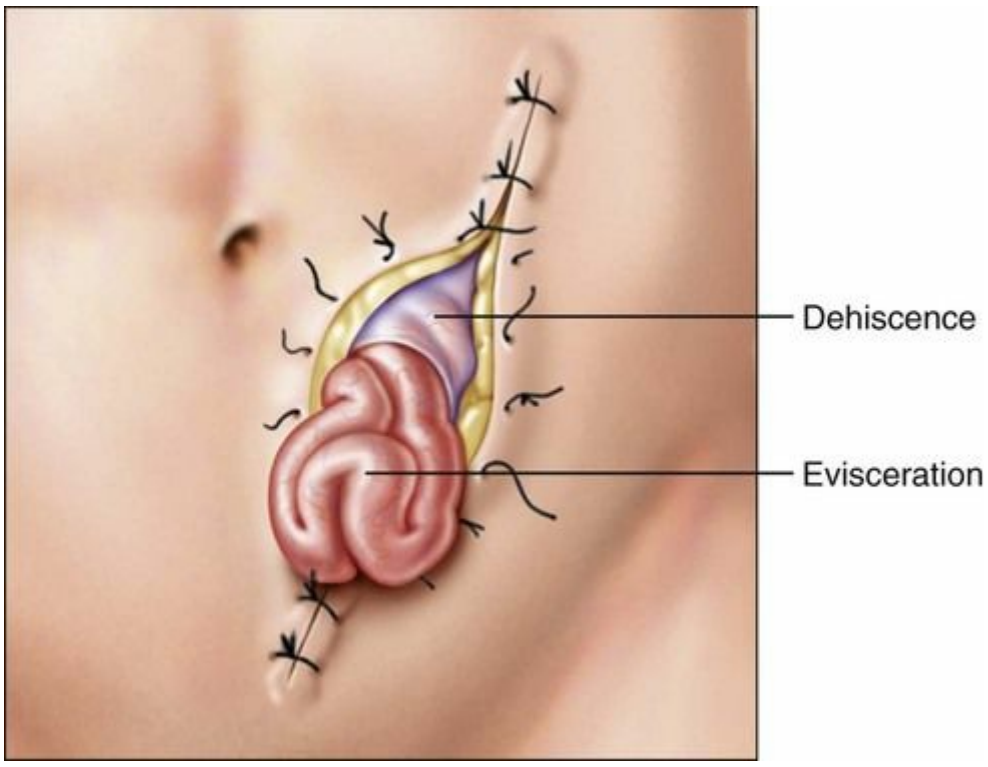

FIG. 16-2 Complications of surgical wound healing.

Dressings and Drains.

Assess all dressings, including casts and elastic (Ace) bandages, for bleeding or other drainage on admission to the PACU and then hourly thereafter. When the patient is on the nursing unit, assess the dressing each time vital signs are taken (at least every 8 hours). During dressing inspection, check for drainage and record its amount, color, consistency, and odor. If drainage is present on a dressing or cast, monitor its progression by outlining it with a pencil and indicating the date and time. Check the area underneath the patient also, because drainage or blood may leak from the side of the dressing and not appear on the dressing itself.

Ensure that the dressing does not restrict circulation or sensation. This problem is most likely to occur when dressings are tight or completely encircle an arm or a leg. Chest dressings that are too tight or that encircle the chest can restrict breathing.

The surgeon inserts a drain into or close to the wound if more than a minimal amount of drainage is expected. A Penrose drain (a single-lumen, soft, open, latex tube) is a gravity-type drain under the dressing. Drainage on the dressing is expected with open tube drains but is not expected with closed drainage systems. Assess closed-suction drains, such as Hemovac, Vacu-Drain, and Jackson-Pratt drains, for maintenance of suction. Specialty drains, such as a T-tube, may be placed for specific drainage purposes. For example, a T-tube drains bile after a cholecystectomy. Chronic wounds or wounds that heal by delayed primary intention are drained with a negative pressure wound device. Fig. 16-3 shows commonly used drains.

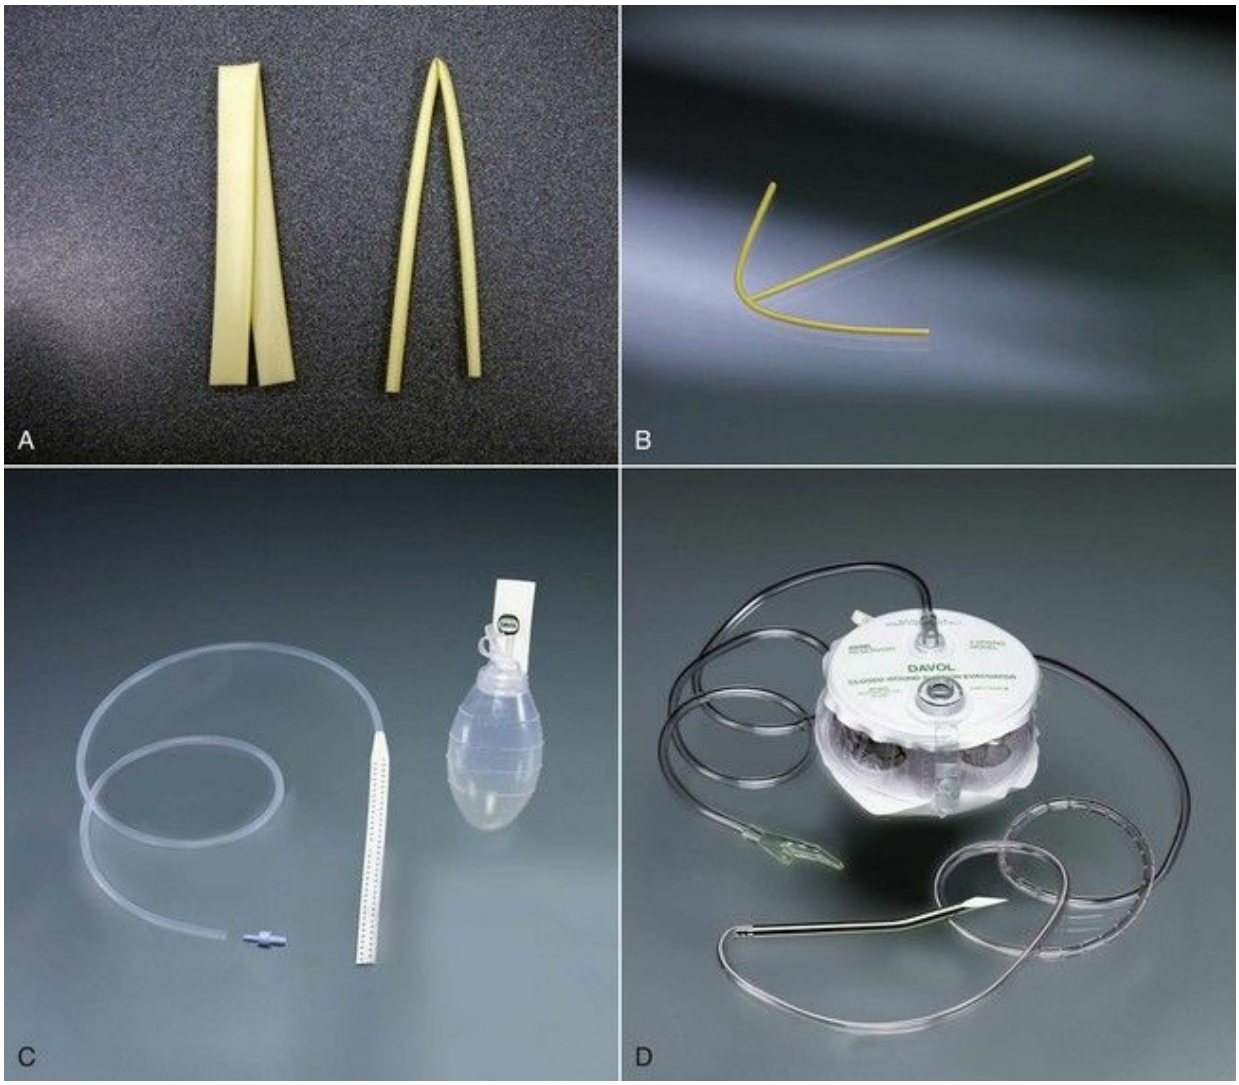

FIG. 16-3 Types of surgical drains. Gravity drains, such as the Penrose **(A)** and the T-tube **(B)** drain directly through a tube from the surgical area. In closed wound drainage systems, such as the Jackson-Pratt **(C)** and Hemovac **(D)**, drainage collects in a collecting vessel by means of compression and re-expansion of the system.

Assess all drains for patency when the patient is admitted to the PACU and every time vital signs are taken. Monitor the amount, color, and type of drainage while the patient is in the PACU and at least every 8 hours after he or she is transferred to the medical-surgical nursing unit. Large amounts of sanguineous drainage may indicate poor clotting and possible internal bleeding.

Discomfort/Pain Assessment.

The patient almost always has pain or discomfort after surgery. Pain is a subjective experience and may be more intense than you can appreciate. Pain after surgery is related to the surgical wound, tissue manipulation, drains, positioning during surgery, presence of an endotracheal tube, and

the patient's experience with pain (Ward, 2014). In accordance with The Joint Commission's National Patient Safety Goals, assess the patient's discomfort and need for medication by considering the type, extent, and length of the surgical procedure. Assess for physical and emotional signs of acute pain, such as increased pulse and blood pressure, increased respiratory rate, profuse sweating, restlessness, confusion (in the older adult), wincing, moaning, and crying. When possible, ask the patient to rate the pain before and after drugs are given (e.g., on a scale of 0 to 10, with 0 being no pain and 10 being extreme pain). Plan the patient's activities around the timing of analgesia to improve mobility. Observe for a return of baseline physical and emotional behaviors. (See Chapter 3 for further discussion of pain assessment.)

Pain assessment is started by the PACU nurse. After the patient is transferred from the PACU, the medical-surgical nurse continues to assess the patient's comfort level. Pain usually reaches its peak on the second day after surgery, when the patient is more awake and more active and the anesthetic agents and drugs given during surgery have been excreted.

Psychosocial Assessment.

Consider the psychological, social, and cultural issues of the patient after surgery as you provide physical care. This assessment may be delayed or difficult to perform in the PACU when the patient is drowsy or confused. Consider the patient's age and medical history, the surgical procedure, and the impact of surgery on recovery, body image, roles, and lifestyle.

Indications of anxiety include restlessness; increased pulse, blood pressure, and respiratory rate; and crying. The patient may be anxious and ask questions about the results or findings of the surgical procedure. Reassure the patient that the surgeon will speak with him or her after he or she is fully awake. If the surgeon has already spoken with the patient, reinforce what was said.

After the patient returns to the medical-surgical unit, continue the psychosocial assessment and also assess family members for psychological discomfort.

Laboratory Assessment.

Laboratory tests are performed after surgery to monitor for complications. Tests are based on the surgical procedure, the patient's medical history, and clinical manifestations after surgery. Common tests include analysis of electrolytes and a complete blood count (see Chart 14-3 in Chapter 14). Changes in electrolyte, hematocrit, and hemoglobin

levels often occur during the first 24 to 48 hours after surgery because of blood and fluid loss and the body's reaction to the surgical process. Fluid loss with minimal blood loss may cause elevated laboratory values. Such test results appear increased but actually are concentrated normal values.

An indication of infection is an increase in the band cells (immature neutrophils) in the white blood cell differential count, known as a "left-shift" or *bandemia*. The source of infection may be the respiratory system, urinary tract, surgical wound, or IV site. Obtain specimens for culture and sensitivity testing, and monitor the culture reports at 24, 48, and 72 hours. Notify the surgeon of positive culture results. (See Chapters 17 and 23 for information on infection.)

Arterial blood gas (ABG) tests may be needed for patients who have respiratory or cardiac disease, those undergoing mechanical ventilation after surgery, and those who had chest surgery. Review ABG results, and notify the surgeon of any acid-base imbalance or hypoxemia that indicates poor gas exchange. (For more discussion on arterial blood gases and acidosis, see Chapter 12.)

Urine and kidney laboratory tests also may be obtained (e.g., urinalysis, urine electrolyte levels, serum creatinine levels). Other laboratory tests depend on the diagnosis, type of surgical procedure, and other health problems. Examples are a serum amylase level for a patient who had pancreatic surgery and a blood glucose level for a patient with diabetes.

Analysis

The priority NANDA-I nursing diagnoses and collaborative problems for patients after surgery include:

1. Potential for hypoxemia related to the effects of anesthesia, pain, opioid analgesics, and immobility
2. Potential for wound infection and delayed healing related to wound location, decreased mobility, drains and drainage, and tubes
3. Acute Pain related to the surgical incision, positioning during surgery, and endotracheal (ET) tube irritation (NANDA-I)

Planning and Implementation

Preventing Hypoxemia

Planning: Expected Outcomes.

The patient is expected to attain or maintain optimal lung expansion and

breathing patterns after surgery as indicated by:

- Partial pressure of arterial oxygen (Pa_{O_2}) within normal range
- Partial pressure of arterial carbon dioxide (Pa_{CO_2}) within normal range
- Oxygen saturation values within normal range

Interventions

Airway Maintenance.

After assessing the airway and gas exchange, you may need to insert an oral airway if the patient does not already have one. The oral airway pulls the tongue forward and holds it down to prevent obstruction. If the patient had oral surgery or has clenched teeth, a large tongue, or upper airway obstruction, insert a nasal airway (nasal trumpet) to keep the airway open. Keep the manual resuscitation bag and emergency equipment for intubation or tracheostomy nearby. For patients whose only airway is a tracheostomy or laryngectomy stoma, alert other staff members by posting signs in the room and notes on the chart.

Monitoring.

Monitor the patient's oxygen saturation (Sp_{O_2}) for adequacy of gas exchange with pulse oximetry at least every hour or more often, according to the patient's condition. Patients who normally have a low Pa_{O_2}, such as those with lung disease or older adults, are at higher risk for hypoxemia. An older adult is often prescribed low-dose oxygen therapy for the first 12 to 24 hours after surgery to reduce confusion from anesthesia and sedation (Sullivan, 2011). A patient who received moderate sedation with a benzodiazepine such as midazolam (Versed) or lorazepam (Ativan, Nu-Loraz) may be overly sedated or have respiratory depression sufficient to need reversal with flumazenil (Romazicon) (Chart 16-4). Hypothermia after surgery causes shivering, which increases oxygen demand and can induce hypoxemia. Many rewarming methods can be used, although prevention is more important. The highest incidence of hypoxemia after surgery occurs on the second postoperative day.

Chart 16-4 Best Practice for Patient Safety & Quality Care QSEN

Emergency Care of the Patient Experiencing a Benzodiazepine Overdose

- Secure the airway and IV access before starting benzodiazepine

antagonist therapy.

- Prepare to administer flumazenil (Romazicon)* in a dose of 0.2 mg to 1 mg IV.
- Repeat drug every 2 to 3 minutes up to 3 mg, as needed, depending on the patient's response.
- Give oxygen if hypoxia is present or if respirations are below 10 breaths per minute.
- Have suction equipment available because flumazenil can trigger vomiting and a drowsy patient is at risk for aspiration.
- Continuously monitor vital signs and level of consciousness for reversal of overdose.
- Do not leave the patient until he or she is fully responsive.
- Continue to monitor the patient's vital signs and level of consciousness every 10 to 15 minutes for the first 2 hours because flumazenil is eliminated from the body more quickly than is the benzodiazepine.
- Determine the need for additional flumazenil therapy 1 to 2 hours after the patient initially becomes fully responsive.
- Observe the patient for tremors or convulsions because flumazenil can lower the seizure threshold in patients who have seizure disorders.
- Assess the IV site every shift because flumazenil can cause thrombophlebitis at the injection site.
- Observe the patient for side effects of flumazenil, including skin rash, hot flushes, dizziness, headache, sweating, dry mouth, and blurred vision. The incidence of these side effects increases with higher total doses of flumazenil.

*There are other benzodiazepine antagonists; however, flumazenil is used most often to manage adult benzodiazepine overdose in the postoperative period.

Positioning.

In the PACU, immediately position the patient in a semi-Fowler's position unless contraindicated. If the patient cannot have the head of the bed raised, either place him or her in a side-lying position or turn the head to the side to prevent aspiration.

Oxygen Therapy.

Hypoxemia is prevented and managed with oxygen therapy. Apply oxygen by face tent, nasal cannula, or mask to eliminate inhaled anesthetic agents, increase oxygen levels, raise the level of consciousness,

and reduce confusion. After the patient is fully reactive and stable, raise the head of the bed to promote respiratory function.

For some patients, oxygen therapy may continue through the second day after surgery. When hypoxemia occurs despite preventive care, interventions such as respiratory treatments and mechanical ventilation may be used to manage the cause of the hypoxemia.

Breathing Exercises.

After the patient regains the gag and cough reflexes and meets the agency's criteria for extubation (if intubated), remove the airway or ET tube. Usual extubation criteria include the ability to raise and hold the head up and evidence of thoracic breathing. Help the patient splint the incision, cough, and deep breathe to promote gas exchange and eliminate anesthetic agents. Chart 14-5 in Chapter 14 reviews breathing exercises and splinting of the surgical area. As soon as the patient is awake enough to follow commands, urge him or her to cough, use the incentive spirometer, and take deep breaths hourly while awake throughout the postoperative period. The patient who is unable to remove mucus or sputum requires oral or nasal suctioning. Perform mouth care after removing secretions.

Movement.

Assist the patient out of bed and to ambulate as soon as possible to help remove secretions and promote ventilation. Even when the patient has had extensive surgery, the expectation may be to get out of bed the day of or the first day after surgery. If this is not possible, assist him or her to turn at least every 2 hours (side to side) and ensure that breathing exercises and leg exercises are performed (see Charts 14-5 and 14-6 in Chapter 14). Early ambulation reduces the risk for pulmonary complications, especially after abdominal, pelvic, or spinal surgery. It increases circulation to extremities and reduces the risk for clotting and venous thromboembolism (VTE), especially deep vein thrombosis (DVT). The patient may resist getting up, but you must stress the importance of activity to prevent complications. When indicated, offer pain medication 30 to 45 minutes before he or she gets out of bed.

Preventing Wound Infection and Delayed Healing

Planning: Expected Outcomes.

The patient is expected to have incision healing without wound complications as indicated by:

- Wound edges remaining together
- No purulent drainage, induration, or redness in, from, or around the incision

Interventions.

Nursing assessment of the surgical area is critical (see the discussion of skin assessment on p. 263). Although most wound complications do not require additional surgical intervention, emergency surgical procedures may be needed.

Nonsurgical Management.

Wound care includes reinforcing the dressing, changing the dressing, assessing the wound for healing and infection, and caring for drains, including emptying drainage containers/reservoirs, measuring drainage, and documenting drainage features. Emphasize the importance of early deep-breathing exercises to prevent forceful coughing. Urge the patient to bend the hips when in the supine position to reduce tension on a chest or abdominal wound. Remind him or her to always splint the chest or abdominal incision when coughing. Promote wound healing and protection of the skin, especially for the older patient (Sullivan, 2011). Chart 16-5 lists best practices for skin care of the older patient after surgery.

Chart 16-5 Nursing Focus on the Older Adult

Best Practice in Postoperative Skin Care

Improve perfusion to the wound to promote wound healing:
- Keep the patient adequately hydrated to maintain cardiac output.
- Keep the airway patent, and provide adequate oxygenation.
- Keep the patient's oxygen saturation on pulse oximetry at greater than 93%.

Conserve the patient's energy:
- Allow the patient to sleep in a darkened, quiet room.
- Administer drugs to combat pain and sleeplessness, as prescribed.
- Provide rest periods throughout the day.
- Control the patient's room temperature.
- Assist in ADLs.

Place the patient on a safety program to prevent falls, if indicated.

Use strict aseptic technique in caring for breaks in the integument (e.g., IV or other catheters, indwelling urethral catheter, wound).

Maintain the patient's psychosocial health:
- Prevent unnecessary stressors.
- Allow the patient liberal visitation of supportive others.
- Enable the patient to use individual successful coping mechanisms.
- Keep the patient well groomed and bathed.

Protect fragile skin:
- Minimize the use of tape on the skin.
- Use hypoallergenic tape or Montgomery straps.
- Change dressings as soon as they become wet.
- Lift the patient during transfer or repositioning.

Dressings.

The surgeon usually performs the first dressing change to assess the wound, remove any packing, and advance (pull partially out) or remove drains. Before the first dressing change, reinforce the dressing (add more dressing material to the existing dressing) if it becomes wet from drainage. Document the added material, as well as the color, type, amount, and odor of drainage fluid and time of observation. Assess the surgical site at least every shift, and report any unexpected findings to the surgeon.

After removal of the dressing, the surgeon may leave the suture or staple line open to the air, which allows easy assessment of the wound and early detection of poor wound edge adherence, drainage, swelling, or redness. Some surgeons believe that air-drying promotes healing. A draining wound, however, is always covered with a dressing.

Dressing changes are prescribed by the surgeon; however, the facility or unit may have standards or policies that dictate specific protocols for dressing changes and incision care. An unchanged wet or damp dressing is a source of infection. Change dressings using aseptic technique until the sutures or staples are removed.

Dressings vary with the surgical procedure and the surgeon's preference. Common dressings for large incisions consist of gauze or nonadherent pads covered with a larger absorbent pad held in place by tape, a tubular stretchy net, or Montgomery straps (Fig. 16-4). Some incisions may be covered with a transparent plastic surgical dressing (e.g., OpSite) or a spray in the operating room. This type of dressing stays intact for 3 to 6 days, allows direct observation of the wound, prevents contamination, and eliminates the need for dressing changes.

FIG. 16-4 Patient with a dressing held in place with Montgomery straps.

Wound or suture line care consists of changing gauze dressings at least once during a nursing shift or daily and may include cleaning the area with sterile saline or some other solution. Some suture lines are left open to air without any dressing to cover the incision. The hospital's policy, the unit's standards, and the surgeon's preference determine what solution, if any, is used to clean the wound and how often dressings are changed. For large dressing changes or drain removal, offer the patient a prescribed analgesic before the procedure. Always assess the skin for redness, rash, or blisters in areas where tape has been used. Tape can cause a skin reaction after surgery even among patients who are not known to be tape sensitive.

Skin sutures or staples are usually removed 5 to 10 days after surgery, although this varies up to 30 days depending on the type of surgery and the patient's health. After sutures or staples are removed, the incision may then be secured with Steri-Strips, which stay in place until they fall off on their own. The surgeon or the nurse removes the sutures or staples, depending on the agency's policy. Clean the incision with the prescribed solution before removing sutures or staples. Before removing sutures, examine the condition and healing stage of the wound. First remove every other suture or staple and re-assess the wound for integrity. If wound healing is progressing normally, the rest of the sutures or staples may then be removed. If the wound does not appear to be healing

well or if any manifestations of infection are present, notify the surgeon before removing any sutures.

Drains.

Drains (see Fig. 16-3) may be placed in the wound or through a separate small incision (known as a "stab" wound) close to the incision during surgery. Drains provide an exit route for air, blood, and bile. Drains also help prevent deep infection and abscess formation during healing.

The Penrose drain is placed into the external aspect of the incision and drains directly onto the dressing and skin around the incision. Change a damp or soiled dressing, and carefully clean under and around the Penrose drain. Then place absorbent pads under and around the exposed drain to prevent skin irritation, wound contamination, and infection. Whether sutured in place or not, the drain can be dislodged or pulled out accidentally during a dressing change. It is also possible for the drain to slip back through the wound into the patient. Usually this complication is prevented when the drain is first placed in the OR. The surgeon pins a sterile safety pin through the drain at an angle perpendicular to the drain and the wound, which prevents the drain from slipping. As the wound heals, the surgeon or nurse shortens (advances) the drain by pulling it out a short distance and trimming off the excess external portion so that only 2 to 3 inches of drain protrudes through the incision. The safety pin must be repositioned each time the drain is advanced. The drain remains in place until drainage stops.

Jackson-Pratt and Hemovac drains are two self-contained drainage systems that drain wounds directly through a tube via gravity and vacuum. These drains are sutured in place with a suture that seals the area when the drain is removed. Use sterile technique to empty the reservoir. Record the amount and color of drainage during every nursing shift or more often if prescribed. After emptying and compressing the reservoir to restore suction, secure the drain to the patient's gown (never to the sheet or mattress) to prevent pulling and stress on the surgical wound.

Drug Therapy.

Wound infection is a major complication after surgery. It usually results from contamination during surgery, preoperative infection, debilitation, or immunosuppression. In accordance with the Surgical Care Improvement Project (SCIP) core measures for prevention of surgical site infection, a patient at risk for wound infection may have received antibiotic therapy with drugs that are effective against organisms

common to the specific surgical site both before and during surgery. The need for these antibiotics is re-evaluated at 24 hours after surgery. If manifestations of infection are not present, the antibiotic is discontinued at that time (SCIP Infection-3, see Table 14-1 in Chapter 14). If manifestations of wound infection are present, they are documented to justify continuation of antibiotic therapy.

Wounds that become infected and open are treated with dressing changes and systemic antibiotic therapy. Depending on the surgeon's prescription, irrigate the wound (e.g., with sterile saline, hydrogen peroxide, povidone-iodine, or acetic acid), loosely pack it with solution-soaked gauze (e.g., neomycin, gentamicin, iodoform, povidone-iodine, saline, or acetic acid), and cover the wound with dry, sterile dressings. These wet-to-damp dressing changes, done 1 to 3 times daily, promote healing from within the wound and **débridement** (removal of the infected or dead tissue) as the wound heals. Negative pressure wound care systems such as Wound VAC may be prescribed to help close the wound. Chapter 25 discusses these systems.

Surgical Management.

Poorly healing wounds, infected wounds, or complicated wounds may require surgical intervention.

Management of Dehiscence.

If dehiscence (wound opening) occurs, apply a sterile nonadherent (e.g., Telfa) or saline dressing to the wound and notify the surgeon. Instruct the patient to bend the knees and to avoid coughing. A wound that becomes infected dehisces by itself, or it may be opened by the surgeon through an incision and drainage (I&D) procedure. In either case, the wound is left open and is treated as described previously.

Management of Evisceration.

*An **evisceration** (a wound opening with protrusion of internal organs) is a surgical emergency.* Chart 16-6 lists best practices for emergency care of the patient with surgical wound evisceration. Provide support by explaining what happened and reassuring the patient that the emergency will be handled competently.

Chart 16-6 Best Practice for Patient Safety & Quality Care QSEN

Emergency Care of the Patient with Surgical Wound Evisceration

1. Call for help! Instruct the person who responds to notify the surgeon or Rapid Response Team immediately and to bring any needed supplies into the patient's room.
2. Stay with the patient.
3. Cover the wound with a nonadherent dressing premoistened with warmed sterile normal saline. **Note:** The supplies needed for this emergency should be in the patient's room, especially if the patient is at high risk for dehiscence or evisceration.
4. If premoistened dressings are not available, moisten sterile gauze or sterile towels in a sterile irrigation tray with sterile saline and then cover the wound.
5. If saline is not immediately available, cover the wound with gauze and then moisten with sterile saline using a sterile irrigation tray as soon as someone brings saline.
6. Do not attempt to reinsert the protruding organ or viscera.
7. While covering the wound, note the patient's response and assess for manifestations of shock.
8. Place the patient in a supine position with the hips and knees bent.
9. Raise the head of the bed 15 to 20 degrees.
10. Take vital signs, and document them. **Note:** If the person who answered the call for help is back in the room before this, instruct him or her to take vital signs while you focus on covering the wound and repositioning the patient.
11. Provide support and reassurance to the patient.
12. Continue assessing the patient, including vital signs assessment, every 5 to 10 minutes until the surgeon arrives.
13. Keep dressings continuously moist by adding warmed sterile saline to the dressing as often as necessary. Do not let the dressing become dry.
14. When the surgeon arrives, report your finding and your interventions. Then follow the surgeon's directions.
15. Document the incident, the activity the patient was engaged in at the time of the incident, your actions, and your assessments.

 **Nursing Safety Priority** QSEN

Critical Rescue

When a surgical wound evisceration occurs, one nurse tends to the patient while another nurse immediately notifies the surgeon.

The surgeon may prescribe a nasogastric (NG) tube to decompress the stomach and relieve internal pressure or to remove the stomach's contents if the patient has been eating and general anesthesia is needed. Prepare the patient for surgery (see Chapter 14) to close the wound. Regional or local anesthesia may be used, depending on the location and type of wound. Nausea and vomiting, which stress the already fragile incision, are reduced when regional or local anesthesia is used. To increase the incision's integrity, stay or retention sutures of wire or nylon are used along with standard sutures or staples (see Fig. 15-11 in Chapter 15).

Prevention.

Patients also are at risk for developing pressure ulcers from positioning during surgery, from contact with damp surgical linens, and from unpadded surfaces. Pressure ulcers acquired during the surgical period prolong stays and increase the risk for complications. Early intervention of pressure ulcers can prevent progression and complications.

Examine the patient's skin for areas of redness or open areas. Document and report any abnormalities. Use padding and positioning to relieve pressure. Treat any open areas according to facility guidelines and the surgeon's prescription. Ensure that information about the patient's skin condition in the PACU is communicated to the medical-surgical nurse. For patients at high risk, collaborate with a certified Wound, Ostomy, and Continence registered nurse (WOCRN) to plan preventive or interventional skin care.

Managing Pain

Planning: Expected Outcomes.

The postoperative patient is expected to attain or maintain optimal comfort levels. Indicators include:

- Reporting that pain is controlled
- Absence of physiologic indicators of acute pain (increased heart rate and blood pressure)
- Absence of facial grimacing, teeth clenching
- Willingness to move and participate in self-care

Interventions.

Pain management after surgery includes drug therapy and other methods of management, such as positioning, massage, relaxation techniques, and diversion. Often the patient has better pain relief from a combination of approaches. Assess the patient's comfort level and the effectiveness of the therapies. See Chapter 3 for discussion of pain assessment and management. The patient who has optimal pain control is better able to cooperate with the therapies and exercises to prevent complications and promote rehabilitation.

Drug Therapy.

The use of opioids or other analgesics for pain management may mask or increase the severity of symptoms of an anesthesia reaction. Therefore give these drugs with caution, especially in the PACU when the patient's condition is not stable. When pain drugs are used in the PACU, they are usually given IV in small doses. After receiving any drug for pain, the patient remains in the PACU for a defined period (often 45 to 60 minutes). Assess for hypotension, respiratory depression, and other side effects. Within 5 to 10 minutes after an IV injection, assess the effectiveness of the drug (i.e., on a rating scale) in relieving pain.

Opioid analgesics are given during the first 24 to 48 hours after surgery to control acute pain. Around-the-clock scheduling or the use of patient-controlled analgesia (PCA) systems is more effective than "on demand" scheduling because more constant blood levels are achieved. Drugs commonly used include morphine (Statex), hydromorphone (Dilaudid), ketorolac (Toradol), codeine, butorphanol (Stadol), and oxycodone with aspirin (Percodan) or oxycodone with acetaminophen (Tylox, Percocet).

Nursing Safety Priority QSEN

Drug Alert

The usual dosage for hydromorphone is much smaller (about one-fifth to one-tenth) that of morphine.

Assess the type, location, and intensity of the pain before and after giving medication (see also Discomfort/Pain Assessment, p. 264). Monitor the patient's vital signs for hypotension and hypoventilation after giving opioid drugs. Chart 16-7 lists more information about analgesics used after surgery.

Chart 16-7 Common Examples of Drug Therapy

Management of Postoperative Pain

DRUG	USUAL DOSAGE	NURSING INTERVENTIONS	RATIONALES
Morphine sulfate (Epimorph, Statex)	2-15 mg IM or IV incrementally	Monitor respiratory status.	Respiratory depression can be severe and require medical intervention.
	10-30 mg orally every 4 hr	Monitor blood pressure. Assess for GI motility and urine output.	Hypotension, constipation, and urinary retention can occur.
Hydromorphone hydrochloride (Dilaudid)	1-4 mg IV or IM every 3-4 hr 2-4 mg orally every 3-4 hr	Monitor respirations. Monitor blood pressure. Monitor for food intolerance. Monitor fluid and electrolyte balance. Assess GI motility.	Respiratory depression, hypotension, anorexia, nausea, vomiting, and constipation can occur.
Codeine sulfate, codeine phosphate (Paveral)	15-60 mg IM or orally every 4 hr	Monitor respiratory status. Monitor for food intolerance. Monitor fluid and electrolyte balance.	Respiratory depression, nausea, and vomiting can occur.
		Assess GI motility.	Constipation is common; prophylactic interventions may be indicated.
Butorphanol tartrate (Stadol)	1-4 mg IM every 3-4 hr 0.5-2 mg IV	Monitor neurologic status and changes in level of consciousness. Monitor respiratory status.	Butorphanol can cause increased intracranial pressure and respiratory depression.
Oxycodone hydrochloride and aspirin (Percodan, Endodan, Oxycodan)	1-2 tablets (5-10 mg) orally every 3-4 hr	Assess GI tolerance of medication. Assess for GI bleeding. Monitor GI motility.	The aspirin component can irritate the stomach and could cause GI bleeding.
		Monitor coagulation studies (PT, aPTT).	Bleeding times and other coagulation study results may be increased because of the aspirin component.
		Monitor respiratory status.	Respiratory depression and constipation can be caused by the oxycodone component.
Oxycodone hydrochloride and acetaminophen (Tylox, Percocet, Endocet, Oxycocet)	1-2 tablets (5-10 mg) orally every 3-4 hr	Monitor blood pressure and respiratory status. Assess for GI motility.	Respiratory depression, hypotension, and constipation can occur.
Ketorolac tromethamine (Toradol)	15-60 mg IM or IV every 6 hr	Monitor for GI bleeding.	GI bleeding, ulceration, and perforation can occur.
		Monitor for kidney effects, especially in older adults.	Decreased urine output, increased serum creatinine, hematuria, and proteinuria can occur. Ketorolac is cleared more slowly in older adults. Older persons are more sensitive to the kidney effects of NSAIDs.
Ibuprofen (Motrin, Amersol, Novoprofen)	300-800 mg orally every 4-6 hr	Monitor upper GI tolerance of medication. Give with food or milk.	Food or milk helps decrease irritation of the stomach.
		Monitor coagulation studies (PT, aPTT). Assess for signs of bleeding or delayed clotting.	Bleeding times and other coagulation study results may be increased. Monitoring leads to early detection of complications.

aPTT, Activated partial thromboplastin time; *GI,* gastrointestinal; *NSAID,* nonsteroidal anti-inflammatory drug; *PT,* prothrombin time.

Patient-controlled analgesia (PCA) by IV infusion or internal pump (the catheter is sutured into or near the surgical area) and epidural analgesia are often used for better pain control. In PCA, the patient adjusts the dosage of the analgesic based on the pain level and response to the drug. This method allows more consistent pain relief and more control by the patient. The maximum dose per hour is "locked in" to the pump so that the patient cannot accidentally overdose. Common drugs used in PCA include morphine and hydromorphone.

Epidural analgesia can be given intermittently by the anesthesia provider or by continuous infusion through an epidural catheter left in

place after epidural anesthesia. Drugs given by epidural catheter include the opioids *fentanyl (Sublimaze), preservative-free morphine (Duramorph),* and *bupivacaine (Marcaine).*

Take care not to overmedicate or undermedicate, especially with older patients. In assessing for overmedication, monitor vital signs, especially blood pressure and respiratory rate, and level of consciousness. Complications from the use of opioid analgesics include respiratory depression, hypotension, nausea, vomiting, and constipation. An opioid antagonist, such as naloxone (Narcan), may be needed to reverse the acute effects of opioid depression. Because of the short effect of the opioid antagonist, monitor the patient's blood pressure and respirations every 15 to 30 minutes until the full effect of the opioid analgesic has passed. You may need to give more doses of the antagonist during this time because it is eliminated from the body more quickly than is the opioid. (See Chart 16-8 for more information on using opioid antagonists to reverse opioid overdose.) In addition, the patient has breakthrough pain after the opioid antagonist is given, so other interventions to promote comfort are needed.

Chart 16-8 Best Practice for Patient Safety & Quality Care QSEN

Emergency Care of the Patient Experiencing an Opioid Overdose

- Prepare to administer naloxone hydrochloride (Narcan)* in a dose of 1 to 2 mg IV.
- Repeat naloxone every 2 to 3 minutes up to 10 mg, as needed, depending on the patient's response.
- Maintain an open airway.
- Give oxygen if hypoxia is present or if respirations are below 10 breaths per minute.
- Have suction equipment available because naloxone can trigger vomiting and a drowsy patient is at risk for aspiration.
- Continuously monitor vital signs and level of consciousness for reversal of overdose.
- Do not leave the patient until he or she is fully responsive.
- Assess the patient for pain because reversal of the opioid overdose also reverses the analgesic effects.
- Continue to monitor the patient's vital signs and level of consciousness every 10 to 15 minutes for the first hour. Naloxone is eliminated from

the body more quickly than is the opioid, and it may induce side effects, including blood pressure changes, tachycardia, and dysrhythmias.

- Determine the need for additional antagonist therapy 1 hour after the patient initially becomes fully responsive.

*There are other opioid antagonists; however, naloxone hydrochloride is used most often to manage adult opioid overdose in the postoperative period.

Assess for undermedication by asking the patient about degree of pain relief and observing for other cues of discomfort (e.g., restlessness, increased confusion, "picking" at bedcovers). Offer prescribed drug(s) after checking for hypotension and respiratory depression.

As recovery progresses, reduce the doses and frequency of drugs for pain control. Drugs are changed from injectable or PCA to oral as soon as the patient can tolerate oral agents. Non-opioid analgesics, such as acetaminophen (Tylenol, Atasol), and NSAIDs, such as ibuprofen (Motrin, Novo-Profen) and ketorolac (Toradol), are used alone or with an opioid analgesic. Antianxiety drugs may be given with an opioid analgesic to decrease pain-related anxiety, reduce muscle tension, and control nausea.

Nursing Safety Priority QSEN

Drug Alert

Do not confuse Toradol with Tramadol (a drug used for central analgesia).

Complementary and Alternative Therapies.

Provide other comfort measures that may lower the amount of drugs needed to control pain. These measures, such as positioning, massage, relaxation, and diversion, reduce anxiety and allow the patient to relax and rest.

In positioning the patient, consider the position during surgery, the location of the surgical incision and drains, and problems such as arthritis and chronic lung disease. Assist the patient to a position of comfort. Support the extremities with pillows. Turn or help the patient turn at least every 2 hours while he or she is bedridden to prevent complications of immobility.

Nursing Safety Priority QSEN

Action Alert

Unless the surgeon prescribes pillow support, place no pillows under the knees, and do not raise the knee gatch, because this position could restrict circulation and increase the risk for venous thromboembolism.

Based on the surgeon's prescription and your assessment of the patient's tolerance, urge the patient to increase activity progressively to prevent complications. When he or she is first allowed out of bed, assist the patient to the side of the bed and into a chair. Teach him or her to splint the surgical wound for support and comfort during the transfer.

Use gentle massage on stiff joints or a sore back to decrease discomfort. Assist the patient to a side-lying position, and apply lotion with smooth, gentle strokes to increase blood flow to the area and promote relaxation. *Do not massage the calves because of the risk for loosening a clot and causing a life-threatening pulmonary embolus.*

Relaxation and diversion are also used to control acute episodes of pain during dressing changes and injections. (See Chapter 3 for how to instruct and guide the patient through these pain control methods.) Music and noise reduction may help decrease awareness of discomfort. Chart 16-9 lists other interventions that may help reduce pain and promote comfort.

Chart 16-9 Best Practice for Patient Safety & Quality Care QSEN

Nonpharmacologic Interventions to Reduce Postoperative Pain and Promote Comfort

- Control or remove noxious stimuli.
- Cushion and elevate painful areas; avoid tension or pressure on those areas.
- Provide adequate rest to increase pain tolerance.
- Encourage the patient's participation in diversional activities.
- Instruct the patient in relaxation techniques; use audio recordings or CDs and breathing exercises.
- Provide opportunities for meditation.
- Help the patient stimulate sensory nerve endings near the painful areas to inhibit ascending pain impulses.

- Use ice to reduce and prevent swelling, as indicated.
- Find a general position of comfort for the patient.
- Help the patient stimulate the area contralateral (opposite) to the painful area.

NCLEX Examination Challenge

Psychosocial Integrity

The nurse is about to give the prescribed pain medication to a client 30 minutes before a scheduled dressing change. The client states that the drug makes him feel sick and he would rather "tough it out." What is the nurse's best first response?

A "Tell me more about the sick feeling."
B "That's fine. You have the right to refuse any drug."
C "Your surgeon would not have prescribed the drug if it wasn't needed."
D "Remember that the pain of the dressing change would be worse than feeling sick."

Community-Based Care

Many patients are discharged after a brief hospital stay or directly from the PACU to home. Because of the shortened length of hospital stays, discharge planning, teaching, and referral begin before surgery and continue after surgery.

Home Care Management.

If the patient is discharged directly to home, assess information about the home environment for safety, patient accessibility, cleanliness, and availability of caregivers. Use the data obtained on admission before surgery to determine the patient's needs. For example, if the patient is unable or not allowed to climb stairs and lives in a two-story house with only one bathroom, advise the patient to rent a bedside commode. Collaborate with the social worker or discharge planner to identify needs related to care after surgery, including meal preparation, dressing changes, drain management, drug administration, equipment rental, physical therapy, and personal hygiene. A referral to a home care nursing agency may be indicated.

The patient is usually concerned about complications, pain, changes in the usual activity level, or payment of the hospital bill. The more extensive the surgical procedure is, the more fearful the patient is of assuming self-care. Support the patient and family members as they

make discharge plans. The patient with visible scars after surgery may need more emotional support from and acceptance by his or her family. The patient may be angry about the surgical outcome or about role changes. He or she may be concerned about financial matters and work. The surgical outcome may not have met the patient's expectations, and further interventions may be needed to assist in resolving his or her feelings. Ensure that referrals are made for additional counseling as indicated.

Self-Management Education.

The teaching plan for the patient and family after surgery includes:

- Prevention of infection
- Care and assessment of the surgical wound
- Management of drains or catheters
- Nutrition therapy
- Pain management
- Drug therapy
- Progressive increase in activity

If dressing changes and drain or catheter care are needed, instruct the patient and family members on the importance of proper handwashing to prevent infection. Explain and demonstrate wound care to the patient and family, who then perform a return demonstration. During teaching sessions, evaluate learning and promote adherence after discharge. At the same time, teach about the manifestations of complications such as wound infection. Also instruct the patient and family about what to do if complications occur.

A diet high in protein, calories, and vitamin C promotes wound healing. Supplemental vitamin C, iron, zinc, and other vitamins are often prescribed after surgery to aid in wound healing and red blood cell formation. Instruct the patient who needs dietary restrictions about the importance of following the prescribed diet while recovering from surgery. Encourage the older adult or debilitated patient to continue using dietary supplements, if prescribed, between meals until the wound is completely healed and the energy levels are restored.

Teach the patient about drugs for pain, especially about the proper dosage and frequency. Instruct the patient to notify the surgeon if pain is not controlled or if the pain suddenly increases. If antibiotics or other drugs are prescribed, stress the importance of completing the entire prescription.

Surgery stresses the body, and time and rest are needed for healing. Teach the patient to increase activity level slowly, rest often, and avoid

straining the wound or the surrounding area. The surgeon decides when the patient may climb stairs, return to work, drive, and resume other usual activities, such as sexual intercourse. The amount of weight that the patient can lift safely after surgery is specifically defined by the surgeon (i.e., in pounds or kilograms). Remind patients of the weights of grocery bags, women's handbags, and common items in the home.

Instruct the patient in the use of proper body mechanics. A patient whose work involves a moderate amount of physical labor may return to work about 6 weeks after abdominal surgery. Stress the importance of adherence to prevent complications or disability. A referral for a home care nurse may be needed for follow-up.

Nursing Safety Priority QSEN

Action Alert

Always ensure that the patient and family receive written discharge instructions to follow at home. Assess the patient's and family's understanding of the instructions by having them explain the instructions in their own words.

Health Care Resources.

After returning home, the patient may need supplies or equipment and assistance with dressing changes, ADLs, and meal preparation. Referral to a home care agency is made if needed. Home care may be paid for by third-party insurance payers, including Medicare, if the patient is homebound and requires skilled care such as dressing changes or physical therapy. The home care nurse provides skilled nursing assessments, dressing supplies, education in self-care, and referrals for services as needed. Such referrals include Meals on Wheels, support groups, and homemaker services (e.g., for housekeeping, food shopping).

Evaluation: Outcomes

Evaluate the care of the patient after surgery based on the identified priority patient problems. The expected outcomes include that the patient:

- Attains and maintains adequate lung expansion and respiratory function
- Has complete wound healing without complications
- Has acceptable comfort levels after surgery

Specific indicators for these outcomes are listed for each priority

patient problem in the Planning and Implementation section (see earlier).

Nursing Concepts and Clinical Judgment Review

What might you NOTICE in a patient after surgery who has a surgical wound infection?

- Elevated body temperature
- Heart rate elevated above the patient's baseline
- Sweating and chills present
- Wound edges are red for 1 cm or more on each side of the wound
- Incision line is swollen, and skin adjacent to the incision is warmer to the touch than is the skin further away from the incision
- Purulent drainage is present
- An odor may emanate from the incision
- An open area or areas may be present within the incision

What should you INTERPRET and how should you RESPOND to a patient who has a wound infection after surgery?

Perform and interpret physical assessment, including:

- Assessing vital signs with temperature at least every 4 hours
- Assessing for increase in pain perception
- Assessing cognition
- Assessing the wound for pain, size, open areas, and drainage
- Assessing the skin immediately surrounding the wound for redness and swelling
- Assessing serial white blood cell counts with differential for changes, including elevations above normal, decreases below normal, and presence of a “left shift”

Respond by:

- Documenting wound features
- Notifying the surgeon or health care provider
- Cleansing the wound (obtaining cultures, if within agency policy)
- Maintaining or starting IV line
- Administering prescribed drug therapy
- Monitoring laboratory test results to determine therapy effectiveness
- Continuing to assess for changes in the patient's condition, especially indications of infection in any other body area.

On what should you REFLECT?

- Identify the patient's personal factors that could have contributed to the wound infection.
- Think about what steps could be taken to identify the problem earlier.

Get Ready for the NCLEX® Examination!

Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Examine individual patient factors for potential threats to safety, especially risk for surgical site infection, hypoventilation, and venous thromboembolism. **Safety** QSEN
- Use aseptic technique during all dressing changes. **Safety** QSEN
- Use established criteria to determine when a patient is ready to leave the postanesthesia care unit (PACU) for discharge to home or a medical-surgical nursing unit.
- Keep suction equipment, oxygen, and artificial breathing equipment near the patient in the PACU. **Safety** QSEN

Health Promotion and Maintenance

- Reinforce to the patient and family after surgery the specific interventions to use to prevent complications (incision splinting, deep-breathing exercises, range-of-motion exercises—as described in Charts 14-5 and 14-6 in Chapter 14).
- Encourage early ambulation.
- Stress the need for following the activity restrictions prescribed by the surgeon.
- Teach the patient and family about any drugs to be continued after discharge from the facility. **Patient-Centered Care** QSEN
- Instruct the patient and family about the clinical manifestations of complications and when to seek assistance. **Patient-Centered Care** QSEN

Psychosocial Integrity

- Keep family members informed of the patient's progress during the time that he or she is in the postanesthesia recovery area.
- Reassure patients and family members that taking pain medication when needed, even opioids, does not make them drug abusers. **Patient-Centered Care** QSEN

Physiological Integrity

- Begin every assessment of the patient after surgery by checking the

airway and breathing effectiveness. **Safety** QSEN

- Assess the incision site each shift (on the medical-surgical nursing unit).
- Offer alternative therapies for relaxation, pain reduction, and distraction, such as massage, music therapy, and guided imagery.
- In the event of wound dehiscence or evisceration, have the patient lie flat (supine) with knees bent to reduce intra-abdominal pressure; apply sterile, nonadherent dressing materials to the wound; and follow the steps outlined in Chart 16-6. **Evidence-Based Practice** QSEN

UNIT V

Problems of Protection: Management of Patients with Problems of the Immune System

OUTLINE

Concept Overview: Protection

The human need for protection is provided through the actions of the concepts of inflammation and immunity (Giddens, 2013). The body works best when the internal environment is kept separate from the external environment. This is especially important for substances and organisms that could harm body cells, tissues, and organs. Normal protection is provided by three types of defenses—similar to how people living in a castle are protected against invaders (Fig. 1).

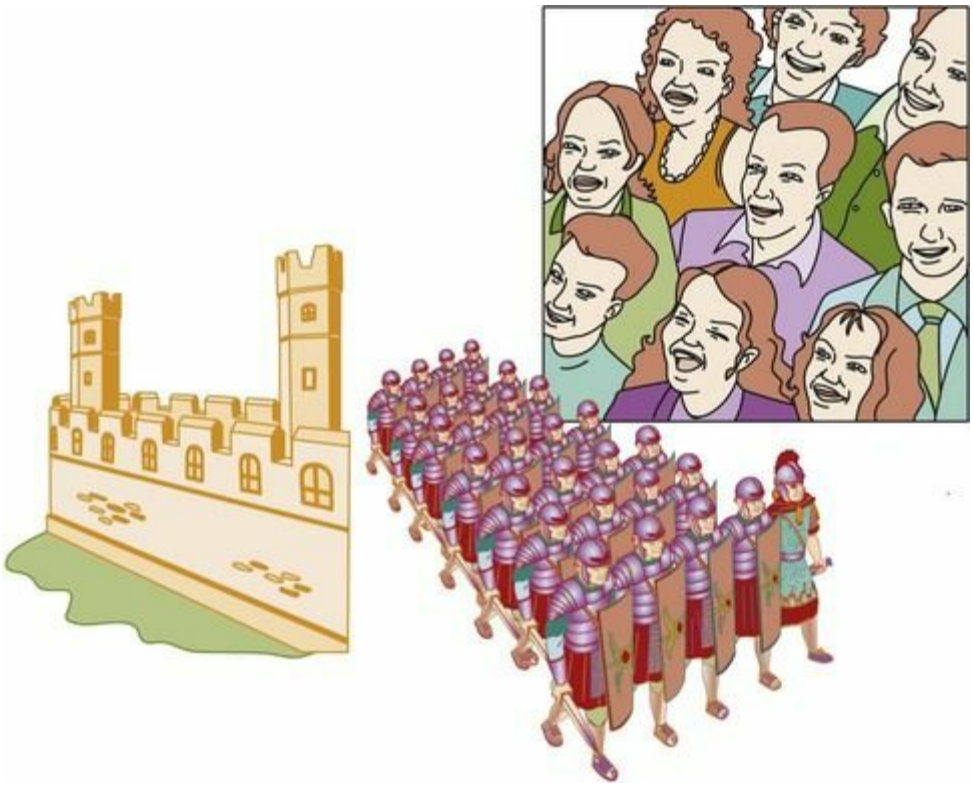

FIG. 1 Three levels of protection (moat, castle wall, knights and soldiers) for people.

The first defense is the moat surrounding the castle walls. Although the moat seldom kills invaders directly, it at least slows them down and sometimes repels them. The human "moat" is the normal flora on the surface of the skin and mucous membranes, sometimes referred to as types of general or innate immunity. This normal flora is made up of bacteria and other organisms that belong on the skin, live peacefully with the human host, and help repel more harmful microorganisms. When the normal flora is changed as a result of some types of drug therapy, procedures, diseases, excessive dryness, and normal aging, this small protection is damaged or lost.

The second defense is the castle wall and the "watchers" and alarm systems embedded within it. When it is tall, thick, and intact and when the watchers and alarms are working, penetration of the castle by invaders is greatly reduced. In humans, this type of protection is provided by intact skin and mucous membranes, which are also part of innate immunity. These structures are a formidable barrier to invaders and help prevent dangerous changes in the internal environment. However, the castle walls do suffer some damage over time and must be repaired and maintained to provide continuing protection.

The last and strongest defense consists of the knights and soldiers within the castle. These individuals have the skills to capture or kill invaders. Some of these skills are common to all the knights and soldiers,

and others are unique to different groups. In humans, the white blood cells (leukocytes) and the substances they produce serve as knights and soldiers, which provide the responses of inflammation and immunity. In addition to the work related directly to the invaders, this defense helps repair and maintain the castle walls. It is important to remember that this level of protection relies on the alarms of the castle wall and its physical barrier to recognize invaders and trigger the protective responses of the knights and soldiers.

Protection occurs best when all three defenses are intact and are working at their highest functional levels. These defenses of inflammation and immunity begin at birth and are at the maximum function in early to middle adulthood. The defenses decline slowly over time, making an older adult at greater risk for illnesses related to invasion and a decreased ability to repair damage. External factors and health status can reduce the ability of inflammation and immunity to provide complete protection. Specific nursing strategies can help reduce risk and protect the person whose defenses are less than perfect.

CHAPTER 17

Inflammation and Immunity

M. Linda Workman

PRIORITY CONCEPTS

- Inflammation
- Immunity

Learning Outcomes

Physiological Integrity

1. Describe the concept of self-tolerance.
2. Explain the differences between inflammation and immunity in terms of cells, functions, and features.
3. Discuss the influences of the aging process on inflammation and immunity and how these changes increase health risks for older adults.
4. Interpret laboratory data to assess a patient's immune status and risk for infection.
5. Differentiate the protection provided by active immunity, passive immunity, and cell-mediated immunity.
6. Describe the expected immune system responses to the presence of transplanted organs and the need for drug therapy to prevent transplant rejection.

http://evolve.elsevier.com/Iggy/

The immune system involves the concepts of both inflammation and immunity to work with other defenses in providing *protection* from harmful microorganisms and cells. As indicated in the Concept Overview defining the issue of *protection* using the concepts of inflammation and

immunity, the cells and cell products of inflammation and immunity are represented mostly by the knights and soldiers behind the castle walls. The products made by cells (e.g., cytokines, growth factors, antibodies) are the weapons of the knights and soldiers. Some of these cells serve as watchers and alarm systems within the castle walls (skin and mucous membranes) and help repair these walls when damage occurs.

Although infectious diseases are common, most people are healthy more often than they are ill. Inflammation and immunity are the major defenses that protect against disease when the body is invaded by organisms. These same defenses also help the body recover after tissue damage. Thus inflammation and immunity are critical to maintaining health and preventing disease. When all the different parts and functions of inflammation and immunity are working well, the person is **immunocompetent** and has maximum protection against infection.

Immunity is reduced by many diseases, injuries, and medical therapies. *Whether immunity is reduced temporarily or permanently, it always endangers the patient's health.* Chapter 19 discusses inadequate immunity and inflammatory responses. Other problems occur when immunity and inflammation are excessive or occur at inappropriate times. Chapters 18 and 20 discuss issues related to excess or inappropriate inflammatory or immune responses.

Overview

Immunity is composed of many cell functions that protect against the effects of injury or invasion. People interact with many other large and small living organisms (bacteria, viruses, molds, spores, pollens, protozoa, and cells from other people or animals). As long as organisms do not enter the body, they pose no health threat. Body defenses to prevent organisms from entering include intact skin and mucous membranes, skin surface normal flora, and natural chemicals that inhibit bacterial growth. These defenses are not perfect, and invasion can occur. However, most invasions do not result in disease or illness because of proper immunity.

The purpose of inflammation and immunity is to provide *protection* by neutralizing, eliminating, or destroying organisms that invade the body. To protect without harming the body, immune system cells exert these actions only against non-self proteins and cells. Immune system cells can distinguish between the body's own healthy self cells and non-self proteins and cells.

Self Versus Non-Self

Non-self proteins and cells include infected body cells, cancer cells, cells from other people, and invading organisms. Recognizing self versus non-self, which is necessary to prevent healthy body cells from being destroyed along with the invaders, is called **self-tolerance.** The immune system cells are the only cells capable of determining self from non-self. Self-tolerance is possible because of the different proteins present on cell membranes.

Each cell is surrounded by a plasma membrane with different proteins protruding through the surface (Fig. 17-1). For example, in liver cells, many different protein types are present on the liver cell membranes. The amino acid sequence of each protein type differs from that of all other protein types. Some of these protein types are found only on human cells, because these protein types are specific markers for human tissues. Also, each person's cells have surface proteins that are specific to that person. These unique proteins would be identical only to the proteins of an identical sibling. These unique proteins, known as **human leukocyte antigens (HLAs)**, are found on the surface of all body cells of that person and serve as a "universal product code" for that person. One person's HLAs are recognized as "foreign," or non-self, by the immune system of another person. Because the cell-surface proteins are non-self to another person's immune system, they are **antigens,** which are

proteins capable of stimulating an immune response.

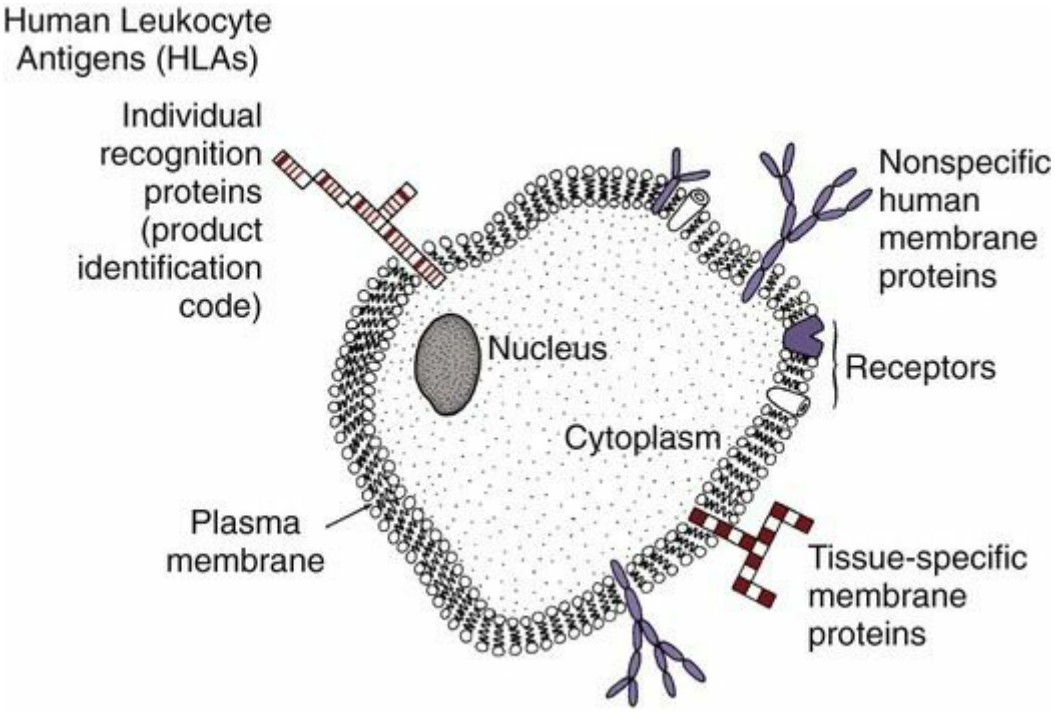

FIG. 17-1 Proteins on human cell plasma membranes.

Human leukocyte antigens are on the surfaces of most body cells—not just leukocytes. They are a normal part of the person and determine the *tissue type* of a person. Other names for these HLAs are *human histocompatibility antigens* and *class I antigens.*

There are many different human major HLAs that are determined by a set of genes called the *major histocompatibility complex (MHC).* However, each human expresses only six of the major HLAs. The specific antigens that any person has (of a large number of possible antigens) are determined by which MHC gene alleles were inherited from his or her parents.

The HLAs are key for recognition and self-tolerance. The immune system cells constantly come into contact with other body cells and with any invader that enters the body. At each encounter, the immune system cells compare the surface protein HLAs to determine whether the encountered cell belongs in the body (Fig. 17-2). If the encountered cell's HLAs perfectly match the HLAs of the immune system cell, the encountered cell is "self" and is not attacked. If the encountered cell's HLAs do not perfectly match the HLAs of the immune system cell, the encountered cell is non-self, or foreign. The immune system cell then takes action to neutralize, destroy, or eliminate this foreign invader.

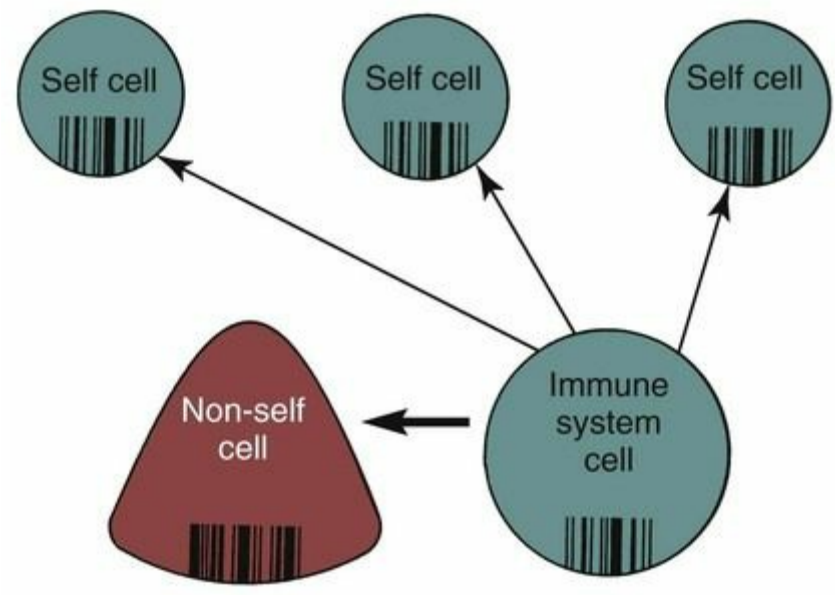

FIG. 17-2 Determination by immune system cell of self versus non-self cells.

Immunity changes during a person's life as a result of nutrition status, environmental conditions, drugs, disease, and age. Immunity is most efficient when people are in their 20s and 30s and slowly declines with increasing age (Touhy & Jett, 2014). Older adults have decreased immune function, increasing their risk for many health problems (Chart 17-1).

Chart 17-1 Nursing Focus on the Older Adult

Changes in Immune Function Related to Aging

IMMUNE COMPONENT	FUNCTIONAL CHANGE	NURSING IMPLICATIONS
Inflammation	Reduced neutrophil function.	Neutrophil counts may be normal, but activity is reduced, increasing the risk for infection.
	Leukocytosis does not occur during acute infection.	Patients may have an infection but not show expected changes in white blood cell counts.
	Older adults may not have a fever during inflammatory or infectious episodes.	Not only is there potential loss of protection through inflammation, but also minor infections may be overlooked until the patient becomes severely infected or septic.
Antibody-mediated immunity	The total number of colony-forming B-lymphocytes and the ability of these cells to mature into antibody-secreting cells are diminished.	Older adults are less able to make new antibodies in response to the presence of new antigens. Thus they should receive immunizations, such as "flu shots," the pneumococcal vaccination, and the shingles vaccination.
	There is a decline in natural antibodies, decreased response to antigens, and reduction in the amount of time the antibody response is maintained.	Older adults may not have sufficient antibodies present to provide protection when they are re-exposed to microorganisms against which they have already generated antibodies. Thus older patients need to avoid people with viral infections and need to receive "booster" shots for old vaccinations and immunizations, especially tetanus and pertussis (whooping cough).
Cell-mediated immunity	The number of circulating T-lymphocytes decreases.	Skin tests for tuberculosis may be falsely negative.
		Older patients are more at risk for bacterial and fungal infections, especially on the skin and mucous membranes, in the respiratory tract, and in the genitourinary tract.

Organization of the Immune System

The immune system is present throughout the body and is influenced by the nervous system, the endocrine system, and the GI system. Most

immune system cells come from the bone marrow. Some cells mature in the bone marrow; others leave the bone marrow and mature in different body sites. When mature, many immune system cells are released into the blood, where they circulate to most body areas and have specific effects.

The bone marrow is the source of all blood cells, including most immune system cells. The bone marrow produces immature, undifferentiated cells called **stem cells.** Stem cells are **pluripotent,** meaning that each cell has more than one potential outcome. When the stem cell is first generated in the bone marrow, it is undifferentiated, not yet committed to maturing into a specific blood cell type. This stem cell is flexible (pluripotent) and could become any one of many mature blood cells. Fig. 17-3 shows the possible outcomes for maturation of stem cells. The type of mature cell that the stem cell becomes depends on which pathway it follows.

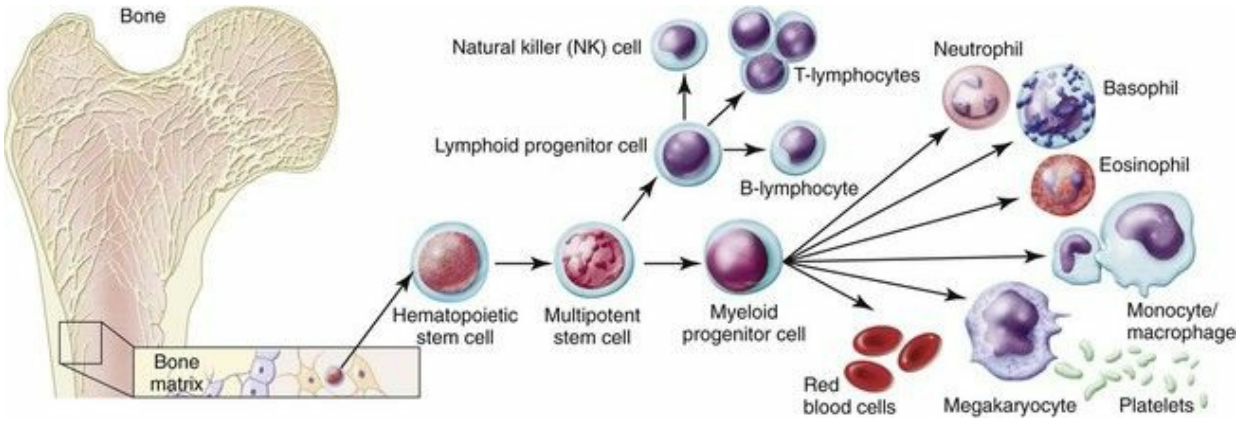

FIG. 17-3 Stem cell differentiation and maturation.

The maturational pathway of any stem cell depends on body needs and on the presence of specific growth factors that direct the cell to a pathway. For example, erythropoietin is a growth factor for red blood cells **(erythrocytes [RBCs]).** When immature stem cells are exposed to erythropoietin, they commit to the erythrocyte pathway and eventually become mature RBCs.

White blood cells **(leukocytes [WBCs])** protect the body from the effects of invasion by organisms. These cells are the immune system cells, the knights and soldiers protecting the castle inhabitants after invaders get through the castle wall. Table 17-1 lists the functions of different immune system cells. The leukocytes provide protection through these defensive actions:

TABLE 17-1

Immune Functions of Specific Leukocytes

VARIABLE	LEUKOCYTE	FUNCTION
Inflammation	Neutrophil	Nonspecific ingestion and phagocytosis of microorganisms and foreign protein
	Macrophage	Nonspecific recognition of foreign proteins and microorganisms; ingestion and phagocytosis
	Monocyte	Destruction of bacteria and cellular debris; matures into macrophage
	Eosinophil	Releases vasoactive amines during allergic reactions to limit these reactions
	Basophil	Releases histamine and heparin in areas of tissue damage
Antibody-mediated immunity	B-lymphocyte	Becomes sensitized to foreign cells and proteins
	Plasma cell	Secretes immunoglobulins in response to the presence of a specific antigen
	Memory cell	Remains sensitized to a specific antigen and can secrete increased amounts of immunoglobulins specific to the antigen on re-exposure
Cell-mediated immunity	Helper/inducer T-cell	Enhances immune activity through secretion of various factors, cytokines, and lymphokines
	Cytotoxic/cytolytic T-cell	Selectively attacks and destroys non-self cells, including virally infected cells, grafts, and transplanted organs
	Natural killer cell	Nonselectively attacks non-self cells, especially body cells that have undergone mutation and become malignant; also attacks grafts and transplanted organs

- Recognition of self versus non-self
- Destruction of foreign invaders, cellular debris, and unhealthy or abnormal self cells
- Production of antibodies directed against invaders
- Complement activation
- Production of cytokines that stimulate increased formation of leukocytes in bone marrow and increase specific leukocyte activity

The three processes needed for human protection through immunity are (1) inflammation, (2) antibody-mediated immunity (AMI), and (3) cell-mediated immunity (CMI). Each process uses different defensive actions, and each influences or requires assistance from the other two processes (Fig. 17-4). *Therefore full immunity (immunocompetence) requires the function and interaction of all three processes.*

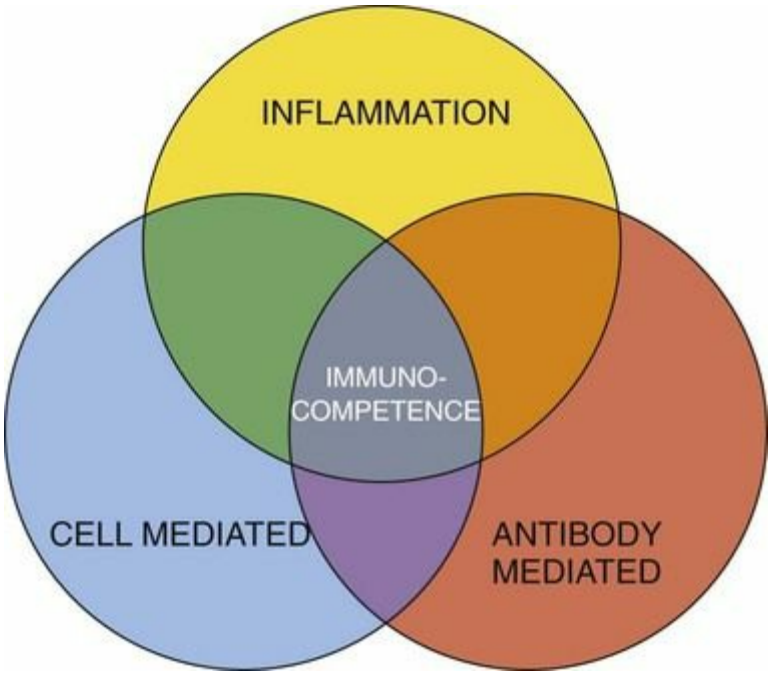

FIG. 17-4 The three divisions of immunity: inflammation, antibody-mediated immunity, and cell-mediated immunity. Optimal function of all three divisions is necessary for complete immunity.

Inflammation

Inflammation, also called *innate-native immunity* or *natural immunity,* provides immediate protection against the effects of tissue injury and invading foreign proteins. Innate-native immunity is any natural protective feature of a person. It can be a barrier to prevent organisms from entering the body or can be an attacking force that eliminates organisms that have already entered the body. This type of immunity cannot be transferred from one person to another and is not an adaptive response to exposure or invasion by foreign proteins.

The inflammatory responses are part of innate immunity. Other parts of innate immunity include skin, mucosa, antimicrobial chemicals on the skin, complement, and natural killer cells.

The ability to respond with inflammation is critical to health and well-being. Inflammation differs from AMI and CMI in two important ways:

- Inflammatory protection is immediate but short-term. It does not provide true immunity on repeated exposure to the same organisms.
- Inflammation is a *nonspecific* body defense to invasion or injury and can be started quickly by almost any event, regardless of where it occurs or what causes it.

So, inflammation triggered by a scald burn to the hand is the same as inflammation triggered by bacteria in the middle ear. How widespread the manifestations of inflammation are depends on the intensity, severity, and duration of exposure to the initiating event. For example, a splinter in the finger triggers inflammation only at the splinter site, whereas a burn injuring 50% of the skin leads to an inflammatory response involving the entire body.

Inflammation starts tissue actions that cause visible and uncomfortable manifestations that are important in ridding the body of harmful organisms. However, if the inflammatory response is excessive, tissue damage may result. Inflammation also helps start both antibody-mediated and cell-mediated actions to activate full immunity.

Infection

A confusing issue about inflammation is that this process occurs in response to tissue injury, as well as to infection by organisms. *Infection is usually accompanied by inflammation; however, inflammation can occur without infection.* Examples of inflammation without infection include joint sprain injuries, myocardial infarction, and blister formation. Examples of inflammation caused by noninfectious invasion include allergic rhinitis, contact dermatitis, and other allergic reactions. Inflammations from

infection include otitis media, appendicitis, and viral hepatitis, among many others. *Inflammation does not always mean that an infection is present.*

Cell Types Involved in Inflammation

The leukocytes (white blood cells [WBCs]) involved in inflammation are neutrophils, macrophages, eosinophils, and basophils. An additional cell type important in inflammation is the tissue mast cell. Neutrophils and macrophages destroy and eliminate foreign invaders. Basophils, eosinophils, and mast cells release chemicals that act on blood vessels to cause tissue-level responses that help neutrophil and macrophage actions.

Neutrophils

Mature neutrophils make up between 55% and 70% of the normal total WBC count. Neutrophils come from the stem cells and complete the maturation process in the bone marrow (Fig. 17-5). They are also called *granulocytes* because of the large number of granules present inside each cell. Other names for neutrophils are based on their appearance and maturity. Mature neutrophils are also called *segmented neutrophils* ("segs") or *polymorphonuclear cells* ("polys," PMNs) because of their segmented nucleus. Less mature neutrophils are called *band neutrophils* ("bands" or "stabs") because of their nuclear shape.

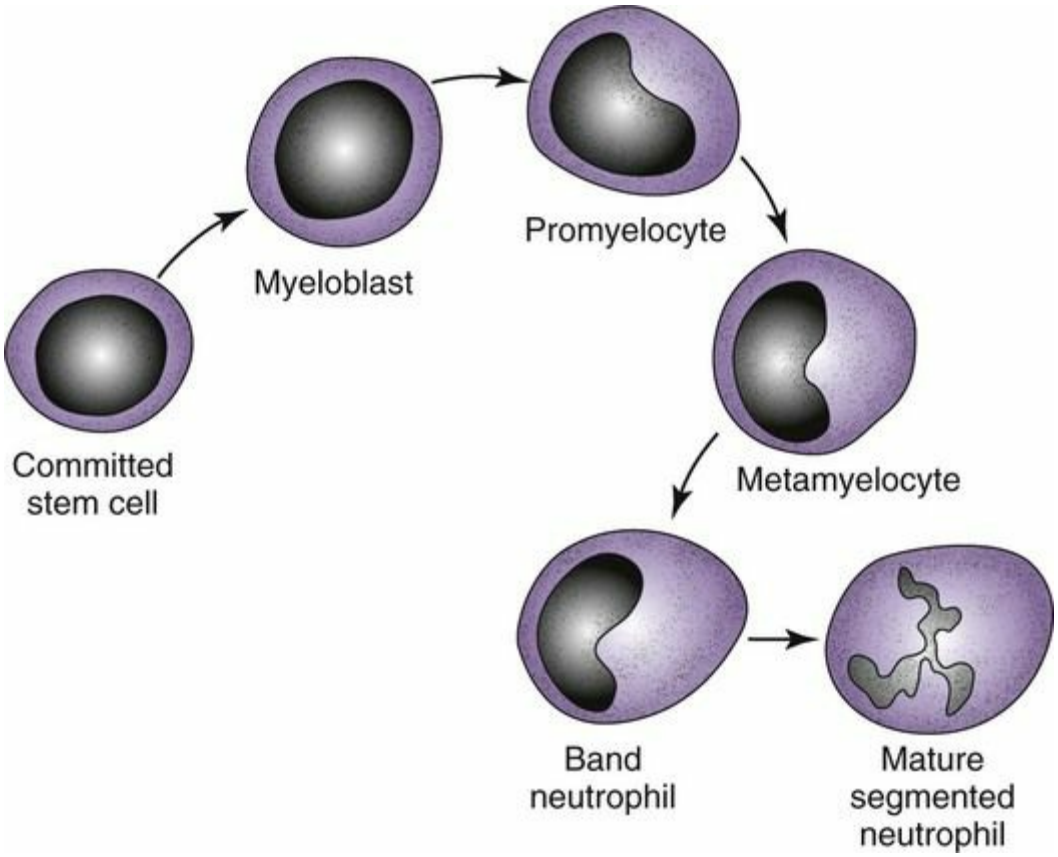

FIG. 17-5 Stem cell maturation into fully functional segmented neutrophils.

Usually, growth of a stem cell into a mature neutrophil requires 12 to 14 days. This time is shortened by the presence of specific growth factors (cytokines), such as granulocyte-macrophage colony-stimulating factor (GM-CSF) and granulocyte colony-stimulating factor (G-CSF). The purpose and action of cytokines are described on p. 286 in the Cytokines section.

In the healthy person with full immunity, more than 100 billion fresh, mature neutrophils are released from the bone marrow into the circulation daily. This huge production is needed because the life span of each neutrophil is short—about 12 to 18 hours.

Neutrophil function provides protection after invaders, especially bacteria, enter the body. This powerful army of small cells destroys invaders by phagocytosis and enzymatic digestion, although each cell is small and can take part in only one episode of phagocytosis.

Mature neutrophils are the only stage of this cell capable of phagocytosis. Because this cell type is responsible for continuous, instant, nonspecific protection against organisms, the percentage and actual number of mature circulating neutrophils are used to measure a patient's risk for infection: the higher the numbers, the greater the resistance to infection. This measurement is the **absolute neutrophil**

count (ANC), also called the *absolute granulocyte count* or *total granulocyte count.*

The differential of a normal white blood cell count shows the number and percent of the different types of circulating leukocytes (Table 17-2). Usually, most neutrophils released into the blood from the bone marrow are segmented neutrophils; only a small percentage are band neutrophils or other less mature forms. Some problems, such as sepsis, cause the neutrophils in the blood to change from being mostly segmented neutrophils to being less mature forms. This situation is termed a **left shift** or *bandemia* because the segmented neutrophil (at the far right of the neutrophil pathway in Fig. 17-5) is no longer the most numerous type of circulating neutrophils. Instead, more of the circulating cells are bands —the less mature cell type found farther left on the neutrophil pathway.

TABLE 17-2

Values of a White Blood Cell Differential for Peripheral Blood Representing a Normal Count

WBC TYPE	%	/MM³
Total WBC	**100**	**10,000**
Segs	62	6200
Bands	5	500
Monos	3	300
Lymphs	28	2800
Eosins	1.5	150
Basos	0.5	50

WBC, White blood cell.

A left shift indicates that the patient's bone marrow cannot produce enough mature neutrophils to keep pace with the continuing infection and is releasing immature neutrophils into the blood. These immature cells are of no benefit because they are not capable of phagocytosis.

Macrophages

Macrophages come from the committed myeloid stem cells in the bone marrow and form the mononuclear-phagocyte system. The stem cells first form monocytes, which are released into the blood at this stage. Until they mature, monocytes have limited activity. Most monocytes move from the blood into body tissues, where they mature into macrophages. Some macrophages become “fixed” in position within the tissues, whereas others can move within and between tissues.

Macrophages in various tissues have slightly different appearances and names (Table 17-3). The liver, spleen, and intestinal tract contain large numbers of these cells.

TABLE 17-3

Tissue Macrophages

TISSUE	MACROPHAGE
Lung	Alveolar macrophage
Connective tissue	Histiocyte
Brain	Microglial cell
Liver	Kupffer cell
Peritoneum	Peritoneal macrophage
Bone	Osteoclast
Joint	Synovial type A cell
Kidney	Mesangial cell

Macrophage function protects the body in several ways. These cells are important in immediate inflammatory responses and also stimulate the longer-lasting immune responses of antibody-mediated immunity (AMI) and cell-mediated immunity (CMI). Macrophage functions include phagocytosis, repair, antigen presenting/processing, and secretion of cytokines for immune system control.

The inflammatory function of macrophages is phagocytosis. Macrophages can easily distinguish between self and non-self, and their large size makes them very effective at trapping invading cells. They have long life spans and can take part in many phagocytic events.

Basophils

Basophils come from myeloid stem cells and make up only about 1% of the total circulating WBC count. These cells cause the manifestations of inflammation.

Basophil function acts on blood vessels with basophil chemicals (vasoactive amines), which include heparin, histamine, serotonin, kinins, and leukotrienes. Basophils have sites that bind the base portion of immunoglobulin E (IgE) molecules, which binds to and is activated by allergens. When allergens bind to the IgE on the basophil, the basophil membrane opens and releases the vasoactive amines into the blood, where most of them act on smooth muscle and blood vessel walls. Heparin inhibits blood and protein clotting. Histamine constricts small veins, inhibiting blood flow and decreasing venous return. This effect causes blood to collect in capillaries and arterioles. Kinins dilate

arterioles and increase capillary permeability. These actions cause blood plasma to leak into the interstitial space *(vascular leak syndrome).* Thus basophils stimulate both general inflammation and the inflammation of allergy and hypersensitivity reactions.

Eosinophils

Eosinophils come from the myeloid line and contain many vasoactive chemicals. Only 1% to 2% of the total WBC count normally is composed of eosinophils.

Eosinophil function is very active against infestations of parasitic larvae and also limits inflammatory reactions. The eosinophil granules contain many different substances. Some are enzymes that degrade the vasoactive chemicals released by other leukocytes. This is why the number of circulating eosinophils increases during an allergic response.

Tissue Mast Cells

Tissue mast cells look like and have functions very similar to basophils and eosinophils. Although mast cells do originate in the bone marrow, they come from a different parent cell than leukocytes and do not circulate as mature cells (Abbas et al., 2012). Instead, they differentiate and mature in tissues, especially those near blood vessels, nerves, lung tissue, skin, and mucous membranes. Like basophils, mast cells have binding sites for the base of IgE molecules and are involved in hypersensitivity reactions. Some mast cells also respond to the inflammatory products made and released by T-lymphocytes. The tissue mast cells have important roles in maintaining and prolonging inflammatory and hypersensitivity reactions.

Phagocytosis

A key process of inflammation is **phagocytosis,** the engulfing and destruction of invaders, which also rids the body of debris after tissue injury. Neutrophils and macrophages are most efficient at phagocytosis. Phagocytosis involves the seven steps shown in Fig. 17-6.

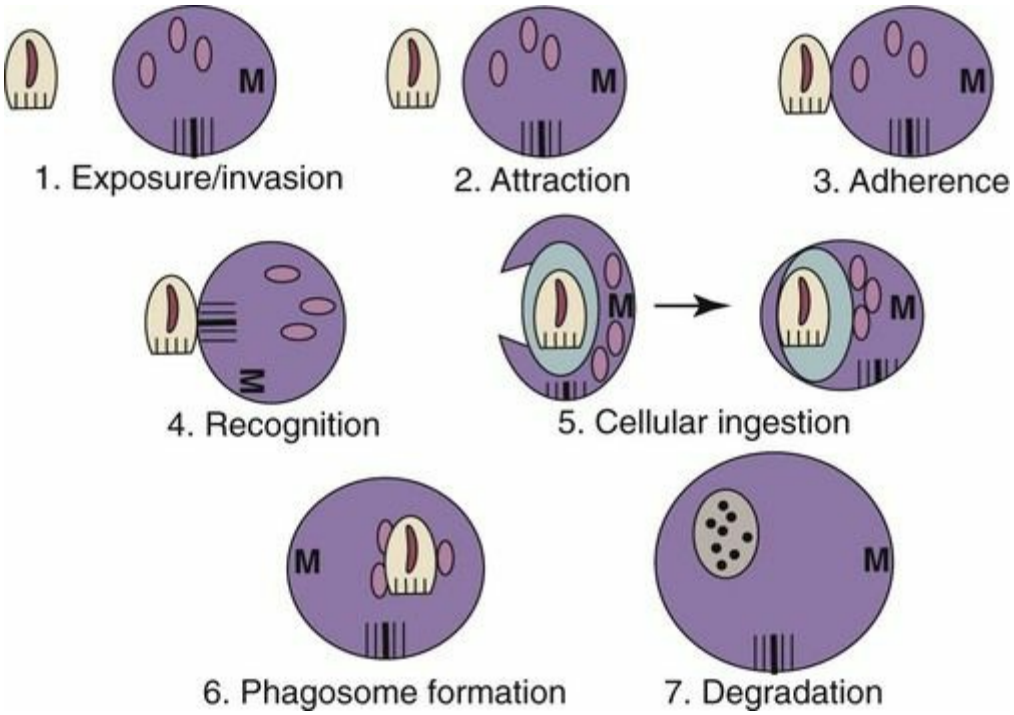

FIG. 17-6 Steps of phagocytosis. *M*, Macrophage.

Exposure and invasion occur as the first step in response to injury or invasion. Leukocytes that engage in phagocytosis and stimulate inflammation are present in the blood and other extracellular fluids. For phagocytosis to start, the body must first be invaded by organisms, foreign proteins, or debris from damaged tissues.

Attraction is needed as the second step because phagocytosis can occur only when the WBC comes into direct contact with the target (antigen, invader, or foreign protein). Damaged tissues secrete chemotaxins that attract neutrophils and macrophages and release debris that can combine with the surface of invading foreign proteins.

Adherence allows the phagocytic cell to bind to the surface of the target. *Opsonins* are substances that increase contact of the cell with its target by coating the target cell (antigen or organism). During inflammation, coating the target makes it easier for phagocytic cells to stick to it. Many substances can act as opsonins. Some are particles from dead neutrophils, antibodies, and activated (fixated) complement components.

Complement activation and fixation are part of opsonization and help with adherence. Twenty different inactive complement proteins are present in the blood. When stimulated, each complement protein is activated, joins other activated complement proteins, surrounds an antigen, and "fixes" or sticks to the antigen. Complement fixation occurs quickly as a cascade.

Recognition occurs when the phagocytic cell sticks to the target cell and "recognizes" it as non-self. The phagocytic cells examine the universal

product codes (human leukocyte antigens [HLAs]) of whatever they encounter. Recognition of non-self is made easier by opsonins on the target cell surface. Phagocytic cells start phagocytosis only when the target cell is recognized as non-self or debris.

Cellular ingestion is needed because phagocytic destruction occurs inside the cell. The target cell is brought inside the phagocytic cell by phagocytosis (engulfment).

Phagosome formation occurs when the phagocyte's granules break and release enzymes that attack the ingested target.

Degradation is the final step. The enzymes in the phagosome digest the engulfed target.

Sequence of Inflammation

Inflammation (inflammatory responses) occurs in a predictable three-stage sequence. The sequence is the same regardless of the triggering event. Responses at the tissue level cause the **five cardinal manifestations of inflammation:** warmth, redness, swelling, pain, and decreased function. The timing of the stages may overlap.

Stage I is the vascular part of the inflammatory response that first involves changes in blood vessels. Injured tissues and the leukocytes and tissue mast cells in this area secrete histamine, serotonin, and kinins that constrict the small veins and dilate the arterioles in the area of injury. These blood vessel changes cause redness and warmth of the tissues. This increased blood flow increases delivery of nutrients to injured tissues.

Blood flow to the area increases **(hyperemia),** and swelling **(edema)** forms at the site of injury or invasion. Capillary leak also occurs, allowing blood plasma to leak into the tissues. This response causes swelling and pain. Edema at the site of injury or invasion protects the area from further injury by creating a cushion of fluid. The duration of these responses depends on the severity of the initiating event, but usually they subside within 24 to 72 hours.

The macrophage is the major cell involved in stage I of inflammation. The action is rapid because macrophages are already in place at the site of injury or invasion. This action is limited because the number of macrophages is so small. To enhance the inflammatory response, the tissue macrophages secrete several cytokines. One cytokine is colony-stimulating factor (CSF), which triggers the bone marrow to shorten the time needed to produce white blood cells (WBCs) from 14 days to a matter of hours. Some cytokines cause neutrophils from the bone

marrow to move to the site of injury or invasion, which leads to the next stage of inflammation.

Stage II is the cellular exudate part of the response. In this stage, **neutrophilia** (an increased number of circulating neutrophils) occurs. Exudate in the form of pus occurs, containing dead WBCs, necrotic tissue, and fluids that escape from damaged cells.

The most active cells in stage II are the neutrophils, basophils, and tissue mast cells. Under the influence of cytokines, the neutrophil count can increase hugely within 12 hours after inflammation starts. Neutrophils attack and destroy organisms and remove dead tissue through phagocytosis. Basophils and tissue mast cells continue or sustain the initial responses.

In acute inflammation, the healthy person produces enough mature neutrophils to keep pace with invasion and prevent the organisms from growing. At the same time, the WBCs and inflamed tissues secrete cytokines, which allow tissue macrophages to increase and trigger bone marrow production of monocytes. This reaction begins slowly, but its effects are long lasting.

During this phase, the arachidonic acid cascade starts to increase the inflammatory response. This action begins by the conversion of fatty acids in plasma membranes into arachidonic acid (AA). The enzyme *cyclooxygenase* (COX) converts AA into many chemicals that are further processed into the substances (mediators) that promote the continued inflammatory response in the tissues. These mediators include histamine, leukotrienes, prostaglandins, serotonin, and kinins. Many anti-inflammatory drugs, including NSAIDs, stop this cascade by preventing cyclooxygenase from converting AA into inflammatory mediators.

When an infection stimulating inflammation lasts longer than just a few days, the bone marrow begins to release immature neutrophils, reducing the number of circulating mature neutrophils. This reduction of mature neutrophils limits the helpful effects of inflammation and increases the risk for sepsis.

Stage III features tissue repair and replacement. Although this stage is completed last, it begins at the time of injury and is critical to the final function of the inflamed area.

Some of the WBCs involved in inflammation start the replacement of lost tissues or repair of damaged tissues by inducing the remaining healthy cells to divide. In tissues that cannot divide, WBCs trigger new blood vessel growth and scar tissue formation. Because scar tissue does not act like the tissue it replaces, function is lost wherever scar tissue forms. The

degree of function lost depends on how much normal tissue is replaced by scar tissue. For example, when heart muscles are destroyed because of a myocardial infarction (heart attack), scar tissue forms in the area to prevent a hole from forming in the muscle wall as the ischemic cells die. (Remember that heart muscle is non-dividing tissue and the heart cannot replace these muscle cells.) The scar tissue serves only as a patch; it does not contract or act in any way like heart muscle. So, if 20% of the left ventricle is replaced with scar tissue, the effectiveness of left ventricular contraction is reduced by at least 20%.

Inflammation alone cannot provide immunity. Inflammatory cells must interact with lymphocytes to provide long-lasting immunity. Long-lasting immune actions develop through antibody-mediated immunity (AMI) and cell-mediated immunity (CMI).

NCLEX Examination Challenge

Safe and Effective Care Environment

The white blood cell count with differential of a client undergoing preadmission testing before surgery indicates a total count of 10,000 cells per cubic millimeter (mm^3) of blood. Which differential counts or percentages does the nurse report to the physician?

A Eosinophils 200/mm^3

B Monocytes 2000/mm^3

C Segmented neutrophils 5700/mm^3

D Lymphocytes 2100/mm^3

Immunity

Immunity is an *adaptive* internal protection that results in long-term resistance to the effects of invading microorganisms. This means that the responses are not automatic. The body has to learn to generate specific immune responses when it is infected by or exposed to specific organisms. Lymphocytes develop actions and products that provide the protection of true immunity. These cells develop specific actions in response to specific invasion (Fig. 17-7).

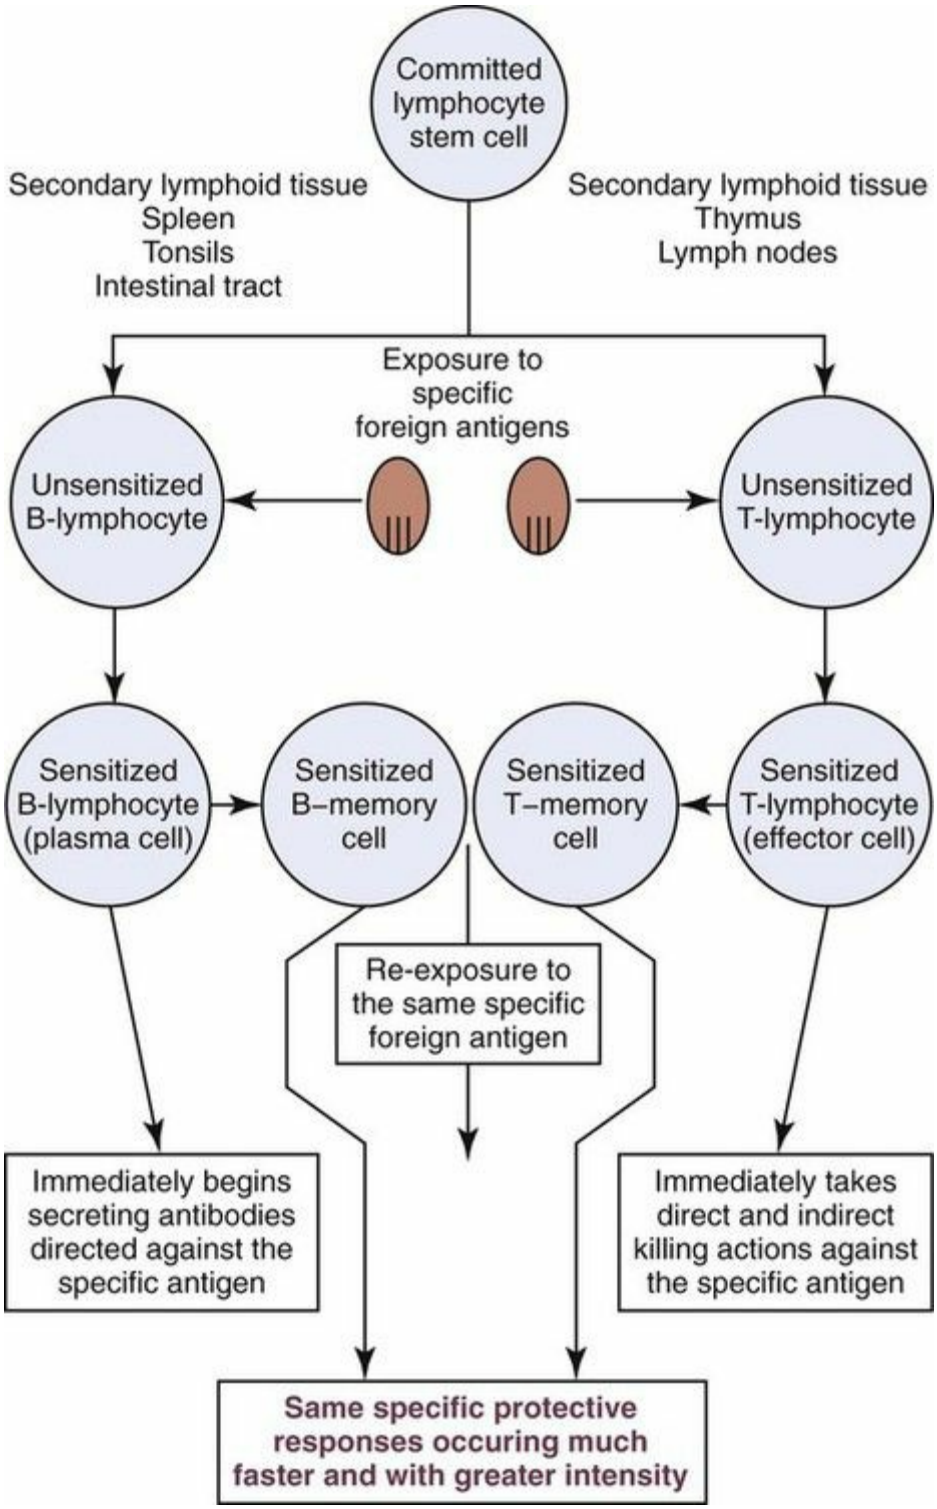

FIG. 17-7 B-lymphocyte and T-lymphocyte differentiation, maturation, and function.

Antibody-Mediated Immunity

Antibody-mediated immunity (AMI), also known as *humoral immunity,* involves antigen-antibody interactions to neutralize, eliminate, or destroy foreign proteins. Antibodies are produced by sensitized B-lymphocytes (B-cells).

B-cells become sensitized to a specific foreign protein (antigen) and produce antibodies directed specifically against that protein. The antibody, rather than the actual B-cell, then causes one of several actions to neutralize, eliminate, or destroy that antigen.

B-cells have the most direct role in AMI. Macrophages and T-lymphocytes (discussed on p. 285 in the Cell-Mediated Immunity section) work with B-cells to start and complete antigen-antibody interactions. *For optimal AMI, the entire immune system must function adequately.*

B-cells start as stem cells in the bone marrow, the primary lymphoid tissue, that commit to the lymphocyte pathway (see Fig. 17-3) and are then restricted in development. The lymphocyte stem cells are released from the bone marrow into the blood. They then migrate into many secondary lymphoid tissues to mature. The secondary lymphoid tissues for B-cell maturation are the spleen, parts of lymph nodes, tonsils, and the mucosa of the intestinal tract.

Antigen-Antibody Interactions

The body learns to make enough of any specific antibody to provide long-lasting immunity against specific organisms or toxins. The seven steps needed to produce a specific antibody directed against a specific antigen whenever the person is exposed to that antigen are shown in Fig. 17-8 and described below.

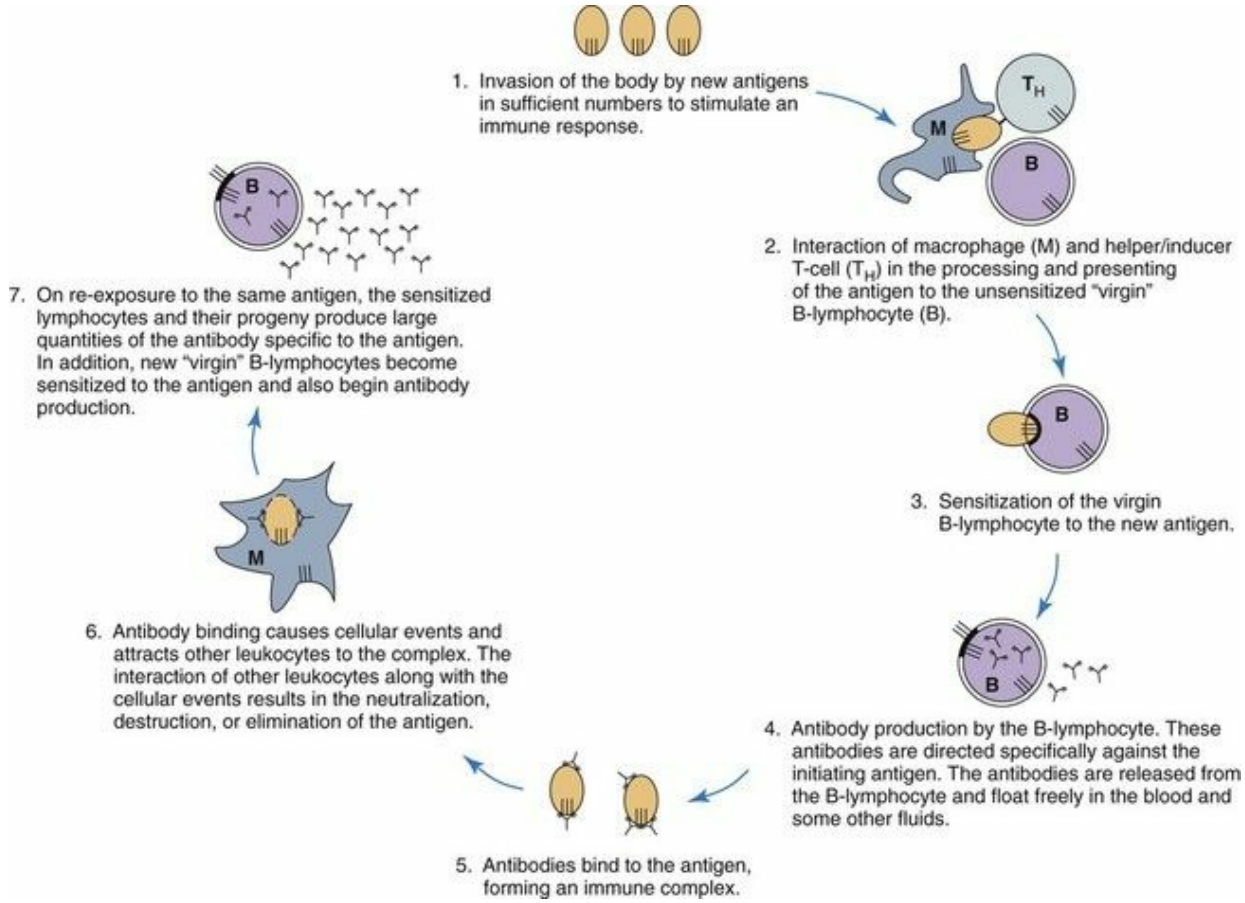

FIG. 17-8 Sequence of the seven steps required to stimulate antibody-mediated immunity.

Exposure or invasion is needed because antibody actions occur inside the body or on a few body surfaces. Thus the antigen must first enter the person to generate an antibody, although not all exposures result in antibody production. Invasion by the antigen must occur in such large numbers that some of the antigen evades detection by the body's natural nonspecific defenses or overwhelms the ability of the inflammatory response to get rid of the invader.

For example, a person who has never been exposed to the viral disease *influenza A* now baby-sits for three children who develop influenza symptoms within the next 10 hours. These children, in the pre-symptomatic stage, shed many millions of live influenza A virus particles by droplets from the upper respiratory tract. They expose the baby-sitter by drinking out of the baby-sitter's cup, kissing him or her directly on the lips, and sneezing and coughing directly into his or her face. During the 5 hours spent with the children, the baby-sitter is heavily invaded by the influenza A virus and will become sick with this disease within 2 to 4 days. While the virus is growing and the disease is developing, the baby-sitter's white blood cells are taking part in antibody-antigen actions to prevent him or her from having influenza A more than once.

Antigen recognition is the next step to begin making antibodies against an antigen. The unsensitized B-cell must first recognize the antigen as non-self. B-cells need the help of macrophages and helper/inducer T-cells to recognize an antigen.

Recognition is started by the macrophages. After the antigen surface has been altered by opsonization (see discussion of "adherence" on p. 280), the macrophage recognizes the invading antigen as non-self and attaches itself to the antigen. This attachment allows the macrophage to "present" the attached antigen to the helper/inducer T-cell. Then the helper/inducer T-cell and the macrophage together process the antigen to expose the antigen's recognition sites (universal product code). After processing the antigen, the helper/inducer T-cell brings the antigen into contact with the B-cell so that the B-cell can recognize the antigen as non-self.

Sensitization occurs when the B-cell recognizes the antigen as non-self and is now "sensitized" to this antigen. A single unsensitized B-cell can become sensitized only once. *So, each B-cell can be sensitized to only one type of antigen.*

Sensitizing allows this B-cell to respond to any substance that carries the same antigens (codes) as the original antigen. The sensitized B-cell always remains sensitized to that specific antigen. In addition, all cells produced by that sensitized B-cell also are already pre-sensitized to that same specific antigen.

Immediately after it is sensitized, the B-cell divides and forms two types of B-lymphocytes, each one remaining sensitized to that specific antigen (see Fig. 17-7). One new cell becomes a **plasma cell,** which starts immediately to produce antibodies against the sensitizing antigen. The other new cell becomes a memory cell. The **memory cell** is a sensitized B-cell but does not produce antibodies until the next exposure to the same antigen (see discussion of sustained immunity (memory) on p. 284).

Antibody production and release allow the antibodies to search out specific antigens. Antibodies are produced by plasma cells, and each plasma cell can make as many as 300 molecules of antibody per second. Each plasma cell produces antibody specific only to the antigen that originally sensitized the parent B-cell. For example, in the case of the baby-sitter who was invaded by the influenza A virus, the plasma cells from those B-cells sensitized to the influenza A virus can make only anti–influenza A antibodies. The antibody class (e.g., immunoglobulin G [IgG] or immunoglobulin M [IgM]) that the plasma cell produces may vary, but the antibody can be forever directed only against the influenza A virus.

Antibody molecules made by plasma cells are released into the blood

and other body fluids as free antibody. Because the antibody is in body fluids (or body "humors") and is separate from the B-cells, this type of immunity is sometimes called **humoral immunity.** *Circulating antibodies can be transferred from one person to another to provide the receiving person with immediate immunity of short duration.*

Antibody-antigen binding is needed for anti-antigen actions. Antibodies are Y-shaped molecules (Fig. 17-9). The tips of the short arms of the Y recognize the specific antigen and bind to it. Because each antibody molecule has two tips (Fab fragments, or arms), each antibody can bind either to two separate antigens or to two areas of the same antigen.

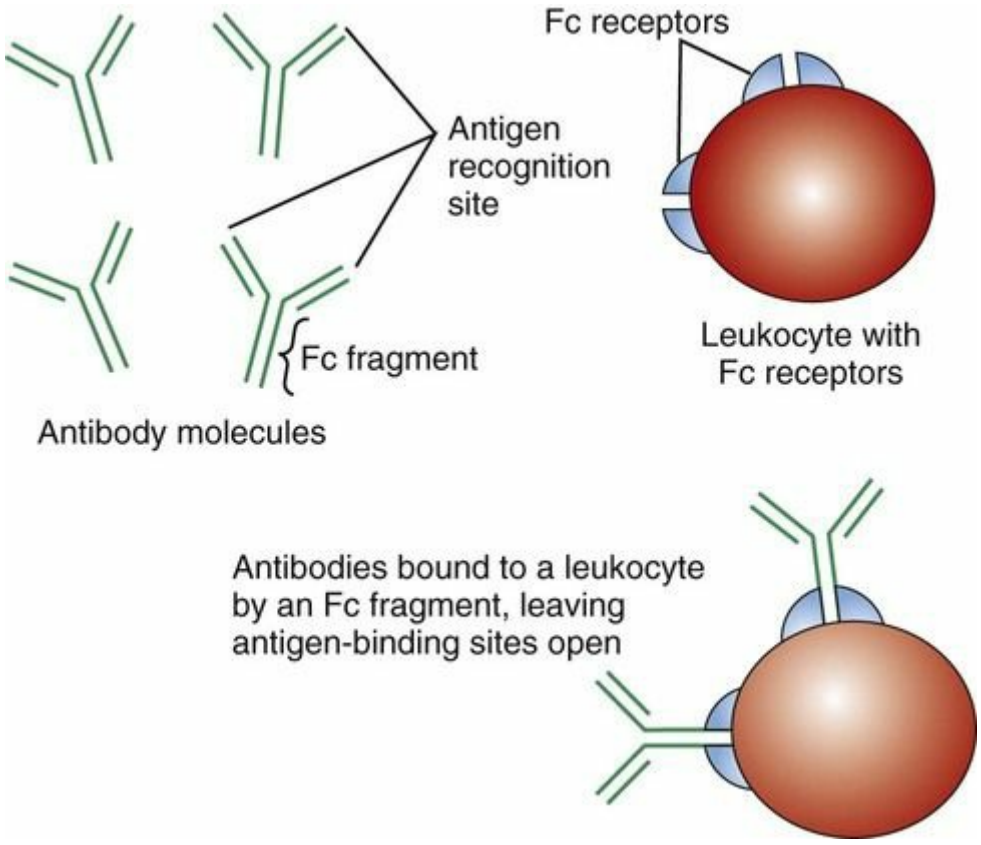

FIG. 17-9 Antibody structure and the Fc receptors on leukocytes.

The stem of the Y is the "Fc fragment." This area can bind to Fc receptor sites on white blood cells (WBCs). The WBC then not only has its own means of attacking antigens but also has the added power of having surface antibodies that can stick to antigens (see Fig. 17-9).

The binding of antibody to antigen may not be lethal to the antigen. Instead, antibody-antigen binding starts other actions that neutralize, eliminate, or destroy the antigen.

Antibody-binding actions are triggered by binding of antibody to antigen. The resulting reactions of agglutination, lysis, complement

fixation, precipitation, and inactivation can then neutralize, eliminate, or destroy the bound antigen.

Agglutination is a clumping action that results from the antibody linking antigens together, forming large and small immune complexes (Fig. 17-10). Agglutination slows the movement of the antigen in body fluids. Also, the irregular shape of the antigen-antibody complex (see Fig. 17-10) increases the actions of macrophages and neutrophils.

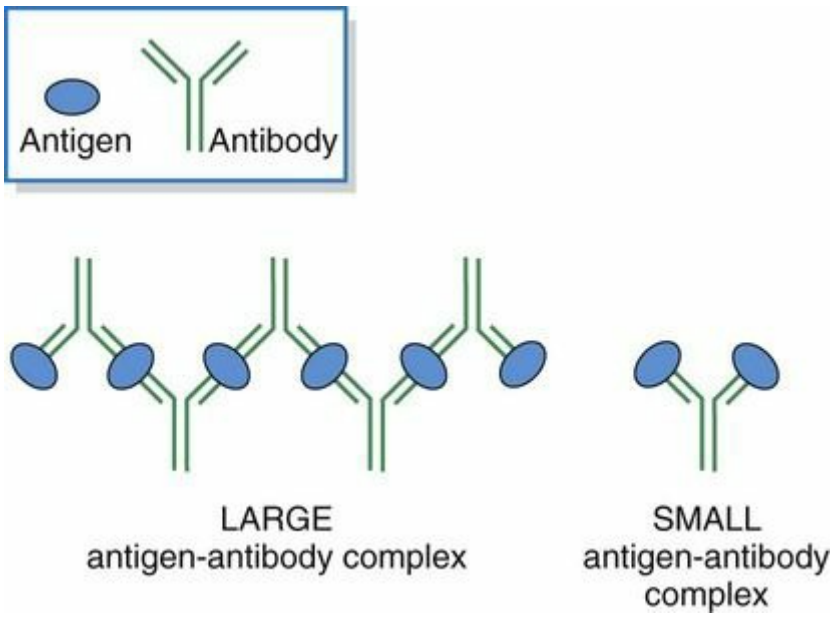

FIG. 17-10 Formation of large and small antigen-antibody complexes (immune complexes).

Lysis is cell membrane destruction, and it occurs now because of antibody binding to membrane-bound antigens of some invaders. The actual binding makes holes in the invader's membrane, weakening the invader, especially bacteria and viruses. This response usually requires that complement be activated and "fixed" to the immune complex.

Complement activation and fixation are actions triggered by the IgG and IgM classes of antibodies that can remove or destroy antigen. (See discussion of adherence on p. 280 for an explanation of how complement assists in immunity.) Binding of either IgG or IgM to an antigen provides a binding site for the first component of complement. Once the first complement molecule is activated, other proteins of the complement system are activated in a cascade.

Precipitation is similar to agglutination but has a larger response. With precipitation, antibody molecules bind so much antigen that large antigen-antibody complexes are formed. These complexes cannot stay in suspension in the blood. Instead, they form a large precipitate, which

then can be acted on and removed by neutrophils and macrophages.

Inactivation (neutralization) is the process of making an antigen harmless without destroying it. Usually only a small area of the antigen, the active site, causes the harmful effects. When an antibody binds to an antigen's active site, covering it up, the antigen is made harmless without destroying it.

Sustained immunity (memory) provides us with long-lasting immunity to a specific antigen. Sustained immunity results from memory B-cells made during the lymphocyte sensitization stage. These memory cells remain sensitized to the specific antigen to which they were originally exposed. On re-exposure to the same antigen, the memory cells rapidly respond by first dividing and forming new sensitized blast cells and plasma cells. The blast cells continue to divide, producing many more sensitized plasma cells. These new sensitized plasma cells rapidly make large amounts of the antibody specific for the sensitizing antigen.

This ability of the memory cells to respond on re-exposure to the same antigen that originally sensitized the B-cell allows a rapid and large immune response *(anamnestic response)* to the antigen. Because so much antibody is made, often the invading organisms are removed completely and the person does not become ill. This process prevents people from becoming ill with chickenpox or any infectious disease more than once, even though they are exposed many times to the causative organism. Without immunologic memory, people would remain susceptible to specific diseases on subsequent exposure to the organisms and no long-term immunity would be generated (Abbas et al., 2012; McCance et al., 2014).

Antibody Classification

All antibodies are immunoglobulins, also called *gamma globulins.* These names are based on the structure and function of antibodies. A globulin is a protein that is globular rather than straight. Because antibodies are globular proteins, they are "globulins." The term **immunoglobulin** is used for antibodies because they are globular proteins that provide immunity. Antibodies also are called **gamma globulins** because all free antibodies in the plasma separate out in the gamma fraction of plasma proteins during electrophoresis. The five antibody types are classified by differences in size, location, amount, function, and timing (Table 17-4).

TABLE 17-4

Antibody Classification

ANTIBODY	FUNCTION
IgA	"Secretory" antibody that is present in high concentrations in the secretions of mucous membranes and in the intestinal mucosa
	Very low circulating levels
	Most responsible for preventing infection in the upper and lower respiratory tracts, the GI tract, and the genitourinary tract
IgD	Present in low blood concentrations in conjunction with IgM
IgE	Variable concentration in blood
	Associated with antibody-mediated hypersensitivity reactions
	Binds to mast cells and causes their degranulation when an allergen (antigen) binds to IgE antigen recognition sites
IgG	Composes at least 75% of circulating antibody population
	Is heavily expressed on second and subsequent exposures to antigens to provide sustained, long-term immunity against invading microorganisms
	Activates classic complement pathway, and enhances neutrophil and macrophage actions
IgM	First antibody formed by a newly sensitized B-lymphocyte plasma cell
	Composes about 10% to 15% of circulating antibody population
	Especially effective at the antibody actions of agglutination and precipitation because of having 10 potential binding sites per molecule
	Activates complement pathway

On first exposure to an antigen, the newly sensitized B-cell produces the IgM antibody type against the antigen. IgM is special because it forms itself into a five-member group. Each IgM group, then, has ten antigen binding sites. So, even though antibody production is slow on first exposure, the antibody type produced forms groups that are very efficient at antigen binding. This process ensures that the initial illness, like influenza A, lasts only 5 to 10 days. On re-exposure to the same antigen, the already sensitized B-cell makes large amounts of the IgG type of antibody against that antigen. Although IgG does not form groups of five, the enormous amounts produced make IgG antibodies efficient at clearing the antigen and protecting the person from becoming ill with the disease again.

Acquiring Antibody-Mediated Immunity

Antibody-mediated immunity (AMI) is a type of **adaptive immunity** in which a person's body learns to make as an adaptive response to invasion by organisms or foreign proteins. Thus antibody-mediated immunity is an *acquired immunity.* Adaptive immunity occurs either naturally or artificially through lymphocyte responses and can be either active or passive.

Active immunity occurs when antigens enter a person's body and it responds by making specific antibodies against the antigen. This type of immunity is *active* because the body takes an active part in making antibodies. Active immunity occurs under natural or artificial conditions.

Natural active immunity occurs when an antigen enters the body naturally without human assistance and the body responds by actively making antibodies against that antigen (e.g., influenza A virus). Usually, the invasion that triggers antibody production also causes the disease. However, processes occurring in the body at the same time as infection create immunity to that antigen. Thus the person will not become ill after a second exposure to the same antigen. *Natural active immunity is the most effective and the longest lasting.*

Artificial active immunity is the protection developed by vaccination or immunization. This type of immunity is used to prevent serious and potentially deadly illnesses (e.g., tetanus, diphtheria, polio). Small amounts of specific antigens are placed as a vaccination into a person. The person's immune system responds by actively making antibodies against the antigen. Because antigens used for this procedure have been specially processed to make them less likely to grow in the body **(attenuated),** this exposure usually does not cause the disease. Artificial active immunity lasts many years, although repeated but smaller doses of the original antigen are required as a "booster" to retain the protection.

Passive immunity occurs when the antibodies against an antigen are transferred to a person's body after first being made in the body of another person or animal. Because these antibodies are foreign to the receiving person, they are recognized as non-self and eliminated quickly. For this reason, passive immunity provides only immediate, short-term protection against a specific antigen. It is used when a person is exposed to a serious disease for which he or she has little or no actively acquired immunity. Instead, the injected antibodies are expected to inactivate the antigen. Artificial passive immunity may be used to prevent disease or death for patients exposed to rabies, tetanus, and poisonous snake bites.

Natural passive immunity occurs when antibodies are passed from the mother to the fetus via the placenta or to the infant through colostrum and breast milk.

AMI works with inflammation to protect against infection. However, AMI can provide the most effective long-lasting immunity only when its actions are combined with those of cell-mediated immunity.

Cell-Mediated Immunity

Cell-mediated immunity (CMI), or cellular immunity, involves many white blood cell (WBC) actions and interactions. CMI is another type of adaptive or acquired true immunity that is provided by lymphocyte stem

cells that mature in the secondary lymphoid tissues of the thymus and pericortical areas of lymph nodes (see Fig. 17-7). Certain CMI responses influence and regulate the activities of antibody-mediated immunity (AMI) and inflammation by producing and releasing cytokines. For total or full immunity, CMI must function optimally.

Cell Types Involved in Cell-Mediated Immunity

The WBCs with the most important roles in CMI include several specific T-lymphocytes (T-cells) along with a special population of cells known as *natural killer (NK) cells*. T-cells have a variety of subsets, each of which has a specific function.

Different T-cell subsets can be identified by the presence of "marker proteins" (antigens) on the cell membrane's surface. More than 200 different T-cell proteins have been identified on the cell membrane, and some of these are commonly used clinically to identify specific cells (Abbas et al., 2012). Most T-cells have more than one antigen on their cell membrane. For example, all mature T-cells contain T1, T3, T10, and T11 proteins.

The names used to identify specific T-cell subsets include the specific membrane antigen and the overall actions of the cells in a subset. The three T-lymphocyte subsets that are critically important for the development and continuation of CMI are helper/inducer T-cells, suppressor T-cells, and cytotoxic/cytolytic T-cells. An additional cell, the natural killer cell, although not a true T-cell, also contributes to CMI.

Helper/inducer T-cells have the T4 protein on their membranes. These cells are usually called *T4+ cells* or T_H *cells*. The most correct name for helper/inducer T-cells is *CD4+* (cluster of differentiation 4).

Helper/inducer T-cells easily recognize self cells versus non-self cells. When they recognize non-self (antigen), helper/inducer T-cells secrete cytokines that can enhance the activity of other WBCs and increase overall immune function. These cytokines increase bone marrow production of stem cells and speed up their maturation. Thus helper/inducer T-cells act as organizers in "calling to arms" various squads of WBCs involved in inflammatory, antibody, and cellular protective actions.

Suppressor T-cells have the T8-lymphocyte antigen on membrane surfaces. These cells are commonly called *T8+ cells*, *CD8+ cells*, or T_S*-cells*. Suppressor T-cells help regulate CMI.

Suppressor T-cells prevent **hypersensitivity** (immune overreactions) on exposure to non-self cells or proteins. This function is important in

preventing the formation of antibodies directed against normal, healthy self cells, which is the basis for many autoimmune diseases. The suppressor T-cells secrete cytokines that have an overall *inhibitory* action on most cells of the immune system.

Suppressor T-cells have the opposite action of helper/inducer T-cells. For optimal function of CMI, then, a balance between helper/inducer T-cell activity and suppressor T-cell activity must be maintained. This balance occurs when the helper/inducer T-cells outnumber the suppressor T-cells by a ratio of 2 : 1. When this ratio increases, indicating that helper/inducer T-cells vastly outnumber the suppressor cells, overreactions can occur, some of which are tissue damaging as well as unpleasant. When the helper/suppressor ratio decreases, indicating fewer-than-normal helper/inducer T-cells, immunity is suppressed and the person's risk for infections increases.

Cytotoxic/cytolytic T-cells are also called *T_C-cells*. Because they have the T8 protein present on their surfaces, they are a subset of suppressor cells. Cytotoxic/cytolytic T-cells destroy cells that contain a processed antigen's human leukocyte antigens (HLAs). This activity is most effective against self cells infected by parasites, such as viruses or protozoa.

Parasite-infected self cells have both self HLA proteins (universal product code) and the parasite's antigens on the cell surface. This allows the person's immune system cells to recognize the infected self cell as abnormal, and the cytotoxic/cytolytic T-cell can bind to it, punch a hole, and deliver a “lethal hit” of enzymes to the infected cell, causing it to lyse and die.

Natural killer (NK) cells are also known as *CD16+ cells* and are very important in providing CMI. The actual site of NK cell differentiation and maturation is unknown, and it is not a true T-cell subset (Abbas et al., 2012).

NK cells have direct cytotoxic effects on some non-self cells without first being sensitized. They conduct “seek and destroy” missions in the body to eliminate non-self cells.

NK cells are most effective in destroying unhealthy or abnormal self cells. The non-self cells most often harmed by NK cells are cancer cells and virally infected body cells.

Cytokines

Cell-mediated immunity (CMI) regulates the immune system by the production and activity of cytokines. **Cytokines** are small protein hormones produced by the many WBCs (and some other tissues).

Cytokines made by the macrophages, neutrophils, eosinophils, and monocytes are called **monokines.** Those produced by T-cells are called **lymphokines.** In addition, we now know that many other body cell types can produce and respond to cytokines.

Cytokines work like hormones: one cell produces a cytokine, which in turn exerts its effects on other cells of the immune system and on other body cells. The cells responding to the cytokine may be located close to or remote from the cytokine-secreting cell. Thus cytokines act like "messengers" that tell specific cells how and when to respond. The cells that change their activity when a cytokine is present are "responder" cells. For a responder cell to respond to the presence of a cytokine, the responder cell must have a specific receptor to which the cytokine can bind. Once the cytokine binds to its receptor, the responder cell changes its activity.

Cytokines control many inflammatory and immune responses and are controlled by interactions with other systems, especially the nervous system. Cytokines include the interleukins (ILs), interferons (IFNs), colony-stimulating factors, tumor necrosis factors (TNFs), and transforming growth factors (TGFs). The interleukins are the largest group of cytokines, with interleukin-33 (IL-33) being the most recently defined. There are many cytokines, and cytokine classification is undergoing changes. Some are considered "proinflammatory" and increase the actions of natural immunity (inflammation). These currently include TNF-α, IL-1, IL-10, IL-12, and interferons (α [alpha], β [beta], and γ [gamma]). Other cytokines have a major influence on AMI and CMI activities. These include IL-2, IL-4, IL-5, IL-10, TGF-β, and IFN-γ. Although there are many cytokines, not all their functions are known or clinically useful at this time; however, this is an area of continuing research and discovery. Table 17-5 lists the cytokines that have current clinical importance. Chapters discussing specific diseases (e.g., lymphoma, rheumatoid arthritis) caused by or treated with certain cytokines have more information about the role of specific cytokines in the disease and its treatment.

TABLE 17-5

Activity of Selected Cytokines

CYTOKINE	ACTIONS
Pro-inflammatory Cytokines	
Interleukin-1 (IL-1)	Induces fever
	Stimulates production of prostaglandins
	Increases growth of CD4+ T-cells
Interleukin-2 (IL-2)	Increases growth and differentiation of T-lymphocytes
	Enhances natural killer cell activity against cancer cells
Interleukin-6 (IL-6)	Stimulates liver to produce fibrinogen and protein C
	Increases rate of bone marrow production of stem cells
	Increases numbers of sensitized B-lymphocytes
Tumor Necrosis Factor (TNF)	Induces fever
	Major cytokine involved in rheumatoid arthritis damage
	Major cytokine involved in the acute inflammatory response to infectious bacteria and starts many of the systemic complications of severe infection or sepsis
	Participates in graft rejection
	Induces cell death
	Stimulates delayed hypersensitivity reactions and allergy
Growth Factors	
Granulocyte Colony-Stimulating Factor (G-CSF)	Increases numbers and maturity of neutrophils
Granulocyte-Macrophage Colony-Stimulating Factor (GM-CSF)	Increases growth and maturation of myeloid stem cells
Erythropoietin	Increases growth and differentiation of erythrocytes
Thrombopoietin	Increases growth and differentiation of platelets

Protection Provided by Cell-Mediated Immunity

Cell-mediated immunity (CMI) helps protect the body through the ability to differentiate self from non-self. The non-self cells most easily recognized by CMI are cancer cells and those self cells infected by organisms that live within host cells, especially viruses. CMI watches for and rids the body of self cells that might potentially harm the body. *CMI is important in preventing the development of cancer and metastasis after exposure to carcinogens.*

Transplant Rejection

Natural killer (NK) cells and cytotoxic/cytolytic T-cells also destroy cells from other people or animals. Although this action is normal and is usually helpful, it is also responsible for rejection of tissue grafts and transplanted organs (also termed *grafts*). Because the solid organ transplanted into the recipient is seldom a perfectly identical match of human leukocyte antigens (unless the organ is obtained from an identical sibling) between the donated organ and the recipient host, the patient's immune system cells recognize a newly transplanted organ as non-self. Without intervention, the recipient's immune system starts

inflammatory and immunologic actions to destroy or eliminate these non-self cells. This activity causes rejection of the transplanted organ. Rejection of transplanted solid organs and other grafts is a result of a complex series of responses that change over time and involve different components of the immune system. Rejection can be hyperacute, acute, or chronic.

Hyperacute Rejection

Hyperacute rejection begins immediately on transplantation and is an antibody-mediated response. Antigen-antibody complexes form in the blood vessels of the transplanted organ. The recipient's (host's) blood has pre-existing antibodies to one or more of the antigens (including blood group antigens) present in the donated organ. The antigen-antibody complexes adhere to the lining of blood vessels and activate complement. The activated complement in the blood vessel linings triggers the blood clotting cascade, causing small clots to form throughout the new organ. Widespread clotting occludes blood vessels and leads to ischemic necrosis, inflammation with phagocytosis of the necrotic blood vessels, and release of lytic enzymes into the new organ. These enzymes cause massive cellular destruction within the transplanted organ and graft loss.

Hyperacute rejection occurs mostly in transplanted kidneys but is less common now as a result of greater efforts in HLA matching. The patients at greatest risk for hyperacute rejection are those who have received donated organs of an ABO blood type different from their own, have received multiple blood transfusions at any time in life before transplantation, have a history of multiple pregnancies, or have received a previous transplant.

The manifestations of hyperacute rejection are apparent within minutes of attachment of the donated organ to the recipient's blood supply. The process cannot be stopped once it has started, and the rejected organ is removed as soon as hyperacute rejection is diagnosed.

Acute Rejection

Acute rejection first occurs within 1 week to 3 months after transplantation and may occur sporadically after that. Two mechanisms are responsible. The first mechanism is antibody mediated and results in vasculitis within the transplanted organ. This reaction differs from hyperacute rejection in that blood vessel necrosis (not occlusion) leads to organ destruction.

The second mechanism is cellular. The recipient's cytotoxic/cytolytic T-cells and NK cells enter the transplanted organ through the blood,

penetrate the organ cells, start an inflammatory response, and cause lysis of the organ cells.

Diagnosis of acute rejection is made by laboratory tests that show impaired function of the donated organ and by biopsy of the donated organ. Manifestations of acute rejection vary with each patient and with the specific organ transplanted. For example, when acute rejection occurs in a transplanted kidney, the patient usually has some tenderness in the kidney area and may have other general manifestations of inflammation.

An episode of acute rejection after solid organ transplantation does not automatically mean that the patient will lose the new organ. Drug management of the recipient's immune responses at this time may limit the damage to the organ and allow the graft to be maintained.

Chronic Rejection

The origin of *chronic rejection* is similar to chronic inflammation and scarring. The smooth muscles of blood vessels overgrow and occlude the vessels. The donated organ tissues are replaced with fibrotic, scarlike tissue. Because this fibrotic tissue is not organ tissue, the transplanted organ's function is reduced in proportion to the amount of normal tissue that is replaced by fibrotic tissue. This type of reaction is long-standing and occurs continuously as a response to chronic ischemia caused by blood vessel injury. The results of chronic rejection are unique to different transplanted organs. For example, in transplanted lungs, chronic rejection thickens small airways. In transplanted livers, chronic rejection destroys bile ducts. In transplanted hearts, this process is called *accelerated graft atherosclerosis (AGA)* and is the major cause of death in patients who have survived 1 or more years after heart transplantation.

Although good control over the recipient's immune function can delay this type of rejection, the process probably occurs to some degree with all transplanted solid organs obtained from donors who are not identical siblings of the recipients. Because the fibrotic changes are permanent, there is no cure for chronic graft rejection. When the fibrosis increases to the extent that the transplanted organ can no longer function, the only recourse is retransplantation.

Management of Transplant Rejection

Rejection of transplanted solid organs involves all three components of immunity, although cell-mediated immune (CMI) responses contribute the most to the rejection process. Approved drugs used to manage transplant rejection are listed in Chart 17-2.

Chart 17-2 Common Examples of Drug Therapy

Transplant Rejection

DRUG/CLASS	ROUTE OF ADMINISTRATION	SIDE EFFECTS
Corticosteroids		
Broadly inhibit cytokine production in most leukocytes, resulting in generalized immunosuppression		
Prednisone (Deltasone)	Oral	Hypertension
		Hyperlipidemia
		Osteoporosis
		Weight gain
		Cushingoid appearance
		Opportunistic infection
		Glaucoma
		GI ulcer formation
		Hyperglycemia
Prednisolone (Millipred, Orapred, Veripred)	Oral	Same as for prednisone
	Calcineurin Inhibitors	
The inhibition of calcineurin stops the production and secretion of IL-2, which then prevents the activation of lymphocytes involved in transplant rejection.		
Cyclosporine (Sandimmune, Neoral, Gengraf)	Oral	Nephrotoxic
		Hypertension
		Tremor
		Coronary artery disease
		Hirsutism
		Gingival hyperplasia
		Opportunistic infections
		Malignancies
		Hyperuricemia
		Hepatoxicity
Tacrolimus (Prograf)	Oral	Nephrotoxic
		Hypertension
		Hyperkalemia
		Hypomagnesemia
		Hyperglycemia
		Opportunistic infections
		Malignancies
Antiproliferatives		
The main action of all antiproliferatives is to inhibit something essential to DNA synthesis, which prevents cell division in activated lymphocytes. Some have additional immune suppressive actions.		
Azathioprine (Imuran)	Oral	Bone marrow suppression
		Thrombocytopenia
		Anemia
		Pancreatitis
		Hepatotoxicity
		Malignancies
Mycophenolate (CellCept, Myfortic)	Oral	Leucopenia
		Thrombocytopenia
		Nausea
		Opportunistic infection
		Malignancies
Sirolimus (Rapamune)	Oral	Leucopenia
		Thrombocytopenia
		Hypercholesterolemia
		Hypertriglyceridemia
Everolimus (Afinitor, Zortress)	Oral	Acne
		GI upsets
		Hepatoxicity
		Cushingoid appearance
		Gingival hyperplasia
		Hyperglycemia
		Hyperlipidemia
		Hypertension
		Leucopenia

DRUG/CLASS	ROUTE OF ADMINISTRATION	SIDE EFFECTS
Monoclonal Antibodies		
Specifically target the activation sites of T-lymphocytes, increasing their elimination from circulation		
Muromonab-CD3 (Orthoclone OKT3)	IV	Systemic inflammatory responses
		Aseptic meningitis
		Opportunistic infections
		Malignancies
		Hypersensitivity reactions
Basiliximab (Simulect)	IV	GI disturbances
Daclizumab (Zenapax)	IV	GI disturbances
Polyclonal Antibodies		
Antibodies derived from other animals (horses or rabbits) that bind to and eliminate most T-lymphocytes, thus stopping a transplant rejection episode.		
Antithymocyte globulin–equine (Atgam)	IV	Leukopenia
		Serum sickness
		Thrombocytopenia
		Pruritus
		Fever
		Arthralgias
		Opportunistic infections
		Malignancies
Antithymocyte globulin–rabbit (RATG, Thymoglobulin)	IV	Same as for antithymocyte globulin–equine

Maintenance therapy is the continuous immunosuppression used after a solid organ transplant. The drugs used for routine therapy after solid organ transplantation are combinations of a calcineurin inhibitor, a corticosteroid, and an antiproliferative agent (Alexander & Susla, 2013). Which drugs are used depends on the transplant type and other patient-specific conditions. These are all oral agents and must be taken for the life of the transplanted organ. All are immunosuppressive to some degree, and the dosage is adjusted to the immune response of each patient. Treatment with these agents increases the risk for bacterial and fungal infections and for cancer development.

Rescue therapy is used to treat acute rejection episodes. The drug categories for this purpose are the monoclonal and polyclonal antibodies (see Chart 17-2). The drugs used for maintenance are often also used during rejection episodes at much higher dosages than for maintenance.

Clinical Judgment Challenge

Patient-Centered Care; Safety QSEN

A patient comes to the emergency room after stepping on a rusty nail while fixing a fence on his horse farm. He tells you that his last tetanus toxoid booster vaccination was about 12 years ago. The health care provider prescribes an injection of HyperTET, which contains concentrated pre-formed antibodies to the tetanus bacterium. The patient is instructed to return to his health care provider in 10 days to

receive a tetanus "booster" vaccination.

1. What type of immunity is provided by the booster vaccination the patient received 12 years ago? Explain your choice.
2. Why does this patient need HyperTET now, and what type of immunity does it provide?
3. Why does the patient have to wait 10 days to receive the next tetanus booster?

Nursing Concepts and Clinical Judgment Review

What might you NOTICE in a patient with adequate protection as a result of appropriate responses for inflammation and immunity?

Vital signs:

- Body temperature within normal range

Physical assessment:

- Skin intact (no rashes, abnormal lesions)
- Skin color normal (no redness)
- No edema or excessively warm body areas
- All body areas fully functional with no pain
- No indicators of infection or illness

Laboratory assessment:

- White blood cell count and differential within the normal range
- No positive cultures of skin, blood, urine, sputum
- No evidence of allergic reactions

Get Ready for the NCLEX® Examination!

Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

Physiological Integrity

- Inflammation and immunity are provided through the actions and products of white blood cells (WBCs), also called *leukocytes.*
- Different types of WBCs provide different types of immune or inflammatory protection.
- The differential of the WBC count can be used to determine the patient's risk for infection, the presence or absence of infection, the presence or absence of an allergic reaction, and whether an infection is bacterial or viral.
- WBCs are the only body cells able to recognize non-self cells and to attack them.
- Self-tolerance is the special ability of WBCs to recognize healthy self cells and not attempt to attack or destroy them.
- Human leukocyte antigens (HLAs) are a person's tissue type and are inherited from parents.
- Immunocompetence requires that all three parts of inflammation and immunity have optimal functioning.
- Inflammation is a general, nonspecific protective response also known as *innate immunity.*
- The five cardinal manifestations of inflammation are redness, warmth, swelling, pain, and loss of function.
- Inflammation and infection are not the same thing. Infection almost always is accompanied by inflammation, but inflammation often occurs without infection.
- The tissue responses to inflammation are helpful if confined to the area of invasion or infection and do not extend beyond the acute phase.
- Chronic inflammation can damage tissues and reduce function.
- The cells and actions of cell-mediated immunity control and coordinate the entire inflammatory and immune responses.
- Inflammatory protection cannot be transferred from one person to another.
- Immune function declines with age, making the older adult at increased risk for infection and cancer development.
- Antibody-mediated immunity (also known as *humoral immunity*) can be transferred from one person or animal to another.
- Antibodies transferred from one person into another person have a

short-term effect.

- Natural, active immunity is the most beneficial and long-lasting type of immunity.
- Vaccinations cause artificial active immunity and require “boosting” for best long-term effects.
- A person's normal membrane proteins would be antigens in another person.
- Transplant rejection is a normal response of the immune system that can damage or destroy the transplanted organ.
- Patients who receive transplanted organs (unless from an identical sibling) need to take immunosuppressive drugs daily to prevent transplant rejection.
- Patients who take immunosuppressive drugs have an increased risk for infection and cancer development.

CHAPTER 18

Care of Patients with Arthritis and Other Connective Tissue Diseases

Donna D. Ignatavicius

PRIORITY CONCEPTS

- Pain
- Mobility
- Infection
- Immunity
- Inflammation

Learning Outcomes

Safe and Effective Care Environment

1. Identify interdisciplinary team members who collaborate to ensure quality care for patients with connective tissue diseases (CTDs).
2. Prioritize collaborative evidence-based interventions for patients with osteoarthritis (OA) and rheumatoid arthritis (RA).

Health Promotion and Maintenance

3. Identify community resources to help patients achieve or maintain independence in ADLs.
4. Describe risk factors for the development of arthritis and other CTDs.
5. Teach patients how to protect and exercise their joints to prevent injury.
6. Teach patients evidence-based strategies for how to prevent osteoarthritis.
7. Teach patients how to prevent Lyme disease and detect it early if it occurs.

Psychosocial Integrity

8. Assess the patient's and family's response to arthritis or other CTD, their support systems, and available resources.
9. Assess the patient's and family's sources of stress and coping mechanisms when living with arthritis or other CTD.

Physiological Integrity

10. Compare and contrast the pathophysiology and clinical manifestations of OA and RA, including those caused by joint inflammation and degenerative changes.
11. Interpret laboratory findings for patients with RA and other CTDs that affect immunity.
12. Assess presence and extent of pain and suffering in patients with arthritis.
13. Apply knowledge of pathophysiology to monitor for and prevent complications of total hip and knee arthroplasty.
14. Teach patients and their families about the postoperative care required after a total joint arthroplasty.
15. Provide information for patients and families about the use and side effects of drug therapy for arthritis or other CTD.
16. Identify the nursing implications associated with drug therapy for patients with rheumatoid arthritis and other CTDs.
17. Document and plan patient care in the electronic health care record for the patient with arthritis.
18. Differentiate between discoid lupus erythematosus and systemic lupus erythematosus.
19. Prioritize nursing interventions for patients who have systemic sclerosis.
20. Describe the patient-centered collaborative care of gout based on knowledge of pathophysiology.
21. Explain the differences between polymyositis, systemic necrotizing vasculitis, polymyalgia rheumatica, ankylosing spondylitis, Reiter's syndrome, and Sjögren's syndrome.
22. Describe current treatment strategies for patients with fibromyalgia syndrome and psoriatic arthritis.

http://evolve.elsevier.com/Iggy/

Connective tissue disease (CTD) is the major focus of *rheumatology,* the study of rheumatic disease. A **rheumatic disease** is any disease or condition involving the musculoskeletal system. In this text, CTDs are discussed separately from other musculoskeletal conditions because most CTDs are classified as autoimmune disorders. In autoimmune disease, antibodies attack healthy normal cells and tissues. For reasons that are unclear, the immune system does not recognize body cells as self and therefore triggers an immune response. The usual *protective* nature of the immune system does not function properly in patients with autoimmune CTDs.

Most common CTDs are characterized by chronic pain and progressive joint deterioration, which results in decreased function and impaired mobility. Some of these disorders have additional localized clinical manifestations, whereas others are systemic. The economic and social costs of these diseases are staggering and will increase steadily as "baby boomers" continue to age. Patient care usually requires an interdisciplinary approach, including medicine, surgery, nursing, rehabilitation therapy, pharmacy, and/or case management.

Arthritis means inflammation of one or more joints. In clinical practice, however, arthritis is categorized as either noninflammatory or inflammatory. Noninflammatory, localized arthritis such as osteoarthritis (OA) is not systemic; OA is not an autoimmune disease. Systemic autoimmune diseases such as rheumatoid arthritis (RA) and systemic lupus erythematosus (SLE) are inflammatory disorders.

Osteoarthritis

Pathophysiology❖

Osteoarthritis is the most common arthritis and a major cause of disability among adults in the United States and the world. It is sometimes called *osteoarthrosis* or *degenerative joint disease (DJD)*.

Osteoarthritis is the progressive deterioration and loss of cartilage and bone in one or more joints. Articular cartilage, also known as *hyaline cartilage,* contains water and a matrix of:

- Proteoglycans (glycoproteins containing chondroitin, keratin sulfate, and other substances)
- Collagen (elastic substance)
- Chondrocytes (cartilage-forming cells)

As people age or experience joint injury, proteoglycans and water decrease in the joint. The production of synovial fluid, which provides joint lubrication and nutrition, also declines because of the decreased synthesis of hyaluronic acid and less body fluid in the older adult (Antonelli & Starz, 2012).

In patients of any age with OA, enzymes, such as stromelysin, break down the articular matrix. In early disease, the cartilage changes from its normal bluish white, translucent color to an opaque and yellowish brown appearance. As cartilage and the bone beneath the cartilage begin to erode, the joint space narrows and **osteophytes** (bone spurs) form (Fig. 18-1). As the disease progresses, fissures, calcifications, and ulcerations develop and the cartilage thins. Inflammatory cytokines (enzymes) such as interleukin-1 (IL-1) enhance this deterioration. The body's normal repair process cannot overcome the rapid process of degeneration (McCance et al., 2014). Secondary joint inflammation can occur when joint involvement is severe.

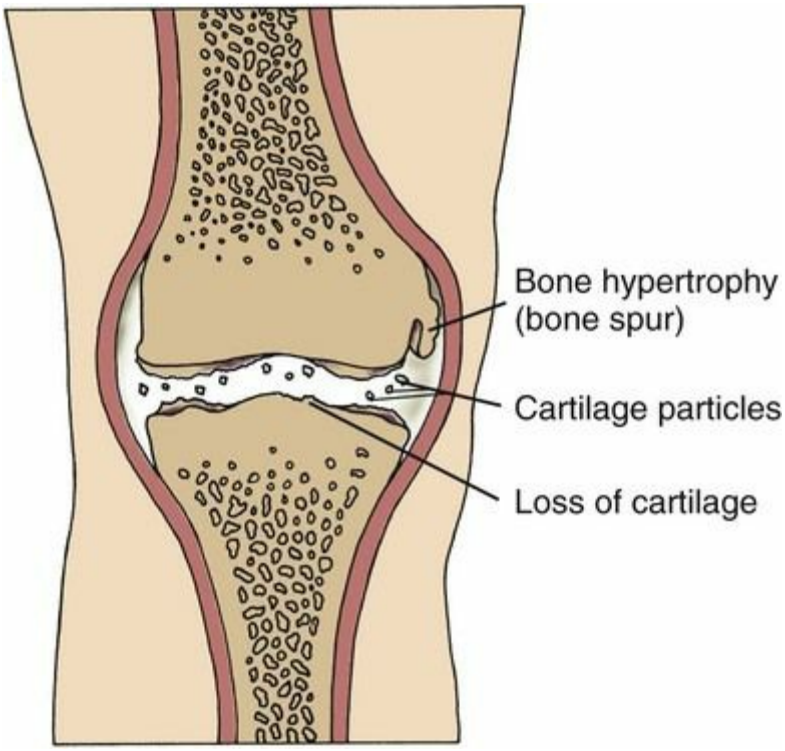

FIG. 18-1 Joint changes in degenerative joint disease.

Eventually the cartilage disintegrates and pieces of bone and cartilage "float" in the diseased joint causing **crepitus,** a grating sound caused by the loosened bone and cartilage. The resulting joint pain and stiffness can lead to decreased mobility and muscle atrophy. Muscle tissue helps support joints, particularly those that bear weight (e.g., hips, knees).

Etiology and Genetic Risk

The cause of OA is a combination of many factors. For patients with *primary* OA, the disease is caused by aging and genetic factors. Weight-bearing joints (hips and knees), the vertebral column, and the hands are most commonly affected, probably because they are used most often or bear the mechanical stress of body weight and many years of use.

Secondary OA occurs less often than primary disease and results from joint injury and obesity (Antonelli & Starz, 2012). Injury to the joints from excessive use, trauma, or other joint disease (e.g., rheumatoid arthritis) predisposes a person to OA. Heavy manual occupations (e.g., carpet laying, construction, farming) cause high-intensity or repetitive stress to the joints. The risk for hip and knee OA is increased in professional athletes, especially football players, runners, and gymnasts. Fractures or other joint tissue injuries can lead to OA years after the trauma. Certain metabolic diseases (e.g., diabetes mellitus, Paget's disease of the bone) and blood disorders (e.g., hemophilia, sickle cell disease) can also cause joint degeneration.

Obesity is a common contributing factor to osteoarthritis. Weight-bearing joints, such as hips and knees, are most often affected in obese people.

Incidence and Prevalence

The prevalence of OA varies among different populations but is a universal problem. Most people older than 60 years have joint changes that can be seen on x-ray examination, although not all of those people actually develop the disease. According to Arthritis Foundation (2013b) estimates, 27 million people in the United States have symptomatic osteoarthritis.

Gender Health Considerations

Patient-Centered Care QSEN

More men than women younger than 55 years have AO, but after 55, women have it more often than men (Antonelli & Starz, 2012). Although the cause for this difference is not known, contributing factors may include increased obesity in women after having children, broader hips in women than men, and more athletic injuries in young men as compared with young women (Arthritis Foundation, 2013b).

Lesbian women and bisexuals are more likely to be overweight or obese when compared with other populations. Although the reason for this difference is not known, it is possible that lesbian women and bisexual people use food as a coping strategy because many have fears and concerns about "coming out" about their sexual orientation, especially to health care professionals and family members (Pettinato, 2012). Be sure to assess all patients in the hospital or community-based setting, particularly those who are older and obese, for clinical manifestations of osteoarthritis.

Health Promotion and Maintenance

The Arthritis Foundation's Osteoarthritis Intervention Working Group produced an evidence-based document that proposed the Public Health Agenda needed to prevent and manage osteoarthritis.

❖ Patient-Centered Collaborative Care

◆ Assessment

History.

Patients with OA usually seek medical attention in ambulatory care settings for their joint pain. However, you will also care for those who have OA as a secondary diagnosis in acute and chronic care facilities. Ask the patient about the course of the disease. Collect information specifically related to OA, such as the nature and location of joint pain and how much pain and suffering he or she is experiencing. *Remember that older patients may underreport pain, resulting in inadequate management.* Use a 0-to-10 scale or other assessment tool to assess pain intensity. Chapter 3 discusses pain assessment in detail.

Other questions to ask include:

- If joint stiffness has occurred, where and for how long?
- When and where has any joint swelling occurred?
- What do you do to control the pain or stiffness?
- Do you have any loss of mobility or difficulty in performing ADLs?

Because this disease occurs more often in older women, age and gender are important factors for the nursing history. Ask patients about their occupation, nature of work, history of injury (including falls), weight history, and current or previous involvement in sports. A history of obesity is significant, even for those currently within the ideal range for body weight. Document any family history of arthritis. Determine whether the patient has a current or previous medical condition that may cause joint symptoms.

Physical Assessment/Clinical Manifestations.

In the early stage of the disease, the clinical manifestations of OA may appear similar to those of rheumatoid arthritis (RA). The distinction between OA and RA becomes more evident as the disease progresses. Table 18-1 compares the major characteristics of both diseases and their common drug therapy.

TABLE 18-1

Differential Features of Rheumatoid Arthritis and Osteoarthritis

CHARACTERISTIC	RHEUMATOID ARTHRITIS	OSTEOARTHRITIS
Typical onset (age)	35-45 yr	Older than 60 yr
Gender affected	Female (3 : 1)	Female (2 : 1)
Risk factors or cause	Autoimmune (genetic basis) Emotional stress (triggers exacerbation) Environmental factors	Aging Genetic factor (possible) Obesity Trauma Occupation
Disease process	Inflammatory	Degenerative
Disease pattern	Bilateral, symmetric, multiple joints Usually affects upper extremities first Distal interphalangeal joints of hands spared Systemic	May be unilateral, single joint Affects weight-bearing joints and hands, spine Metacarpophalangeal joints spared Nonsystemic
Laboratory findings	Elevated rheumatoid factor, antinuclear antibody, ESR	Normal or slightly elevated ESR
Common drug therapy	NSAIDs (short-term use) Methotrexate Leflunomide (Arava) Corticosteroids Biological response modifiers Other immunosuppressive agents	NSAIDs (short-term use) Acetaminophen Other analgesics

ESR, Erythrocyte sedimentation rate; *NSAIDs*, nonsteroidal anti-inflammatory drugs.

The typical patient with OA is a middle-aged or older woman who reports *chronic joint pain and stiffness.* Early in the course of the disease, the pain diminishes after rest and worsens after activity. Later the pain occurs with slight motion or even when at rest. Because cartilage has no nerve supply, the pain is caused by joint and soft-tissue involvement and by spasms of the surrounding muscles. During the joint examination, the patient may have tenderness on palpation or when putting the joint through range of motion. **Crepitus** may be felt or heard as the joint goes through range of motion. One or more joints may be affected. The patient may also report joint stiffness that usually lasts less than 30 minutes after a period of inactivity.

On inspection, the joint is often enlarged because of bony hypertrophy. The joint feels hard on palpation. The presence of inflammation in patients with OA indicates a secondary synovitis. About half of patients with hand involvement have **Heberden's nodes** (bony nodules at the distal interphalangeal [DIP] joints) and **Bouchard's nodes** (bony nodules at the proximal interphalangeal [PIP] joints) (Fig. 18-2). Although OA is *not* a

bilateral, symmetric disease, these large bony nodes appear on both hands, especially in women. The nodes may be painful and red. Some patients experience discomfort when developing nodes or when nodes are palpated. These deformities tend to be familial and are often a cosmetic concern to patients.

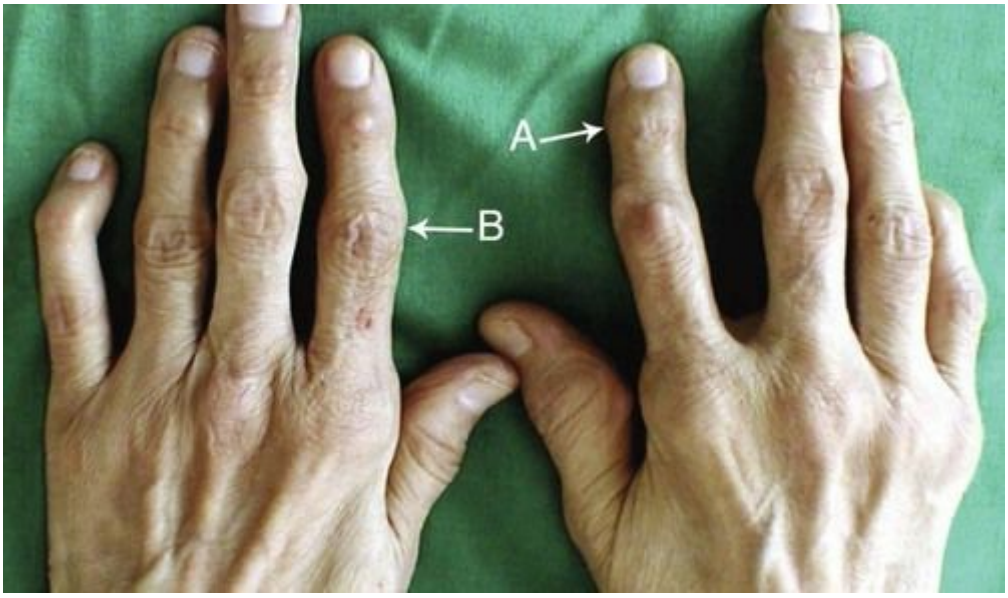

FIG. 18-2 Heberden's and Bouchard's nodes are enlarged bony nodules affecting the joints of the hand.

Joint effusions (excess joint fluid) are common when the knees are inflamed. Observe any *atrophy of skeletal muscle* from disuse. The vicious cycle of the disease discourages the movement of painful joints, which may result in contractures, muscle atrophy, and further pain. *Loss of function* or mobility may result, depending on which joints are involved. Hip or knee pain may cause the patient to limp and restrict walking distance.

Osteoarthritis (OA) can affect the spine, especially the lumbar region at the L3-4 level or the cervical region at C4-6 (neck). Compression of spinal nerve roots may occur as a result of vertebral facet bone spurs. The patient typically reports radiating pain, stiffness, and muscle spasms in one or both extremities.

Severe pain and deformity interfere with ambulation and self-care. In addition to performing a musculoskeletal assessment, collaborate with the physical and occupational therapists to conduct a functional assessment. Assess the patient's mobility and ability to perform ADLs. Chapter 6 describes functional assessment.

Psychosocial Assessment.

OA is a chronic condition that may cause permanent changes in lifestyle. An inability to care for oneself in advanced disease can result in role changes and other losses. Constant pain interferes with quality of life. Chronic pain can also affect sexuality. Patients may not have the energy for sexual intercourse or may find positioning uncomfortable.

Patients with continuous pain from arthritis may develop depression or anxiety. The patient may also have a role change in the family, workplace, or both. To identify changes that have been or need to be made, ask his or her roles before the disease developed. Identify coping strategies to help live with the disease. Ask the patient about his or her expectations regarding treatment for OA.

In addition to role changes, joint deformities and bony nodules often alter body image and self-esteem. Observe the patient's response to body changes. Does he or she ignore them or seem overly occupied with them? Ask patients directly how they perceive their body image. Document your assessment findings in the interdisciplinary electronic health record per agency policy.

Laboratory Assessment.

The health care provider uses the history and physical examination to make the diagnosis of OA. The results of routine laboratory tests are usually normal but can be helpful in screening for associated conditions. The erythrocyte sedimentation rate (ESR) and high-sensitivity C-reactive protein (hsCRP) may be slightly elevated when secondary synovitis (synovial inflammation) occurs. The ESR also tends to rise with age, infection, and other inflammatory disorders.

Imaging Assessment.

Routine x-rays are useful in determining structural joint changes. Specialized views are obtained when the disease cannot be visualized on standard x-ray film but is suspected. Magnetic resonance imaging (MRI) and computed tomography (CT) may be used to determine vertebral or knee involvement.

Analysis

The priority NANDA-I nursing diagnoses and collaborative problems for patients with osteoarthritis (OA) include:

1. Chronic Pain related to cartilage deterioration (NANDA-I)
2. Impaired Mobility related to joint pain and muscle atrophy (NANDA-I)

Planning and Implementation

In 2010, the Osteoarthritis Research Society International (OARSI) committee updated its evidence-based expert consensus guidelines for patients with knee, hand, and hip OA (Zhang et al., 2010). These interdisciplinary best practice guidelines were also supported by the Arthritis Foundation and have major implications for nursing care.

Managing Chronic Pain

Planning: Expected Outcomes.

The patient with OA is expected to have pain control that is acceptable to the patient (e.g., at a 3 on a pain intensity scale of 0 to 10).

Interventions.

No drug therapy can influence the course of OA. Optimal management of patients with OA requires a multimodal approach (combination of therapies) to manage pain. If these measures are ineffective, surgery may be performed to reduce pain (Zhang et al., 2010). Perform a pain assessment before and after implementing interventions.

Nonsurgical Management.

Management of chronic joint pain can be challenging for both the patient and the health care professional. Drug therapy and a variety of nonpharmacologic therapies are used to manage the patient with OA. Chapter 3 elaborates on interventions for chronic non-cancer pain.

Drug Therapy.

The purpose of drug therapy is to reduce pain caused by cartilage destruction, muscle spasm, and/or secondary joint inflammation. The American Pain Society, American Geriatrics Society, and OARSI committee recommend regular *acetaminophen* (Tylenol, Atasol) as the primary drug of choice because OA is not a primary anti-inflammatory disorder (Davies, 2011).

Nursing Safety Priority QSEN

Drug Alert

Patients are at risk for liver damage if they take more than 3000 mg daily of acetaminophen, have alcoholism, or have liver disease. *Older adults are particularly at risk because of normal changes of aging, such as*

slowed excretion of drug metabolites. Remind patients to read the labels of over-the-counter (OTC) or prescription drugs that could contain acetaminophen before taking them. Teach them that their liver enzyme levels will be monitored while taking this drug.

Topical drug applications may help with temporary relief of pain. Prescription lidocaine 5% patches (Lidoderm) have been approved by the Federal Drug Administration (FDA) for postherpetic neuralgia (nerve pain) but may also relieve joint pain (especially the knee) for some patients. Teach the patient to apply the patch on clean, intact skin for 12 hours each day. Up to three patches may be applied to painful joints at one time. Remind him or her that Lidoderm can cause skin irritation. Teach the patient that the lidocaine patch is contraindicated in those patients taking class I antidysrhythmics. Topical salicylates, such as OTC Aspercreme patch, gel, or cream, are also useful for some patients as a temporary pain reliever, especially for knee pain. Buspirone HCl (Buspar) topical cream may also relieve local joint pain for some patients.

If acetaminophen or topical agents do not relieve pain, the analgesic drug class of choice is *nonsteroidal anti-inflammatory drugs (NSAIDs)* if the patient can tolerate them. These traditional drugs supported by OARSI guidelines include oral COX-2 nonselective and selective NSAIDs and topical NSAIDs.

Before beginning oral NSAID therapy, baseline laboratory information is obtained, including a complete blood count (CBC) and kidney and liver function tests. Celecoxib (Celebrex), a COX-2 inhibitor, is usually the first choice unless the patient has hypertension, kidney disease, or cardiovascular disease.

Nursing Safety Priority QSEN

Drug Alert

All of the COX-2 inhibiting drugs are thought to cause cardiovascular disease, such as myocardial infarction, and kidney problems. Older NSAIDs, such as ibuprofen, can cause severe GI side effects, bleeding, and acute kidney failure. Therefore they are prescribed at the lowest effective dose for a short period of time (Davies, 2011). Teach your patient about adverse effects from NSAIDs and the need to report them to his or her health care provider. Examples include having dark, tarry stools; shortness of breath; edema; frequent dyspepsia (indigestion); **hematemesis** (bloody vomitus); and changes in urinary output.

Topical NSAIDs are considered to be safe and effective nonsystemic drugs for pain relief. For example, the diclofenac-epolamine patch and diclofenac solution are used for patients with signs and symptoms associated with knee OA.

When topical or systemic drugs are not effective and for temporary relief of pain in a single joint, the health care provider may inject an individual joint with cortisone, a commonly used steroid. Patients may have the same joint injected up to 4 times a year, or once every 3 months. Frequently injected joints include the knee, base of the thumb, shoulder, and trochanteric bursa, which people often call the *hip.*

Other agents, such as hyaluronate (Hyalgan) and hylan G-F 20 (Synvisc), are specific injections for knee and hip pain associated with OA. These synthetic joint fluid implants replace or supplement the body's natural hyaluronic acid, which is broken down by inflammation and aging.

Other oral drugs that can be given to patients with OA include muscle relaxants and opioids. Muscle relaxants, such as cyclobenzaprine hydrochloride (Flexeril), are sometimes given for painful muscle spasms, especially those occurring in the back from OA of the vertebral column. *These drugs should be used with caution in older adults because they can cause acute confusion. Remind any patient not to drive or operate dangerous machinery when taking muscle relaxants.* Weak opioid drugs such as tramadol (Ultram or Ultram ER) may also be given for patients with OA. Chapter 3 discusses drug therapy for pain relief in more detail.

NCLEX Examination Challenge

Physiological Integrity

The health care provider prescribes celecoxib (Celebrex) for a client with osteoarthritis. What health teaching will the nurse provide for this client regarding this drug? **Select all that apply.**

A "Take the drug on an empty stomach before breakfast."
B "Stop taking the drug if unusual bleeding occurs and call your health care provider."
C "Report frequent episodes of indigestion to your health care provider."
D "Expect fluid accumulation in your legs and feet that usually gets worse during the day."
E "Call 911 immediately if chest pain occurs."

Nonpharmacologic Interventions.

In addition to analgesics, many nonpharmacologic measures can be used for patients with OA, such as rest balanced with exercise, joint positioning, heat or cold applications, weight control, and a variety of complementary and alternative therapies.

Teach the patient to *position joints in their functional position*. For example, when in a supine position (recumbent), he or she should use a small pillow under the head or neck but avoid the use of other pillows. The use of large pillows under the knees or head may result in flexion contractures. If needed, the legs may be elevated 8 to 12 inches (20 to 30 cm) to reduce back discomfort. Remind him or her to use proper posture when standing and sitting to reduce undue strain on the vertebral column. Teach the patient to wear supportive shoes; foot insoles may help relieve pressure on painful metatarsal joints. Collaborate with the physical therapist (PT) to plan a program for muscle-strengthening exercises to better support the joints.

Most patients apply *heat* or *cold* for temporary relief of pain, but not all patients find these modalities effective. Heat may help decrease the muscle tension around the tender joint and thereby decrease pain. Suggest hot showers and baths, hot packs or compresses, and moist heating pads. *Regardless of treatment, teach him or her to check that the heat source is not too heavy or so hot that it causes burns.* A temperature just above body temperature is adequate to promote comfort.

If needed, collaborate with the PT to provide special heat treatments, such as paraffin dips, diathermy (using electrical current), and ultrasonography (using sound waves). A 15- to 20-minute application usually is sufficient to temporarily reduce pain, spasm, and stiffness. Cold packs or gels that feel hot and cold at the same time may also be used.

Cold therapy has limited use for most patients in controlling pain. Cold works by numbing nerve endings and decreasing secondary joint inflammation, if present.

Nursing Safety Priority QSEN

Action Alert

Teach the patient to use ice packs that are not too heavy. Do not place them directly on skin; instead, wrap them in a towel or soft cloth.

There is no one food that causes or cures arthritis. Instead, a well-balanced diet is recommended. Gradual *weight loss* for obese patients may lessen the stress on weight-bearing joints, decrease pain, and perhaps slow joint

degeneration. If needed, collaborate with the registered dietitian to provide more in-depth teaching and meal planning or make referrals to community resources.

Complementary and Alternative Therapies.

Some patients with OA have reported that a variety of complementary and alternative medicine (CAM) therapies are useful. However, the evidence supporting their effectiveness is often inconsistent and inconclusive (see the Evidence-Based Practice box).

Evidence-Based Practice QSEN

Which Complementary and Alternative Methods Best Relieve Osteoarthritis Symptoms?

Fouladbakhsh, J. (2012). Complementary and alternative modalities to relieve osteoarthritis symptoms. *Orthopaedic Nursing, 31*(2), 115-121.

The author conducted a systematic review of current literature to determine the effectiveness and safety of commonly used complementary and alternative medicine (CAM) therapies in patients with osteoarthritis (OA), including mind-body therapies, supplements, and body-based treatments.

Research findings related to mind-body therapies revealed limited evidence for the use of yoga and a moderate level of evidence supporting the use of tai chi for patients with OA. According to the literature review, the only energy therapy that is moderately effective for OA is acupuncture for pain relief. Evidence for the use of glucosamine and chondroitin sulfate supplement is inconsistent. No evidence exists to support the use of most other supplements except for pycnogenol (pine bark extract). Research shows that massage therapy, a body-based treatment, for patients with OA is moderately effective for the relief of back pain.

Level of Evidence: 1

The author conducted a systematic literature review (previous 10 years) to draw conclusions about the effectiveness of selected CAM therapies for patients who have OA.

Commentary: Implications for Practice and Research

Further study is needed to examine the effectiveness of commonly used CAM therapies by patients with OA. Consistency in studies is needed to provide clearer answers and explore the complexity of these therapies.

Nurses caring for patients with OA need to provide information about the evidence or lack of evidence for CAM therapies. Before patients take supplements such as glucosamine, remind them to check with their health care provider about their safety.

Topical *capsaicin* products are safe over-the-counter (OTC) drugs. They work by blocking or modifying substance P and other neurotransmitters for pain. Tell the patient using capsaicin to expect a burning sensation for a short time after applying it. Recommend the use of plastic gloves for application. To prevent burning of eyes or other body areas, wash hands immediately after applying the substance.

Dietary supplements may complement traditional drug therapies. Glucosamine and chondroitin are widely used and are the most effective nonprescription supplements taken to decrease pain and improve functional ability. However, the evidence to support their use is inconsistent (Fouladbakhsh, 2012). These natural products are found in and around bone cartilage for repair and maintenance. **Glucosamine** may decrease inflammation, and **chondroitin** may play a role in strengthening cartilage. These supplements are used topically or taken in oral form. Chart 18-1 summarizes what you should teach your patients about glucosamine, with or without chondroitin.

Chart 18-1 Patient and Family Education: Preparing for Self-Management

Considerations for Taking Glucosamine Supplements

- Tell your health care provider if you decide to take glucosamine.
- Do not take glucosamine if you have hypertension.
- Do not take glucosamine if you are pregnant or breast-feeding.
- Monitor for bleeding if you take chondroitin with glucosamine or chondroitin alone if you are on anticoagulant therapy.
- If diabetic, monitor your blood glucose levels carefully because taking glucosamine for a prolonged time can increase them.
- Be aware that glucosamine can cause adverse effects such as a rash; GI disturbances, especially diarrhea; drowsiness; and headache.
- Be sure to take the recommended dosage based on your weight.
- Read drug labels to ensure that you do not take too much glucosamine for your weight; some drug names may not indicate they contain glucosamine (e.g., Bioflex, Arth-X Plus, Nutri-Joint).

Clinical Judgment Challenge

Patient-Centered Care; Evidence-Based Practice QSEN

A 66-year-old woman visits a new health care provider for a physical examination. She tells you that she works in a school cafeteria and has to stand most of the day. When you take an admission history, she tells you that she has pain and stiffness in her knees, feet, hands, and cervical spine. She takes ibuprofen when needed with some pain relief but has frequent indigestion for which she takes OTC Zantac. The patient is 5′4″ tall and weighs 183 pounds today.

During her physical assessment, you note that the patient has multiple Heberden's and Bouchard's nodes on both hands and a swollen right knee. She has a joint effusion in her right third PIP, and she is right-handed. The health care provider diagnoses her joint involvement as osteoarthritis (OA).

1. What additional physical assessment do you need to perform to determine the patient's level of functioning?
2. What risk factors contribute to her diagnosis of OA?
3. What OTC, nonpharmacologic, or CAM therapies for joint pain and stiffness might you recommend? What evidence supports those recommendations?
4. How might this patient's OA affect her ability to continue working in her current job?
5. What health teaching is needed for this patient to help manage her OA?

Surgical Management.

Surgery may be indicated when conservative measures or drug therapy no longer provides pain control, when mobility becomes so restricted that the patient cannot participate in activities he or she enjoys, and when he or she cannot maintain the desired quality of life. The most common surgical procedure performed for *older adults* with OA is **total joint arthroplasty (TJA)** (surgical creation of a joint), also known as **total joint replacement (TJR)**. Almost any synovial joint of the body can be replaced with a prosthetic system that consists of at least two parts—one for each joint surface. TJAs are expected to increase exponentially as baby boomers age over the next 20 years.

Total joint arthroplasty is a procedure used most often to manage the pain of OA and to improve mobility, although other conditions causing cartilage destruction may require the surgery. These disorders include

RA, congenital anomalies, trauma, and osteonecrosis. **Osteonecrosis** is bony necrosis secondary to lack of blood flow, usually from trauma or chronic steroid therapy. Hip and knee joints are most commonly replaced, but finger and wrist joint, elbow, shoulder, toe joint, and ankle replacements have been improved in the past 15 years.

The *contraindications* for TJA are active infection anywhere in the body, advanced osteoporosis, and rapidly progressive inflammation. An infection elsewhere in the body or from the joint being replaced can result in an infected TJA and subsequent prosthetic failure. Therefore if a patient has a urinary tract infection, for example, the physician treats the infection before surgery. Advanced osteoporosis can cause bone shattering during insertion of the prosthetic device. Severe medical problems, such as uncontrolled diabetes or hypertension, put the patient at risk for major postoperative complications and possible death.

Total Hip Arthroplasty.

The number of total hip arthroplasty (THA) procedures (also known as *total hip replacement [THR]*) has steadily increased over the past 35 years. The first time a patient receives any total joint arthroplasty, it is referred to as **primary arthroplasty.** If the implant loosens, **revision arthroplasty** may be performed. Availability of improved joint implant materials and better custom design features allow longer life of a replaced hip. Although patients of any age can undergo THR, the procedure is performed most often in those older than 60 years. *The special needs and normal physiologic changes of older adults often complicate the perioperative period and may result in additional postoperative complications.*

Preoperative Care.

As with any surgery, preoperative care begins with assessing the patient's level of understanding about the surgery and his or her ability to participate in the postoperative plan of care. The surgeon explains the procedure and postoperative expectations (including possible complications) during the office visit, but this patient education may have occurred weeks or months before the scheduled surgery. Some patients may not know what questions to ask or may forget the important information that was taught. Information may be provided in a notebook or DVD format that the patient can take home to review and share with family. This is particularly useful to patients with poor reading skills or poor memory. Written materials or other media provided in the patient's language appropriate for the patient's educational level are essential.

In some hospitals or orthopedic office practices, the physical therapist

(PT) may have the patient practice transfers, positioning, and ambulation. An occupational therapist (OT) may partner with the PT to assist in exercises or learning to ambulate with an assistive device, such as crutches or a walker. The OT may also help obtain assistive/adaptive equipment that will be needed after surgery. The cost of some items, such as an elevated toilet seat, is covered by Medicare and other insurers because they are essential to prevent hip dislocation. Other helpful equipment, such as grab bars and shower chairs, may not be paid for by third-party payers and can be purchased at local pharmacies or medical supply stores, based on the patient's specific needs.

All patients are also told to visit a dentist and have any necessary dental procedures done before surgery. After surgery, he or she must take extreme care not to acquire an infection that could migrate to the surgical area and cause prosthetic failure. *Remind the patient to tell any future health care provider that he or she has had any total joint arthroplasty.*

In addition to usual preoperative laboratory tests, the surgeon may ask the patient with RA to have a cervical spine x-ray if he or she is having general anesthesia. Those with RA often have cervical spine disease that can lead to subluxation during intubation. Hip x-rays, CT scan, and/or MRI may be done to assess the operative joint and surrounding soft tissues.

Because venous thromboembolism (VTE) is a serious postoperative complication, especially for hip surgery, assess the patient's risk factors for clotting problems, including history of previous clotting, obesity, smoking, and advanced age. *Teach patients that drugs that increase the risks for clotting and bleeding, such as NSAIDs, vitamins C and E, and hormone replacement therapy (HRT) or oral contraceptive drugs, must be discontinued about a week before surgery.*

Patients are also assessed for the need for possible blood transfusion after surgery. For patients who are at risk for postoperative anemia, one or more blood transfusions may be needed. Autologous (patient's own) or banked blood can be used. If desired, the patient may donate blood several weeks before surgery to be used after surgery. This pre-deposit autologous blood donation is a safe and cost-effective blood replacement alternative for those who are undergoing elective surgeries. It also decreases the risk for blood transfusion reactions.

For some patients, the surgeon may prescribe several weeks of epoetin alfa (Epogen, Procrit, Eprex) with or without iron to prevent anemia that can occur after hip or knee replacement. Epoetin alfa is recombinant human erythropoietin, a substance that is essential for developing red blood cells. This drug is particularly useful for older adults, who

frequently have mild anemia before surgery.

Remind patients that they will likely be asked to take a shower with special antiseptic soap the night before surgery to decrease bacteria that could cause infection after surgery. Tell them to wear clean nightwear after their shower and sleep on clean linen. Review which drugs are safe to take or necessary the morning of the operation, such as antihypertensives, and which ones should be avoided. Medication should be taken with a very small amount of water to prevent vomiting and aspiration during surgery. See Chapter 14 for additional preoperative care for any type of surgery.

Operative Procedures.

Similar to other orthopedic surgeries, the patient receives an IV antibiotic, usually a cephalosporin such as cefazolin (Ancef), within an hour before the initial surgical incision to help prevent infection.

The anesthesiologist or nurse anesthetist places the patient under general or **neuraxial** (epidural/spinal) anesthesia for lower extremity surgery. Neuraxial induction reduces blood loss and the incidence of deep vein thrombosis. Intraoperative blood loss with hypotensive neuraxial anesthesia is usually less than that with general anesthesia, thereby decreasing the need for postoperative blood transfusions. Patients receiving general anesthesia may have a regional nerve block, which lasts up to 24 hours after surgery.

Some patients are candidates for *minimally invasive surgery* (MIS) using a smaller incision with special instruments to reduce muscle cutting. This newer technique cannot be used for patients who are obese or those with osteoporosis. It is done only for primary THAs, not for revision surgeries. Like those of any MIS, the benefits of minimally invasive THA are decreased soft tissue damage and postoperative pain. Patients often have a shorter hospital stay and quicker recovery. They are generally satisfied with the cosmetic appearance of the incision because there is less scarring. Postoperative complications are not as common in patients having minimally invasive ("mini") hip replacements when compared with those having the traditional technique.

Regardless of procedure type, two components are used in the THA—the acetabular component and the femoral component (Fig. 18-3). A non-cemented prosthesis is most often used. Bone surfaces are smoothed as they are prepared to receive the artificial components. The non-cemented components are press-fitted into the prepared bone. The acetabular cup may be placed using computer or robotic assistance. If the prosthesis is cemented, polymethyl methacrylate (an acrylic fixating substance) is

used. A closed wound drainage system may be placed in the wound before the surgeon closes the incision.

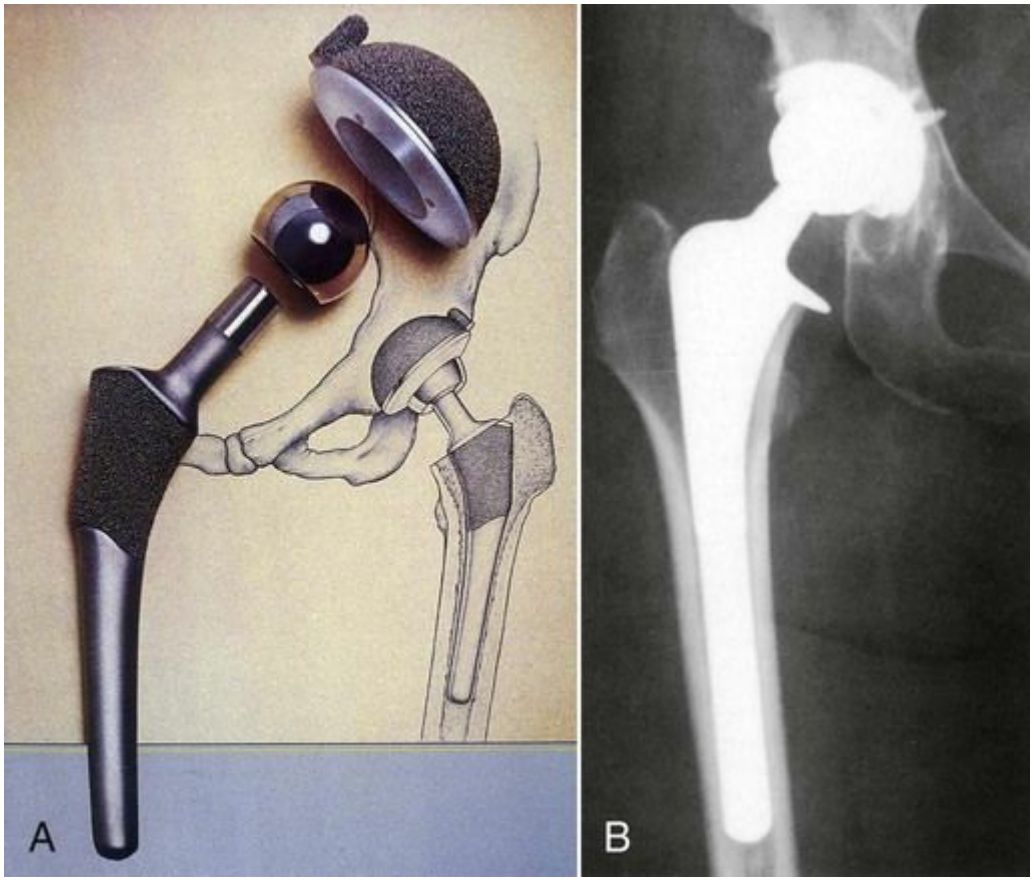

FIG. 18-3 **A,** Two major components of total hip arthroplasty. **B,** X-ray showing the components in place.

Considerations of a non-cemented prosthesis include protection of weight-bearing status to allow bone to grow into the prosthesis and decreased problems with loosening of the prosthesis. With a cemented prosthesis, cement can fracture or deteriorate over time, leading to loosening of the prosthesis, which causes pain and can lead to the need for a revision arthroplasty. In revision arthroplasty, the old prosthesis is removed and new components are replaced. Bone graft may be placed if bone loss is significant. Outcomes from revision arthroplasty may not be as positive as with primary arthroplasty.

Postoperative Care.

In addition to providing the routine postoperative care discussed in Chapter 16, assess for and help prevent possible postoperative complications. Table 18-2 summarizes these complications, including nursing measures for prevention, assessment, and intervention. Chart 18-2 highlights special concerns for the care of older adults in the

postoperative period. Collaborate with your patient and his or her family to become safety partners to keep the patient free from harm, including complications, such as:

Chart 18-2 Nursing Focus on the Older Adult

Postoperative Care of the Older Adult with a Total Hip Arthroplasty

- Use an abduction pillow or splint to prevent adduction after surgery if the patient is very restless or has an altered mental state.
- Keep the patient's heels off the bed to prevent pressure ulcers.
- Do not rely on fever as a sign of infection; older patients often have infection without fever. Decreasing mental status typically occurs when the patient has an infection.
- When assisting the patient out of bed, move him or her slowly to prevent orthostatic (postural) hypotension.
- Encourage the patient to deep breathe and cough and to use the incentive spirometer every 2 hours to prevent atelectasis and pneumonia.
- As soon as permitted, get the patient out of bed to prevent complications of immobility.
- Anticipate the patient's need for pain medication, especially if he or she cannot verbalize the need for pain control.
- Expect a temporary change in mental state immediately after surgery as a result of the anesthetic and unfamiliar sensory stimuli. Reorient the patient frequently.

TABLE 18-2

Nursing Interventions to Prevent Complications of Lower Extremity Total Joint Arthroplasty

COMPLICATION	PREVENTION/INTERVENTION
Dislocation	Position correctly.
	For hip, keep leg slightly abducted.
	For hip, prevent hip flexion beyond 90 degrees.
	Assess for acute pain, rotation, and extremity shortening.
	Report immediately to physician.
Infection	Use aseptic technique for wound care and emptying of drains.
	Wash hands thoroughly when caring for patient.
	Culture drainage fluid, if change.
	Monitor temperature.
	Report excessive inflammation or drainage to physician.
Venous thromboembolism	Have patient wear elastic stockings and/or sequential compression device per agency policy.
	Teach leg exercises to patient.
	Encourage fluid intake.
	Observe for signs of thrombosis (redness, swelling, or pain).
	Observe patient for changes in mental status.
	Administer anticoagulant as prescribed.
	Do not massage legs.
	Do not flex knees for a prolonged period of time.
Hypotension, bleeding, or infection	Take vital signs at least every 4 hours.
	Observe patient for bleeding.
	Report excessively low blood pressure or bleeding to physician.

- Hip dislocation
- Venous thromboembolism (VTE)
- Infection
- Anemia
- Neurovascular compromise

Preventing Hip Dislocation.

A major complication of THA is **subluxation** (partial dislocation) or total dislocation.

Nursing Safety Priority QSEN

Action Alert

Teach patients to maintain correct positioning at all times. When the

patient returns from the postanesthesia care unit (PACU), place him or her in a supine position with the head slightly elevated. Place a regular or abduction pillow between the patient's legs to prevent adduction beyond the midline of the body according to agency policy or surgeon preference.

In some hospitals, abduction devices with straps are placed on patients who are restless or cannot follow instructions, especially older adults with delirium or dementia. One or two regular bed pillows are used in most cases to remind patients to keep their legs abducted. For devices with straps, be sure to loosen the straps every 2 hours and check the patient's skin for irritation or breakdown.

Place and support the affected leg in neutral rotation. *Keep the patient's heels off the bed to prevent skin breakdown, particularly older adults.* The procedure for postoperative turning is controversial and specified by agency policy or surgeon preference. In most cases, you are safe to turn the patient if the pillow is in place. Some surgeons allow only turning directly onto one side or the other, depending on the surgical approach.

Teach the patient and family about other precautions to prevent dislocation as outlined in Chart 18-3. In addition to preventing adduction, remind them that the patient should avoid flexing the hips more than 90 degrees at all times. Use diagrams or demonstrate correct positioning to help reinforce this information before the patient gets out of bed (Fig. 18-4).

Chart 18-3 Patient and Family Education: Preparing for Self-Management

Care of Patients with Total Hip Arthroplasty After Hospital Discharge

Hip Precautions

- Do not sit or stand for prolonged periods.
- Do not cross your legs beyond the midline of your body.
- Do not bend your hips more than 90 degrees.
- Do not twist your body when standing.
- Use an ambulatory aid, such as a walker, when walking.
- Use assistive/adaptive devices for dressing, such as for putting on shoes and socks.
- Do not put more weight on your affected leg than allowed.

- Resume sexual intercourse as usual on the advice of your surgeon.

Pain Management

- Report increased hip pain to the surgeon immediately.
- Take oral analgesics as prescribed and only as needed.
- Do not overexert yourself; take frequent rests.

Incisional Care

- Inspect your hip incision every day for redness, heat, or drainage; if any of these are present, call your physician immediately.
- Cleanse your hip incision with a mild soap and water every day; be sure to dry it thoroughly.

Other Care

- Continue walking and performing the leg exercises as you learned in the hospital.
- Do not cross your legs to help prevent blood clots.
- Report pain, redness, or swelling in your legs to your physician immediately.
- Call 911 for acute chest pain or shortness of breath.
- If you are taking an anticoagulant, follow the precautions learned in the hospital to prevent bleeding; avoid using a straight razor, avoid injuries, and report bleeding or excessive bruising to your surgeon immediately.
- Perform postoperative exercises as instructed, including straight leg raises, gluteal sets, ankle pumps, and “ham” sets.

FIG. 18-4 Correct **(A, B)** and incorrect **(C)** hip flexion after a total hip replacement.

Nursing Safety Priority QSEN

Critical Rescue

Observe for possible signs of hip dislocation, which include severe hip pain, shortening of the affected leg, and leg rotation. If any of these clinical manifestations occur, keep the patient in bed and notify the surgeon immediately!

If the hip is dislocated, the surgeon manipulates and relocates the affected hip after the patient receives moderate sedation. The hip is then immobilized by an abduction splint or other device until healing occurs —usually in about 6 weeks.

Preventing Venous Thromboembolism.

The most potentially life-threatening complication after THA is venous thromboembolism (VTE), which includes deep venous thrombosis (DVT) and pulmonary embolism (PE). *Older patients are especially at increased risk for VTE because of age and decreased circulation before surgery. Obese patients and those with a history of VTE are also at high risk for thrombi.* Apply sequential compression devices (SCDs) and/or antiembolism stockings according to agency policy.

Anticoagulants, such as warfarin (Coumadin, Warfilone), subcutaneous low-molecular-weight heparin (LMWH), or factor Xa inhibitors, help prevent VTE. Patients are usually on anticoagulants for 3 to 6 weeks after surgery, depending on the patient's response and risk

factors. The use of subcutaneous LMWHs has markedly increased for patients with total hip and knee replacements. Examples include enoxaparin (Lovenox), dalteparin (Fragmin), and tinzaparin (Innohep).

As an alternative to LMWHs, subcutaneous fondaparinux (Arixtra), a factor Xa inhibiting agent, may be prescribed for some patients undergoing hip and knee arthroplasty. A newer Xa inhibitor, rivaroxaban (Xarelto), is given orally once a day. You do not need to monitor the international normalized ratio (INR), prothrombin time (PT), or activated partial thromboplastin time (aPTT) for patients receiving these drugs because they do not affect coagulation values. Like other anticoagulants, however, patients are at risk for bleeding. A complete discussion of nursing care associated with patients taking anticoagulants and VTE is found in Chapter 36. The Joint Commission's *VTE Core Measures* are also discussed in that chapter.

Early ambulation and exercise help prevent VTE. Teach the patient about leg exercises, which should begin in the immediate postoperative period and continue through the rehabilitation period. These exercises include plantar flexion and dorsiflexion (heel pumping), circumduction (circles) of the feet, gluteal and quadriceps muscle setting, and straight-leg raises (SLRs). Teach the patient to perform gluteal exercises by pushing the heels into the bed and achieve **quadriceps-setting exercises** ("quad sets") by straightening the legs and pushing the back of the knees into the bed. In addition to preventing clots, these exercises improve muscle tone, which helps restore the function of the extremity.

Preventing Infection.

infection can occur during hospitalization or months or years later after a hip replacement. Most infections are caused by contamination during surgery and are considered "deep" infections.

Monitor the surgical incision and vital signs carefully—every 4 hours for the first 24 hours and every 8 to 12 hours thereafter. Observe for signs of infection, such as an elevated temperature and excessive or foul-smelling drainage from the incision. *An older patient may not have a fever with infection but, instead, may experience an altered mental state.* If you suspect this problem, obtain a sample of any drainage for culture and sensitivity to determine the offending organisms and the antibiotics that may be needed for treatment.

Assessing for Bleeding and Managing Anemia.

Observe the surgical hip dressing for bleeding or other type of drainage at least every 4 hours or when vital signs are taken. Empty and measure

the bloody fluid in the surgical drain(s) every shift. The total amount of drainage is usually less than 50 mL/8 hr. Patients who have the minimally invasive procedure may not have a drain. The surgeon usually removes the drains and operative dressing 24 to 48 hours after surgery. *Take special care when removing tape from the skin to prevent tape burns and skin tears as the surgical dressing is changed, especially for older adults.*

The surgeon also requests periodic hemoglobin and hematocrit (H&H) tests to assess for anemia. Although some patients receive several units of blood during surgery, the H&H levels may continue to fall; in this case, additional blood is given 1 to 2 days after surgery. Blood pressure may be lower than usual because of blood loss during surgery.

Assessing for Neurovascular Compromise.

As with other musculoskeletal surgery, monitor neurovascular assessments frequently for a possible compromise in circulation to the affected distal extremity.

Nursing Safety Priority QSEN

Action Alert

Check and document color, temperature, distal pulses, capillary refill, movement, and sensation. Remember to compare the operative leg with the nonoperative leg. These assessments are performed at the same time the vital signs are checked. Report any changes in neurovascular assessment to the surgeon, and carefully monitor for changes. Early detection of changes in neurovascular status can prevent permanent tissue damage.

In addition to implementing interventions to prevent potential postoperative complications and monitoring for early signs of complications, the interdisciplinary team plans care to manage pain, improve mobility and activity, and promote self-management.

Managing Pain.

Although hip arthroplasty is performed to relieve joint pain, patients experience pain related to the surgical procedure. Many state that their pain is different and less severe than before surgery. Immediate pain control is typically achieved by extended-release epidural morphine (EREM) or patient-controlled analgesia (PCA) with morphine or another opioid. An NSAID should be taken with the opioid to decrease

inflammation. Chapter 3 contains information on the nursing care associated with these acute pain modalities. *Keep in mind that the patient may also receive additional analgesic drugs for chronic arthritic pain in other joints.*

Regardless of the pain management method used, most patients do not require parenteral analgesics after the first day. Oral opioids, such as oxycodone plus acetaminophen (Percocet, Tylox), are then commonly prescribed until the pain can be controlled by NSAIDs such as ketorolac (Toradol, Acular) or ibuprofen (Motrin, Apo-Ibuprofen).

Nonpharmacologic methods for acute and chronic pain control can also be used to decrease the amount of drug therapy used (see Chapter 3). A study by Thomas and Sethares (2010) found that guided imagery can be helpful in controlling pain in patients with total joint arthroplasty.

Promoting Mobility and Activity.

Depending on the time of day that the surgery is performed, the patient with a THA gets out of bed with assistance the night of surgery to prevent problems related to impaired mobility (e.g., atelectasis, pneumonia), especially in older adults.

Nursing Safety Priority QSEN

Action Alert

Be sure to assist the patient the first time he or she gets out of bed to prevent falls and observe for dizziness. When getting the patient out of bed, stand on the same side of the bed as the affected leg. After the patient sits on the side of the bed, remind him or her to stand on the unaffected leg and pivot to the chair with guidance. *To avoid injury, do not lift the patient!*

Remind the patient to avoid flexing the hips beyond 90 degrees as discussed earlier (see Fig. 18-4). Raised toilet seats and reclining chairs help prevent hyperflexion of the replaced hip joint. Be sure to teach the patient to also *avoid* twisting the body or crossing his or her legs to prevent hip dislocation.

The surgeon, type of prosthesis, and surgical procedure determine the amount of weight bearing that can be applied to the affected leg. A patient with a cemented implant is usually allowed immediate partial weight bearing (PWB) and progresses to full weight bearing (FWB). Typically, only "toe-touch" or minimal weight bearing is permitted for patients with uncemented prostheses. When x-ray evidence of bony

ingrowth can be seen, the patient can progress to PWB and then to FWB.

In collaboration with the physical therapist (PT), teach the patient how to follow weight-bearing restrictions. Most patients use a walker (may be a rolling walker), but younger adults may use crutches. They are usually advanced to a single cane or crutch if they can walk without a severe limp 4 to 6 weeks after surgery. When the limp disappears, they no longer need an ambulatory/assistive device and may be permitted to sit in chairs of normal height, use regular toilets, and drive a car.

NCLEX Examination Challenge

Physiological Integrity

A client had a right total hip arthroplasty 2 days ago. Which precautions will the nurse teach the client to prevent surgical complications? **Select all that apply.**

A "Stand on your right leg and pivot to the chair."
B "Do not bend your hips more than 90 degrees."
C "Cross your legs to be most comfortable."
D "Avoid twisting your body when moving."
E "Use a long-handled shoe horn to put on your shoes."

Promoting Self-Management.

The hospital's occupational therapy department may supply assistive/adaptive devices to help with ADLs, especially for those having traditional surgery. Particularly important are devices designed for reaching to prevent patients from bending or stooping and flexing the hips more than 90 degrees. Extended handles on shoehorns and dressing sticks may be very useful to achieve ADL independence. Third-party payers may or may not pay for these devices, depending on the patient's status.

For those who have *traditional surgery,* the length of stay in the acute care hospital is typically 2 to 3 days, but older adults or those experiencing postoperative complications may stay longer. Those who have the *minimally invasive THA* are discharged on the second postoperative day or the day of surgery (23-hour stay). Those patients are discharged to home on crutches to practice their own rehabilitative exercises. Most of them are able to return to work in 2 weeks. For that reason, some hospitals have started Rapid Recovery Hip Replacement programs for patients who are candidates for MIS.

Discharge for patients having *traditional surgery* may be to the home, a

rehabilitation unit, a transitional care unit, or a skilled unit or long-term care facility for continued rehabilitation before discharge to home. The interdisciplinary team provides written instructions for posthospital care and reviews them with patients and their family members (see Chart 18-3). Be sure to provide a copy of these instructions for the patient.

In some acute care settings, postoperative classes are provided to the caregivers of patients who have joint replacements to improve the quality of the postoperative experience (Mazaleski, 2011). These classes are provided by the interdisciplinary team and include pain management, new medications, activity level, discharge instructions, and home preparation (see the Quality Improvement box).

Quality Improvement QSEN

Improving Postoperative Total Joint Replacement Education for Caregivers

Mazaleski, A. (2011). Postoperative total joint replacement class for support persons: Enhancing patient and family centered care using a quality improvement model. *Orthopaedic Nursing, 30*(6), 361-364.

Postoperative education is essential to ensure positive patient outcomes and increase patient satisfaction. The orthopedic clinical nurse specialist for an active orthopedic unit suggested a postoperative class on the unit for caregivers of patients who had total joint replacements. The ultimate goal of the education was to promote patient- and family-centered care.

The Plan, Do, Study, Act (PDSA) quality improvement (QI) model was used to guide the planning and implementation of the project. A review of patient and family satisfaction scores revealed poor understanding of drug therapy and its side effects. The class included information on new medications, pain management, activity level, and home preparation. A post-class survey was given to class attendees and used to improve future classes. For example, specific discharge instruction sheets were developed for oxycodone and Warfarin. Since the classes were started, patient and family satisfaction scores increased and over 90% of the class attendees strongly agreed that the information was helpful.

Readmission rates will be monitored for patients whose caregivers attended the class. In addition, questions and concerns related to office staff during follow-up visits will be tracked.

Commentary: Implications for Practice and Research

Research indicates that discharge teaching after surgery improves

quality of care and improves patient and family satisfaction. This QI project planned and implemented a class for caregivers of patients who had total joint replacements to educate them on postoperative care at home. The attendees for each class were surveyed to determine their satisfaction with the class. The staff made changes to subsequent classes based on those findings.

Other outcome data are needed to evaluate the effectiveness of the classes. The authors plan to collect these data, including hospital readmission rate and postoperative complications.

Acute rehabilitation usually takes 1 to 2 weeks or longer, depending on the patient's age and tolerance and the type of prosthesis used. However, it often takes 6 weeks or longer for complete recovery. Some patients who are discharged to their home are able to attend physical therapy sessions in an office or ambulatory care setting. Others have no means or cannot use community resources and need physical therapy in the home, depending on their health insurance coverage. *Collaborate with the case manager to determine which option is best for your patient.*

Total Knee Arthroplasty.

Although many adults require total knee arthroplasty (TKA, also known as *total knee replacement [TKR]*), those who have a knee replaced are often younger than those who have a hip replaced. Continued improvements in total knee implants have increased the expected life of a TKA to 20 years or more, depending on the age and activity level of the patient. An increasing number of patients who have TKAs are overweight or obese. Obesity increases wear and tear on weight-bearing joints, which can lead to revision surgeries. Unilateral (one joint) or bilateral joint replacements done at the same time may be performed, depending on the patient.

Preoperative Care.

TKA, like hip replacement, is performed when joint pain cannot be managed by conservative measures. When limited mobility severely prevents patients from participating in work or activities they enjoy, this procedure can restore a high quality of life. The preoperative care and teaching for patients undergoing a TKA are similar to that for total hip replacement. However, precautions for positioning are not the same. Differences in patient and family teaching depend on the procedure used by the orthopedic surgeon.

Like the minimally invasive surgery (MIS) for the hip, the knee can also be replaced using MIS. Candidates for mini–knee replacement cannot

have severe bone loss, obesity, or previous knee surgery. They should be in good general health. Patients having MIS usually have less blood loss during surgery, less pain, more joint range of motion (less stiffness from scarring), and a faster recovery, leading to a shorter hospital stay. Rapid Recovery Knee Replacement programs for patients having minimally invasive TKA are becoming popular in a number of hospitals.

All patients are given verbal and either written or video preoperative instructions, which include the activity protocol to follow after surgery. The PT and OT provide information about transfers, ambulation, postoperative exercises, and ADL assistance. Patients may practice walking with walkers or crutches to prepare them for ambulation after TKA. Teach patients about the possible need for assistive-adaptive devices to assist with ADLs, including an elevated toilet seat, safety handrails, and dressing devices like a long-handled shoehorn. Some third-party payers cover these devices, depending on the patient's condition and age; however, other insurers may not pay for them. Teach the patient and family how and where this equipment can be obtained to have it available after surgery.

Some surgeons prescribe a continuous passive motion (CPM) machine after knee surgery to increase joint mobility. Others have found that the range of motion for the surgical knee is not improved by using this device. If the patient will have a CPM machine after surgery, be sure to explain what it is and how it is used.

Routine diagnostic testing is requested, as well as any additional tests, such as cervical spine x-rays for patients with rheumatoid arthritis (RA) to determine if the patient can be intubated for anesthesia. Cervical spine involvement occurs in about half of all patients with RA. Changes in the cricoarytenoid joint of the larynx can also make intubation difficult (Nelson, 2011). Knee x-rays, CT scan, and/or MRI may be done to assess the joint and surrounding soft tissues. Rheumatoid arthritis is discussed later in this chapter.

Teach patients that they will need to shower with a special antiseptic soap the night before surgery to decrease bacteria on the skin that could cause infection after surgery. Remind them to wear clean nightwear and sleep on clean linen. Ask them to check with their surgeon about what medications they can take the morning of surgery, including antihypertensives and corticosteroids (taken by many patients with RA). Take these drugs with a small amount of water to prevent vomiting and aspiration during surgery. See Chapter 14 for additional preoperative care for any type of surgery.

Operative Procedures.

As with the hip, the knee can be replaced with the patient under general or neuraxial (epidural or spinal) anesthesia. An antibiotic, usually an IV cephalosporin, is given shortly before surgical opening to help prevent infection. In the *traditional surgery,* the surgeon makes a central longitudinal incision about 8 inches (20 cm) long. Osteotomies of the femoral and tibial condyles and of the posterior patella are performed, and the surfaces are prepared for the prosthesis. The femoral component is often non-cemented (using a press-fit) with the tibial component being cemented. The surgeon typically inserts a surgical drain and applies a pressure dressing to decrease edema and bleeding.

Minimally invasive TKA may be performed using a shorter incision and special instruments to spare muscle and other soft tissue. Computer-guided or robotic equipment may be used to ensure accurate positioning of the knee implants. This procedure is referred to as a *computer-assisted TKA.*

Complementary and Alternative Therapies.

A newer intervention to reduce the severe pain that occurs after knee arthroplasty is the intraoperative insertion of Adlea, a refined capsaicin product, directly into the surgical joint. Most patients who were given Adlea during knee surgery have less acute postoperative pain when compared with others who did not receive the treatment.

Postoperative Care.

Postoperative nursing care of the patient with a TKA is similar to that for the patient with a total hip arthroplasty; however, maintaining hip abduction is not necessary. The surgeon may prescribe a CPM machine, which can be applied in the postanesthesia care unit (PACU) or soon after the patient is admitted to the postoperative unit (Fig. 18-5). The CPM machine keeps the prosthetic knee in motion and may prevent the formation of scar tissue, which could decrease knee mobility and increase postoperative pain. In the immediate postoperative period, the surgeon may also prescribe ice packs or an ice machine to decrease swelling at the surgical site. Swelling and bruising are more common with this type of surgery than with hip surgery.

FIG. 18-5 A continuous passive motion (CPM) machine in use.

The surgeon, PT, or technician presets the CPM machine for the appropriate range of motion and cycles per minute. A typical initial setting is 20 to 30 degrees of flexion and full extension (0 degrees) at two cycles per minute, but this setting varies according to surgeon preference. The machine is generally used on an intermittent schedule of a designated number of hours several times a day, with the range of motion increased gradually. Observe and document the patient's response to the device, and follow the surgeon's protocol for settings. Chart 18-4 outlines your responsibility when caring for a patient using the CPM machine.

Chart 18-4 Best Practice for Patient Safety & Quality Care QSEN

The Patient Using a Continuous Passive Motion (CPM) Machine

- Ensure that the machine is well padded.
- Check the cycle and range-of-motion settings at least once every 8 hours.
- Ensure that the joint being moved is properly positioned on the machine.
- If the patient is confused, place the controls to the machine out of his

or her reach.
- Assess the patient's response to the machine.
- Turn off the machine while the patient is having a meal in bed.
- When the machine is not in use, do not store it on the floor.

In general, pain control measures for patients with TKA are similar to those with total hip arthroplasty. Many patients report high ratings on the pain intensity scale and require IV opioid medications longer than patients with THA, particularly if they have had bilateral surgery. *Be sure to manage your patient's pain to provide comfort, increase his or her participation in physical therapy, and improve joint mobility.*

One of the most recent advances in postoperative pain management for lower extremity total joint arthroplasty is *peripheral nerve blockade (PNB).* In this procedure, the anesthesiologist injects the femoral or sciatic nerve with local anesthetic; the patient may receive a continuous infusion of the anesthetic by portable pump. This method not only decreases pain but also allows patients to participate in rehabilitation earlier than when using opioid analgesia alone. Patients having continuous femoral nerve blockade (CFNB) after TKA require less opioids and antiemetics when compared with patients receiving no CFNB and those who had a single-shot femoral nerve blockade (FNB).

When caring for a patient receiving a CPNB, perform neurovascular assessments every 2 to 4 hours or according to hospital protocol. The patient should be able to plantarflex and dorsiflex the affected foot but not feel pain in the lower leg. Check for movement, sensation, warmth, color, pulses, and capillary refill.

Nursing Safety Priority QSEN

Critical Rescue

Monitor the patient for signs and symptoms that could indicate that the local anesthetic is getting into the patient's system, such as:
- Metallic taste
- Tinnitus
- Nervousness
- Slurred speech
- Bradycardia
- Hypotension
- Decreased respirations
- Seizures

Report any of these new signs and symptoms to the surgeon or anesthesiologist immediately, and carefully continue monitoring the patient for changes.

Because dislocation is a rare problem for a patient with TKA, special positioning to prevent adduction is not required. Maintain the knee in a neutral position and not rotated internally or externally. If a CPM machine is not used, the surgeon may recommend that the knee should rest flat on the bed or with one pillow under the lower calf and foot to encourage slight extension of the knee joint. Be sure that the surgical knee does not hyperextend.

Some complications that affect patients with total hip arthroplasty may also affect those having TKA, such as venous thromboembolism, infection, anemia, and neurovascular compromise. Assessments and interventions associated with these complications are described in the Postoperative Care section of the discussion of Total Hip Arthroplasty on pp. 297-300.

The desired outcome for discharge from the acute hospital unit is that the patient can walk independently with crutches, walker, or cane and has adequate flexion in the operative knee for ambulation. Patients who had minimally invasive TKA are discharged to home in 1 to 2 days with instructions for postoperative exercises, weight bearing, and activity progression. Many of these instructions (except for preventing hip dislocation) are similar to those provided for teaching patients after a total hip arthroplasty (see Chart 18-3).

Patients are able to partially weight bear unless the prosthesis is not cemented. During the home rehabilitation phase, the use of a stationary bicycle or CPM machine may help gain flexion. These patients can return to work and other usual activities in 2 to 3 weeks, depending on their age and other health status factors.

Acute rehabilitation for *traditional* TKA usually takes about 1 to 2 weeks longer, depending on the age and tolerance of the patient. These patients may be discharged to their home or to an acute rehabilitation unit, transitional care unit, skilled unit, or long-term care facility for therapy. They may also be instructed to use a continuous passive motion (CPM) machine at home. If able, they may attend physical therapy sessions in an office or ambulatory care setting. If not, home care services can provide physical therapy and nursing care in their home, depending on the insurance available. *Collaborate with the case manager to determine which option is best for your patient*. Total recovery from traditional TKA takes 6 weeks or longer, especially for those older than 75

years.

NCLEX Examination Challenge

Safe and Effective Care Environment

A nursing technician is assigned to care for a client who has a CPM machine in place after a total knee arthroplasty. Which statement by the "tech" indicates a need for further teaching and supervision by the nurse?
A "I will turn off the machine if the client has any pain."
B "I will turn off the machine when the client eats."
C "I will store the machine on a chair when not used."
D "I will check to make sure the client's leg is correctly placed."

Other Joint Arthroplasties.

After the hip and knee, the shoulder and hand are the most common joints replaced for severe OA, RA, or trauma. Elbow, wrist, ankle, and foot replacements are not performed as often as other types of arthroplasties. The shoulder and other upper extremity joints do not bear weight and therefore tend to have less degeneration and subsequent pain. Preoperative teaching for patients having any of these surgeries depends on the surgeon's technique and postoperative protocols. For example, the continuous passive motion (CPM) machine may be prescribed postoperatively in the hospital and in the posthospital setting (home or other facility). These devices are available for almost any joint surgery in the body. Some surgeons find that the CPM machine is not helpful in promoting joint mobility and may be uncomfortable for patients.

Total shoulder arthroplasty (TSA) has gained popularity as newer prostheses and technology have been developed. This procedure usually decreases arthritic pain and increases the patient's ability to perform ADLs. Because the shoulder joint is complex and has many **articulations** (joint surfaces), **subluxation** (partial dislocation) or complete dislocation is a major potential complication. Usually the glenohumeral joint, created by the glenoid cavity of the shoulder blade (scapula) and the head of the humerus, is replaced because it moves the most and is therefore most affected by arthritis. A **hemiarthroplasty** (replacement of part of the joint), typically the humeral component, may be performed as an alternative to TSA.

The surgeon makes an incision to replace the joint while the patient is under general anesthesia. The implant may be cemented or press-fitted

without cement. Some surgeons perform *minimally invasive TSA,* which decreases postoperative complications like infection and nerve damage. A sling is applied to immobilize the joint until therapy begins.

In addition to dislocation, postoperative complications are similar to those for other total joint replacements and include infection and neurovascular compromise. Active and passive exercises are needed to begin shoulder movement. *As for any other total joint arthroplasty, perform frequent neurovascular assessments, at least every 4 to 8 hours*. The hospital stay for TSA is shorter than for a total hip or knee replacement. Rehabilitation with an occupational therapist generally takes several months.

Total elbow arthroplasty (TEA) is performed most often for patients with rheumatoid arthritis (RA), but it is done for anyone whose severe arthritis limits mobility and causes uncontrolled pain. TEA may be successful in increasing range of motion, but infection and loosening may occur because of extensive tissue cutting during surgery. Active and passive exercises are used postoperatively. In general, elbow motion is allowed as tolerated. Occupational therapy may not be necessary, but the need depends on the individual patient. Lifting is usually restricted on a long-term basis after TEA. Generalized swelling usually resolves in 3 to 6 months.

Any joint of the hand or foot can be replaced *(phalangeal joint, metacarpal or metatarsal arthroplasties),* often for patients with RA. Hand prostheses are implanted without the use of cement because they stay in place and do not bear weight.

For the hand, a bulky dressing is used temporarily after surgery and is then replaced with a dynamic splint. Edema is controlled by having the patient elevate the arm as much as possible. The rehabilitation program for phalangeal joint arthroplasties may last for many weeks until normal function and strength return. These procedures are typically performed in specialized hand centers. Joint replacements in the toe usually require less rehabilitation.

Any bone of the *wrist* can also be replaced, including the heads of the radius and ulna. The postoperative pressure dressing is removed in 1 to 2 days, and a splint is applied. The patient usually regains full function within 6 to 12 weeks, but lifting may be restricted for a longer period. Special hand therapists work with these patients for the extensive rehabilitation that is required for phalangeal and wrist replacements.

Because the ankles support about 25% of the body's weight and are complex joints, developing an implant that is both small enough and strong enough has been difficult. Although total ankle arthroplasties

(TAAs) have been problematic for more than three decades, newer non-cemented prosthetic systems have renewed interest in ankle replacements. Surgeons who specialize in foot and ankle surgeries are available in some parts of the country.

Postoperative complications include infection, delayed wound healing, nerve injuries, and loosening. Therefore TAA is not as successful as total hip or knee replacements. Non-cemented prostheses seem to be preferred over cemented ones to prevent loosening. The patient is allowed to begin weight bearing at about 6 weeks, and rehabilitation continues for about 3 months.

Improving Mobility

Planning: Expected Outcomes.

The patient with osteoarthritis (OA) is expected to maintain or improve a level of mobility and activity that allows him or her to function independently with or without an assistive ambulatory device.

Interventions.

Management of the patient with OA is an interdisciplinary effort. If needed, collaborate with the physical therapist (PT) and occupational therapist (OT) to meet the outcome of independent function and mobility. Major interventions include therapeutic exercise and the promotion of ADLs and ambulation by teaching about health and the use of assistive devices.

Certain recreational activities may also be therapeutic, such as swimming to enhance chest and arm muscles. Aerobic exercises (e.g., walking, biking, swimming, aerobic dance) are also recommended. Kim et al. (2012) reported the effectiveness of an aquarobic (water exercise) program for patients with osteoarthritis in increasing mobility and reducing pain. Exercises may be prescribed by rehabilitation therapists for the patient with OA, but you will need to reinforce their techniques and principles. The ideal time for exercise is immediately after the application of heat. To prevent further joint damage, teach patients to carefully follow the instructions for exercise outlined in Chart 18-5.

Chart 18-5 Patient and Family Education: Preparing for Self-Management

Exercises for Patients with Osteoarthritis or Rheumatoid

Arthritis

- Follow the exercise instructions that have been prescribed specifically for you. There are no universal exercises; your exercises have been specifically tailored to your needs.
- Do your exercises on both "good" and "bad" days. Consistency is important.
- Respect pain. Reduce the number of repetitions when the inflammation is severe and you have more pain.
- Use active rather than active-assist or passive exercise whenever possible.
- Do not substitute your normal activities or household tasks for the prescribed exercises.
- Avoid resistive exercises when your joints are severely inflamed.

Collaborate with the PT to evaluate the patient's need for ambulatory aids such as canes, walkers, or platform crutches. Although some patients do not like to use these aids or may forget how to use them, they can help prevent further joint deterioration and pain. Collaborate with the OT, if needed, to provide suggestions and devices for assistance for ADLs.

Community-Based Care

The patient with OA is not usually hospitalized for the disease itself but is admitted for surgical management. Expect that any patient older than 60 years will have some degree of arthritis and possibly chronic pain that needs to be managed.

Home Care Management.

If weight-bearing joints are severely involved, the patient may have difficulty going up or down stairs. Making arrangements to live on one floor with accessibility to all rooms is often the best solution. A home care nurse or case manager may collaborate with a rehabilitation therapist to assess the need for structural alterations to the home to accommodate ambulatory aids and enable the patient to perform ADLs. For example, a kitchen counter may need to be lowered or a seat and handrails may need to be installed in the shower. If the patient has undergone a total hip replacement, an elevated toilet seat is necessary for several weeks postoperatively to prevent excessive hip flexion. Patients who have TKAs may also find elevated toilet seats easier to use.

Self-Management Education.

Self-management education (SME) is an effective psychosocially focused nonpharmacologic intervention (Shin & Kolanowski, 2010). Learning how to protect joints is the most important part of patient and family education. Preventing further damage to joints slows the progression of OA and minimizes pain. Explain the general principles of joint protection, and give practical examples (Chart 18-6).

Chart 18-6 Patient and Family Education: Preparing for Self-Management

Evidence-Based Instructions for Joint Protection

- Use large joints instead of small ones; for example, place your purse strap over your shoulder instead of grasping the purse with your hand.
- Do not turn a doorknob clockwise. Turn it counterclockwise to avoid twisting your arm and promoting ulnar deviation.
- Use two hands instead of one to hold objects.
- Sit in a chair that has a high, straight back.
- When getting out of bed, do not push off with your fingers; use the entire palm of both hands.
- Do not bend at your waist; instead, bend your knees while keeping your back straight.
- Use long-handled devices, such as a hairbrush with an extended handle.
- Use assistive/adaptive devices, such as Velcro closures and built-up utensil handles, to protect your joints.
- Do not use pillows in bed except a small one under your head.
- Avoid twisting or wringing your hands.

As with other diseases in which drugs and nutritional therapy are used, teach the patient and family the drug therapy protocol, desired effects and potential side effects, and toxic effects. Emphasize the importance of reducing weight and eating a well-balanced diet to promote tissue healing.

Many patients with arthritis look for a cure after becoming frustrated and desperate about the course of the disease and treatment. Better control of arthritis is possible, but cure is not yet available. Unfortunately, tabloids, books, media, and the Internet often report "curative" remedies. People spend billions of dollars each year on quackery, including liniments, special diets, and copper bracelets. More hazardous

substances, such as snake venom and industrial cleaners, are also advertised as remedies. Refer the patient to the Arthritis Foundation for up-to-date information about these "cures." The practice of wearing a copper bracelet will not cure arthritis, but it will not cause harm. If the patient is using a potentially harmful substance or method, however, reinforce the need to avoid the unproven remedy and explain why it should not be used. Respect the patient's preferences, values, and beliefs for using benign remedies that do not cause harm.

With most types of arthritis and connective tissue disease (CTD), patients must live with a chronic, unpredictable, and painful disorder. Their roles, self-esteem, and body image may be affected by these diseases. Body image is often not as devastating in OA as in the inflammatory arthritic diseases, such as RA. The psychosocial component associated with having arthritis is discussed in more detail later in this chapter in the Rheumatoid Arthritis section.

Health Care Resources.

The patient who has undergone surgery may need help from community resources. After an arthroplasty, he or she may need assistance with mobility. The patient may be discharged to home or an inpatient unit. Collaborate with the case manager and surgeon to determine the best placement. If the patient is discharged to home, home care nurses may be approved for third-party payment for several visits, depending on the presence of any existing systemic diseases. A home care aide may visit the home to help with hygiene-related needs, and a physical therapist may work with ambulatory and mobility skills. For older patients, a family member, significant other, or other caregiver should be in the home for at least the first few weeks when the patient needs the most assistance. Emphasize the need for patient safety, especially interventions to prevent falls as described in Chapter 2.

Provide written instructions about the required care, regardless of whether the patient goes home or to another inpatient facility. As required by The Joint Commission's National Patient Safety Goals (NPSGs) and other health care accrediting organizations, hand-off communication with the new care provider is essential for seamless continuity of care.

The Arthritis Foundation (www.arthritis.org) is an important community resource for all patients with arthritis and other CTDs. This organization provides information to lay people and health care professionals and refers patients and their families to other resources as needed. Local support groups can help them cope with these diseases.

Evaluation: Outcomes

Evaluate the care of the patient with OA on the basis of the identified priority problems. The expected outcomes are that he or she:

- Achieves pain control to a pain intensity level of 3 to 4 on a scale of 0 to 10 or at a level that is acceptable to the patient
- Moves and functions in his or her own environment independently with or without assistive devices

Rheumatoid Arthritis

Pathophysiology

Rheumatoid arthritis (RA) is a chronic, progressive, systemic inflammatory autoimmune disease process that affects primarily the synovial joints. **Systemic** means this disease affects the body system, affecting many joints and other tissues. RA affects over 1.3 million people, and Euro-Americans have the disease more often than other groups (Arthritis Foundation, 2013c). The cause for this trend is not known.

In RA, transformed autoantibodies (rheumatoid factors [RFs]) are formed that attack healthy tissue, especially synovium, causing inflammation. The disease then begins to involve the articular cartilage, joint capsule, and surrounding ligaments and tendons. immunity and inflammation factors cause cartilage damage in patients with RA (McCance et al., 2014):

- CD4 T–helper cells and other immune cells in synovial fluid promote cytokine release, especially interleukin-1 (IL-1) and tumor necrosis factor–alpha (TNFA), which attack cartilage.
- Neutrophils and other inflammatory cells in the joint are activated and break down the cartilage.
- Immune complexes deposit in synovium, and osteoclasts are activated.
- B- and T-lymphocytes of the immune system are stimulated and increase the inflammatory response. (Also see Chapter 17 for a complete discussion of the inflammatory response.)

The synovium then thickens and becomes hyperemic, fluid accumulates in the joint space, and a pannus forms. The **pannus** is vascular granulation tissue composed of inflammatory cells; it erodes articular cartilage and eventually destroys bone. As a result, in late disease, fibrous adhesions, bony ankylosis, and calcifications occur; bone loses density, and secondary osteoporosis occurs.

Permanent joint changes may be avoided if RA is diagnosed early. Early and aggressive treatment to suppress synovitis may lead to a remission. RA is a disease characterized by natural remissions and exacerbations. Interdisciplinary health care team management helps control the disease to decrease the intensity and number of exacerbations. Preventing flares helps prevent joint erosion and permanent joint damage.

Because rheumatoid arthritis is a systemic disease, areas of the body besides the synovial joints can be affected. Inflammatory responses similar to those occurring in synovial tissue may occur in any organ or body system in which connective tissue is prevalent. If blood vessel

involvement **(vasculitis)** occurs, the organ supplied by that vessel can be affected, leading to eventual failure of the organ or system in late disease.

The etiology of RA remains unclear, but research suggests a *combination of environmental and genetic factors.* Some researchers also suspect that female reproductive hormones influence the development of RA because it affects women more often than men—usually young to middle-aged women. Others suspect that infectious organisms may play a role, particularly the Epstein-Barr virus (McCance et al., 2014). Physical and emotional stresses have been linked to exacerbations of the disorder and may be contributing factors or "triggers" to its development.

Genetic/Genomic Considerations

Patient-Centered Care QSEN

Research has shown that there is a strong association between RA and several human leukocyte antigen (HLA)-*DR* alleles. The cause of this association is not clear, but most HLA diseases are autoimmune (Nussbaum et al., 2007). *DR* alleles, especially *DR4* and *DRB1,* are the primary genetic factors contributing to the development of RA. *DR4* is associated with more severe forms of the disease. Other contributing factors are being researched.

Patient-Centered Collaborative Care

Assessment

The onset of rheumatoid arthritis (RA) may be acute and severe or slow and progressive; patients may have vague symptoms that last for several months before diagnosis. The onset of the disease is more common in the winter months than in the warmer months. The manifestations of RA can be categorized as early or late disease and as articular (joint) or extra-articular (Chart 18-7).

Chart 18-7 Key Features

The Patient with Rheumatoid Arthritis

Early Manifestations

Joint

- Inflammation

Systemic

- Low-grade fever
- Fatigue
- Weakness
- Anorexia
- Paresthesias

Late Manifestations

Joint

- Deformities (e.g., swan neck or ulnar deviation)
- Moderate to severe pain and morning stiffness

Systemic

- Osteoporosis
- Severe fatigue
- Anemia
- Weight loss
- Subcutaneous nodules
- Peripheral neuropathy
- Vasculitis
- Pericarditis
- Fibrotic lung disease
- Sjögren's syndrome
- Kidney disease
- Felty's syndrome

Physical Assessment/Clinical Manifestations

Early Disease Manifestations.

The patient with RA typically reports joint signs and symptoms of joint inflammation, generalized weakness, and fatigue. Anorexia and a weight loss of about 2 to 3 pounds (1 kg) usually occur early in the disease process. Persistent low-grade fever may accompany these manifestations. In patients with early disease, the upper-extremity joints are involved initially—often the proximal interphalangeal (PIP) and metacarpophalangeal (MCP) joints of the hands. These joints may be slightly reddened, warm, stiff, swollen, and tender or painful, particularly on palpation (caused by synovitis). The typical pattern of joint involvement in RA is bilateral and symmetric (e.g., both wrists). The number of joints involved usually increases as the disease progresses. In early disease, the patient may report migrating symptoms known as

migratory arthritis.

The presence of only *one* hot, swollen, painful joint (out of proportion to the other joints) may mean the joint is infected. *Refer the patient to the health care provider (generally the rheumatologist) immediately if this is the case.* Single hot, swollen joints are considered infected until proven otherwise and require immediate long-term antibiotic treatment.

Late Disease Manifestations.

As the disease worsens, the joints become progressively inflamed and very painful. The patient usually has frequent morning stiffness (also called the **gel phenomenon**), which lasts for 45 minutes to several hours after awakening. On palpation, the joints feel soft and look puffy because of synovitis and **effusions** (joint swelling with fluid, especially the knees). The fingers often appear spindle-like. Note any muscle atrophy (which can result from disuse secondary to joint pain) and a decreased range of motion in the affected joints.

Most or all synovial joints are eventually affected. The temporomandibular joint (TMJ) may be involved in severe disease, but such involvement is uncommon. When the TMJ is affected, the patient may have pain when chewing or opening the mouth.

When the spinal column is involved, the cervical joints are most likely to be affected. During clinical examination, gently palpate the posterior cervical spine and identify it as cervical pain, tenderness, or loss of motion.

Nursing Safety Priority QSEN

Critical Rescue

Cervical disease may result in subluxation, especially of the first and second vertebrae. This complication may be life threatening because branches of the phrenic nerve that supply the diaphragm are restricted and respiratory function may be compromised. The patient is also in danger of becoming quadriparetic (weak in all extremities) or quadriplegic (paralyzed in all extremities). If a person with RA reports cervical pain (may radiate down one arm) or loss of range of motion in the cervical spine, notify the health care provider immediately.

Joint Involvement.

Joint deformity occurs as a late, articular manifestation, and secondary osteoporosis can cause bone fractures. Observe common deformities,

especially in the hands and feet (Fig. 18-6). Extensive wrist involvement can result in carpal tunnel syndrome (see Chapter 51 for assessment and management of carpal tunnel syndrome).

FIG. 18-6 Common joint deformities seen in rheumatoid arthritis.

Gently palpate the tissues around the joints to elicit pain or tenderness associated with other rheumatoid complications, unless the patient is having severe joint pain. For example, **Baker's cysts** (enlarged popliteal bursae behind the knee) may occur and cause tissue compression and pain. Tendon rupture is also possible, particularly rupture of the Achilles tendon.

Systemic Complications and Associated Syndromes.

Numerous extra-articular clinical manifestations are associated with advanced disease. Assess the patient to ascertain systemic involvement. In addition to increased joint swelling and tenderness, *moderate to severe weight loss, fever, and extreme fatigue* are common in late disease **exacerbations,** often called "flare-ups." Some patients have the characteristic round, movable, nontender **subcutaneous nodules,** which usually appear on the ulnar surface of the arm, on the fingers, or along the Achilles tendon. These nodules can disappear and reappear at any time and are associated with severe, destructive disease. Rheumatoid nodules usually are not a problem themselves; however, they occasionally open and become infected and may interfere with ADLs.

Accidentally bumping the nodules may cause discomfort. Occasionally, nodules occur in the lungs.

Inflammation of the blood vessels results in *vasculitis,* particularly of small to medium-size vessels. When arterial involvement occurs, major organs can become ischemic and malfunction. Assess for ischemic skin lesions that appear in groups as small, brownish spots, most commonly around the nail bed **(periungual lesions).** Monitor the number of lesions, note their location each day, and report vascular changes to the health care provider. Increased lesions indicate increased vasculitis, and a decreased number indicates decreased vasculitis. Also carefully assess any larger lesions that appear on the lower extremities. These lesions can lead to ulcerations, which heal slowly as a result of decreased circulation. Peripheral neuropathy associated with decreased circulation can cause footdrop and **paresthesias** (burning and tingling sensations), usually in older adults.

Respiratory complications may manifest as *pleurisy, pneumonitis, diffuse interstitial fibrosis, and pulmonary hypertension.* Cardiac complications include *pericarditis and myocarditis.* These health problems are discussed elsewhere in this text. Assess for eye involvement, which typically manifests as *iritis and scleritis.* If either of these complications is present, the sclera of one or both eyes is reddened and the pupils have an irregular shape. Visual disturbances may occur.

Several syndromes are seen in patients with advanced RA. The most common is **Sjögren's syndrome,** which includes a triad of:

- Dry eyes (keratoconjunctivitis sicca [KCS], or the sicca syndrome)
- Dry mouth **(xerostomia)**
- Dry vagina (in some cases)

Note the patient's report of dry mouth or dry eyes. Some patients state that their eyes feel "gritty," as if sand is in their eyes. Inspect the mouth for dry, sticky membranes and the eyes for redness and lack of tearing.

Less commonly observed is **Felty's syndrome,** which is characterized by RA, hepatosplenomegaly (enlarged liver and spleen), and leukopenia. **Caplan's syndrome** is characterized by the presence of rheumatoid nodules in the lungs.

Psychosocial Assessment.

Rheumatoid arthritis (RA) and other inflammatory types of arthritis are chronic diseases that can be crippling if not well controlled. Fear of becoming disabled and dependent, uncertainty about the disease process, altered body image, devaluation of self, frustration, and depression are common psychosocial problems. Physical limitations and

pain caused by disease may limit mobility and ADLs. These limitations can result in role changes in the family and society. For example, the person may not be able to cook for the family or be an active sexual partner. In addition, extreme fatigue often causes patients to desire an early bedtime and may result in a reluctance to socialize.

Body changes caused by joint changes and steroid therapy (if used) may also cause poor self-esteem and body image. Because many societies value people with physically fit, attractive bodies, the patient with RA may be embarrassed to be seen in public places. The patient may grieve or experience degrees of depression. He or she may have feelings of helplessness caused by a loss of control over a disease that can "consume" the body. Fortunately, newer drugs have improved the treatment of RA and provide the patient with hope and better disease control. Only a small percentage of patients with RA become wheelchair dependent.

Living with a chronic disease and its pain is difficult for the patient and family. Chronic suffering and pain affect quality of life. Assess the patient's emotional and mental status in relation to the disease and its problems. Evaluate his or her support systems and resources. Patients who are knowledgeable about their disease and treatment options feel emotionally stronger to cope with their disease and better able to discuss treatment options with their health care provider.

Laboratory Assessment.

Laboratory tests help support a diagnosis of RA, but no single test or group of tests can confirm it. Chart 18-8 summarizes the most common laboratory tests that the health care provider may use for diagnosing connective tissue diseases.

Chart 18-8 Laboratory Profile

Connective Tissue Disease

TEST	NORMAL RANGE FOR ADULTS	SIGNIFICANCE OF ABNORMAL FINDINGS
Rheumatoid factor	Negative	Positive or increase indicative of possible RA or other CTD; may also be elevated in leukemia, liver disease, and kidney disease
ANA (total)	Negative (if positive, types of ANA identified [e.g., anti-ENA, anti-Smith, anti–ss-A (Ro)] to indicate what part of cells are involved)	Elevations common in SLE, SSc, RA, and other inflammatory CTDs (5% of healthy adults have positive ANA results)
Serum complement	*Total*: 30-75 units/mL (*C3:* 75-175 mg/dL; *C4:* 22-45 mg/dL)	Decreased values indicative of active autoimmune disease, such as SLE, and other problems like anemia, infection, and malnutrition
Erythrocyte sedimentation rate (ESR)	*Male:* up to 15 mm/hr *Female:* up to 20 mm/hr	Increased in inflammatory diseases, like RA, SLE, PMR, temporal arteritis; also elevated in patients with bacterial infections or severe anemias
SPEP	*Total:* 6.4-8.3 g/dL	
Albumin	3.5-5.0 g/dL	Decreased level occurs with chronic inflammation or infection; also decreased in malnutrition and advanced cirrhosis
Globulin	2.3-3.4 g/dL	
Alpha$_1$ globulin	0.1-0.3 g/dL	Increased level possible in RA
Alpha$_2$ globulin	0.6-1.0 g/dL	
Beta globulin	0.7-1.1 g/dL	
Gamma globulin	0.8-1.6 g/dL	Increased levels indicative of CTD (inflammatory type)
HLA testing *(HLA-B27)*	None	Presence of *HLA-B27* indicative of Reiter's syndrome or ankylosing spondylitis

ANA, Antinuclear antibody; *CTD,* connective tissue disease; *ENA,* extractable nuclear antigens; *HLA,* human leukocyte antigen; *PMR,* polymyalgia rheumatica; *RA,* rheumatoid arthritis; *SLE,* systemic lupus erythematosus; *SPEP,* serum protein electrophoresis; *SSc,* systemic sclerosis.

The test for *rheumatoid factor (RF)* measures the presence of unusual antibodies of the immunoglobulins G (IgG) and M (IgM) types that develop in a number of connective tissue diseases. Many patients with RA have a positive titer (greater than 1 : 80), but not all positive results indicate the disease, *especially in older adults* (Pagana & Pagana, 2014).

The *antinuclear antibody (ANA)* test measures the titer of a group of antibodies that destroy the nuclei of cells and cause tissue death in

patients with autoimmune disease. The fluorescent method is sometimes referred to as *FANA*. If this test result is positive (a value higher than 1 : 40), various subtypes of this antibody are identified and measured.

When RA patients also have Sjögren's syndrome (SS) or if the syndrome occurs as a separate disease, several unusual anti–SS antibody types may be present. In particular, *anti–SS-A (Ro)* and *anti–SS-B (La)* antibodies are present in about 60% to 70% of those with Sjögren's syndrome or those with secondary Sjögren's and RA (Pagana & Pagana, 2014).

Serum *complement proteins*, especially C3 and C4, are usually decreased in autoimmune diseases, including RA and lupus. An elevated *erythrocyte sedimentation rate (ESR)*, or "sed rate," can confirm inflammation or infection anywhere in the body. An elevated ESR helps support a diagnosis of an unspecified inflammatory disease. The test is most useful to monitor the course of a disease, especially for inflammatory autoimmune diseases. In general, the more severe the disease gets, the higher the ESR rises; as the disease improves or goes into remission, the ESR level decreases.

The *high-sensitivity C-reactive protein*, or *hsCRP*, is another useful test to measure inflammation and may be done with or instead of the ESR. As the name implies, it is more sensitive to inflammatory changes than the ESR. It is also very useful for detecting infection anywhere in the body.

The presence of most chronic diseases usually causes mild to moderate anemia, which contributes to the patient's fatigue. Therefore monitor the patient's complete blood count (CBC) for a low hemoglobin, hematocrit, and red blood cell (RBC) count. An increase in white blood cell (WBC) count is consistent with an inflammatory response. A decrease in the WBC count may indicate Felty's syndrome, a complication associated with late RA. Thrombocytosis (increased platelets) can also occur in patients with late RA. Additional laboratory tests may be performed depending on the body systems and organs that may be affected by the disease. For example, if heart involvement is suspected, the health care provider may request cardiac enzymes.

Other Diagnostic Assessment.

A standard x-ray is used to visualize the joint changes and deformities typical of RA. A CT scan may help determine the presence and degree of cervical spine involvement.

An *arthrocentesis* is an invasive procedure that may be used for patients with joint swelling caused by excess synovial fluid (effusion). It may be performed at the bedside or in a health care provider's office or clinic. After administering a local anesthetic, the provider inserts a large-gauge

needle into the joint (usually the knee) to aspirate a sample of synovial fluid to relieve pressure. The fluid is analyzed for inflammatory cells and immune complexes, including RF. Fluid from patients with RA typically reveals increased WBCs, cloudiness, and volume.

Teach the patient to use ice and rest the affected joint for 24 hours after arthrocentesis. Often the health care provider will recommend acetaminophen as needed for pain. If increased pain or swelling occurs, teach the patient or family to notify the health care provider immediately.

Nursing Safety Priority QSEN

Action Alert

After an arthrocentesis, monitor the insertion site for bleeding or leakage of synovial fluid. Notify the health care provider if either of these problems occurs.

A bone scan or joint scan can also assess the extent of joint involvement. MRI may be performed to assess spinal column disease or other joint involvement.

Because RA can affect multiple body systems, tests to diagnose specific systemic manifestations are performed as necessary. For example, electromyography helps confirm peripheral neuropathy. Pulmonary function tests help determine the presence of lung involvement.

NCLEX Examination Challenge

Physiological Integrity

Which assessment findings will the nurse expect for the client with early-stage rheumatoid arthritis? **Select all that apply.**

A Heberden's nodes
B Elevated erythrocyte sedimentation rate (ESR)
C Positive antinuclear antibody (ANA) titer
D Severe weight loss
E Joint inflammation
F Red, swollen joints

Interventions

As in other types of arthritis, the interdisciplinary health care team manages pain by using a combination of pharmacologic and

nonpharmacologic measures. A **synovectomy** to remove inflamed synovium may be needed for joints like the knee or elbow. Total joint arthroplasty (TJA) may be indicated when other measures fail to relieve pain. TJA is discussed in the Osteoarthritis section of this chapter.

Managing Inflammation and Pain.

The expected outcome is that the disease goes into remission and its progression slows to decrease pain, prevent joint destruction, and increase mobility. Drug therapy and nonpharmacologic interventions are used to help meet this outcome.

Drug Therapy.

Some drugs prescribed for RA have anti-inflammatory and/or analgesic actions. Other drugs are immunosuppressive and disease modifying, which may cause remission of the illness and prevent erosive joint changes. Biological response modifiers make up the newest class of disease-modifying drugs that help reduce signals for the immune system to cause inflammation (Chart 18-9). Patients with inflammatory diseases other than RA are also using various biological response modifying drugs successfully. Although RA is a chronic disease and no cure is yet available, drugs now used can better control the disease and prevent further deterioration.

Chart 18-9 Common Examples of Drug Therapy

Biological Response Modifiers Used for Rheumatoid Arthritis and Other Connective Tissue Diseases*

DRUG AND USUAL DOSAGE	PURPOSE OF DRUG	NURSING INTERVENTIONS	RATIONALES
For *all* biological response modifiers (BRMs) (also called *biologics*)	Neutralize biologic activity of tumor necrosis factor–alpha (TNFA), interleukins (IL), T-lymphocytes, or tyrosine kinase (TK) to decrease immune response and inflammation	Do not give BRMs if patient has a serious infection, TB, or MS. Teach patients taking BRMs to avoid getting live vaccines.	Drugs may exacerbate infections, MS, or lupus.
		Teach patient to avoid crowds and people with infections.	Serious infections, especially respiratory infections, can lead to hospitalization or cause death.
Etanercept (Enbrel): Usually 25 mg subcutaneously twice weekly	TNFA inhibitor	Teach patient to report site reaction. Teach patient how to self-administer drug.	Site reactions can be painful. Patients need to self-administer the drug at home or have another person learn how to give the injections.
Infliximab (Remicade): 3 mg/kg of body weight as IV infusion, followed by the same dose at Weeks 2 and 6. If patient responds, maintenance infusions are given at the same dose every 8 weeks.	TNFA inhibitor	Refrigerate all BRMs except Remicade.	Refrigeration prevents drug decomposition.
		Teach patient to report chest pain or difficulty breathing during infusion; monitor blood pressure and infusion site.	Severe allergic reaction is potentially life threatening; infusion reactions usually subside.
Adalimumab (Humira): 40 mg subcutaneously every 2 weeks	TNFA inhibitor	Teach patient to report site reaction.	Site reactions may occur to indicate local allergic response.
Anakinra (Kineret): Typically 100 mg subcutaneously daily	IL-1 receptor antagonist	Teach patient to monitor site for reaction (occurs more commonly when compared with other BRMs).	Site reactions may occur.
		Monitor WBC count.	Drug can cause a severe decrease in WBC count and make patient very susceptible to infection.
		Teach patient to report respiratory symptoms, such as cough and fever. Teach patient that malignancies can result from taking this drug.	Drug can cause serious respiratory infections and various types of cancers.
Abatacept (Orencia): Based on body weight from 500 to 1000 mg IV each week for 2 wks, and then may be given at longer intervals for maintenance	Selective T-lymphocyte co-stimulator modulator (T-cell inhibitor)	Report cough, dizziness, and sore throat; do not receive live vaccines while taking the drug.	Serious respiratory infections can occur.
		Monitor for dyspnea, wheezing, flushing, itching.	This drug can cause a mild to moderate allergic reaction.
Rituximab (Rituxan): Two 1000-mg IV doses given 2 weeks apart initially, followed by the same dosing every 4-6 months depending on the patient's response	Monoclonal antibody	Observe for infusion reaction as above.	Drug can cause a local allergic response.
Golimumab (Simponi): 50 mg subcutaneously once a month	TNFA inhibitor	Teach patient to report signs and symptoms of infection, including fever and malaise; teach patient to avoid live vaccines while taking drug.	Drug has a black box warning about serious infections from opportunistic pathogens that can lead to hospitalizations or death.
		Teach patient about adverse drug effects including hypertension, GI distress, and infection from opportunistic pathogens; report signs and symptoms of these problems to the health care provider.	These adverse drug effects can lead to serious illness.
Tocilizumab (Actemra): Dose varies based on weight; given IV initially at 4 mg/kg and then increased to 8 mg/kg of body weight; drug may also be self-administered as a subcutaneous prefilled injection; dosing intervals depend on the patient's response and route of administration	IL-6 inhibitor	Teach patient the importance of having frequent WBC, platelet, and liver enzyme testing.	Drug can cause decreased WBCs and platelets, and liver dysfunction.

MS, Multiple sclerosis; *TB*, tuberculosis; *TNF,* tumor necrosis factor; *WBC,* white blood cell.

*This is not a comprehensive list; this chart lists only the common biological response modifiers (BRMs) used for rheumatoid arthritis and other connective tissue diseases.

The health care provider, often a rheumatologist, makes decisions about appropriate drug therapy for patients with rheumatoid disease based on the severity of the disease. Initially, most patients are managed with **disease-modifying antirheumatic drugs (DMARDs)**. As the name implies, these drugs are given to slow the progression of the disease.

First-Line Disease-Modifying Antirheumatic Drugs.

Methotrexate (MTX) (Rheumatrex), an immunosuppressive medication, in a low, once-a-week dose (generally 25 mg or less per week orally) is the mainstay of therapy for RA because it is effective and relatively inexpensive. It is a slow-acting drug, taking 4 to 6 weeks to begin to control joint inflammation. Observe for desired therapeutic drug effects, such as a decrease in joint pain and swelling.

Monitor patients for potential adverse effects, such as decreasing WBCs and platelets (as a result of bone marrow suppression) or elevations in liver enzymes or serum creatinine.

Nursing Safety Priority QSEN

Drug Alert

Patients taking MTX are at risk for infection. Teach them to avoid crowds and people who are ill. Remind patients to avoid alcoholic beverages while taking MTX to prevent liver toxicity. Teach them to observe and report other side and toxic effects, which include mouth sores and acute dyspnea from pneumonitis. Rarely, lymph node tumor (lymphoma) has been associated in those who have RA and are taking MTX. Folic acid, one of the B vitamins, is often given to those who are taking MTX to help decrease some of the drug's side effects.

Pregnancy is not recommended while taking methotrexate because birth defects are possible. *Strict birth control is recommended for childbearing women who are in need of MTX to control their RA.* If pregnancy is ever desired, instruct the patient to consult the rheumatologist as well as an obstetric/gynecologic (OB/GYN) health care provider. Generally, the health care provider will discontinue the drug at least 3 months before planned pregnancy. MTX may be restarted after birth if the patient does not breast-feed (Lilley et al., 2014).

Leflunomide (Arava) may be prescribed for some patients. It is a slow-acting immune-modulating medication that helps diminish inflammatory symptoms of joint swelling and stiffness and improves

mobility. The drug is generally prescribed as a loading dose of 100 mg orally daily for 3 days followed by 20 mg orally daily thereafter. Inform the patient that Arava takes 4 to 6 weeks and sometimes up to 3 months before maximum benefit is realized.

Arava is a potent medication that is generally tolerated, but side effects of hair loss, diarrhea, decreased WBCs and platelets, or increased liver enzymes have been reported. *Teach patients to report these changes, and monitor laboratory results carefully. Remind them to avoid alcohol. Inform them that Arava can cause birth defects, and therefore recommend strict birth control to women of childbearing age. Tell patients to contact the health care provider immediately if pregnancy occurs while taking the drug.* Cholestyramine (Questran) is available to help block the drug's action.

Another DMARD sometimes used for RA is hydroxychloroquine (Plaquenil). This drug slows the progression of mild rheumatoid disease before it worsens (see Chart 18-9). It is an antimalarial drug that helps decrease joint and muscle pain. Patients generally tolerate Plaquenil quite well. In a few cases, mild stomach discomfort, light-headedness, or headache has been reported.

Nursing Safety Priority QSEN

Drug Alert

The most serious adverse effect of Plaquenil is retinal damage. Teach patients to report blurred vision or headache. Remind them to have an eye examination before taking the drug and every 6 months to detect changes in the cornea, lens, or retina. If this rare complication occurs, the health care provider discontinues the drug (Lilley et al., 2014).

Nonsteroidal Anti-inflammatory Drugs.

NSAIDs are sometimes used for RA to relieve pain and inflammation. The choice of which one to prescribe depends on the patient's needs and tolerance, as well as the scientific evidence supporting the drug therapy. To decrease GI problems, the NSAID may be given with an H2-blocking agent, such as ranitidine (Zantac) or misoprostol (Cytotec). If there is no clinical change after 6 to 8 weeks, the health care provider may discontinue the current NSAID and try another one or change to a different drug class.

It was once thought that celecoxib (Celebrex), a COX-2 inhibiting NSAID, should be given rather than the older NSAIDs like ibuprofen. However, all COX-2 inhibiting drugs have recently been associated with

cardiovascular disease, such as myocardial infarction, and some have been taken off the market. The risk for GI bleeding is also high in patients taking Celebrex, and the drug cannot be given to those who have had recent open heart surgery.

Biological Response Modifiers.

As a group, **biological response modifiers (BRMs),** sometimes called **biologics,** are one of the newest classes of DMARDs. Most BRMs neutralize the biologic activity of tumor necrosis factor–alpha (TNFA) by inhibiting its binding with TNF receptors. Any one of the BRMs may be tried. If one drug is not effective, the health care provider prescribes another drug in the same class. All these drugs are extremely expensive at this time, and insurance companies may not completely pay for their use. Some patients receive one of these drugs in addition to the drugs in this Drug Therapy section.

Teach patients receiving any one of the BRMs that they are at a high risk for developing infection. Instruct them to stay away from people with infections and to avoid large crowds if possible. Remind patients with multiple sclerosis (MS), tuberculosis (TB), or a positive TB test that they should not receive TNF inhibitors because they make patients susceptible to flare-ups of these diseases. Determine whether the patient has had a recent negative purified protein derivative (PPD) test for TB. If not, a PPD skin test is typically administered and the selected BRM is not started until a negative test result is confirmed. Collaborate with the health care provider to ensure that this process is complete.

Etanercept (Enbrel) is given subcutaneously as 25 mg twice weekly for most patients. Immunosuppression with medications such as methotrexate is generally tried before using Enbrel or other biological response modifiers. Methotrexate is often given in combination with biologic therapies because the combination may be more effective than either drug alone (Cranwell-Bruce, 2011). Most patients tolerate Enbrel or Enbrel and methotrexate together; however, laboratory monitoring is important. Combination therapy requires CBC, serum creatinine, and a liver panel to be drawn regularly, generally every 4 to 8 weeks. In general, clinical outcomes with Enbrel have been excellent.

Teach the patient or family member how to self-administer Enbrel injections. Injection site reaction and systemic infection (especially respiratory) are possible adverse effects. Ice and hydrocortisone 1% cream can be used if a red, itchy rash at the injection site develops. Teach the patient to notify the health care provider if infection or a delay in wound healing occurs.

Infliximab (Remicade), first approved to treat Crohn's disease, is given in a single IV infusion over several hours. The initial dose generally used for RA is 3 mg/kg of body weight. The drug dosage is repeated at weeks 2 and 6. After these first three infusions, a maintenance dose of 3 mg/kg of body weight is given every 8 weeks, depending on the response of the patient. For patients who do not respond to the first three infusions, the drug dosage may be increased up to 10 mg/kg of body weight given at 4-week intervals. The risk of side effects and adverse effects increases at higher doses. Patients typically take methotrexate before starting Remicade and continue on combination therapy.

Nursing Safety Priority QSEN

Drug Alert

Teach the patient to report and observe for symptoms of Remicade infusion reaction: chest discomfort, tachycardia, shortness of breath, or light-headedness. If any of these symptoms are reported, decrease the IV rate or discontinue it!

The symptoms of infusion reaction generally subside, but the health care provider must be notified in case medical assistance is needed. Dose, rate, and interval changes may be needed. Acetaminophen and Benadryl are medications often given before the start of Remicade and are often used at the time of reported infusion reaction. Those who experience serious adverse effects, such as hypertension or anaphylaxis, require permanent discontinuation of the drug.

Adalimumab (Humira) is the first fully human TNFA inhibitor and is given by subcutaneous injection. Symptoms of inflammatory arthritis tend to decrease with the use of Humira, including less joint swelling, less stiffness, and better mobility. Injection site reactions and adverse effects similar to the other TNFA inhibitors have been reported. Careful monitoring, especially with combination therapy of Humira and methotrexate or other drug that affects the body's immunity, is important and similar to combination therapy with other BRMs.

Anakinra (Kineret) is another biological response modifier. Instead of affecting tumor necrosis factor–alpha (TNFA), however, it works to inhibit a different protein signal of the immune system called *interleukin-1 (IL-1)*. IL-1 is also a pro-inflammatory protein that signals the immune system to increase inflammation (Cranwell-Bruce, 2011). It is thought that IL-1 is a weaker protein than TNF, but having an alternative drug that

targets a different receptor site is helpful when a patient cannot take other biologics. Those who have multiple sclerosis or tuberculosis cannot take TNF inhibitors, but Kineret can be used with this population.

Injection site reactions occur more often with Kineret compared with other BRMs. Ice and hydrocortisone 1% cream are recommended. Remind patients to rotate injection sites. Kineret is administered with a simple jet for self-administration. The patient has the option to use the simple jet or administer the subcutaneous injection traditionally.

Abatacept (Orencia) and *rituximab (Rituxan, MabThera)* require IV infusions every 2 weeks to start and then may be more spread out, depending on the drug. Like the results of the other BRMs, patients usually report feeling a benefit from these drugs in 2 weeks, but it may take months for the maximum benefit to be seen. *Golimumab (Simponi)* is the first biologic that is administered only once each month for both RA and psoriatic arthritis. Teach patients that this drug has a black box warning for serious infections that may lead to hospitalization or death from opportunistic pathogens (Cranwell-Bruce, 2011).

Tocilizumab (Actemra) is given when the patient cannot tolerate other drugs. Tocilizumab is different from other biologics because it is the first humanized interleukin-6 (IL-6) receptor-inhibiting monoclonal antibody that is available for patients with RA. It can be used alone or in combination with other DMARDs. Teach patients about adverse drug effects, including hypertension, GI distress, infection, and an increase in low-density lipoproteins (LDLs) and liver enzymes. Like for other biologics, teach the patient about the high risk of infection (e.g., tuberculosis) when taking Actemra.

One of the newest biologics is *tofacitinib (Xeljanz)*, which has been approved for moderate to severe RA as monotherapy or in combination with methotrexate. This drug is a tyrosine kinase inhibitor (TKI). Tyrosine kinases usually facilitate cytokine-mediated (e.g., interleukin) signals that promote the inflammatory process. Teach patients that tofacitinib carries a black box warning alerting patients about its potential for serious opportunistic infections, tuberculosis, lymphoma, and other cancers.

Other Drugs.

A few drugs may be given as adjuncts to or instead of the previously described drugs. It is not unusual for a patient to be taking several disease-modifying drugs, such as methotrexate, a BRM, and an adjunct medication. Each drug works differently to relieve symptoms and slow the progression of the disease.

Glucocorticoids (steroids)—usually prednisone (Deltasone)—are given for their fast-acting anti-inflammatory and immunosuppressive effects. Prednisone may be given in high dose for short duration **(pulse therapy)** or as a low chronic dose. Moderate-dose short-term tapering bridge therapy may be used when inflammation is symptomatic and other RA medications are insufficient or have not yet had an effect.

Chronic steroid therapy can result in numerous complications, such as:

- Diabetes mellitus
- infection
- Fluid and electrolyte imbalances
- Hypertension
- Osteoporosis
- Glaucoma

Some drug effects are dose related, whereas others are not. Observe the patient for complications associated with chronic steroid therapy, and report them to the health care provider. For example, if blood pressure becomes elevated or significant laboratory values change, notify the health care provider.

Instruct patients taking chronic steroids to take calcium 1200 to 1500 mg daily plus vitamin D 400 mg daily to help prevent osteoporosis. Bisphosphonate drugs may also be prescribed. Bone density measurements (DEXA [dual-energy x-ray absorptiometry] scans) are done every 2 to 3 years to monitor for bone loss.

Patients with RA may experience one or a few joints that have more pain and inflammation than the others. Cortisone injections in single joints may be used to relieve local pain and inflammation. Have the patient ice and rest the joint for 24 hours after the procedure. Oral analgesics also are sometimes needed during that time.

Other immunosuppressive agents that may be used as a last resort are *azathioprine (Imuran)* and *cyclophosphamide (Cytoxan).* Cyclophosphamide is sometimes given specifically to control RA vasculitis. Such immunosuppressive drugs may cause bone marrow suppression and occasionally leukemia or lymphoma. White blood cell counts are expected to decrease 7 to 14 days after the administration of IV cyclophosphamide; therefore monitor laboratory results closely to ensure safe limits. Hemorrhagic cystitis is a concern more with oral cyclophosphamide. Instruct the patient to drink water and void frequently (about every 2 hours while awake), which dilutes the urine and empties the bladder, thus decreasing opportunity for bladder irritation from residual drug. Hair thinning or loss can be seen with immunosuppressive medications. Cyclophosphamide may also cause

sterility; strict birth control is recommended.

Nonpharmacologic Interventions.

Adequate rest, proper positioning, and ice and heat applications are important in pain management. If acute inflammation is present, ice packs may be applied to "hot" joints for pain relief until the inflammation lessens. The ice pack should not be too heavy. At home, the patient can use a small bag of frozen peas or corn as an ice pack.

Heated paraffin (wax) dips may help increase comfort of arthritic hands. Finger and hand exercises are often done more easily after paraffin treatment. To relieve morning stiffness or the pain of late-stage disease, recommend a hot shower rather than a sponge bath or a tub bath. It is often difficult for the patient with RA to get into and out of a bathtub, although special hydraulic lifts and tub chairs are available to allow the patient to bathe. Safety (grab) bars and nonskid tread in the tub or shower floor are important safety features to discuss with all patients. Some older adults prefer using shower chairs and a walk-in shower that does not have a ledge that could cause falls.

Hot packs applied directly to involved joints may be beneficial. Most physical therapy departments have machines that keep hot packs ready anytime they are needed. Teach patients to use the microwave or stovetop heating instructions to warm heat packs at home. Remind them to follow the instructions given with each heating device used.

Plasmapheresis (sometimes called *plasma exchange*) is an in-hospital procedure prescribed by a health care provider in which the patient's plasma is treated to remove the antibodies causing the disease. Although not commonly done, this procedure may be combined with steroid pulse therapy for patients with severe, life-threatening disease.

Complementary and Alternative Therapies.

Some patients may have pain relief from hypnosis, acupuncture, imagery, music therapy, or other technique. Stress management is also popular as a pain relief intervention. Chapter 3 discusses these therapies in more detail.

Adequate nutrition is an important part of the management of RA. Obesity should be avoided or treated if present. The inflammatory state may place a greater burden on the metabolism of some essential nutrients. This catabolic state may be related to increased cytokine production, specifically tumor necrosis factor.

According to the National Center for Complementary and Alternative Medicine, some supplements have been found to help decrease

inflammation and include:

- Cold water fish or fish oil capsules containing omega-3 fatty acids at 2.5 to 5 g daily (should not be taken if the patient is taking anticoagulant therapy)
- Gamma-linolenic acid (GLA), an omega-6 fatty acid found in the oils of certain plant seeds, such as primrose and black currant

According to the Arthritis Foundation, no one food causes or cures RA; however, healthy nutrition in general is important. Refer the patient to the Arthritis Foundation's pamphlet regarding diet and arthritis. Refer him or her to the dietitian for vitamin- and nutrition-specific questions or recommendations. Teach patients to take any herbal or nutrition supplement under the supervision of a qualified health care provider to prevent adverse events and drug-food or drug-drug interactions.

Other complementary and alternative medicine (CAM) therapies are safe and have been scientifically proven to be effective to help control RA pain for most people. Examples include mind-body therapies, such as relaxation techniques, imagery, and spiritual practices. For information about these techniques, see Chapter 3.

Promoting Self-Management.

Although the physical appearance of a patient with severe RA may create the image that ADL independence is not possible, a number of alternative and creative methods can be used to perform these activities. *Do not perform these activities for the patient unless asked. Those with RA do not want to be dependent*. For example, hand deformities often prevent a patient from opening packages of food, such as a box of crackers; however, he or she may prefer to use the teeth to open the crackers rather than depend on someone else.

In the hospital or long-term care facility, a patient may not eat because of the barriers of heavy plate covers, milk cartons, small packages of condiments, and heavy containers. Styrofoam or paper cups may bend and collapse as he or she attempts to hold them. A china or heavy plastic cup with handles may be easier to manipulate. Collaborate with the dietitian to assist with access to food and total independence in eating.

When fine motor activities (e.g., squeezing a tube of toothpaste) become impossible, larger joints or body surfaces can substitute for smaller ones. For example, teach how to use the palm of the hand to press the paste onto the brush. Devices such as long-handled brushes can help patients brush their hair; dressing sticks can assist with putting on pants. These examples illustrate the need to assess the problem area, suggest alternative methods, and refer the patient to an occupational or

physical therapist for special assistive and adaptive devices if necessary.

Managing Fatigue.

Nursing interventions depend in part on identifying the factors contributing to fatigue. For example, increases in pain, sleep disturbances, and weakness are positively associated with increased fatigue. Anemia may also be a contributing factor and may be treated with iron (if an iron deficiency anemia is present), folic acid, or vitamin supplements prescribed by the health care provider. Chronic normochromic or chronic hypochromic anemia often occurs in most chronic systemic diseases. Assess for drug-related blood loss, such as that caused by NSAIDs, by checking the stool for gross or occult blood. *Older white women are the most likely to experience GI bleeding as a result of taking these medications. The reason for this trend is not known.*

When fatigue results from muscle atrophy, the health care provider prescribes an aggressive physical therapy program to strengthen muscles and prevent further atrophy. Patients experience increased fatigue when pain prevents them from getting adequate rest and sleep. Measures to facilitate sleep include promoting a quiet environment, giving warm beverages, and administering hypnotics or relaxants as prescribed, if necessary.

In addition to identifying and managing specific reasons for fatigue, determine the patient's usual daily activities and teach principles of **energy conservation,** including:

- Pacing activities
- Allowing rest periods
- Setting priorities
- Obtaining assistance when needed

Chart 18-10 lists specific suggestions for conserving energy and thus increasing activity tolerance and mobility.

Chart 18-10 Patient and Family Education: Preparing for Self-Management

Energy Conservation for the Patient with Arthritis

- Balance activity with rest. Take one or two naps each day.
- Pace yourself; do not plan too much for one day.
- Set priorities. Determine which activities are most important, and do them first.
- Delegate responsibilities and tasks to your family and friends.

- Plan ahead to prevent last-minute rushing and stress.
- Learn your own activity tolerance, and do not exceed it.

Enhancing Body Image.

Body image may be affected by both the disease process and drug therapy. Steroids can cause a moonfaced appearance, acne, striae, "buffalo humps," and weight gain. Determine the patient's perception of these changes and the impact of the reactions of family and significant others. The most important intervention is communicating acceptance of the patient. When a trusting relationship is established, encourage him or her to express personal feelings.

As a reaction to body image disturbance and the presence of a chronic, painful disease, some patients display behaviors indicative of loss. They may use coping strategies that range from denial or fear to anger or depression. In an attempt to regain control over the effects of the disease process, they may appear to be "manipulative and demanding" and sometimes may be referred to as having an "arthritis personality." *This personality, which represents a negative label, is a myth; using these terms should be avoided.* Patients are trying to cope with the effects of their illness and should be treated with patience and understanding. Continually assess and accept these behaviors, but remain realistic in discussing goals to improve self-esteem. Emphasize their strengths, and help them identify previously successful coping strategies.

Community-Based Care

Patients with rheumatoid arthritis (RA) are usually managed at home but, in a few cases, may be institutionalized in a long-term care facility if they become restricted to bed or a wheelchair. Some patients may be transferred to a rehabilitation facility for several weeks to aid in developing strategies, techniques, and skills for independent living at home.

Home Care Management.

The amount of home care preparation depends on the severity of the disease. Structural changes may be necessary if there are deficits in ADLs or mobility. Doors must be wide enough to accommodate a wheelchair or walker if one is used. Ramps are needed to prevent the patient in a wheelchair from becoming homebound. If the person cannot use stairs, he or she must have access to facilities for all ADLs on one floor. Handrails should be available in the bathroom and halls.

To promote continued homemaking functions, countertops and appliances may require structural changes. The patient may also require handrails and elevated chairs and toilet seats, which facilitate transfers (Fig. 18-7). *These devices are especially important for older adults with arthritis.*

FIG. 18-7 Handrails and an elevated toilet seat make transfers easier for the patient.

Self-Management Education.

Self-management education (SME) is a vital role for nurses in collaborative management of arthritis. Many people have signs and symptoms of joint inflammation but do not seek medical attention. Teach them to seek professional health care to reduce pain and disability.

Teach patients to discuss any questions with their health care provider before trying any over-the-counter or home remedies. Some remedies may be harmful. Check with the Arthritis Foundation for the latest information on arthritis myths and quackery (www.arthritis.org).

Provide information to the patient and family about drug therapy, as well as joint protection, energy conservation, rest, and exercise. This SME is summarized in Charts 18-5, 18-6, and 18-10.

Assess the patient's coping strategies. The patient with RA often reports being on an "emotional roller coaster" from coping with a chronic illness every day. Control over one's life is an important human need. The patient with an unpredictable chronic disease may lose this

control, and this lowers self-esteem. Health care providers must allow the patient to make decisions about care. Families and significant others must also include him or her in decision making. Although the patient's behavior may be perceived as demanding or manipulative, his or her self-esteem cannot be improved without this important aspect of interpersonal relationships.

Increased dependency also affects a sense of control and self-esteem. Some people ignore their health needs and portray a tough image for others by insisting that they need no assistance. Emphasize to the patient and family that asking for help may be the best decision at times to prevent further joint damage and disease progression.

RA may also affect work and social roles. The patient may have physical difficulty doing tasks that require lifting, climbing, grasp, or gross or fine motor activities. The severity of RA disease may cause difficulty with total number of hours worked. Some people with RA can do their jobs well without problem; others may have varying degrees of difficulty. Those who can no longer do their job at work may need to discuss with their employer having a lighter workload, but some may need to file for disability with their company and Social Security office.

Health Care Resources.

The need for health care resources for the patient with RA is similar to that for the patient with osteoarthritis. A home care nurse or aide, physical therapist, or occupational therapist may be needed during severe exacerbations or as the disease progresses. In collaboration with the case manager, identify these resources and make sure they are available as needed. The Arthritis Foundation is an excellent source of information and support.

Arthritis support groups and self-help courses provide the education and the support that patients, families, and friends need. Refer the patient to a psychological counselor or religious or spiritual leader for emotional support and guidance during times of crisis or as needed. Identify and recommend other support systems within the family and community when necessary.

Clinical Judgment Challenge

Teamwork and Collaboration; Safety QSEN

An 81-year-old woman with RA has been controlled with methotrexate for 18 years. Recently she experienced increased joint pain and swelling

in her right knee that have affected her mobility and activity level. She walks with a cane in the community but uses a walker at home. Earlier in the week, she almost fell while walking to her car after she left the bank. The rheumatologist plans to add etanercept (Enbrel) to her drug regimen.

1. With what members of the health care team might you collaborate as part of her plan of care?
2. What safety measures are needed before she begins taking Enbrel?
3. What self-management education will she need before starting Enbrel?
4. What home and community assessment might be needed to ensure her safety?

Lupus Erythematosus

Pathophysiology

The two main classifications of lupus are discoid lupus erythematosus (DLE) and systemic lupus erythematosus (SLE). A small percentage of patients with lupus have the DLE type, which affects only the skin.

Unlike DLE, **systemic lupus erythematosus** is a chronic, progressive, inflammatory connective tissue disorder that can cause major body organs and systems to fail. It is characterized by spontaneous remissions and **exacerbations** ("flare-ups"), and the onset may be acute or insidious (slow). The condition is potentially fatal, but most patients with SLE live many years after diagnosis and lead productive lives. Improvements in determining the cause, diagnosis, and treatment of lupus account for the prolonged survival.

Lupus is thought to be an autoimmune process. Antinuclear antibodies (ANAs) primarily affect the DNA, ribonucleic acid (RNA), and other components within the cell nuclei. As a result, immune complexes form in the serum and organ tissues, which cause inflammation, damage, and destruction (McCance et al., 2014). These complexes invade organs directly or cause **vasculitis** (vessel inflammation), which deprives the organs of arterial blood and oxygen.

Autoimmune complexes in SLE tend to be most attracted to the glomeruli of the kidneys. Therefore many of these patients have some degree of kidney involvement, called *lupus nephritis*—the leading cause of death from the disease. Other causes of death are cardiac and central nervous system involvement.

Cultural Considerations

Patient-Centered Care QSEN

Lupus affects women 10 times more often than men; women of color are affected far more often than Euro-Americans. The reason for this difference is unknown (McCance et al., 2014). The disease also occurs among American Indians, Asian Americans, and Hispanics (Lupus Foundation of America, 2014).

The onset of the disease occurs most often during the childbearing years (ages 20 to 40 years), but it has been reported in young children and older adults. A genetic predisposition is based on the trend to develop the disease in some twins and the occurrence of autoimmune

disease in some families of patients who have lupus. However, it is not the only basis of the disease. Like RA, lupus is probably caused by a complex *combination of genetic and environmental factors.*

A transient lupus-like syndrome can occur in some patients taking select medications, especially procainamide (Pronestyl) and hydralazine (McCance et al., 2014). When these drugs are discontinued, the syndrome usually resolves. Neither of these drugs is commonly used.

Patient-Centered Collaborative Care

Assessment

It is impossible to describe a typical textbook picture of a patient with lupus because of the extreme range of symptoms. There is no classic presentation of this disease. When lupus is in remission, the patient may appear healthy and have few or no activity limitations. When the disease flares, some patients may be so ill that admission to a critical care unit is needed. Chart 18-11 highlights the clinical manifestations that can occur with systemic lupus.

Chart 18-11 Key Features

Systemic Lupus Erythematosus (SLE) and Systemic Sclerosis (SSc)

SYSTEMIC LUPUS ERYTHEMATOSUS	SYSTEMIC SCLEROSIS
Skin Manifestations	
Inflamed, red rash Discoid lesions	Inflamed Fibrotic Sclerotic Edematous
Renal Manifestations	
Nephritis	Kidney failure
Cardiovascular Manifestations	
Pericarditis Raynaud's phenomenon	Myocardial fibrosis Raynaud's phenomenon
Pulmonary Manifestations	
Pleural effusions	Interstitial fibrosis Pulmonary hypertension
Neurologic Manifestations	
CNS lupus	Not common
Gastrointestinal Manifestations	
Abdominal pain	Esophagitis Ulcers
Musculoskeletal Manifestations	
Joint inflammation Myositis	Joint inflammation Myositis
Other Manifestations	
Fever Fatigue Anorexia Vasculitis	Fever Fatigue Anorexia Vasculitis

CNS, Central nervous system.

Physical Assessment/Clinical Manifestations

Skin Involvement.

The major skin manifestation of DLE and SLE is a dry, scaly, raised rash on the face **("butterfly" rash)** (Fig. 18-8). This rash may also appear on other sun-exposed areas. The rash is initially nonscarring and may increase in a lupus flare and disappear when the disease is in remission.

FIG. 18-8 The characteristic "butterfly" rash of systemic lupus erythematosus.

Individual round **discoid** (coinlike) **lesions** are the scarring lesions of discoid lupus. The lesions are especially evident when the patient is exposed to sunlight or ultraviolet light. Alopecia is also common in lupus. Observe and document all skin changes, and monitor them daily while the patient is in an acute care setting or during an ambulatory care or home visit. Mouth ulcers are not uncommon.

Other Manifestations.

In addition to skin changes, *polyarthritis* occurs in most patients with SLE. The early joint changes are similar to those seen in rheumatoid arthritis (RA), but severe deformities are not common even in late disease. Small joints and the knees are most commonly inflamed. **Osteonecrosis** (bone necrosis from lack of oxygen) is often seen in those who have been treated for at least 5 years with steroids like prednisone. Chronic steroid therapy may cause the constriction of small blood vessels supplying the joint, which causes the tissue to die. The hip is most commonly affected, and reports of pain and decreased mobility result. As a

result, a total hip arthroplasty may be done.

Observe for *muscle atrophy,* which can result from disuse, from skeletal muscle invasion by the immune complexes **(myositis),** or from chronic steroid therapy. Myalgia (muscle pain) may also occur. Inspect and palpate the major muscles, especially those in the extremities.

Because SLE is an inflammatory condition, *fever* and *fatigue* are common findings. *Fever is the classic sign of a flare, or exacerbation.* Various degrees of generalized weakness, fatigue, anorexia, and weight loss may occur. These signs may be the only evidence of disease, which makes diagnosis by the health care provider difficult. Therefore some patients have a diagnosis of "probable SLE."

Any or all body systems may be affected by SLE. Because lupus nephritis is the leading cause of death, carefully assess for signs of renal involvement (e.g., changes in urine output, proteinuria, hematuria, fluid retention).

Pleural effusions or *pneumonia* is found in almost half of all cases of SLE, but this complication is usually not life threatening. Pulmonary restrictive or obstructive changes may not result in overt clinical signs; however, progressive involvement can lead to dyspnea and arterial blood gas abnormalities. Perform a complete respiratory assessment to determine any abnormalities in respiratory pattern or breath sounds.

Pericarditis is the most common cardiovascular manifestation and causes tachycardia, chest pain, and myocardial ischemia. Monitor the vital signs at least every 4 hours while the patient is in the hospital, and report chest pain immediately to the physician. *Anemia, leukopenia, and thrombocytopenia* are also common in patients with SLE.

Raynaud's phenomenon occurs in a small portion of lupus patients. On exposure to cold or extreme stress, the patient reports the characteristic red, white, and blue color changes and severe pain in the digits; these changes are caused by arteriolar vasospasm. Ask patients whether color changes occur when their hands or feet are exposed to cold or when they are extremely stressed.

Neurologic manifestations are varied. Central nervous system effects include psychoses, paresis, seizures, migraine headaches, and cranial nerve palsies. Peripheral neuropathies are also common. Perform a neurologic assessment as described in Chapter 41.

Monitor *abdominal pain,* which usually results from **serositis** (peritoneal involvement). Mesenteric arteritis, pancreatitis from arteritis of the pancreatic artery, and colonic ulcers also can cause abdominal pain with lupus. Jaundice is rare. Many patients have lymph enlargement, and a few have splenomegaly (enlarged spleen). Palpate the lymph nodes, and

document findings. Vasculitis affecting any major or small vessels can lead to organ failure.

Psychosocial Assessment.

The psychosocial results of lupus can be devastating. With either DLE or SLE, the rash can be disfiguring and embarrassing. Young adult women who never had a blemish are confronted with a rash that cannot be completely covered with makeup. If chronic steroid therapy is used, side effects such as acne, striae, fat pads, and weight gain intensify the problem of an already altered body image.

Chronic fatigue and generalized weakness may prevent the patient from being as active as in the past. He or she may avoid social gatherings and may withdraw from family activities. The unpredictability and chronicity of SLE can cause fear and anxiety. Fear may increase if the patient knows another person with the disease, particularly if the other person has more advanced severe disease. Unfortunately, the myth that lupus is fatal is still common. Inform the patient and family that control of lupus is generally possible with regular medical monitoring, medications, and healthy practices, such as limiting sun exposure to prevent exacerbation of the disease.

Assess the patient's and family's feelings about the illness to identify areas requiring intervention. Determine their usual coping mechanisms and support systems before developing a plan of care. See p. 293 in the Psychosocial Assessment section of the Rheumatoid Arthritis section for additional information.

Laboratory Assessment.

Because discoid lupus erythematosus (DLE) is not a systemic condition, the only significant test is a *skin biopsy.* The physician gently scrapes skin cells from the rash for microscopic evaluation. The characteristic lupus cell and a number of inflammatory cells confirm the diagnosis.

Some of the immunologic-based laboratory tests used to diagnose SLE are the same as those performed for rheumatoid arthritis (RA): rheumatoid factor, antinuclear antibody, erythrocyte sedimentation rate, serum protein electrophoresis, serum complement (especially C3 and C4), and immunoglobulins (see Chart 18-8). A false-positive Venereal Disease Research Laboratory (VDRL) syphilis test is common with lupus (Pagana & Pagana, 2014).

More specific immunologic tests, such as anti–SS-a (Ro), anti–SS-b (La), anti-Smith (anti-Sm), anti-DNA, and extractable nuclear antigens (ENAs), are also performed (Pagana & Pagana, 2014). High titers of some

of these antibodies are associated with lupus.

A CBC commonly shows **pancytopenia** (a decrease of all cell types), probably caused by direct attack of the blood cells or bone marrow by immune complexes. Serum electrolyte levels, kidney function, cardiac and liver enzymes, and clotting factors are also routinely assessed to determine other body system functioning.

Interventions

The health care provider often prescribes potent drugs that are used topically and systemically. In addition, precautions are taken to prevent further skin impairment and exacerbations. Many of the skin lesions do not disappear, even with treatment, but they usually fade when the disease is in remission.

Managing Lupus with Drug Therapy.

With DLE, the patient's major concern is the rash or discoid lesions. Patients with SLE are also concerned about skin changes. Topical cortisone preparations help reduce inflammation and promote fading of the skin lesions. Acetaminophen (Tylenol) or NSAIDs may be used to treat joint and muscle pain and inflammation.

In addition, the health care provider may prescribe the anti-malarial agent *hydroxychloroquine* (Plaquenil) for some patients. Plaquenil decreases the absorption of ultraviolet light by the skin and therefore decreases the risk for skin lesions. *Teach patients to have frequent eye examinations (before starting the drug and every 6 months thereafter) if they are receiving Plaquenil*.

The health care provider often prescribes chronic steroid therapy to treat the systemic disease process. For renal or central nervous system lupus, he or she may also prescribe immunosuppressive agents, such as methotrexate (Rheumatrex) or azathioprine (Imuran). Although clinical manifestations improve during remission, maintenance doses of these drugs are usually continued to prevent further exacerbations of the disease. These drugs make patients susceptible to infection.

Nursing Safety Priority QSEN

Drug Alert

When patients are taking steroids and/or immunosuppressants, stress the importance of avoiding large crowds and people who are ill. Teach patients to report any early sign of infection to their health care provider.

Observe for side effects and toxic effects of these drugs, and report their occurrence immediately. Remind patients to take their medication early in the morning before breakfast because that is the time when the body's natural corticosteroid level is the lowest.

For severe renal involvement, immunosuppressants may be given in combination with steroids. For patients who do not respond to this regimen, a high-dose IV bolus of glucocorticoids, cyclophosphamide, and plasmapheresis may be tried for 3 consecutive days. Kidney transplantation has been successful for some patients.

The first drug approved for SLE in 60 years is *belimumab (Benlysta).* In SLE, abnormal B-cells contribute to autoantibodies. Belimumab is an IV human monoclonal antibody (mAb) that prevents B-lymphocyte stimulator protein from binding to B-cell receptor sites, thus decreasing B-cell survival. It is given with other drugs to treat SLE. Like for other biologics, teach patients that the drug increases their risk for serious infections. Teach patients not to receive live vaccines for 30 days before treatment.

Protecting the Skin.

Teach patients to protect their skin to prevent an exacerbation of the disease.

Nursing Safety Priority QSEN

Action Alert

Instruct patients to avoid prolonged exposure to sunlight and other forms of ultraviolet lighting, including certain types of fluorescent light. Remind them to wear long sleeves and a large-brimmed hat when outdoors. Patients should use sun-blocking agents with a sun protection factor (SPF) of 30 or higher on exposed skin surfaces.

In addition, teach patients to clean the skin with mild soap (e.g., Ivory) and to avoid harsh, perfumed substances. The skin should be rinsed and dried well and lotion applied. Excess powder and other drying substances should be avoided. Cosmetics must be carefully selected and should include moisturizers and sun protectors. If desired, refer the patient to a medical cosmetologist who specializes in applying makeup for skin lesions of all types.

Patients' hair should receive special attention because alopecia (hair

loss) is common. Recommend the use of mild protein shampoos and the avoidance of harsh treatments (e.g., permanents or highlights) until the hair regrows during remission.

Community-Based Care

Community-based care for the patient with lupus is similar to that for RA. In general, the patient is home but may need repeated hospitalizations during exacerbations of disease. He or she usually does not need rehabilitation unless having surgery, because severe joint deformity and prolonged immobility are not common in lupus.

Two major differences exist between SLE and RA in terms of education of the patient and family or significant others. First, instruct patients with SLE how to protect the skin (Chart 18-12). Second, teach them to monitor body temperature. Fever is the major sign of an exacerbation, during which they can become seriously ill. Teach the importance of reporting any other unusual or new clinical manifestations to the health care provider immediately.

Chart 18-12 Patient and Family Education: Preparing for Self-Management

Evidence-Based Practice for Skin Protection in Patients with Lupus Erythematosus

- Cleanse your skin with a mild soap, such as Ivory.
- Dry your skin thoroughly by patting rather than rubbing.
- Apply lotion liberally to dry skin areas.
- Avoid powder and other drying agents, such as rubbing alcohol.
- Use cosmetics that contain moisturizers.
- Avoid direct sunlight and any other type of ultraviolet lighting, including tanning beds.
- Wear a large-brimmed hat, long sleeves, and long pants when in the sun.
- Use a sun-blocking agent with a sun protection factor (SPF) of at least 30.
- Inspect your skin daily for open areas and rashes.

Many patients become frustrated that family members, significant others, and lay people do not have a thorough understanding of lupus. When lupus is in complete remission, patients appear to be healthy; however, an exacerbation can lead to a critical care admission. This

unpredictability disrupts the patient's life and can cause fear and anxiety. Help him or her identify coping strategies and support systems that can help with functioning in the community.

Teach the possible effects of the disease on lifestyle, including fatigue. Women of childbearing age need to know that pregnancy can be a stressor and can cause an exacerbation of the disease, either during pregnancy or after delivery. The pregnant woman also has an increased risk for miscarriage, stillbirth, or premature birth. Pregnancy is not recommended for those with cardiac, renal, or central nervous system involvement. Sexual counseling regarding contraception options may be necessary.

The Arthritis Foundation is a general resource for all patients with connective tissue disease. The Lupus Foundation (www.lupus.org) is a resource specific for patients with lupus. It is a national organization and has chapters in every state to provide information and assistance for patients with lupus and their families. Local support groups and services are offered free of charge.

NCLEX Examination Challenge

Health Promotion and Maintenance

What self-management education by the nurse is important for clients diagnosed with systemic lupus erythematosus who are taking prednisone? **Select all that apply.**

A "Take calcium supplements to prevent osteoporosis from the steroid."
B "Stay away from crowds and people with infections."
C "Avoid being in the sun to prevent disease flare-ups."
D "Get up slowly to prevent dizziness from orthostatic hypotension."
E "Take your prednisone early in the morning before breakfast."

Systemic Sclerosis

Pathophysiology

Systemic sclerosis (SSc), also called *scleroderma,* is an uncommon chronic, inflammatory, autoimmune connective tissue disease. Formerly called *progressive systemic disease,* or *PSS,* this illness is not always progressive. **Scleroderma** means hardening of the skin, which is only one clinical manifestation of the problem. Some patients, often children, have only skin involvement, or localized scleroderma (also called *linear scleroderma*). However, adults usually have skin and other body system involvement. SSc is less common than systemic lupus erythematosus (SLE) but is associated with a higher mortality rate. See Chart 18-11 for a comparison of the clinical manifestations of these two diseases. The manifestations for both diseases vary widely from person to person.

The early inflammatory process of SSc is so similar to that of lupus that patients may first be diagnosed as having probable SLE until the disease progresses or until antibody testing supports the diagnosis. The inflamed tissue in patients with SSc becomes fibrotic and then **sclerotic** (hard). Renal involvement is the leading cause of death. Respiratory involvement and hypertension are also common. Patients with SSc do not respond well to the steroids and immunosuppressants used for lupus, and therefore the mortality rate is higher.

The classification for systemic sclerosis is:

- **Diffuse cutaneous SSc**—skin thickening on the trunk, face, and proximal and distal extremities (over most of the body)
- **Limited cutaneous SSc**—thickened skin limited to sites distal to the face, neck, and distal extremities

Patients with the *limited* form of the disease often have the **CREST syndrome:**

- **C**alcinosis (calcium deposits)
- **R**aynaud's phenomenon (first symptom that occurs)
- **E**sophageal dysmotility
- **S**clerodactyly (scleroderma of the digits)
- **T**elangiectasia (spider-like hemangiomas)

The first symptom that usually occurs in patients with the *diffuse* form of the disease is hand and forearm edema, which may exist with bilateral carpal tunnel syndrome. Gastroesophageal reflux disease (GERD) is commonly present in patients with either type of the disease.

Little is known about the cause of SSc, but autoimmunity is suspected. The occurrence of more than one case per family is uncommon, but other connective tissue diseases may be noted in the family history. At this

time, specific genetic causes have not been confirmed.

Systemic sclerosis has been described in people of all races and in all geographic areas and affects over 300,000 people. Women are affected more often than men. The onset of the disease is usually between 25 and 55 years of age, with most women getting it in their 40s (Scleroderma Foundation, 2013).

❖ Patient-Centered Collaborative Care

◆ Assessment

Physical Assessment/Clinical Manifestations.

Arthralgia (joint pain) and stiffness are common manifestations that you can assess during the musculoskeletal examination. The acute joint inflammation that occurs with rheumatoid arthritis (RA) is not common, and deformities are rare.

Findings on inspection of the skin depend on the stage of the scleroderma. Typically, a painless, symmetric, pitting edema of the hands and fingers is present, especially in patients with the diffuse form of the disease. The edema may progress to include the entire upper and lower extremities and face. In this phase, the fingers are described as *sausage-like.* The skin is taut, shiny, and free of wrinkles. If diffuse scleroderma occurs, swelling is replaced by tightening, hardening, and thickening of skin tissue; this phase is sometimes called the *indurative phase* (Fig. 18-9). The skin loses its elasticity, and range of motion is markedly decreased; ulcerations may occur. Joint contractures may develop, and the patient may be unable to perform ADLs independently.

FIG. 18-9 Late-stage skin changes seen in patients with systemic sclerosis.

Major organ damage is likely to develop with diffuse scleroderma, specifically affecting the renal and cardiopulmonary systems. The initial GERD symptoms progress into other problems, especially affecting the esophagus. The esophagus loses its motility, resulting in *dysphagia (difficulty swallowing).* Assess for the ability of the patient to swallow before allowing him or her to drink or eat food. A small, sliding hiatal hernia may be present, and swallowing may be difficult. Reflux of the gastric contents can cause esophagitis and subsequent ulceration, particularly in the lower two thirds of the esophagus. Intestinal changes are similar to those of the esophagus. Peristalsis is diminished, which causes clinical manifestations similar to a partial bowel obstruction. Malabsorption is a common complication, causing malodorous *diarrheal stools.*

In addition to assessing problems of the digestive tract, observe for *cardiovascular manifestations. Raynaud's phenomenon* occurs in various degrees in most patients with SSc. On exposure to cold or emotional stress, the small arterioles in the digits of both hands and feet rapidly constrict, which causes decreased blood flow. In severe cases, the patient experiences digit necrosis, excruciating pain, and **autoamputation of the distal digits** (the tips of the digits fall off spontaneously). In many patients, vasculitic lesions, often around the nail beds **(periungual lesions),** are evident. *Myocardial fibrosis,* another common problem, is evidenced by electrocardiographic (ECG) changes, cardiac dysrhythmias, and chest pain.

Lung involvement in the patient with SSc may go undetected until late in the disease or sometimes until autopsy. *Fibrosis of the alveoli and interstitial tissues* is present in almost all cases of the disease, but clinical

manifestations may not be present. Patients with scleroderma and *pulmonary arterial hypertension* have a more serious prognosis. *Renal involvement* is an important aspect of the overall disease process and often causes malignant hypertension and death. Assess for signs of impending organ failure, such as changes in urine output and increased blood pressure.

Laboratory Assessment.

The laboratory findings for SSc are similar to those for SLE. Clinical findings and the patient's response to drug therapy help the health care provider differentiate between the two diseases. Additional tests depend on which organs seem to be affected. Upper and lower GI series are commonly performed because of the frequency of GI clinical manifestations.

Interventions

The medical management of SSc aims to force the disease into remission and thus slow disease progression. The health care provider uses drug therapy primarily for this purpose, but it is often unsuccessful. Systemic steroids and immunosuppressants are used in large doses and often in combination. Another desired outcome of disease management is to identify early organ involvement and treat it before it becomes severe and irreversible. For example, a patient who has lung involvement receives aggressive respiratory therapy and other treatments as the condition requires.

Recently, bosentan (Tracleer), the first of a new class of drugs called *endothelin receptor antagonists,* demonstrated improved walk tests for patients with class III or class IV pulmonary arterial hypertension. Various doses improved patients' breathing during exercise, but the potential for liver injury at the highest dose caused recommended doses to be lowered. Teach the patient the desired and potential adverse effects, including liver toxicity and birth defects. Remind him or her of the importance of follow-up testing for liver enzyme levels.

New oral tyrosine kinase inhibitors (TKIs), including nilotinib (Tasigna) and imatinib mesylate (Gleevec), are being tested for use for patients with systemic sclerosis. These drugs work to decrease inflammation and slow the progression of the disease. They are currently approved in the United States for use in certain types of cancer.

Local skin protective measures can help maintain skin integrity. Teach the patient to use mild soap and lotions and gentle cleaning techniques.

Inspect the skin for further changes or open lesions. Skin ulcers are treated according to their type and location.

In addition to drug therapy to control the overall disease process, specific measures can provide comfort. The patient with SSc not only experiences chronic joint pain but also has severe, acute pain during episodes of Raynaud's phenomenon. Remind unlicensed nursing personnel to use a bed cradle and foot board to keep bed covers away from the skin in severe cases. Adjust the room temperature to prevent chilling, which can precipitate digit vasospasm. The patient who can tolerate touching of the affected areas can wear gloves and socks to increase warmth. Because cigarette smoking and extreme emotional stress can also cause symptoms to recur, teach the patient to avoid or minimize these factors as much as possible.

If the patient has esophageal involvement, collaborate with the speech and language pathologist to schedule a swallowing study. The patient may need small, frequent meals rather than the traditional three meals daily. He or she should minimize the intake of foods and liquids that stimulate gastric secretion (e.g., spicy foods, caffeine, alcohol). Teach the patient to keep his or her head elevated for 1 to 2 hours after meals. He or she may need to be in this position continuously. Histamine antagonists and antacids help reduce and neutralize gastric acid. To help prevent choking, collaborate with the dietitian for dietary changes (Chart 18-13).

Chart 18-13 Best Practice for Patient Safety & Quality Care QSEN

The Patient with Systemic Sclerosis and Esophagitis

- Keep the patient's head elevated at least 60 degrees during meals and for at least 1 hour after each meal.
- Provide small, frequent meals rather than three large meals each day.
- Give the patient small amounts of food for each bite, and explain the importance of chewing each bite carefully before swallowing.
- Provide semisoft foods, such as mashed potatoes and pudding or custard; liquids are most likely to cause choking.
- Collaborate with the dietitian about the patient's diet.
- Teach the patient to avoid foods that increase gastric secretion, such as caffeine, pepper, and other spices.
- Give antacids or histamine antagonists as needed.

Nursing care for the patient with joint pain and decreased mobility is very

similar to that for rheumatoid arthritis (see the Interventions section of the Rheumatoid Arthritis section on p. 293). NSAIDs are given for inflammation and pain. Joint protection and energy conservation are also important for these patients.

Community-Based Care

Community-based care for the person with SSc is similar to that for lupus. The patient is treated at home but may need frequent hospitalizations if major organ involvement occurs during exacerbations. The Arthritis Foundation (www.arthritis.org) and Scleroderma Foundation (www.scleroderma.org) are excellent resources for more information about the disease and how to manage it.

Gout

Pathophysiology

Gout, or gouty arthritis, is a systemic disease in which urate crystals deposit in the joints and other body tissues, causing inflammation. It is the most common inflammatory arthritis in older adults, affecting an estimated 6.1 million people (Arthritis Foundation, 2013a). The cause and treatment of gout have been firmly established. The classic case of well-advanced disease is seldom seen today unless the patient does not adhere to the therapeutic regimen. The two major types of gout are primary and secondary.

Primary gout is the most common type and results from one of several inborn errors of purine metabolism. An end product of purine metabolism is uric acid, which is usually excreted by the kidneys. In primary gout, the production of uric acid exceeds the excretion capability of the kidneys. Sodium urate is deposited in synovium and other tissues, resulting in inflammation. For some patients, primary gout is inherited as an X-linked trait; males are affected through female carriers. A number of patients have a family history of gout. Primary gout affects middle-aged and older men and postmenopausal women. The peak time of onset in men is between 40 and 50 years of age (McCance et al., 2014).

Secondary gout involves **hyperuricemia** (excessive uric acid in the blood) caused by another disease or factor. Secondary gout affects people of all ages. Renal insufficiency, diuretic therapy, "crash" diets, and certain chemotherapeutic agents decrease the normal excretion of uric acid and other waste products. Disorders such as multiple myeloma and certain carcinomas result in increased production of uric acid because of a greater turnover of cellular nucleic acids. Treatment involves management of the underlying disorder.

Hyperuricemia and gout are often seen in older patients with cardiovascular health problems, obese people, and postmenopausal women. The incidence of gout is increasing as the baby boomer generation reaches 65 years of age.

The three clinical stages of the primary disease process are asymptomatic hyperuricemia, acute gouty arthritis, and chronic or tophaceous gout (McCance et al., 2014). The patient is usually unaware of the *asymptomatic hyperuricemic stage* unless he or she has had a serum uric acid level determination. The serum level is elevated, but no obvious signs of the disease are present. No treatment is needed in this stage.

The first "attack" of gouty arthritis begins the *acute stage.* The patient experiences excruciating pain and inflammation in one or more small joints,

usually the metatarsophalangeal joint of the great toe, called **podagra.** The erythrocyte sedimentation rate (ESR) is usually increased as a result of the inflammatory process. Months or years may pass before additional attacks occur. The patient is asymptomatic, and no abnormalities are found during examination of the joints.

After repeated episodes of acute gout, deposits of urate crystals develop under the skin and within the major organs, particularly in the renal system. The patient is then classified as having *chronic tophaceous gout.* In chronic gout, urate kidney stone formation is more common than renal insufficiency. Chronic gout can begin anywhere between 3 and 40 years after the initial gout symptoms occur (McCance et al., 2014).

Patient-Centered Collaborative Care

Assessment

Note the patient's age, gender, and family history of gout. A complete history is needed to determine whether gout has been caused by another problem. Some women overuse diuretics, which can lead to secondary gout.

Overt manifestations are present in the acute and chronic phases of gout. You will likely encounter a patient with acute gout, but chronic gout is not as common in the United States today. *Joint inflammation is the most common finding of acute gout. The joint is usually so painful that the patient seeks medical care immediately.* Inspect the inflamed area. It is usually too painful and swollen to be touched or moved.

The health care provider requests a serum uric acid level to check for hyperuricemia. Because the level can be altered by food intake, several measurements may be obtained. A consistent level of more than 6.5 mg/dL is generally considered abnormal, depending on the laboratory test used. Urinary uric acid levels are also measured; an overproduction of uric acid is confirmed by an excretion of more than 750 mg/24 hr (Pagana & Pagana, 2014).

The health care provider may request kidney function tests, such as blood urea nitrogen (BUN) and serum creatinine levels, to monitor possible kidney involvement. A definitive diagnostic test for the disease is synovial fluid aspiration (arthrocentesis) to detect the needle-like crystals in the affected joint that are characteristic of the disorder.

With *chronic* gout, inspect the skin for **tophi,** or deposits of sodium urate crystals (Fig. 18-10). Although tophi are rarely seen today, they may appear on the outer ear, arms, and fingers near the joints. The tophi are hard on palpation and are irregular in shape. When the skin over the

tophi is irritated, it may break open and a yellow, gritty substance is discharged. Infection may result.

FIG. 18-10 Typical appearance of tophi, which may occur in chronic gout, on an index finger.

Other manifestations of chronic gout include signs of renal calculi (stones) or renal dysfunction, such as severe pain or changes in urinary output. In some cases, urate kidney stones occur before the arthritis is present.

Interventions

Gout is one of the easiest diseases for the health care provider to diagnose and treat in its early phases. If the patient receives treatment and adheres to drug therapy, he or she should experience no further symptoms and no change in body image or lifestyle. The patient with gout is treated on an ambulatory basis, but hospitalized patients may have a secondary diagnosis of the disease.

Drug Therapy.

Drug therapy is the key to managing patients with gout. In acute gouty "attacks," the inflammation subsides spontaneously within 3 to 5 days; however, most patients cannot tolerate the pain for that long. The drugs used for acute gout are different from those used for chronic gout. The health care provider typically prescribes a combination of colchicine (Colcrys) and an NSAID, such as indomethacin (Indocin, Novomethacin

) or ibuprofen (Motrin, Amersol) for acute gout. IV colchicine works within 12 hours. The patient takes oral medications until the inflammation subsides, usually for 4 to 7 days.

For patients with repeated acute episodes or with chronic gout, the health care provider prescribes drugs on a continuous, maintenance basis to promote uric acid excretion or to reduce its production. Allopurinol (Zyloprim, Purinol) or febuxostat (Uloric) is the drug of choice. Febuxostat may cause a greater risk to cardiovascular health than allopurinol (Lilley et al., 2014). As xanthine oxidase inhibitors, these drugs prevent the conversion of xanthine to uric acid. Teach patients to take them after meals and drink a glass of water with each dose to prevent GI distress. Drinking at least 8 glasses of water each day helps prevent renal dysfunction. Remind patients that periodic follow-up laboratory tests, including liver enzymes, kidney function studies, and complete blood count, are important because xanthine oxidase inhibitors cause liver dysfunction and bone marrow suppression.

Probenecid can also be effective as a uricosuric drug in gout because it promotes the excretion of excess uric acid. Combination drugs that contain probenecid and colchicine (e.g., ColBENEMID) are also available. The health care provider and nurse monitor serum uric acid levels to determine the effectiveness of these medications. Aspirin should be avoided because it inactivates the effects of the drug.

For patients with severe gout who do not respond to other drugs (refractory gout), pegloticase (Krystexxa) can be prescribed as an IV dose every 2 weeks. This drug is an enzyme that works directly on uric acid and converts it to allantoin, which can be excreted by the kidneys. Monitor patients carefully for allergic reactions, including anaphylaxis, during and immediately after drug administration because pegloticase is a protein that is foreign to the body.

Nutrition Therapy and Lifestyle Recommendations.

The American College of Rheumatology best practice guidelines recommend a strict low-purine diet and suggest that patients avoid foods such as organ meats, shellfish, and oily fish with bones (e.g., sardines). Some health care providers and dietitians believe that limiting protein foods, especially red and organ meats, is sufficient. It is well known, however, that excessive alcohol intake and fad "starvation" diets can cause a gouty attack. *Teach patients to determine which foods precipitate acute attacks and try to avoid them.*

In addition to food and beverage restrictions, patients with gout should avoid all forms of aspirin and diuretics because they may

precipitate an attack. Likewise, excessive physical or emotional stress can exacerbate the disease. Surgery or acute illness, like a myocardial infarction, can also trigger an attack. Stress-management techniques may be helpful for the patient with gout.

Teach the patient to drink plenty of fluids to prevent the formation of urinary stones. Increasing fluid intake helps dilute urine and prevent sediment formation. Uric acid is more soluble in urine with a high pH and therefore is less likely to form urinary stones in that environment. The patient's urinary pH can be increased with an intake of alkaline ash foods, such as citrus fruits and juices, milk, and certain other dairy products. The value of adhering to a strict diet rich in these foods is questionable, however. If the patient is overweight, recommend community resources for losing weight, including increasing exercise.

NCLEX Examination Challenge

Physiological Integrity

The nurse is preparing to give medications to a group of clients. Which drug is not appropriate to treat the disease with which it is matched?

A Rheumatoid arthritis—methotrexate (MTX)
B Osteoarthritis—acetaminophen (Tylenol)
C Acute gout—allopurinol (Zyloprim)
D Systemic lupus erythematosus—prednisone (Deltasone)

Infectious Arthritis

Any infectious agent can invade the joint space and cause pain, inflammation, and tissue destruction. Certain pathogens, such as *Staphylococcus aureus,* destroy tissue rapidly; others, especially viruses, do not cause irreversible damage. The cornerstone of management is local or systemic antibiotic therapy for 6 to 8 weeks.

Lyme Disease

Lyme disease is a reportable systemic infectious disease caused by the spirochete *Borrelia burgdorferi* and results from the bite of an infected deer tick, also known as the *black-legged tick*. It is the most common vector-borne disease in the United States and Europe. Most cases of the disease in the United States are seen in New England; the mid-Atlantic states, including Maryland and Virginia; the upper Midwest, including Wisconsin and Minnesota; and northern California, especially during the summer months.

In the early and *localized stage I,* the patient appears with *flu-like symptoms,* **erythema migrans** (round or oval, flat or slightly raised rash), and *pain and stiffness in the muscles and joints.* Most patients in the United States tend to have only one lesion, sometimes referred to as a *"bull's-eye lesion."* Symptoms begin within 3 to 30 days of the tick bite, but most present in 7 to 14 days. Antibiotic therapy, such as doxycycline or amoxicillin, is prescribed during this uncomplicated stage for 14 to 21 days. Erythromycin can be used for patients who are allergic to penicillin. Without treatment, these symptoms may disappear in about 4 to 5 weeks.

If not treated or if treatment is not successful, the patient may progress to the more serious complications of Lyme disease. *Stage II (early disseminated stage)* occurs 2 to 12 weeks after the tick bite. The patient may develop *carditis* with *dysrhythmias, dyspnea, dizziness, or palpitations,* as well as central nervous system disorders such as *meningitis, facial paralysis* (often misdiagnosed as Bell's palsy), and *peripheral neuritis.* For severe disease, IV antibiotics (e.g., ceftriaxone or cefotaxime) are given for at least 30 days.

If Lyme disease is not diagnosed and treated in the earlier stages, later chronic complications (e.g., *arthritis, chronic fatigue, memory/thinking problems*) can result. This *late stage III (chronic persistent stage)* occurs months to years after the tick bite. *For some patients, the first and only sign of Lyme disease is arthritis.* In some cases, the disease may not respond to antibiotics in any stage and the patient develops permanent damage to joints and the nervous system. *Prevention is the best strategy for Lyme disease.* Teach patients to follow the measures outlined in Chart 18-14 to prevent Lyme and other tick-borne diseases. Tell them about community resources such as the Lyme Disease Foundation (www.lyme.org) for more information.

Chart 18-14 Patient and Family Education: Preparing

for Self-Management

Prevention and Early Detection of Lyme Disease

- Avoid heavily wooded areas or areas with thick underbrush, especially in the spring and summer months.
- Walk in the center of the trail.
- Avoid dark clothing. Lighter-colored clothing makes spotting ticks easier.
- Use an insect repellent (DEET) on your skin and clothes when in an area where ticks are likely to be found.
- Wear long-sleeved tops and long pants; tuck your shirt into your pants and your pants into your socks or boots.
- Wear closed shoes or boots and a hat or cap.
- Bathe immediately after being in an infested area, and inspect your body for ticks (about the size of a pinhead); pay special attention to your arms, legs, and scalp.
- Check your pets for ticks.
- Gently remove with tweezers or fingers covered with tissue or gloves any tick that you find (do not squeeze). Dispose of the tick by flushing it down the toilet (burning a tick could spread infection).
- After removal, clean the tick area with an antiseptic such as rubbing alcohol.
- Wait 4 to 6 weeks after being bitten by a tick before being tested for Lyme disease (testing before this time is not reliable).
- Report symptoms, such as a rash or influenza-like illness, to your physician immediately.

Psoriatic Arthritis

Psoriatic arthritis (PsA) affects some people who have psoriasis—a skin condition characterized by a scaly, itchy rash, usually on the elbows, knees, and scalp. Fingernail and toenail lifting and pitting may also occur (see Chapter 25 for discussion of this disease). The joint pain associated with psoriasis is often associated with stiffness, especially in the morning. Neck and back pain are particularly common, but various forms of the disease can cause small joint arthritis or involvement of the sacroiliac joints of the spine.

PsA occurs most often in people between 30 and 50 years of age in men and women of all races. Nail symptoms are common in patients who have the associated arthritis. Causes may include genetic and environmental factors, infectious agents, and immune system dysfunction.

Most patients do not experience destructive and deforming arthritis affecting more than three joints, but for those who do, the experience has a major impact on their quality of life. Treatment is focused on managing joint pain and inflammation, controlling skin lesions, and slowing the progression of the disease. Health teaching for skin care is similar to that for lupus. Management of joint inflammation is similar to that for rheumatoid arthritis as described earlier in this chapter. Methotrexate (Rheumatrex), sulfasalazine (Azulfidine), and biological response modifiers (also called *biologics*), such as etanercept (Enbrel) and golimumab (Simponi), are being used with success.

Teach the patient or family member how to self-administer Enbrel injections. Injection site reactions and infections (especially respiratory) are possible adverse effects. Ice and hydrocortisone 1% cream can be used if a red, itchy rash at the injection site develops.

Golimumab (Simponi) is the first biologic that is administered only once each month for psoriatic arthritis. Teach patients that this drug has a black box warning for serious infections that may lead to hospitalization or death from opportunistic pathogens (Cranwell-Bruce, 2011).

Several newer types of biologics have also been approved for psoriatic arthritis. Ustekinumab (Stelara) targets the cytokines *interleukin (IL)-12* and *IL-23* to decrease inflammation. Alefacept (Amevive) is an IV immunosuppressive drug (T-cell blocker) that is reserved for moderate to severe disease. Teach patients taking these drugs about their risk for infection. Remind them to avoid crowds and anyone with an infection.

Acitretin (Soriatane) is an oral retinoid given for patients with severe disease. Teach patients to take the drug once a day with a meal and

follow up with laboratory testing for liver enzymes.

The National Psoriasis Foundation (www.psoriasis.org) is an excellent community resource for patients and their families. Further discussion regarding management of psoriasis can be found in Chapter 25.

Fibromyalgia Syndrome

Fibromyalgia syndrome (FMS), also referred to as simply *fibromyalgia,* is a chronic pain syndrome, not an inflammatory disease. However, arthritis and other comorbidities are commonly present in patients diagnosed with FMS. Pain, stiffness, and tenderness are located at specific sites in the back of the neck, upper chest, trunk, low back, and extremities. These tender points are also known as **trigger points** and can typically be palpated to elicit pain in a predictable, reproducible pattern. The pain is typically described as burning and gnawing. Increased muscle tenderness may be caused by the inability to tolerate pain, possibly related to dysfunction in the brain, especially the thalamus and hypothalamus (McCance et al., 2014).

The pain and tenderness tend to come and go but typically worsen in response to stress, increased activity, and weather conditions. The patient reports mild to severe fatigue, and sleep disturbances are common. Some people report numbness or tingling in their extremities, and others are sensitive to noxious odors, loud noises, and bright lights. Headaches and jaw pain are also common. Secondary FMS can accompany any connective tissue disease (CTD), particularly lupus and rheumatoid disease, and may not necessarily be related to sleep patterns.

Other symptoms include:

- Gastrointestinal (GI), including abdominal pain, diarrhea and constipation, and heartburn
- Genitourinary, including dysuria, urinary frequency, urgency, and pelvic pain
- Cardiovascular, including dyspnea, chest pain, and dysrhythmias
- Visual, including blurred vision and dry eyes
- Neurologic, including forgetfulness and concentration problems

Many with these symptoms become frustrated because they are not properly diagnosed and are in constant pain and discomfort.

Some patients are diagnosed as having chronic fatigue syndrome (CFS). CFS, migraine headache, irritable bowel syndrome (IBS), and myofascial pain are often present in those with FMS. As a result, patients can become depressed and anxious.

Most patients are women between 30 and 50 years of age. It is unlikely that the disease is caused by one factor. Possible precipitating factors include CFS, Lyme disease, trauma, and flu-like illness (McCance et al., 2014). FMS may also be aggravated by deep-sleep deprivation. Teach patients to limit caffeine, alcohol, or other unnecessary substances that could interfere with deep sleep. Establish a regular sleep pattern.

Pregabalin (Lyrica) and duloxetine HCl (Cymbalta), which are antidepressant drugs, are approved for fibromyalgia nerve pain. These drugs work to increase the release of serotonin and norepinephrine, neurotransmitters in the brain (Lilley et al., 2014). Teach the patient that these drugs can cause drowsiness and sleepiness and that alcohol should be avoided while taking them.

Tricyclic antidepressive agents, such as amitriptyline (Elavil, Apo-Amitriptyline) or nortriptyline (Pamelor), may promote sleep and reduce pain or muscle spasm. These drugs should be used with caution in older adults because they can cause confusion and orthostatic hypotension. Trazodone (Desyrel) may be preferred for this population because of its minimal side effects. Tramadol (Ultram) is also effective for managing fibromyalgia. This drug has tricyclic effects and opioid properties to help relieve pain (see Chapter 3).

Physical therapy along with NSAIDs and possibly muscle relaxants may also be prescribed to help decrease fibromyalgia pain. Instruct the patient to exercise regularly. Home exercise should include stretching, strengthening, and low-impact aerobic exercise. Walking, swimming, rowing, biking, and water exercise are good examples of low-impact exercise. Complementary and alternative therapies, such as tai chi, acupuncture, hypnosis, and stress management, may help some patients with symptom relief. Refer patients to the land, water, and walking exercise pamphlets produced by the Arthritis Foundation (www.arthritis.org). Inform them about the National Fibromyalgia Association for additional information and patient and family support (www.fmaware.org).

Chronic Fatigue Syndrome

Chronic fatigue syndrome (CFS), also known as *chronic fatigue and immune dysfunction syndrome (CFIDS),* is a chronic illness in which patients have severe fatigue for 6 months or longer, usually following flu-like symptoms. In addition, four or more of these criteria must be met for a diagnosis of CFS:

- Sore throat
- Substantial impairment in short-term memory or concentration
- Tender lymph nodes
- Muscle pain
- Multiple joint pain with redness or swelling
- Headaches of a new type, pattern, or severity (not familiar to the patient)
- Unrefreshing sleep
- Postexertional malaise lasting more than 24 hours

Chronic fatigue syndrome is most common in women and is not limited to any socioeconomic group or age. There is no laboratory test to confirm the diagnosis, and therefore many people with the disease probably have not been diagnosed. The cause is unknown, although immune, endocrine, neurologic, and environmental factors are being studied.

Management of the patient is challenging in that there is no cure for CFS. Treatment is supportive and focuses on alleviation or reduction of symptoms. For example, NSAIDs may help with body aches and pain. Low-dose antidepressants, such as pregabalin (Lyrica), may also be effective in promoting sleep and preventing or treating depression. Teach the patient to follow healthy practices, such as adequate sleep, proper nutrition, regular exercise (but not excessive to increase fatigue), stress management, and energy conservation. Complementary and alternative therapies, such as acupuncture, tai chi, massage, and herbal supplements, may be helpful for some patients.

Refer the patient to the National Chronic Fatigue Syndrome and Fibromyalgia Association for information and support groups.

Other Connective Tissue Diseases

Many other connective tissues diseases (CTDs) may be seen, but they are not as common as those health problems previously described. Table 18-3 describes some of these CTDs, their key assessments, and primary collaborative interventions.

TABLE 18-3

Other Connective Tissue Diseases That Affect Joints

DISEASE	DESCRIPTION/ PATHOPHYSIOLOGY	ASSESSMENT/CLINICAL MANIFESTATIONS	COLLABORATIVE INTERVENTIONS
Polymyositis/ dermatomyositis	Autoimmune, inflammatory disease that causes symmetric muscle atrophy; when skin rash is also present, disease is called *dermatomyositis (DM);* women between 30 and 60 years affected most often.	Severe muscle weakness Dysphagia (difficulty swallowing) Periorbital edema and lilac eyelid rash (DM) Malignant neoplasms in older patients	Comfort measures Swallowing precautions Nutritional support PT/OT support Immunosuppressant agents and/or chronic steroid therapy (Teach about risk for infection.) Health teaching about progression of disease, comfort measures, and dietary needs
Systemic necrotizing vasculitis	A group of autoimmune diseases that result in arteritis (inflammation of arterial walls) causing ischemia in the tissues or organs that are supplied by the arteries.	Peripheral arterial disease causing severe pain and necrosis of toes or fingers Signs and symptoms of organ dysfunction or failure, such as kidney or heart failure; also can cause stroke-like symptoms	Chronic steroid therapy and other immunosuppressants Vasodilators, depending on type of vasculitis Management of organ dysfunction or failure
Polymyalgia rheumatica (PMR) and temporal arteritis (TA)	Autoimmune, genetic-based disease affecting middle-aged and older women most often that causes proximal muscle weakness (shoulder and pelvic girdles) (PMR). TA (also known as *giant cell arteritis*) may occur as a separate disease or with PMR.	Shoulder, neck, pelvic, and hip weakness, stiffness, joint aches, low-grade fever, fatigue, and weight loss caused by inflammation (PMR) Headache and visual disturbances (TA)	Responds well to high-dose steroid therapy to cause remission of disease Symptom management Short-term PT/OT as needed Health teaching about medication and pain modalities, such as heat application for joints
Ankylosing spondylitis	Autoimmune, inflammatory disease affecting the spine that is thought to be genetic (strongly associated with specific variations in the *HLA-27* allele on chromosome 6). Can occur in both men and women, but white men younger than 40 years most commonly affected.	Chronic back pain Compromised respiratory function due to rigid chest wall Visual disturbances caused by iritis (inflammation of the iris) Joint pain and aching Malaise Weight loss	Chronic pain management modalities NSAIDs DMARDs, such as methotrexate and biologic response modifiers Symptom management
Reiter's syndrome	Complex syndrome associated with the *HLA-27* allele causing a triad of arthritis, conjunctivitis, and urethritis (inflammation of the urethra). Triggered by exposure to infection, especially sexually transmitted disease or intestinal infection.	Joint pain Eye infection causing redness, pain, and drainage Pain or burning on urination and changes in urinary pattern	Antibiotic therapy to manage infection Pain management NSAIDs Other symptom management
Marfan syndrome	Autosomal dominant disorder resulting from mutations in the *fibrillin 1* gene (FBN1). Fibrillin important in limiting the stretch of elastic connective tissues and allowing them to return to their original resting shape. Disease shortens life expectancy, often with death in the 30s.	Excessive height Elongated hands and feet Joint discomfort or pain Scoliosis Visual problems, such as decreased visual acuity or glaucoma Cardiovascular problems, such as mitral valve prolapse and aortic aneurysm, leading to heart failure or death	Symptom management Frequent echocardiography monitoring and physical examinations to detect heart problems Genetic counseling

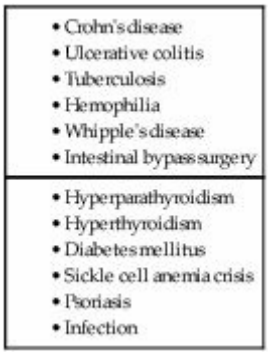
DMARDs, Disease-modifying antirheumatic drugs; *OT,* occupational therapy; *PT,* physical therapy.

Other Disease-Associated Arthritis

A number of other diseases can cause secondary arthritis. Tuberculosis, Crohn's disease, ulcerative colitis, hemophilia, and sickle cell anemia are typical examples. To manage joint involvement, the primary disease is treated. For example, when a patient with Crohn's disease is in remission, joint manifestations also subside. Conditions in which joint involvement can occur are presented in Table 18-4.

TABLE 18-4

Common Disorders Associated with Arthritis



Mixed Connective Tissue Disease

A diagnosis of mixed CTD is made when a patient presents with clinical manifestations that are not typical of any one CTD. About 10% of patients with CTDs are classified as having mixed disease. Some of these are overlap syndromes, in which two or more diseases occur at the same time. Common examples are (1) systemic lupus erythematosus (SLE) plus systemic sclerosis (SSc) and (2) rheumatoid arthritis (RA) plus SLE. Management depends on the clinical manifestations, but often the patient is treated as having SLE.

Nursing Concepts and Clinical Judgment Review

What might you NOTICE if the patient has impaired immunity as a result of arthritis or other connective tissue disease (CTD)?

- Joint inflammation (redness, swelling, pain)
- Impaired joint mobility and stiffness
- Joint deformity
- Difficulty ambulating
- Fever
- Rash
- Report of weight loss and fatigue
- Other manifestations that indicate organ involvement, such as dysrhythmias (heart) and decreased urinary output (kidneys)

What should you INTERPRET and how should you RESPOND to a patient with impaired immunity as a result of arthritis or other CTD?

Perform and interpret focused physical assessment findings, including:

- Joint assessment, including range of motion
- ADL ability
- Pain intensity and quality
- Body weight
- Ability to cope with disease
- Vital signs
- Other assessments related to specific organ involvement (e.g., cardiac assessment)

Respond:

- Provide pain control interventions, including drug therapy and

nonpharmacologic measures (e.g., heat and cold application).
- Collaborate with members of the health care team to improve mobility and ambulation, if needed.
- Teach about drug therapy, including the expected and adverse effects.
- Teach about nonpharmacologic measures to control pain, including ice and heat, and CAM therapies, such as glucosamine.
- Report manifestations of organ involvement to the health care provider for possible immediate intervention (e.g., drug therapy for severe dysrhythmias).
- Monitor laboratory test results to determine progress of treatment.
- Continue to assess for changes in the patient's condition, including new or additional manifestations of organ involvement.
- Encourage patients and their families to discuss their feelings about chronic illness and possible body image changes.
- Help identify coping strategies, and provide information about community and professional resources and support groups.

On what should you REFLECT?

- Monitor the patient's response to pain control interventions.
- Evaluate the patient's and family's knowledge of the disease and its management.
- Evaluate the patient's and family's stress levels and coping strategies.
- Think about what else you might do to promote mobility.
- Decide whether you need to provide alternative interventions or additional health teaching.

Get Ready for the NCLEX® Examination!

Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Collaborate with the health care team to manage chronic pain and increase mobility for patients with arthritis and other CTDs. **Teamwork and Collaboration** QSEN
- Prioritize care for patients with systemic lupus erythematosus (SLE) and systemic sclerosis (SSc) by monitoring for life-threatening complications, such as kidney failure.

Health Promotion and Maintenance

- Provide information about community resources for patients, especially professional organizations such as the Arthritis Foundation and Lupus Foundation.
- Teach patients to prevent joint trauma and reduce weight as needed to help prevent osteoarthritis. **Evidence-Based Practice** QSEN
- Recall that a combination of environmental, genetic, and immune risk factors can cause arthritis and other connective tissue diseases.
- Reinforce the importance of good health practices, such as adequate sleep, proper nutrition, regular exercise, and stress-management techniques for patients with arthritis and other CTDs.
- Teach patients with arthritis what exercises to do (Chart 18-5), joint protection techniques (Chart 18-6), and energy conservation guidelines (Chart 18-10). **Evidence-Based Practice** QSEN
- Teach patients with SLE to avoid sunlight; exacerbations of the disease may be triggered.
- Remind patients with gout to avoid factors that trigger an attack, such as aspirin, organ meats, and alcohol. **Evidence-Based Practice** QSEN
- Teach people ways to prevent or detect early Lyme disease as listed in Chart 18-14.

Psychosocial Integrity

- Recognize that patients with rheumatoid arthritis (RA) may have body image disturbance as a result of potentially deforming joint involvement and nodules.
- Encourage patients with arthritis and connective tissue diseases to

discuss their chronic illness and identify coping strategies that have previously been successful. **Patient-Centered Care** QSEN

- Be aware that chronic, painful diseases affect the patient's quality of life and role performance.
- Recognize that patients with fibromyalgia syndrome (FMS) and chronic fatigue syndrome (CFS) are often frustrated because they have not been diagnosed or have been misdiagnosed.
- Teach patients with FMS and CFS that antidepressant drugs can promote sleep and decrease pain, as well as prevent or treat the depression that is common with these illnesses.

Physiological Integrity

- Be aware that most of the connective tissue diseases and arthritic disorders have a genetic basis as part of their etiology; most are also classified as autoimmune diseases and have remissions and exacerbations.
- Differentiate OA as primarily a degenerative joint problem that can affect one or more joints, and RA as a systemic disease that presents as a bilateral symmetric joint inflammation.
- Realize that older patients have OA more than younger patients; younger patients have RA more than older adults; other differences between the two diseases are summarized in Table 18-1.
- Teach patients who have osteoarthritis (OA) or are prone to the disease to lose weight (if obese), avoid trauma, and limit strenuous weight-bearing activities.
- Instruct patients with arthritic pain to use multiple modalities for pain relief, including ice/heat, rest, positioning, complementary and alternative therapies, and medications as prescribed.
- Teach patients to monitor and report side and adverse effects of drugs used to treat OA and other connective tissue diseases.
- Assess patients with rheumatoid arthritis for early or late clinical manifestations as listed in Chart 18-7.
- Teach patients who are taking hydroxychloroquine (Plaquenil) to have frequent (every 6 months) eye examinations to monitor for retinal changes. **Safety** QSEN
- Remind patients to avoid crowds and other possible sources of infection when they are taking immunosuppressant drugs. **Safety** QSEN
- Implement interventions for patients having total joint arthroplasty (TJA) to prevent venous thromboembolitic complications (e.g., anticoagulants, exercises, sequential compression devices); observe the

patient for bleeding when he or she is taking anticoagulants.

- Be careful when positioning a patient after a total hip arthroplasty (THA) to prevent dislocation; do not hyperflex the hips or adduct the legs (see Chart 18-3). **Safety** QSEN
- Be aware that disease-modifying antirheumatic drugs (DMARDs) and biological response modifiers (BRMs) slow the progression of connective tissue diseases, especially RA and SLE.
- Remind patients taking methotrexate (Rheumatrex) to avoid people with infections; check the patient's PPD test or history of tuberculosis before starting the drug. **Safety** QSEN
- Teach patients receiving BRMs and other disease-modifying agents to avoid crowds and people with infections; opportunistic pathogens may cause serious infections or death (see Chart 18-9).
- Monitor and interpret laboratory test results for patients with autoimmune connective tissue diseases as highlighted in Chart 18-8.
- Differentiate clinical manifestations and prognosis for patients with systemic lupus erythematosus (SLE) versus systemic sclerosis (SSc) as listed in Chart 18-11.
- Prioritize care by assessing for swallowing ability in patients who have SSc; collaborate with the dietitian for food modifications if needed. **Teamwork and Collaboration** QSEN
- Monitor for acute joint inflammation in patients with a history of gout; the great toe and other small joints are most typically affected.
- Keep in mind that patients with psoriatic arthritis have skin and joint involvement that require collaborative management (also see Chapter 25 for discussion of psoriasis).
- Assess for visual symptoms (indicating possible giant cell arteritis) in patients with polymyalgia rheumatica; report changes immediately to the health care provider.
- Be aware that arthritis often accompanies other diseases, such as Crohn's disease and hemophilia.

CHAPTER 19

Care of Patients with HIV Disease and Other Immune Deficiencies

James Sampson and M. Linda Workman

PRIORITY CONCEPTS

- Immunity
- Infection
- Nutrition
- Tissue Integrity
- Pain

Learning Outcomes

Safe and Effective Care Environment

1. Use appropriate techniques to reduce the risk for infection in an immunosuppressed patient.
2. Prevent human immune deficiency virus (HIV) transmission to yourself and others.

Health Promotion and Maintenance

3. Assess all patients for high-risk behaviors related to HIV infection.

Psychosocial Integrity

4. Reduce the psychological impact of HIV disease or other immune deficiencies for the patient and family.
5. Work with other members of the health care team to ensure that the values, preferences, and expressed needs of patients with HIV disease or other immune deficiencies are respected.

Physiological Integrity

6. Use clinical manifestations and laboratory data to assess for immune deficiencies and their complications.
7. Integrate the contributions of others who play a role in helping the patient/family experiencing HIV disease achieve health goals.
8. Prioritize nursing care for the patient with AIDS.

 http://evolve.elsevier.com/Iggy/

Immunity is complex and functions to help the body stay healthy by preventing the growth of infectious organisms and abnormal cells, such as cancer cells. Infectious organisms and cancer cells are considered "non-self," as described in Chapter 17. The immune system monitors all cells and substances, maintaining those that are considered "self" (belonging to the body) and attacking and destroying "non-self" (foreign) substances. Infection from different organisms is a major threat, and exposure occurs daily. The efficiency of the immune system prevents disease despite this exposure. As discussed in Chapter 17, an important function of the immune system is detecting body cells that undergo changes to cancer cells. When detected early enough, the immune system destroys these precancerous cells before a tumor forms.

When the immune system fails to recognize infectious agents, severe local and systemic infections are not suppressed or controlled. Immune system failure can be the result of a primary (congenital) immune deficiency in which one or more parts of the system are not functioning properly from birth. It can also be secondary (acquired after birth) as the result of viral infection, contact with a toxin, or medical therapy that can cause a normal immune system to function less efficiently. Then the immune system can no longer recognize foreign invaders (non-self). The consequences can range from mild, localized health problems to total immunity failure, leaving the body open to attack from any foreign pathogen.

Acquired (Secondary) Immune Deficiencies

HIV Infection and AIDS

❖ Pathophysiology

Human immune deficiency virus (HIV) infection and disease can progress to acquired immune deficiency syndrome (AIDS), which is the most common immune deficiency disease and is now a serious worldwide epidemic (World Health Organization [WHO], 2013).

Etiology and Genetic Risk

The cause of HIV infection is a virus—the human immune deficiency virus. HIV is a parasite looking for a way into a cell, to take over the cell, and to force the cell into making more copies of the virus (viral particles). These new viral particles then look for additional cells to infect, repeating the cycle as long as there are new host cells to infect.

The HIV Infectious Process.

Viral particle features include an outer envelope with special "docking proteins," known as *gp41* and *gp120,* that assist in finding a host (Fig. 19-1). Inside, the virus has genetic material along with the enzymes *reverse transcriptase (RT)* and *integrase*. The HIV must get inside a host cell. It does this by first entering the host's bloodstream and then "hijacking" certain cells, especially the *CD4+ T-cell*, also known as the *CD4+ cell*, *helper/inducer T-cell*, or *T4-cell* (see Chapter 17). This cell directs immune system defenses and regulates the activity of all immune system cells. When HIV enters a CD4+ T-cell, it can then create more virus particles.

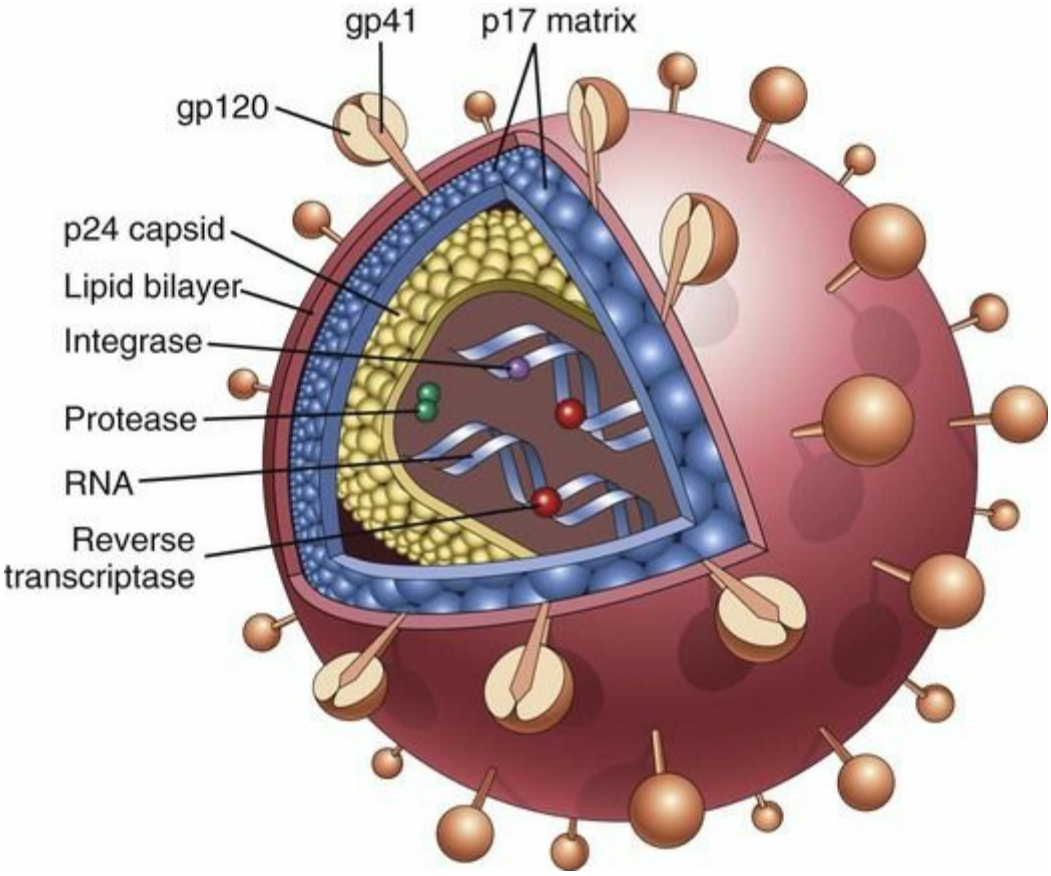


FIG. 19-1 The human immune deficiency virus (HIV).

Virus-host interactions are needed after infection for disease development. When a person is infected with HIV, the virus randomly "bumps" into many cells. The docking proteins on the outside of the virus must find special receptors on a host cell for the virus to bind and then enter the cell. The CD4+ T-cell has surface receptors known as *CD4*, *CCR5*, and *CXCR4* (Fig. 19-2). Proteins on the HIV particle surface, known as *gp120* and *gp41*, recognize these receptors on the CD4+ T-cell. For the virus to enter this cell, *both* the *gp120* and the *gp41* must bind to the receptors. The *gp120* first binds to the primary CD4 receptor, which changes its shape and allows the *gp120* to bind to either the *CCR5* co-receptor or the *CXCR4* co-receptor. Once co-receptor binding occurs, *gp41* inserts a fusion peptide into the T-cell membrane, boring a hole to allow insertion of viral genetic material and enzymes into the host cell. This attachment allows the virus to then enter the CD4+ T-cell (see Fig. 19-2). *Viral binding to the CD4 receptor and to either of the co-receptors is needed to enter the cell.* (The drug class known as *entry inhibitors* works here to prevent the interaction needed for entry of HIV into the CD4+ T-cell.)

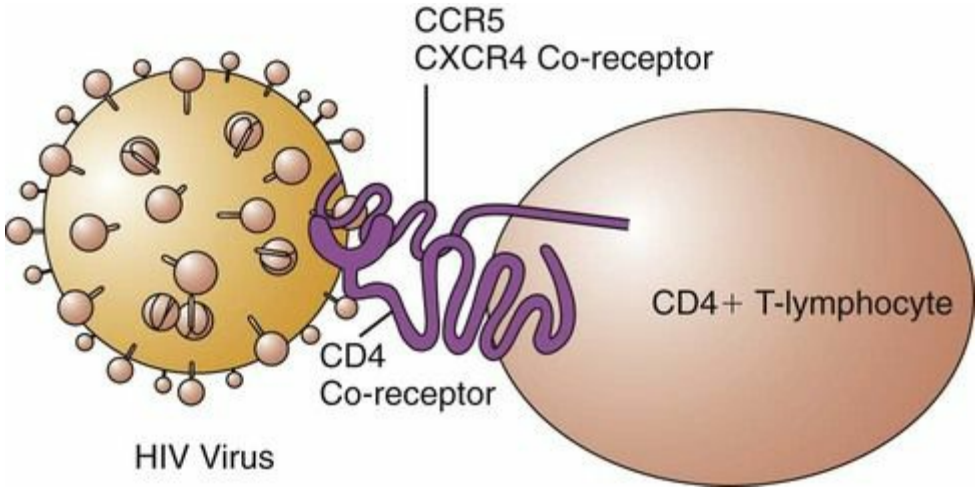

FIG. 19-2 The HIV "docking" proteins and the successful interaction of these proteins with the CD4+ T-lymphocyte receptors.

After entering a host cell, HIV must get its genetic material into the host cell's DNA. HIV is a **retrovirus,** which is able to insert its single-stranded ribonucleic acid (ss-RNA) genetic material into the host's DNA. The genetic material of the human cell is double-stranded DNA (ds-DNA). To infect and take over a human cell, the genetic material must be the same. The HIV enzyme *reverse transcriptase (RT)* converts HIV's ss-RNA into ds-DNA, which makes the viral genetic material the same as human DNA. (The drug classes known as *nucleoside reverse transcriptase inhibitors [NRTIs]* and *non-nucleoside reverse transcriptase inhibitors [NNRTIs]* work here to prevent viral replication [Fig. 19-3] by reducing how well reverse transcriptase can convert HIV genetic material into human genetic material.) HIV then uses its enzyme *integrase* to get its DNA into the nucleus of the host's CD4+ T-cell and insert it into the host's ds-DNA. This action completes the infection of the CD4+ T-cell. (The drug class known as *integrase inhibitors* works here to prevent viral DNA from integrating into the host's DNA.)

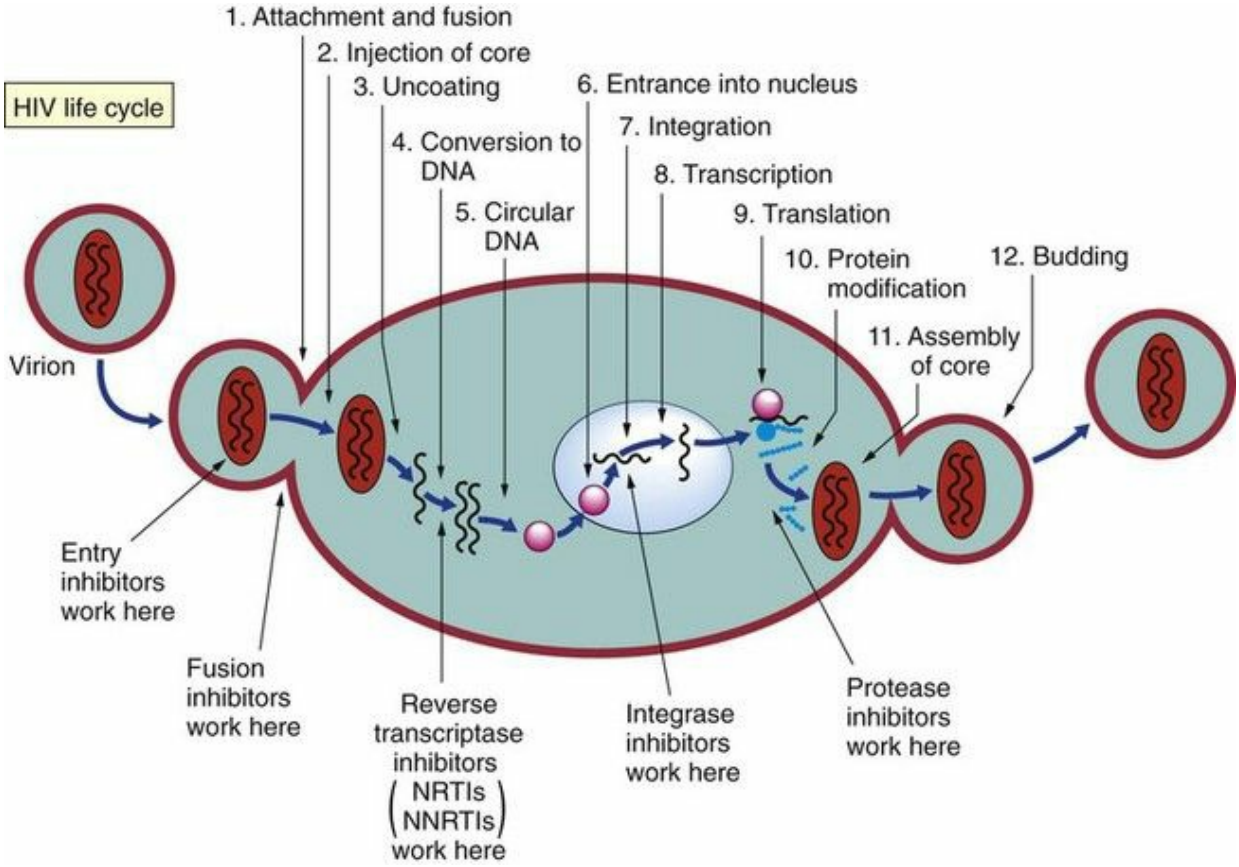

FIG. 19-3 The life cycle of the HIV and sites of action for anti-HIV therapy.

HIV particles are made within the infected CD4+ T-cell, using all the metabolic machinery of the host. The new virus particle is made in the form of one long protein strand. The strand is clipped by the enzyme *HIV protease* into smaller functional pieces. These pieces are formed into a new finished viral particle. (The drug class known as *protease inhibitors* works here to inhibit HIV protease.) Once the new virus particle is finished, it fuses with the infected cell's membrane and then buds off in search of another CD4+ T-cell to infect (see Fig. 19-3).

Effects of HIV infection are related to the new genetic instructions that now direct CD4+ T-cells to change their role in immune system defenses. The new role is to be an "HIV factory," making up to 10 billion new viral particles daily. In addition, the immune system is made weaker by removing some CD4+ T-cells from circulation. In early HIV infection before HIV disease is evident, the immune system can still attack and destroy most of the newly created virus particles. With time, however, the number of HIV particles overwhelms the immune system. Gradually, CD4+ T-cell counts fall, viral numbers *(viral load)* rise, and without treatment, the patient eventually dies of opportunistic infection or cancer.

Everyone who has AIDS has HIV infection; however, not everyone who has HIV infection has AIDS. The distinction is the number of CD4+ T-cells and

whether any opportunistic infections have occurred. A healthy adult usually has at least 800 to 1000 CD4+ T-cells per cubic millimeter (mm^3) of blood. This number is reduced in the person with HIV disease.

Some people develop an acute infection within 4 weeks of first being infected. Manifestations of this acute HIV infection can be fever, night sweats, chills, headache, and muscle aches, which are similar to those of any viral infection—not just HIV. A sore throat and rash also may accompany this acute HIV infection. With time, these symptoms cease and the person feels well again, although a "war is going on" between HIV and the immune system.

As time passes, more CD4+ T-cells are infected and taken out of service. The count decreases, and those that remain function poorly. Poor CD4+ T-cell function leads to these immune system abnormalities:

- Lymphocytopenia (decreased numbers of lymphocytes)
- Increased production of incomplete and nonfunctional antibodies
- Abnormally functioning macrophages

As the CD4+ T-cell level drops, the patient is at risk for bacterial, fungal, and viral infections, as well as opportunistic cancers. **Opportunistic infections** are those caused by organisms that are present as part of the body's normal environment and are kept in check by normal immune function. They occur because of the profound immunosuppression in the person with AIDS.

A diagnosis of AIDS requires that the person be HIV positive and have either a CD4+ T-cell count of less than 200 cells/mm^3 or less than 14% (even if the total CD4+ count is above 200 cells/mm^3) or an opportunistic infection. Once AIDS is diagnosed, even if the patient's T-cell count goes higher than 200 cells/mm^3 or if the percentage rises above 14%, or the infection is successfully treated, the AIDS diagnosis remains and the patient does not revert to being just HIV positive.

HIV Classification.

The Centers for Disease Control and Prevention (CDC) currently defines four stages of HIV disease. In this definition, laboratory confirmation of HIV infection (by enzyme-linked immunosorbent assay [ELISA] and Western blot analysis) plus CD4+ T-lymphocyte count or percentage and the presence or absence of the 27 AIDS-defining conditions (Table 19-1) determine the classification (Centers for Disease Control and Prevention [CDC], 2013b). *The person with HIV infection can transmit the virus to others at all stages of disease, but the recently infected person with a high viral load and those at end stage without drug therapy can be particularly infectious.*

TABLE 19-1

Centers for Disease Control and Prevention Classification of Aids-Defining Conditions in Adults

- Bacterial infections, multiple or recurrent
- Candidiasis of bronchi, trachea, or lungs
- Candidiasis of esophagus
- Cervical cancer, invasive
- Coccidioidomycosis, disseminated or extrapulmonary
- Cryptococcosis, extrapulmonary
- Cryptosporidiosis, chronic intestinal (>1-month's duration)
- Cytomegalovirus disease (other than liver, spleen, or nodes)
- Cytomegalovirus retinitis (with loss of vision)
- Encephalopathy, HIV-related
- Herpes simplex: chronic ulcers (>1-month's duration) or bronchitis, pneumonitis, or esophagitis
- Histoplasmosis, disseminated or extrapulmonary
- Isosporiasis, chronic intestinal (>1-month's duration)
- Kaposi's sarcoma
- Lymphoid interstitial pneumonia or pulmonary lymphoid hyperplasia complex
- Lymphoma, Burkitt's (or equivalent term)
- Lymphoma, immunoblastic (or equivalent term)
- Lymphoma, primary, of brain
- *Mycobacterium avium* complex or *Mycobacterium kansasii*, disseminated or extrapulmonary
- *Mycobacterium tuberculosis* of any site, pulmonary, disseminated, or extrapulmonary
- *Mycobacterium*, other species or unidentified species, disseminated or extrapulmonary
- *Pneumocystis jirovecii* pneumonia
- Pneumonia, recurrent (two instances within 12 months)
- Progressive multifocal leukoencephalopathy
- *Salmonella* septicemia, recurrent
- Toxoplasmosis of brain
- Wasting syndrome attributed to HIV

From Schneider, E., Whitmore, S., Glynn, K.M., Dominguez, K., Mitsch, A., McKenna, M.T.; Centers for Disease Control and Prevention. (2008). Revised surveillance case definitions for HIV infection among adults, adolescents, and children aged <18 months and for HIV infection and AIDS among children aged 18 months to <13 years—United States, 2008. *Morbidity and Mortality Weekly Report: Recommendations and Reports, 57*(RR-10), 9. Retrieved December 2013 from www.cdc.gov/mmwr/preview/mmwrhtml/rr5710a2.htm

Stage 1 CDC Case Definition describes a patient with a CD4+ T-cell count of greater than 500 cells/mm^3 or a percentage of 29% or greater. A person at this stage has no AIDS-defining illnesses.

Stage 2 CDC Case Definition describes a patient with a CD4+ T-cell count between 200 and 499 cells/mm^3 or a percentage between 14% and 28%. A person at this stage has no AIDS-defining illnesses.

Stage 3 CDC Case Definition describes any patient with a CD4+ T-cell count of less than 200 cells/mm^3 or a percentage of less than 14%. A person who has higher CD4+ T-cell counts or percentages but who also has an AIDS-defining illness meets the Stage 3 CDC Case Definition.

Stage 4 CDC Case Definition is used to describe any patient with a confirmed HIV infection but no information regarding CD4+ T-cell counts, CD4+ T-cell percentages, and AIDS-defining illnesses is available.

HIV Progression.

The time from the beginning of HIV infection to development of AIDS ranges from months to years. The range depends on how HIV was acquired, personal factors, and interventions. For people who have been transfused with HIV-contaminated blood, for example, AIDS often develops quickly. For those who become HIV positive as a result of a single sexual encounter, the period is much longer before progression to AIDS. Other personal factors that influence progression to AIDS include frequency of re-exposure to HIV, presence of other sexually transmitted diseases (STDs), nutrition status, and stress.

Genetic/Genomic Considerations

Patient-Centered Care QSEN

About 1% of people with HIV infection are long-term nonprogressors (LTNPs). These people have been infected with HIV for at least 10 years and have remained asymptomatic, with CD4+ T-cell counts within the normal range and a viral load that is either undetectable or very low.

A genetic difference for this population is that their *CCR5/CXCR4* co-receptors on the CD4+ T-cells are abnormal and nonfunctional as a result of gene mutations for these co-receptors. The mutation creates defective co-receptors that do not bind to the HIV docking proteins. Cells with this defective co-receptor successfully resist the entrance of HIV. People who have only one mutated co-receptor gene allele have fewer normal co-receptors and can be infected with HIV, although disease progression is relatively slow.

Incidence and Prevalence

Since the beginning of the epidemic in the United States, more than 636,000 people have died of AIDS. Currently, about 50,000 people are diagnosed yearly and more than 1,148,200 people in the United States are living with HIV/AIDS (CDC, 2013b). Worldwide, about 40 to 60 million people are currently infected with HIV, at least 30 million deaths from AIDs have occurred, and 33 million people are living with AIDS (WHO, 2013).

Most AIDS cases in North America occur among men who have sex with men (MSM) (59%-69%) or people of either gender who have used injection drugs (16%) (CDC, 2013b). *The changing demographics of the infection indicate that the perception that HIV/AIDS is only a problem for homosexual white men is false (Kirton, 2011).*

Cultural Considerations

Patient-Centered Care QSEN

Most new HIV infections reported in the United States occur in racial and ethnic minority groups, particularly among African Americans and Hispanics (CDC, 2013b). These two groups show an increasing trend in HIV infection and disease compared with a leveling off among white people.

Gender Health Considerations

Patient-Centered Care QSEN

About 25% of newly diagnosed cases are women. In less affluent countries, 50% of cases occur in women (WHO, 2013). The largest risk factor is sexual exposure. Strategies specifically targeted to reducing sexual exposures of HIV to women may help prevent an increase in HIV infection in that group. Women with HIV disease have a poorer outcome with shorter mean survival time than that of men. This outcome may be the result of late diagnosis and social or economic factors that reduce access to medical care.

Gynecologic problems, especially persistent or recurrent vaginal candidiasis, may be the first signs of HIV disease in women. Other problems include pelvic inflammatory disease, genital herpes, other sexually transmitted diseases (STDs), and cervical dysplasia or cancer.

The effect of HIV on pregnancy outcomes includes higher incidence of premature delivery, low-birth-weight infants, and transmission of the disease to the infant. Appropriate antiretroviral drug therapy during pregnancy reduces the risk for transmitting the infection to the infant. (See the discussion on p. 332 in the Perinatal Transmission section.)

Considerations for Older Adults

Patient-Centered Care QSEN

Infection with HIV can occur at any age. Assess the older patient for risk behaviors, including a sexual and drug use history (Foster et al., 2012). (See the Evidence-Based Practice box for specific risky behaviors often practiced by older adults.) Age-related decline in immunity increases the likelihood that the older adult will develop the infection after an HIV exposure.

Evidence-Based Practice QSEN

How Are Older Adults at Risk for HIV Infection?

Foster, V., Clark, P., Holstad, M., & Burgess, E. (2012). Factors associated with risky sexual behaviors in older adults. *Journal of the Association of Nurses in AIDS Care, 23*(6), 487-499.

The incidence of human immune deficiency virus (HIV) infection is significant among adults over 50 years of age in North America and contributes to earlier mortality and morbidity in this age-group. Many programs for HIV risk reduction focus on younger adults, teenagers, and racial/ethic minorities. However, the older adult age-group continues to develop HIV infection. This correlational study sought to (1) determine whether higher levels of HIV knowledge and higher levels of motivation to practice safer sex were associated with lower levels of risky sexual behaviors and (2) identify what factors were associated with continued practice of risky sexual behaviors among adults ages 50 years and older.

A convenience sample of 106 sexually active, community-dwelling, single men and women ranging in age from 50 to 74 years were recruited into the study. (Some participants planned to be sexually active, whereas others were sexually active during the study period.)

Level of Evidence: 4

The study method was prospective, cross-sectional, and correlational. Statistical evaluation methods were appropriate for the design.

Commentary: Implications for Practice and Research

The study is important for many reasons. First, it established the incidence of sexual behaviors in a relatively large group of older adult participants. It also highlighted the fact that many health care professionals, as well as older adult patients, are reluctant to discuss sexual behaviors and risk for HIV infection in the defined age-group. In addition, the knowledge of correct condom use, a well-established deterrent to HIV transmission, is lacking among many older adults.

The study defined important areas for future nursing research. Among these are the need for nurses and other health care professionals to understand that aging does not limit the risks for HIV transmission and the absolute need for consistently addressing sexuality in older adults. Strategies to increase correct condom use among sexually active older adults (who may only see the use as a no-longer-needed form of birth control) need to be developed and tested.

Health Promotion and Maintenance

AIDS is a disease with a mortality rate of at least 60% for adults. Although a very few people who have been given high doses of antiretroviral drugs immediately upon diagnosis have subsequently shown no detectable virus, there are too few cases to indicate whether such therapy can result in an enduring cure. Thus, at this time, there is no available cure for AIDS and a major focus for health care worldwide is prevention of HIV infection.

HIV has been found in blood, semen, vaginal secretions, breast milk, amniotic fluid, urine, feces, saliva, tears, cerebrospinal fluid, lymph nodes, cervical cells, corneal tissue, and brain tissue of infected patients. The fluids with the highest concentrations of HIV are semen and blood. HIV is transmitted most often in these three ways:

- Sexual: genital, anal, or oral sexual contact with exposure of mucous membranes to infected semen or vaginal secretions
- Parenteral: sharing of needles or equipment contaminated with infected blood or receiving contaminated blood products
- Perinatal: from the placenta, from contact with maternal blood and body fluids during birth, or from breast milk from an infected mother to child

Teach everyone about the transmission routes and ways to reduce their exposure (discussed next). Also stress that HIV is not transmitted by casual contact in the home, school, or workplace. Sharing household utensils, towels and linens, and toilet facilities does not transmit HIV. In addition, HIV is not spread by mosquitoes or other insects.

Nursing Safety Priority QSEN

Action Alert

Teach all people, regardless of age, gender, ethnicity, or sexual orientation, that they are susceptible to HIV infection.

Sexual Transmission

Safer sex methods of *A, abstinence; B, be faithful;* and *C, condom use* can reduce HIV transmission. *Abstinence and mutually monogamous sex with a noninfected partner are the only absolutely safe methods of preventing HIV infection from sexual contact.* Many forms of sexual expression can spread HIV infection if one partner is infected. *The risk for becoming infected from a partner who is HIV positive is always present,* although some sexual practices are more risky than others. Because the virus concentrates in

blood and seminal fluid and is also present in vaginal secretions, risk differs by gender, sexual act, and the viral load of the infected partner.

Gender affects HIV transmission, like all other sexually transmitted diseases (STDs), and it is more easily transmitted from infected male to uninfected female than vice versa. This is because HIV is most easily transmitted when infected body fluids come into contact with mucous membranes or nonintact skin. The vagina has more surface area of mucous membrane than does the penis. Teach women the importance of always either using a vaginal or dental dam or female condom or having their male partners use a condom.

Sexual acts or practices that permit infected seminal fluid to come into contact with mucous membranes or nonintact skin are the most risky for sexual transmission of HIV. The practice with the highest risk is anal intercourse with the penis and seminal fluid of an infected person coming into contact with the mucous membranes of the uninfected partner's rectum. *Anal intercourse in which the semen depositor (inserting or active partner) is infected is a very risky sexual practice regardless of whether the semen receiver (receiving partner) is male or female.* Anal intercourse not only allows seminal fluid to make contact with the mucous membranes of the rectum but also tears the mucous membranes, making infection more likely. Teach patients who engage in anal intercourse that the semen depositor needs to wear a condom during this act.

Viral load, or the amount of virus present in blood and other body fluids, affects transmission. The higher the blood level of HIV (**viremia**), the greater the risk for sexual and perinatal transmission. Current highly active antiretroviral therapy (HAART) has caused the viral load of some infected patients to drop below detectable levels. *Although there is less virus in seminal or vaginal fluids of people receiving HAART, the risk for transmission still exists.*

Safer sex practices are those that reduce the risk for nonintact skin or mucous membranes coming in contact with infected body fluids and blood. Teach everyone the importance of consistently using these safer sex practices:

- A latex or polyurethane condom for genital and anal intercourse
- A condom or latex barrier (dental dam) over the genitals or anus during oral-genital or oral-anal sexual contact
- Latex gloves for finger or hand contact with the vagina or rectum

New research for prevention of sexual transmission has resulted in the use of drug therapy for *pre-exposure prophylaxis* (Aschenbrenner, 2012). The use of the combination drug *Truvada* (emtricitabine and tenofovir) by HIV-1–negative sexual partners of known HIV-1–positive people appears

to reduce HIV transmission.

Nursing Safety Priority QSEN

Drug Alert

Pre-exposure prophylaxis does not replace the standard safer sex practices recommended to prevent HIV transmission. Also, if this type of drug therapy is used in patients who become infected with HIV-1, the risk for developing drug resistance greatly increases. Therefore remind people prescribed Truvada to use the safer sex practices previously described and to adhere to an every-3-month HIV testing schedule along with monitoring for side effects of this drug.

For those who believe they have been exposed to HIV as a result of sexual relations or other types of non-occupational exposure, the CDC has guidelines for *postexposure prophylaxis.* The length and type of prophylaxis therapy depend on the nature of the exposure (Fig. 19-4, *A*).

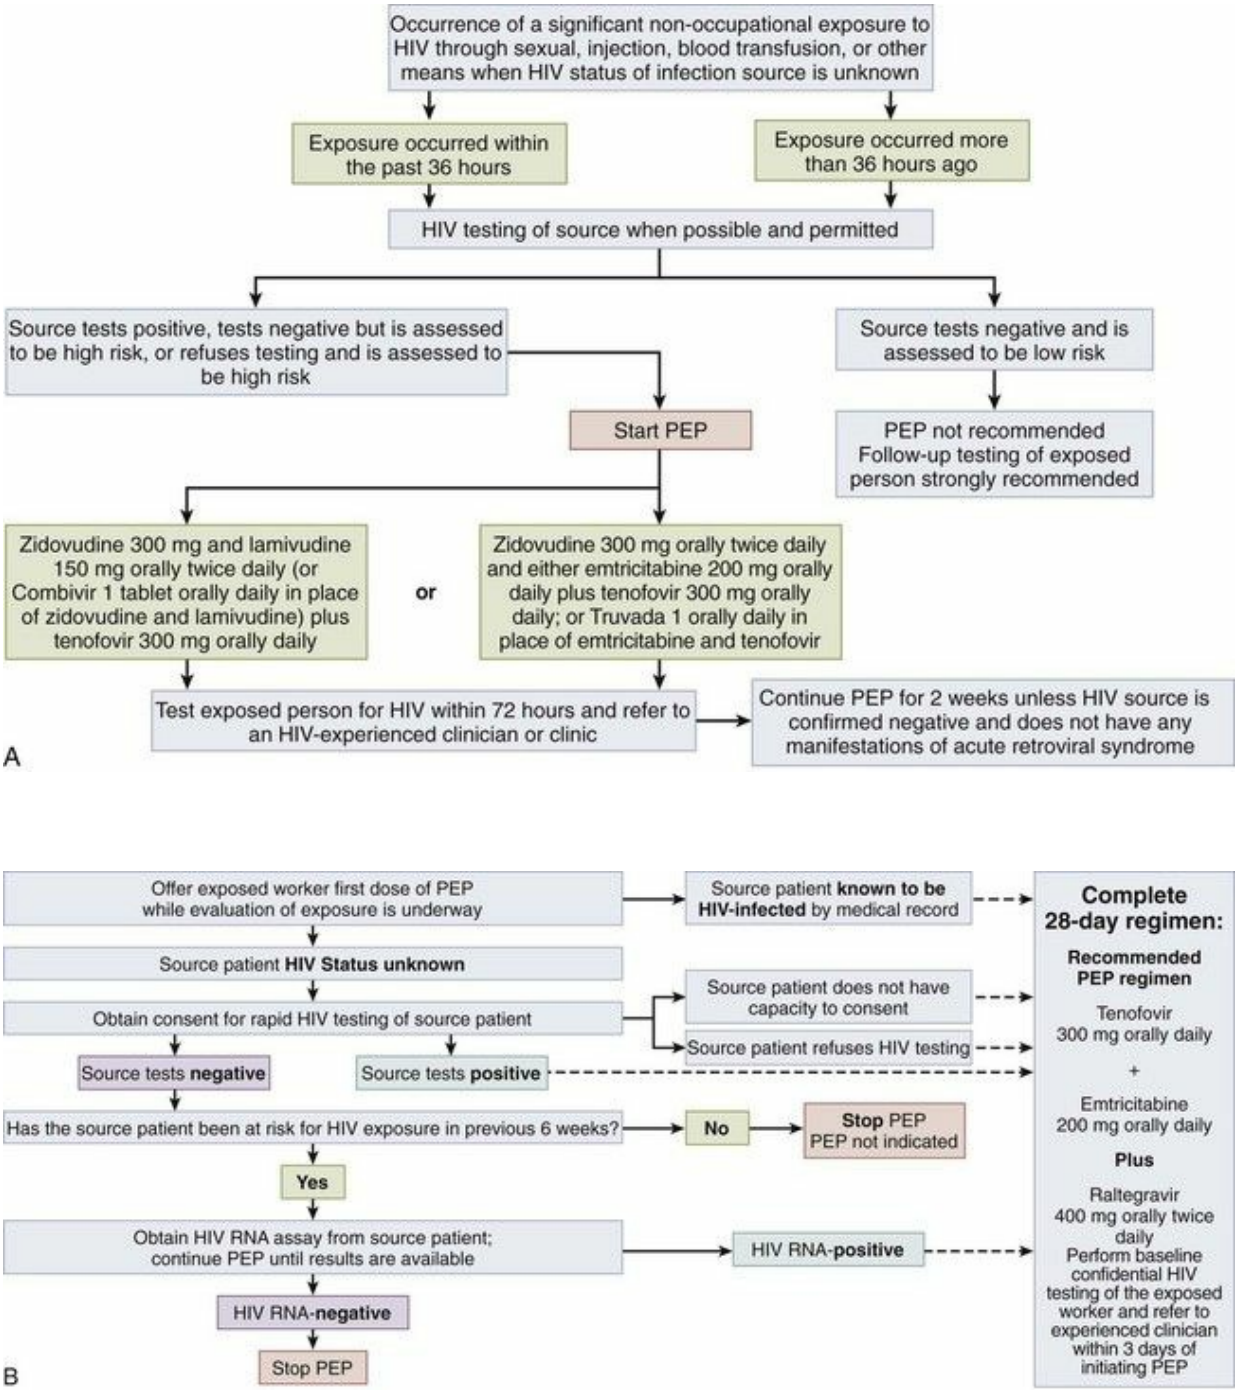

FIG. 19-4 New York State Health Department HIV guidelines. **A,** Recommendations for non-occupational postexposure prophylaxis for HIV infection. **B,** Recommendations for occupational postexposure prophylaxis for HIV infection.

NCLEX Examination Challenge

Physiological Integrity

Which couple has the highest risk for sexual transmission of HIV without the use of a condom or dental dam?

A Uninfected male performing vaginal intercourse with an infected

female
B Infected male performing vaginal intercourse with an uninfected female
C Uninfected male performing anal intercourse with an infected male
D Infected male performing oral sex on an uninfected male

Parenteral Transmission

Preventive practices to reduce transmission among injection drug users (IDUs) include the use of proper cleaning of "works" (needles, syringes, other drug paraphernalia). Instruct IDUs to clean a used needle and syringe by first filling and flushing them with clear water. Next, the syringe should be filled with ordinary household bleach. The bleach-filled syringe should be shaken for 30 to 60 seconds. Advise IDUs to carry a small container with this solution whenever sharing needles. Some communities have a needle exchange program in which needles and syringes are used only once and are then exchanged for clean ones.

The risk for AIDS transmission through blood and blood products has been reduced to a national average of 0.02%. All donated blood in North America is screened for the HIV antibody, and blood that is positive for HIV antibodies is discarded. Because of the time lag in antibody production after exposure to HIV, infected blood can test negative for HIV antibodies. False-negative results also can occur for other reasons. Inform patients that there is a small but real possibility of HIV transmission through blood and blood products. As a result, methods for reducing transfusion-related infection have included the use of growth factors to promote more rapid blood production in the patient and an increase in autologous transfusion in which the patient donates his or her own blood to be transfused back at a later time.

Perinatal Transmission

HIV transmission can occur across the placenta during pregnancy, with infant exposure to blood and vaginal secretions during birth, or with exposure after birth through breast milk. Inform women of childbearing age with HIV infection about the risks for perinatal transmission. The risk for perinatal transmission to infants in pregnant patients with HIV infection is about 25% in woman who are not using drug therapy for the disease compared with about 8% for women who are using drug therapy for HIV. Therefore encourage HIV-positive women who are pregnant to continue the therapy or, if they are not on antiviral therapy, to start the therapy as soon as possible.

NCLEX Examination Challenge

Health Promotion and Maintenance

During a health assessment, a 22-year-old college student tells the nurse that she is sexually active and protects herself from HIV and other sexually transmitted diseases (STDs) by using oral contraceptives. What is the nurse's best action?

A Remind the student that only abstinence prevents STDs.
B Ask the health care provider to order an HIV test for this student.
C Inform the student that oral contraceptives protect against pregnancy but not against any STD.
D Reinforce the student's preferred use of oral contraceptives, and refrain from commenting on her sexual activity.

Transmission and Health Care Workers

Needle stick or "sharps" injuries are the main means of occupation-related HIV infection for health care workers. In addition, health care workers can be infected through exposure of nonintact skin and mucous membranes to blood and body fluids. *The best prevention for health care providers is the consistent use of Standard Precautions for all patients as recommended by the CDC and required by The Joint Commission's (TJC) National Patient Safety Goals (NPSGs)* (see Chapter 23). Fig. 19-4, *B* shows the recommended actions for prevention of HIV infection after a needle stick or other occupational exposure (postexposure prophylaxis [PEP]). When the source patient is known to be HIV negative, PEP is not recommended.

To prevent HIV transmission to patients, health care workers should wear gloves when in contact with patients' mucous membranes or nonintact skin. Infected workers with weeping dermatitis or open lesions should not perform direct care. The CDC guidelines for preventing HIV transmission by health care workers during exposure-prone invasive procedures are listed in Chart 19-1. These include any procedure in which there is a risk for broken skin injury to the health care worker and the worker's blood is likely to make contact with the patient's body cavity, subcutaneous tissues, or mucous membranes.

Chart 19-1

Best Practice for Patient Safety & Quality Care QSEN

Recommendations for Preventing HIV Transmission by Health Care Workers

- Workers should adhere to Standard Precautions.
- Workers with exudative lesions or weeping dermatitis should not perform direct patient care or handle patient care equipment and devices used in invasive procedures.
- Workers must follow guidelines for disinfection and sterilization of reusable equipment used in invasive procedures.
- Workers infected with HIV are not restricted from practice of non–exposure-prone procedures, as long as they comply with Standard Precautions and sterilization and disinfection recommendations.
- Workers should identify exposure-prone procedures by institutions where they are performed.
- Workers who perform exposure-prone procedures should know their HIV antibody status.
- Workers who are infected with HIV should seek advice from an expert review panel before performing exposure-prone procedures to determine under what circumstances they may continue to practice these procedures. These circumstances would include notification of prospective patients of HIV positivity.

Adapted from Centers for Disease Control and Prevention. (1991). Recommendations for preventing transmission of human immunodeficiency virus and hepatitis B virus to patients during exposure-prone invasive procedures. *Morbidity and Mortality Weekly Report: Recommendations and Reports, 40*(RR-8), 1-9.

Testing

Testing for HIV antibodies or other features of the virus is complex, requiring interpretation, counseling, and confidentiality. Testing plays a role in prevention because tests are a way of diagnosing HIV infection before immune changes or disease manifestations develop. A primary health care focus for testing is to teach those who test positive to modify their behaviors to prevent transmission to others. *Therefore all sexually active people should know their HIV status.* Chart 19-2 lists additional conditions for which HIV antibody testing is advised.

Chart 19-2

Patient and Family Education: Preparing for Self-Management

CDC Recommendations for HIV Testing

You should be tested for HIV if you fall within one or more of these groups:

- People with sexually transmitted disease
- Injection drug users
- People who consider themselves at risk
- Women of childbearing age with identifiable risks, including:
  - Used injection drugs
  - Engaged in prostitution
  - Had sexual partners who were infected or at risk
  - Had sexual contact with men from countries with high HIV prevalence
- People who received a transfusion between 1978 and 1985
- People planning to get married
- People undergoing medical evaluation or treatment for manifestations that may be HIV related
- People admitted to hospitals
- People in correctional institutions such as jails and prisons
- Prostitutes and their customers

CDC, Centers for Disease Control and Prevention.

Adapted from Centers for Disease Control and Prevention. (1987). Public Health Service guidelines for counseling and antibody testing to prevent HIV infection and AIDS. *Morbidity and Mortality Weekly Report, 36*(31), 509-515.

Pretest and post-test counseling must be performed by personnel trained in HIV issues. These counselors may be nurses, physicians, social workers, health educators, or even lay educators who have specialized training. Counseling helps the patient make an informed decision about testing and provides an opportunity to teach risk-reduction behaviors. Post-test counseling is needed to interpret the results, discuss risk reduction, and provide psychological support and health promotion information for the patient with a positive test result. People who test positive should also be counseled on how to inform sexual partners and those with whom they have shared needles. Testing methods, their accuracy, and indications are presented on p. 336 in the Laboratory Assessment section.

Patient-Centered Collaborative Care

Assessment

The person who has HIV disease is monitored on a regular basis for changes in immune function or health status that indicate disease progression and the need for intervention. The frequency of monitoring varies from every 2 to 6 months based on disease progression and

responses to treatment. This continuing assessment of the patient with HIV disease is crucial, because he or she may have problems related to disease in many organ systems and to ensure that the drug continues to work optimally. Assess subtle changes so that infections and other problems can be found early and treated.

History.

Ask about age, gender, occupation, and where the person lives. Thoroughly assess the current illness, including when it started, the severity of symptoms, associated problems, and any interventions to date. Ask the patient about when the HIV infection was diagnosed and what manifestations led to that diagnosis. Ask him or her to give a chronologic history of infections and problems since the diagnosis. Assess the patient's health history, including whether he or she received a blood transfusion between 1978 and 1985 in the United States (before routine blood testing for HIV contamination). Because blood testing for HIV contamination is not consistently performed in all parts of the world, ask the immigrant patient about his or her history of transfusion therapy before coming to the United States.

Ask the patient about sexual practices, sexually transmitted diseases (STDs), and major infectious diseases, including tuberculosis and hepatitis. If the patient has hemophilia, ask about treatment with clotting factors. Determine whether the patient has engaged in past or present injection drug use, including needle sharing. Assess the patient's level of knowledge regarding the diagnosis, symptom management, diagnostic tests, treatments, community resources, and modes of HIV transmission. Also assess his or her understanding and use of safer sex practices. If knowledge deficits are found, provide the appropriate patient teaching.

Physical Assessment/Clinical Manifestations.

HIV disease and AIDS are a progression continuum. The patient with HIV disease may either have few manifestations and problems or may have problems that are acute rather than chronically present. As the disease progresses, however, more severe health problems occur and the patient may not realize that the disease is progressing. Assess for clusters of symptoms that may indicate disease progression (Chart 19-3).

Chart 19-3 Key Features

AIDS

Immunologic Manifestations

- Low white blood cell counts:
  - CD4+/CD8+ ratio <2
  - CD4+ count <200/mm^3
- Hypergammaglobulinemia
- Opportunistic infections
- Lymphadenopathy
- Fatigue

Integumentary Manifestations

- Dry skin
- Poor wound healing
- Skin lesions
- Night sweats

Respiratory Manifestations

- Cough
- Shortness of breath

Gastrointestinal Manifestations

- Diarrhea
- Weight loss
- Nausea and vomiting

Central Nervous System Manifestations

- Confusion
- Dementia
- Headache
- Fever
- Visual changes
- Memory loss
- Personality changes
- Pain
- Seizures

Opportunistic Infections

- Protozoal infections:
  - Toxoplasmosis
  - Cryptosporidiosis

  - Isosporiasis
  - Microsporidiosis
  - Strongyloidiasis
  - Giardiasis
- Fungal infections:
  - Candidiasis
  - *Pneumocystis jiroveci* pneumonia
  - Cryptococcosis
  - Histoplasmosis
  - Coccidioidomycosis
- Bacterial infections:
  - *Mycobacterium avium* complex infection
  - Tuberculosis
  - Nocardiosis
- Viral infections:
  - Cytomegalovirus infection
  - Herpes simplex virus infection
  - Varicella-zoster virus infection

Malignancies

- Kaposi's sarcoma
- Non-Hodgkin's lymphoma
- Hodgkin's lymphoma
- Invasive cervical carcinoma

Opportunistic Infections.

The patient with HIV/AIDS often develops pathogenic infections and opportunistic infections. *Pathogenic infections* are caused by virulent organisms and occur even among people with normal immunity. *Opportunistic infections* are those caused by organisms that are present as part of the body's normal environment and are kept in check by normal immune function. Only when immunity is depressed are such organisms capable of causing infection.

Opportunistic infections occur because of the profound immunosuppression of the person with HIV disease. They may result from primary infection or reactivation of a latent infection. Opportunistic infections account for many of the clinical manifestations observed in HIV infection and can be protozoan, fungal, bacterial, or viral. More than one infection may be present at the same time. The presence of opportunistic infections may represent disease progression or a temporary further reduction of immune status. *In either case, these*

infections can result in death if appropriate treatment is not started quickly. Priority nursing actions when caring for a patient who is HIV positive are continually assessing for and documenting the presence of an opportunistic infection and monitoring the patient's response to therapy. Report to the health care provider those manifestations that may indicate an infection.

Opportunistic infections do not pose a threat to the immunocompetent health care worker caring for a patient with HIV disease or AIDS. When the patient with HIV disease or AIDS has a pathogenic infection, however, health care personnel must use precautions appropriate to the specific disease to prevent disease spread. For example, when the person with HIV/AIDS also has tuberculosis at a transmissible stage, Airborne Precautions are needed in addition to Standard Precautions. See Chapter 23 for a more complete discussion on Transmission-Based Precautions for specific infectious diseases.

Protozoal and fungal infections are common among patients with AIDS. *Pneumocystis jiroveci* pneumonia (PCP) is the most common opportunistic infection in persons infected with HIV. This organism is now considered a fungus. Assess for dyspnea on exertion, tachypnea, a persistent dry cough, and a persistent low-grade fever. The patient may report fatigue and weight loss. Auscultate breath sounds for crackles.

Toxoplasmosis encephalitis, caused by *Toxoplasma gondii,* is acquired through contact with contaminated cat feces or by ingesting infected undercooked meat. Assess the patient for subtle changes in mental status, neurologic deficits, headaches, and fever. Additional changes may include difficulties with speech, gait, and vision; seizures; lethargy; and confusion. Perform a comprehensive mental status examination and monitor the patient to detect subtle changes.

Cryptosporidiosis is an intestinal infection caused by *Cryptosporidium* organisms. In AIDS, this illness ranges from a mild diarrhea to a severe wasting with electrolyte imbalance. Diarrhea may result in fluid loss of up to 15 to 20 L/day. Ask the patient about the presence of diarrhea and whether he or she has had an unplanned weight loss of 5 pounds or more.

Fungal infection occurs by overgrowth of normal body flora. *Candida albicans* is part of the intestinal tract's natural flora. In the person with AIDS, candidiasis (overgrowth of the *Candida* fungus) occurs because the immune system can no longer control fungal growth. *Candida* stomatitis or esophagitis occurs often in AIDS. Patients may report food tasting "funny," mouth pain, difficulty in swallowing, and pain behind the sternum. On examination of the mouth and throat, you may see cottage cheese–like, yellowish white plaques and inflammation (Fig. 19-5).

Esophagitis is diagnosed by endoscopic examination with biopsy and culture. Women with HIV disease or AIDS may have persistent vaginal candidiasis with severe pruritus (itching), perineal irritation, and a thick, white vaginal discharge.

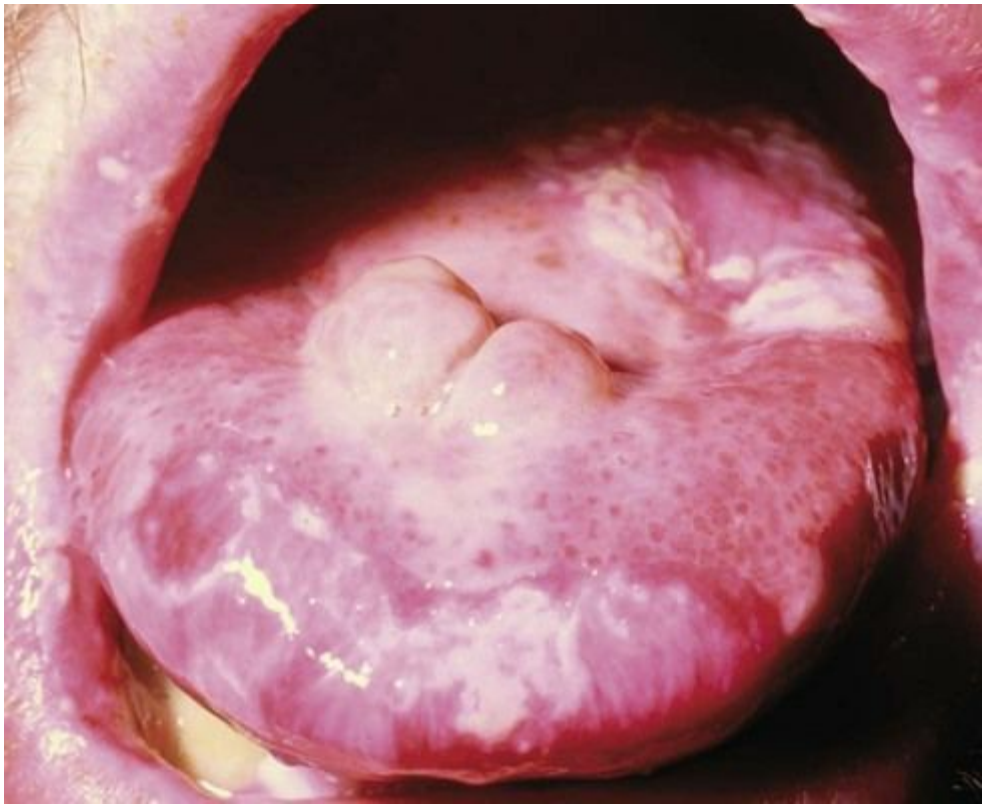

FIG. 19-5 Oral candidiasis (thrush).

Cryptococcosis, caused by *Cryptococcus neoformans*, is a debilitating meningitis and can be a widely spread infection in AIDS. Ask about fever, headache, blurred vision, nausea and vomiting, neck stiffness, confusion, and other mental status changes. Patients may have seizures and other neurologic problems, or they may have mild malaise, fever, and headaches.

Histoplasmosis, caused by *Histoplasma capsulatum,* begins as a respiratory infection and progresses to widespread infection in the person with AIDS. Assess for dyspnea, fever, cough, and weight loss. Check for enlargement of lymph nodes, the spleen, or the liver.

Bacterial infections are acquired from other people or sources and as overgrowth of skin flora. *Mycobacterium avium* complex (MAC) is the most common bacterial infection associated with AIDS. This problem is caused by *M. intracellulare* or *M. avium,* which infects the respiratory or GI tract. MAC is a systemic infection. Assess for fever, debility, weight loss, malaise, and sometimes swollen lymph glands or organ disease.

Tuberculosis (TB), caused by *Mycobacterium tuberculosis*, occurs in 2% to 10% of persons with AIDS (CDC, 2009). More than 50% of all patients with AIDS and TB have extrapulmonary disease sites, including the central nervous system, bones, liver, spleen, skin, and intestinal tract. Ask about cough, dyspnea, chest pain, fever, chills, night sweats, weight loss, and anorexia. Manifestations of extrapulmonary infection vary with the site. *The person with TB and a CD4+ T-cell count below 200/mm^3 may not have a positive TB skin test (purified protein derivative [PPD]) because of an inability to mount an immune response to the antigen, a condition known as* ***anergy***. Blood analysis by the fully automated nucleic acid amplification test (NAAT) for tuberculosis with results available in less than 2 hours is the most sensitive and rapid test for the presence of *M. tuberculosis*. It is very useful in the acute care setting to determine whether a symptomatic patient actually has TB. Other diagnostic tests include a chest x-ray, acid-fast sputum smear, and sputum culture.

Nursing Safety Priority QSEN

Action Alert

Until parameters other than a skin test come back negative for TB in a patient with AIDS who also has TB manifestations, maintain Airborne Precautions along with Standard Precautions.

The tuberculosis bacillus is spread by airborne routes. When particles from the patient's respiratory tract are aerosolized, anyone near him or her is at risk for inhaling the particles and the bacillus. Therefore the nurse or respiratory therapist who gives cough-inducing aerosol treatments, such as pentamidine isethionate, to patients with AIDS should be screened with a PPD skin test or QuantiFERON blood test every 6 months to determine whether he or she has been infected with TB.

Pneumonia from bacterial infection recurs often among patients with AIDS, and two or more episodes of any type of bacterial pneumonia in a 12-month period are an AIDS case definition. Assess for chest pain, productive cough, fever, and dyspnea.

Viral infection from a virus other than HIV is common among people with HIV disease that has progressed to AIDS. Cytomegalovirus (CMV) can infect many sites in persons with AIDS, including the eye (CMV retinitis), respiratory and GI tracts, and the central nervous system. CMV infection can also cause many nonspecific problems such as fever, malaise,

weight loss, fatigue, and swollen lymph nodes. CMV retinitis impairs vision, ranging from slight impairment to total blindness. CMV can also cause diarrhea, abdominal bloating and discomfort, and weight loss. Ask the patient whether he or she has any of these manifestations. In addition, CMV can cause encephalitis, pneumonitis, adrenalitis, hepatitis, and disseminated infection.

Herpes simplex virus (HSV) infection in people with HIV disease or AIDS occurs in the perirectal, oral, and genital areas. The manifestations are more widespread and of longer duration among patients with HIV/AIDS than among those who are immunocompetent. Numbness or tingling at the site of infection occurs up to 24 hours before blisters form. Lesions are painful, with chronic open areas after blisters rupture. Assess for fever, pain, bleeding, and enlarged lymph nodes in the affected area. Also assess for headache, myalgia, and malaise.

Varicella-zoster virus (VZV) infection (*shingles*) is not a new infection for people with AIDS. This virus causes chickenpox and then remains present in the nerve ganglia. When people who have had chickenpox previously are immunocompromised, VZV leaves the nerve ganglia and enters other tissue areas, causing shingles. Ask whether the patient has pain and burning along sensory nerve tracts (see Chapter 41 for the dermatomes of sensory nerve locations), headache, and low-grade fever. Examine the skin for fluid-filled blisters with or without crusts.

Malignancies.

Weakened immunity increases the risk for some cancers. These include Kaposi's sarcoma, lymphomas, invasive cervical cancer, lung cancer, GI cancer, and anal cancer (Kirton, 2011).

Kaposi's sarcoma (KS) is the most common AIDS-related malignancy. The risk for KS appears to be related to co-infection with human herpes virus-8.

KS develops as small, purplish brown, raised lesions that are usually not painful or itchy. The skin and mucous membrane lesions can occur anywhere on the body (Fig. 19-6). In some patients, lesions develop in the lymph nodes, mouth and throat, intestinal tract, or lungs. KS is diagnosed by biopsy and histologic examination of the lesion. Assess KS lesions for number, size, location, and whether they are intact, and monitor their progression.

FIG. 19-6 Kaposi's sarcoma lesions.

Malignant lymphomas occurring with AIDS are Hodgkin's lymphoma, non-Hodgkin's B-cell lymphomas (such as Burkitt's lymphoma), immunoblastic lymphoma, and primary brain lymphoma. Manifestations include swollen lymph nodes, weight loss, fever, and night sweats.

Human papilloma virus (HPV) infection results in multiple types of malignancies and manifestations, but the most common in HIV infection are cervical and anal cancers. Cervical Papanicolaou (Pap) testing every 6 months is the standard of care for HIV-positive patients. In MSM patients, performing an anal Pap test, using the same medium as for a cervical Pap test, is now becoming standard of care and is being extended to both male and female patients for the early detection and treatment of cervical and anal cancers.

Endocrine Complications.

Patients with HIV disease may have disease-related and treatment-related endocrine problems, such as gonadal dysfunction, body shape changes, adrenal insufficiency, diabetes mellitus, and elevated triglycerides and cholesterol (which increase the risk for cardiovascular problems).

Many HIV-positive men have low testosterone levels, and HIV-positive women often have irregular menstrual cycles. With this gonadal dysfunction comes a decrease in body muscle mass for both genders, with a decrease in weight, and a change in libido, accompanied by a decrease in energy and an increase in fatigue.

Body shape changes from fat redistribution or fat disposition (known

as *lipodystrophy*) are common in patients receiving antiretroviral therapies, especially protease inhibitors and nucleoside reverse transcriptase inhibitors. Manifestations include "buffalo humps" or cervical (neck) fat development and large abdominal fat accumulations. Other body areas, such as the face, arms, and legs, have a wasted appearance and show prominent vein patterns or sunken facial cheeks from loss of subcutaneous fat, known as *lipoatrophy*.

Adrenal dysfunction can result from the glands being infected by opportunistic infections, resulting in adrenal insufficiency. This problem manifests as fatigue, weight loss, nausea, vomiting, low blood pressure, and electrolyte disturbances and can be life threatening.

Patients taking protease inhibitors have a higher-than-expected incidence of type 1 diabetes and hyperlipidemia. These problems are seen even among patients who have no other risks for these problems or the associated heart disease.

Other Clinical Manifestations.

All body systems are affected in AIDS. *AIDS dementia complex (ADC)*, also called *HIV-associated dementia complex*, refers to the manifestations of central nervous system involvement. ADC occurs in about 70% of people with AIDS and is a result of infection of cells within the central nervous system by HIV. ADC causes cognitive, motor, and behavioral impairments. Manifestations range from barely noticeable to severe dementia. (See Chapter 42 for more discussion on dementia.)

Some neurologic problems may be a result of HIV infection or drug side effects, including peripheral neuropathies and myopathies. Assess for manifestations of peripheral neuropathies, which include paresthesias and burning sensations, reduced sensory perception, pain, and gait changes. Myopathies are accompanied by leg weakness, ataxia, and muscle pain.

AIDS wasting syndrome is not due to any single factor. It may be a result of altered metabolism from cancer or infection. Diarrhea, malabsorption, anorexia, and oral and esophageal lesions can all contribute to persistent weight loss, and the patient may appear quite emaciated.

Skin changes include dry, itchy, irritated skin and many types of rashes. Folliculitis, eczema, or psoriasis may occur. Ask the patient about skin sensation changes, and examine any rash or irritation. When the platelet count is low, petechiae or bleeding gums may be present.

Kidney problems, including HIV-associated nephropathy (HIVAN) are common. These problems range from discrete glomerular injury to acute and chronic kidney diseases. Compared with the general population,

patients with HIV have a sixteenfold higher risk for requiring a renal replacement intervention.

Psychosocial Assessment.

Psychosocial data collection for a patient with AIDS is very important. Ask about the patient's social support system, including family, significant others, and friends. To protect confidentiality, learn who in this support system is aware of the diagnosis so that it is not inadvertently mentioned. Health care professionals must respect the patient's choices as much as possible without compromising care. Offer resources to help with disclosure to sexual partners or significant others.

The patient may be closest to a lover or a friend who is not legally recognized as next of kin. Obtain the name and telephone number of that person, and learn whether a health care proxy or durable power-of-attorney document has been signed.

Ask about the patient's ADLs and any changes that may have occurred since the diagnosis. Assess his or her employment status and occupation, immigration status, social activities and hobbies, living arrangements, and financial resources, including health insurance. Ask whether he or she uses drugs, including tobacco, alcohol, supplements, opioids, benzodiazepines, cocaine, crystal methamphetamine, or injection drugs.

To plan care and monitor changes, assess the patient's anxiety level, mood, cognitive ability, and energy level. Ask about any experiences with discrimination and how they were handled. After assessing the patient's level of self-esteem and changes in body image, work with him or her to identify strengths and coping strategies. Gather information about any suicidal ideation, depression, or other psychological problems. Also ask about the use of support groups or other community resources.

The patient with HIV disease has less energy as the disease progresses, and there are many causes. Pace interviews, assessments, and interventions to match his or her energy level. When the patient is greatly fatigued, postpone or eliminate nonurgent tests or care activities.

Laboratory Assessment

Lymphocyte Counts.

Lymphocyte counts are performed as part of a complete blood count (CBC) with differential (see Chapter 17). The normal white blood cell (WBC) count is between 5000 and 10,000 cells/mm^3, with a differential of about 30% to 40% lymphocytes (an absolute number of 1500 to 4500). Patients with AIDS are often leukopenic, with a WBC count of less than

3500 cells/mm^3, and lymphopenic (<1500 lymphocytes/mm^3).

CD4+ T-cell and CD8+ T-cell counts and percentages are part of an immune profile. People with HIV disease and AIDS usually have a lower-than-normal number of CD4+ T-cells, whereas the number of CD8+ T-cells remains normal. The normal ratio of CD4+ to CD8+ T-cells is 2 : 1. In HIV disease and AIDS, because of the low number of CD4+ T-cells, this ratio is low. Low CD4+ T-cell counts and a low ratio are associated with more disease manifestations.

Antibody Tests.

Antibody tests are used to measure the patient's response to the virus (the antigen) rather than to measure parts of the virus. When the body is infected with HIV, the body makes an antibody to the virus, usually within 3 weeks to 3 months after the infection first occurs. In some people, antibodies are not made until 36 months after initial infection.

HIV antibodies can be measured by enzyme-linked immunosorbent assay (ELISA) and Western blot analysis. False-negative results (incorrectly indicating the absence of HIV infection) have been reported early in the infection, in people with cancer, and in people receiving long-term immunosuppressive therapy.

ELISA is an inexpensive and accurate test. The patient's serum is mixed with HIV grown in culture. If the patient has antibodies to HIV, they bind to the HIV antigens and can be detected (a positive test). However, this test can be negative even when the person has HIV infection if the test is performed before antibodies are made in sufficient amounts. The time between when a person is first infected with the virus and when viral replication is occurring but the immune system has not yet started making antibodies is called the "window period." *So, if the patient has unprotected sex with an HIV-positive person one night and comes in for testing a week later, the ELISA will be negative even though the patient may have active HIV. Thus testing during the window does not provide useful information.*

False-positive test results (incorrectly indicating HIV infection) occur in about 0.1% (1 of 1000) of those tested with ELISA. False-positive results sometimes occur in pregnant women and women who have had children, injection drug users, people who have had malaria, patients with lymphomas, and other conditions. Therefore anyone who has a positive ELISA needs to have additional testing to confirm or rule out infection.

Western blot is used to confirm the diagnosis when the results of an ELISA are positive. This test is more sophisticated and expensive than

the ELISA. The Western blot detects serum antibodies to four specific major HIV antigens. A positive Western blot result is based on the presence of antibodies to at least two of the major HIV antigens.

The result is inconclusive if two of the major antibodies are not detected but other antibodies to HIV are. The person should then be retested. *If a person has a positive test result for HIV antibodies, it does not mean that he or she has HIV disease or AIDS—only that he or she has been infected with the virus.*

Both the ELISA and Western blot are blood-based tests. This requires special equipment and trained personnel to test for HIV infection. Some HIV testing is simpler, using techniques that are not blood-based so that testing can be done anywhere, even at home. One test involves oral testing for HIV antibody. This test uses a device that is placed against the gum and cheek for 2 minutes. Fluid (called *transmucosal exudate,* not saliva) is drawn into an absorbable pad, which, in an HIV-positive person, contains HIV-specific antibodies. The pad is placed in a solution; a positive result shows a change similar to a positive result in a urine pregnancy test. Total testing time is about 20 minutes. This test has the same accuracy as blood testing and can provide results quickly. If results are positive for HIV, a blood test is needed to confirm the result.

Home test kits require that a drop of blood be placed on a test card with a special code number. The card is mailed to a laboratory where the blood is tested for HIV antibodies. A special telephone number is called and the code entered. Test results are then given.

A newly approved HIV home test kit is the OraQuick In-Home HIV Test. This test uses oral transmucosal exudate and results are ready in 20 to 40 minutes. The manufacturer recommends that the test be performed at least 3 months after a risk event has occurred. A positive result indicates the need for additional testing. The manufacturer provides a 24-hour telephone support service for correct use of the product and general counseling.

Viral Load Testing.

Viral load testing (also called *viral burden testing*) measures the presence of HIV viral genetic material (RNA) or other viral proteins in the patient's blood rather than the body's response to the virus. These tests are quantitative and indicate the level of viral burden or viral load, which is useful to monitor disease progression and treatment effectiveness.

Quantitative RNA assays quantify viral load. These assays are the reverse transcriptase-polymerase chain reaction (RT-PCR), the branched DNA (bDNA) method, and the nucleic acid sequence–based assay

(NASBA). All three assays use gene amplification to determine the amount of HIV RNA present in a patient's serum, and all have a specificity of 100%. Even if only a few infected cells are present in a serum sample, tiny amounts of the HIV RNA are amplified to allow detection and diagnosis of people who have no indication of infection. These tests are used to monitor therapy effectiveness and the need to change drug regimens.

Other Laboratory Assessment.

Other laboratory tests monitor the patient's overall health and detect or diagnose any infections or other problems related to HIV disease. These tests include blood chemistries, a CBC with differential and platelets, toxoplasmosis antibody titer, liver function tests, a serologic test for syphilis (STS), antigens and antibodies to hepatitis viruses A, B, and C, lipid profile, QuantiFERON TB testing or PPD, and cervical and anal Pap testing. Other tests to evaluate the immune profile may include bone marrow aspiration with biopsy and cultures. Other tests may be performed to monitor toxicities from antiretroviral drugs.

Genetic/Genomic Considerations

Patient-Centered Care QSEN

The HIV genotype test is used to determine whether any mutations exist in the strain of HIV that has infected the patient. This test is useful before starting antiretroviral therapy to learn whether the patient is infected with a resistant strain of HIV. The test helps the clinician choose which antiretroviral drugs are most likely to be effective against viral replication. It is also useful in patients who demonstrate initial success in antiretroviral therapy and then have rapid disease progression. The human leukocyte antigen (HLA) *B5701* allele test is a genetic test to determine how a person will respond to a drug. Patients with a variant of this gene allele have a hypersensitivity reaction to abacavir (Ziagen) that ranges from mild fever, rash, nausea, and vomiting to fatal anaphylaxis. Abacavir should not be used without first testing for *B5701*, and if positive, abacavir is never used either as an individual drug or in combined drug preparations.

Other Diagnostic Assessment.

Other diagnostic tests are performed on the basis of the patient's manifestations. These may include testing stool for ova and parasites;

biopsies of the skin, lymph nodes, lungs, liver, GI tract, or brain; a chest x-ray; gallium scans; bronchoscopy, endoscopy, or colonoscopy; liver and spleen scans; CT scans; pulmonary function tests; and arterial blood gas (ABG) analysis.

◆ Analysis

The priority NANDA-I nursing diagnoses and collaborative problems for patients with AIDS include:
1. Risk for Infection related to immune deficiency (NANDA-I)
2. Inadequate oxygenation related to anemia, respiratory infection (*P. jiroveci* pneumonia [PCP], cytomegalovirus [CMV] pneumonitis), pulmonary Kaposi's sarcoma (KS), or anemia
3. Chronic Pain related to neuropathy, myelopathy, cancer, or infection (NANDA-I)
4. Imbalanced Nutrition: Less Than Body Requirements related to high metabolic need, nausea and vomiting, diarrhea, difficulty chewing or swallowing, or anorexia (NANDA-I)
5. Diarrhea related to infection, food intolerance, or drugs (NANDA-I)
6. Impaired Skin Integrity related to KS, infection, altered nutritional state, incontinence, immobility, hyperthermia, or cancer (NANDA-I)
7. Confusion (Acute and Chronic) related to AIDS dementia complex (ADC), central nervous system infection, or cancer (NANDA-I)
8. Reduced self-esteem related to changes in body image, role, or independence

◆ Planning and Implementation

Preventing Infection.

The patient with AIDS is susceptible to opportunistic other infections because of immune deficiency. Initial management focuses on supporting the patient's immunity by controlling the HIV infection with antiretroviral therapy. When the patient's immunity declines, management includes both prophylaxis and treatment of opportunistic infections.

Planning: Expected Outcomes.

The patient is expected to remain free of opportunistic diseases and other infection. Indicators include:
- Absence of chills, fever, or temperature instability
- Absence of purulent drainage or sputum
- Absence of diarrhea

- Absence of chest x-ray infiltration
- Maintenance of white blood cell (WBC) count within the patient's normal range

Interventions.

The person who has HIV infection and is immunosuppressed is at greater risk for any type of infection. Teach him or her to avoid exposure to infection (Chart 19-4). Chart 19-5 outlines best practices for prevention of infection in a hospitalized patient with decreased immune function.

Chart 19-4 Patient and Family Education: Preparing for Self-Management

Prevention of Infection

During the times when your white blood cell counts are low:

- Avoid crowds and other large gatherings of people who might be ill.
- Do not share personal toilet articles, such as toothbrushes, toothpaste, washcloths, or deodorant sticks, with others.
- If possible, bathe daily, using an antimicrobial soap. If total bathing is not possible, wash the armpits, groin, genitals, and anal area twice a day with an antimicrobial soap.
- Clean your toothbrush at least weekly by either running it through the dishwasher or rinsing it in liquid laundry bleach (and then rinsing out the bleach with hot running water).
- Wash your hands thoroughly with an antimicrobial soap before you eat or drink, after touching a pet, after shaking hands with anyone, as soon as you come home from any outing, and after using the toilet.
- Avoid eating salads; raw fruits and vegetables; undercooked meat, fish, and eggs; and pepper and paprika.
- Wash dishes between use with hot, sudsy water, or use a dishwasher.
- Do not drink water, milk, juice, or other cold liquids that have been standing for longer than an hour.
- Do not reuse cups and glasses without washing.
- Do not change pet litter boxes. If unavoidable, use gloves and wash hands immediately.
- Avoid turtles and reptiles as pets.
- Do not feed pets raw or undercooked meat.
- Take your temperature at least once a day and whenever you do not feel well.
- Report any of these manifestations of infection to your physician

immediately:
  - Temperature greater than 100° F (37.8° C)
  - Persistent cough (with or without sputum)
  - Pus or foul-smelling drainage from any open skin area or normal body opening
  - Presence of a boil or abscess
  - Urine that is cloudy or foul smelling or that causes burning on urination
- Take all prescribed drugs.
- Do not dig in the garden or work with houseplants.
- Wear a condom (if you are a man) when having sex. If you are a woman having sex with a male partner, ensure that he wears a condom or use a female vaginal polyurethane condom.
- Avoid travel to areas of the world with poor sanitation or less-than-adequate health care facilities.

Chart 19-5 Best Practice for Patient Safety & Quality Care QSEN

Care of the Hospitalized Immunosuppressed Patient

- Place the patient in a private room whenever possible.
- Use good handwashing technique or use alcohol-based hand rubs before touching the patient or any of his or her belongings.
- Ensure that the patient's room and bathroom are cleaned at least once each day.
- Do not use supplies from common areas for neutropenic patients. For example, keep a dedicated box of disposable gloves in his or her room and do not share this box with any other patient. Provide single-use food products, individually wrapped gauze, and other individually wrapped items.
- Limit the number of health care personnel entering the patient's room.
- Monitor vital signs, including temperature, every 4 hours.
- Inspect the patient's mouth at least every 8 hours.
- Inspect the patient's skin and mucous membranes (especially the anal area) for the presence of fissures and abscesses at least every 8 hours.
- Inspect open areas, such as IV sites, every 4 hours for manifestations of infection.
- Change gauze-containing wound dressings daily.
- Obtain specimens of all suspicious areas for culture (as specified by the agency), and promptly notify the physician.

- Assist the patient in performing coughing and deep-breathing exercises.
- Encourage activity at a level appropriate for the patient's current health status.
- Keep frequently used equipment in the room for use with this patient only (e.g., blood pressure cuff, stethoscope, thermometer).
- Limit visitors to healthy adults.
- Use strict aseptic technique for all invasive procedures.
- Avoid the use of indwelling urinary catheters.
- Keep fresh flowers and potted plants out of the patient's room.
- Teach the patient to eat a low-bacteria diet (e.g., avoiding raw fruits and vegetables; undercooked meat, eggs, and fish; pepper and paprika as seasonings sprinkled on food right before eating).

Drug Therapy.

All currently licensed antiretroviral drugs have excellent activity against HIV; however, *it is important to remember that antiretroviral therapy only inhibits viral replication and does not kill the virus.* Treatment with only one antiretroviral agent (i.e., *monotherapy*) promotes drug resistance and does not improve the patient's life span. Instead, multiple drugs are used together in combinations from different classes of antiretroviral agents. This approach is termed *highly active antiretroviral therapy (HAART)* and has reduced viral load, improved CD4+ T-cell counts, and slowed disease progression. As a general rule, patients are told they must take the drugs correctly 90% of the time, making sure that out of 10 doses, 9 are taken on time and correctly. This is a tall order when considering that this drug therapy is for the rest of one's life.

An important issue with HAART is the development of drug-resistant mutations in the HIV organism. When resistance develops, viral replication is no longer suppressed by the drugs. Testing is now possible to determine whether a strain of HIV has developed resistance to specific drugs (see the Genetic/Genomic Considerations box on p. 337). Several factors contribute to the development of drug resistance to HAART, with the most important being missed doses of drugs. When doses are missed, the blood drug concentrations become lower than what are needed for inhibition of viral replication (often called the *minimum inhibitory concentration*). When this concentration is too low, the HIV can replicate and produce new viral particles that are resistant to the drugs being used.

An important understanding about HIV resistance to one or more drugs is that once a patient has HIV with resistant mutations, the

resistant virus is stored in the body indefinitely, a process known as *archiving*. The drugs to which the virus is resistant are no longer used for that patient. Even years later, if the drug to which the HIV demonstrated resistance is tried again, the viruses with the resistant mutation come out of archival storage to defeat the drug.

Nursing Safety Priority QSEN

Drug Alert

Ensure that HAART drugs are not missed, delayed, or administered in lower-than-prescribed doses in the inpatient setting. Teach patients the importance of taking their drugs exactly as prescribed to maintain the effectiveness of HAART drugs. Even a few missed doses per month can promote drug resistance (remember the 90% rule).

The main actions of each drug category and representative drugs in each category are presented in Chart 19-6. These categories are nucleoside reverse transcriptase inhibitors (NRTIs), non-nucleoside reverse transcriptase inhibitors (NNRTIs), protease inhibitors (PIs), integrase inhibitors, fusion inhibitors, and entry inhibitors. Drawbacks to HAART include the expense of the drugs, food and timing requirements, and the number of daily drugs. Newer combination drug formulations have reduced the number of tablets and capsules that need to be taken daily; however, the daily regimen is lifelong and burdensome.

Chart 19-6 Common Examples of Drug Therapy

HIV Infection

DRUG CATEGORY	MECHANISM OF ACTION	REPRESENTATIVE DRUGS
Nucleoside Reverse Transcriptase Inhibitors (NRTIs)	Drugs have a similar structure to the four nucleoside bases of DNA, making them "counterfeit" bases. Fools the HIV enzyme *reverse transcriptase* into using these counterfeit bases so that viral DNA synthesis and replication are suppressed.	Abacavir (Ziagen)
		Didanosine (Videx EC)
		Emtricitabine (Emtriva)
		Lamivudine (Epivir)
		Stavudine (Zerit)
		Tenofovir (Viread)
		Zidovudine (Retrovir)
Non-Nucleoside Reverse Transcriptase Inhibitors (NNRTIs)	Drugs bind directly to the HIV-1 enzyme *reverse transcriptase*, preventing viral cell DNA replication, RNA replication, and protein synthesis. This action suppresses viral replication of the HIV-1 virus but does not affect HIV-2 viral replication.	Delavirdine (Rescriptor)
		Efavirenz (Sustiva)
		Etravirine (INTELENCE)
		Nevirapine (Viramune, Viramune XR)
		Rilpivirine (EDURANT)
Protease Inhibitors (PIs)	Drugs competitively block the HIV protease enzyme, preventing viral replication and release of viral particles. The HIV initially produces all of its proteins in one long strand, which must be broken down into separate smaller proteins by HIV protease to be active. Thus, when inhibited, viral proteins are not functional and viral particles cannot leave the cell to infect other cells.	Atazanavir (Reyataz)
		Darunavir (Prezista)
		Fosamprenavir (Lexiva)
		Indinavir (Crixivan)
		Lopinavir/ritonavir (Kaletra)
		Nelfinavir (Viracept)
		Saquinavir (Invirase)
		Tipranavir (Aptivus)
Integrase Inhibitors	Drugs inhibit the HIV enzyme *integrase*, which the virus uses to insert the viral DNA into the host cell's human DNA. Without this action, viral proteins are not made and viral replication is inhibited.	Dolutegravir (TIVICAY)
		Elvitegravir (EVG)
		Raltegravir (Isentress)
Fusion Inhibitors	Drugs block the fusion of HIV with a host cell by blocking the ability of *gp41* to fuse with the host cell's CD4 receptor. Without fusion, infection of new cells does not occur.	Enfuvirtide (Fuzeon)
Entry Inhibitors/*CCR5* Antagonists	Drug works to prevent infection by blocking the *CCR5* receptor on CD4+ T-cells. (The virus's *gp120* must bind to the CD4 receptor and its *gp41* must bind to the *CCR5* receptor or to the *CXCR4* receptor for entry into host cells. This class of drug prevents cellular infection with HIV.	Maraviroc (Selzentry)
Combination Products	Each ingredient has the same mechanism of action as the parent drug class.	Atripla (emtricitabine, tenofovir, & efavirenz)Combivir (lamivudine & zidovudine)
		Complera (emtricitabine, rilpivirine, & tenofovir)
		Epzicom (lamivudine & abacavir)
		Stribild (elvitegravir, cobicistat, emtricitabine, & tenofovir)
		Truvada (emtricitabine & tenofovir)
		Trizivir (lamivudine, zidovudine, & abacavir)

Most antiretroviral drugs have significant side effects and many possible drug interactions. Be sure to consult a drug reference book for usual dosages, side effects, and nursing interventions.

An interesting complication of effective HAART in some patients whose CD4+ T-cell counts rise and immune responses return to normal is the development of immune reconstitution inflammatory syndrome (IRIS) (Carr & Traufler, 2011). As the drugs begin to suppress HIV replication and the T-cells slowly begin to rebound, the T4-cells "recognize" several opportunistic infections (e.g., tuberculosis,

cryptococcosis, *Mycobacterium avium* complex, pneumocystis pneumonia, cytomegalovirus, hepatitis, and others) that were present before but not recognized because of severe immunosuppression. With the T-cells now in sufficient numbers and active, they begin to sound the alarm about the presence of these opportunistic infections. The T4-cells generate an inflammatory reaction, high fever, chills and, depending on which opportunistic infection the immune system is reacting against, worsening disease. For example, IRIS is common with those co-infected with HIV and TB. TB manifestations initially become much worse after starting HAART. Because some of these manifestations are similar to those of drug therapy side effects and other problems, IRIS may go undiagnosed and untreated, increasing the risk for death. When IRIS is recognized, short-term therapy with corticosteroids can reduce the inflammatory responses.

Clinical Judgment Challenge

Safety; Evidence-Based Practice; Patient-Centered Care QSEN

J.L. and C.R. are two men in a 2-year monogamous relationship, who were recently married in Washington state. J.L. has been HIV-positive for 4 years. C.R. is HIV-negative and in good health. J.L. is currently an inpatient for an elective cholecystectomy this afternoon. His HIV infection is well controlled on a three-drug cocktail, which he is tolerating well. During the assessment, you ask J.L. how they keep C.R. HIV-negative. A sheepish grin follows. J.L. is generally the insertive (active) partner and C.R. and J.L. have mutually agreed to not use condoms for either oral or rectal sex, as that affects the quality of their sexual pleasure. They continue to make sure that J.L.'s viral load is kept undetectable and he always "pulls out" prior to ejaculation.

1. How safe are their sexual practices for C.R. if he chooses to remain HIV-negative?
2. What should you tell them about condom use?
3. Is C.R. an appropriate candidate for pre-exposure prophylaxis (Pr-EP)?
4. After checking out the information about Pr-EP, what can you tell them about the pros and cons of this therapy?

Immune Enhancement.

Research is being conducted to evaluate treatments that may enhance or replenish the immune system of patients with AIDS. Some of these methods include bone marrow transplantation, lymphocyte transfusion,

and infusions of lymphokines, white blood cell colony-stimulating factors, and red blood cell growth factors.

Complementary and Alternative Therapies.

Complementary therapies are often used by people with HIV/AIDS. Such therapies include vitamins, shark cartilage, and botanical products available at health food stores. The usefulness of these products has yet to be established through well-controlled clinical trials. In addition, some botanicals alter the effects of prescription drugs. Ask the patient which botanicals or homeopathic agents he or she is using, and check with the pharmacist to determine known drug interactions with HAART therapy.

NCLEX Examination Challenge

Safe and Effective Care Environment

What is the most important question the nurse asks the client prescribed to begin highly active antiretroviral therapy?
A Do you have any symptoms now of active infection?
B Is there any possibility that you are pregnant?
C Are you currently sexually active?
D What other medications do you take?

Enhancing Oxygenation

Planning: Expected Outcomes.

The patient is expected to maintain adequate gas exchange with oxygenation and perfusion and to have minimal dyspnea. Indicators include:

- Rate and depth of respiration within the normal range
- Pulse oximetry within the normal range
- Absence of cyanosis or pallor and abnormal breath sounds

Interventions.

The nurse or respiratory therapist uses drug therapy, respiratory support and maintenance, comfort, and rest to enhance oxygenation.

Drug therapy is a mainstay for gas exchange problems resulting from infection. Drug therapy is started after an infectious cause for respiratory difficulty is identified. A common respiratory infection among people with HIV disease is *P. jiroveci* pneumonia (PCP). The treatment of choice for PCP is trimethoprim with sulfamethoxazole (Apo-Sulfatrim ,

Bactrim, Cotrim, Septra). Many patients have adverse reactions to this drug, including nausea, vomiting, hyponatremia, rashes, fever, leukopenia, thrombocytopenia, and hepatitis.

Pentamidine isethionate (Pentacarinat, Pentam), usually given IV or IM, is also used to treat PCP. Aerosolized pentamidine isethionate is used as prophylaxis for patients with CD4+ T-cell counts below 200 (or 14%), as well as for those who have already had PCP.

Other drug therapies include bronchodilators to improve airflow, as well as dapsone (Avlosulfon) and atovaquone (Mepron), which can be used as alternative therapies to trimethoprim-sulfamethoxazole for existing PCP or as prophylaxis. For moderate to severe PCP, steroids may be used to reduce the inflammation.

Respiratory support and maintenance help maintain respiratory function and avoid complications. Assess the respiratory rate, rhythm, and depth, breath sounds, and vital signs and monitor for cyanosis at least every 8 hours. Apply oxygen and humidify the room as prescribed. Also monitor mechanical ventilation, perform suctioning and chest physical therapy as needed, and evaluate blood gas results.

Comfort can help improve gas exchange. Assess the patient's comfort. The patient with difficulty breathing is often more comfortable with the head of the bed elevated. Pace activities to reduce shortness of breath and fatigue.

Rest and activity changes are needed when gas exchange is impaired. Most patients with HIV/AIDS have fatigue, especially when respiratory problems also are present. Some treatments worsen fatigue. Consult with the patient to pace activities to conserve energy. Guide the patient in active and passive range-of-motion (ROM) exercises. Schedule non–time-critical activities, such as bathing, so that he or she is not fatigued at mealtime.

Managing Pain.

The patient with severe HIV disease or AIDS often has pain from many causes. Pain can result from enlarged organs stretching the viscera or compressing nerves. Tumor invasion of bone and other tissues can cause pain, as can compression of nerves from swollen lymph nodes. Many patients with AIDS have peripheral neuropathy–induced pain from the disease or drug therapies (Anastasi et al., 2013). Many have generalized joint and muscle pain.

Planning: Expected Outcomes.

The patient is expected to achieve an acceptable level of comfort and pain

reduction. Indicators include:

- Reporting that pain is controlled to a level that is acceptable to him or her
- Absence of indicators of acute pain (increased heart rate and blood pressure)
- Absence of facial grimacing, teeth clenching
- Willingness to move and participate in self-care

Interventions.

Drug therapy and other approaches are used together to manage pain in the patient with HIV/AIDS, depending on the cause of the pain.

Comfort measures include the use of pressure-relieving mattress pads, warm baths or other forms of hydrotherapy, massage, and applying heat or cold to painful areas to reduce pain levels, with or without drug therapy. Take care when moving or assisting the patient. Use lift sheets to avoid pulling or grasping the patient with joint pain. The patient may be thin and have poor circulation, contributing to pain and discomfort. Help him or her change positions often.

Drug therapy with different drug classes is used to manage different types of pain. For arthralgia and myalgia, NSAIDs may reduce inflammation and increase comfort. Pregabalin (Lyrica) may provide some relief from muscle and joint pain. Neuropathic pain may respond to tricyclic antidepressants such as amitriptyline (Elavil) or to anticonvulsant drugs such as gabapentin (Neurontin), phenytoin (Dilantin), or carbamazepine (Tegretol), although these drugs often interact with antiretroviral drugs. These drugs may take days to weeks before a full effect is seen. During this time, opioids may be needed to control pain.

When opioids are used, assess the patient for pain intensity and quality. Mild to moderate pain is treated with weaker opioids such as hydrocodone, tramadol, or codeine. More intense pain is treated with stronger opioids such as oxycodone, morphine, hydromorphone (Dilaudid), or fentanyl transdermal (Duragesic). Combinations of weak and strong opioids along with non-opioid drugs may be used to provide the best sustained pain relief and allow the patient to participate in activities to the extent that he or she wishes.

Complementary and alternative therapies are used by many patients with pain from HIV/AIDS. These include acupuncture, massage, guided imagery, distraction, progressive relaxation, body-talk, and biofeedback and can be used with traditional and pharmacologic measures to improve comfort.

Enhancing Nutrition.

Many patients with AIDS have difficulty maintaining their weight and nutrition status. This problem may be caused by fatigue, anorexia, nausea and vomiting, difficult or painful swallowing, diarrhea, intestinal malabsorption, or wasting syndrome.

Planning: Expected Outcomes.

The patient is expected to maintain optimal weight through adequate nutrition and hydration. Indicators include:

- Selecting foods high in calories and protein
- Maintaining current weight or gaining weight
- Drinking at least 2 to 3 L of fluids per day
- Maintaining normal blood levels of ferritin, albumin, prealbumin, and hemoglobin

Interventions.

Because there are many factors for poor nutrition in AIDS, diagnostic procedures are needed to determine the cause. Once the cause is determined, appropriate therapy is initiated. For example, in candidal esophagitis, nutrition is affected by swallowing difficulties.

Drug therapy can include ketoconazole (Nizoral) or fluconazole (Diflucan) orally, or IV amphotericin B (Fungizone). Administer the drug as prescribed, and monitor for side effects such as nausea and vomiting, which also affect nutrition. Provide mouth care and ice chips, and keep unpleasant odors out of the patient's environment. Antiemetics are used as needed.

Nutrition therapy includes monitoring weight, intake and output, and calorie count. Assess food preferences and dietary cultural or religious practices. Teach the patient about the need for a high-calorie and high-protein diet. Encourage him or her to avoid dietary fat, because fat intolerance often occurs as a result of the disease and as a side effect of some antiretroviral drugs. Collaborate with the registered dietitian to provide an appropriate diet, including small, frequent meals (better tolerated than large meals). Supplemental vitamins and fluids are indicated in some cases. For the patient who cannot achieve adequate nutrition through food, tube feedings or total parenteral nutrition may be needed.

Mouth care can improve appetite. When this nursing action is delegated to unlicensed assistive personnel (UAP), instruct them to offer the patient rinses of sodium bicarbonate with sterile water or normal

saline several times a day. Explain to UAP why the patient should use a soft toothbrush and the need to drink plenty of fluids. For oral pain, general analgesics or oral anesthetic gels and solutions may be needed. Avoid the use of alcohol-based mouthwashes.

Complementary and alternative therapies to promote healing of mouth sores can help improve food intake. Some patients have found relief from oral thrush with the use of lemon juice and lemongrass infusions.

Minimizing Diarrhea.

Patients with AIDS often suffer from diarrhea. Sometimes an infectious cause (e.g., *Giardia, Cryptosporidium,* or amoeba) can be determined and treated, or the cause is determined but no effective therapy is available. Many patients are lactose intolerant, and HIV disease worsens the condition. Diarrhea may occur as a side effect of drug therapy. In some cases, no cause can be identified.

Planning: Expected Outcomes.

The patient is expected to have decreased diarrhea; to maintain fluid, electrolyte, and nutrition status; and to reduce incontinence. Indicators include:

- Has a stool amount and character that are appropriate for the diet
- Recognizes urge to defecate
- Maintains control of stool passage

Interventions.

For most patients with AIDS and diarrhea, symptom management is all that is available. Antidiarrheals, such as diphenoxylate hydrochloride (Diarsed, Lomotil) or loperamide (Imodium), given on a regular schedule, provide some relief. Consult with the dietitian, and teach about appropriate foods. Recommended dietary changes include less roughage; less fatty, spicy, and sweet food; and no alcohol or caffeine. Some patients obtain relief when they eliminate dairy products or eat smaller amounts of food more often and drink plenty of fluids, especially between meals.

Assess the perineal skin every 8 to 12 hours for a change in skin tissue integrity. Provide the patient with a bedside commode or a bedpan if needed because some patients cannot reach the bathroom in time. Teach UAP performing this care to provide the patient with privacy, support, and understanding. Explain the need to keep the patient's perineal area clean and dry. Instruct UAP to report any skin changes in the perineal area, including persistent redness, rashes, blisters, or open areas. Collaborate with a wound care specialist for more interventions to

manage anal excoriation and discomfort.

NCLEX Examination Challenge

Health Promotion and Maintenance

Which dietary change does the nurse suggest for the client who has diarrhea associated with HIV disease?
A "Avoid fatty foods."
B "Increase your intake of fiber."
C "Take an antacid 30 minutes before each meal."
D "Restrict your intake of fluids to 1 liter per day."

Restoring Skin Integrity.

Impaired Tissue integrity in AIDS may be related to Kaposi's sarcoma (KS) of the skin, mucous membranes, and internal organs. Lesions may be localized or widespread. Large lesions can cause pain, restrict movement, and impede circulation, causing open, weeping, painful lesions. Another cause of impaired tissue integrity may be skin infection with herpes simplex virus (HSV) or varicella zoster virus (VZV) (shingles).

Planning: Expected Outcomes.

The patient is expected to have healing of any existing lesions and avoid increased skin breakdown or secondary infection. Indicators include:
- Absence of new lesions or open skin areas
- Existing lesions become smaller in diameter
- Absence of pus, induration, or redness in, from, or around skin lesions

Interventions.

Often, KS responds well to effective antiretroviral drug therapy. With time and HAART, many lesions disappear and do not reappear as long as the patient remains on HAART. For lesions that do not respond to HAART, KS can be treated with local radiation, intralesional or systemic chemotherapy, cryotherapy, or topical retinoids. Systemic therapy with chemotherapy or interferon is used in patients with rapidly progressive disease or with major involvement of the intestinal tract, lungs, or other organs.

Treatment of painful KS lesions includes analgesics and comfort measures. Keep open, weeping KS lesions clean and dressed to prevent infection. Many patients with KS are concerned about their appearance and the risk for being identified as HIV positive. Makeup (if lesions are

closed), long-sleeved shirts, and hats may help maintain a normal appearance.

For the patient with a herpes simplex virus (HSV) outbreak, provide good skin care directly or delegate this care to UAP. Stress the importance of keeping the area clean and dry. Teach UAP to clean abscesses at least once per shift with normal saline and allow them to air-dry. This infection is painful and requires analgesics, assistance with position, and other comfort measures. Modified Burow's solution (Domeboro) soaks promote healing for some patients. HSV infection is treated with acyclovir (Zovirax) or valacyclovir (Valtrex).

Minimizing Confusion.

Neurologic changes and confusion are major areas of concern for patients with HIV disease or AIDS. These changes may be due to psychological stressors accompanying the disease or to organic disorders caused by opportunistic infections, cancer, or HIV encephalitis.

Planning: Expected Outcomes.

The patient is expected to show improved mental status. Indicators include that the patient demonstrates these behaviors:

- Identifies self and significant others
- Identifies correct month and year
- Recalls immediate, recent, and remote information accurately

Interventions.

Patients with AIDS suffer from enormous loss and psychological stress, which complicates the assessment of changes in behavior or affect. Assess baseline neurologic and mental status by using neurologic assessment tools (see Chapter 41) to compare any changes. Evaluate the patient for subtle changes in memory, ability to concentrate, affect, and behavior. It is important to determine whether the cause of the neurologic changes is treatable.

Reorient the confused patient to person, time, and place as needed. Coordinate with all members of the health care team to ensure that reorientation methods are performed by everyone who interacts with the patient. Remind the patient of your identity and explain what is to be done at any given time. Give simple directions; use short, uncomplicated sentences; explain activities in simple language; and involve him or her in daily planning. Ask significant others to bring in familiar items from home. When possible, arrange all items in the patient's environment in the same location as at home. Calendars, clocks, radios, and putting the

bed close to a window may help keep the patient oriented.

Drug therapy is used for different conditions that can cause confusion in the person with AIDS. Psychotropic drugs are used to manage ongoing behavioral problems or emotional disorders. Antidepressants and anxiolytics may be prescribed.

Safety measures are crucial to the well-being of the confused patient. He or she may not be aware of activities or surroundings and may need help with bathing, dressing, eating, ambulating, and other ADLs. Make the environment, whether a hospital room or long-term care facility, safe and comfortable.

Some patients with AIDS have seizures. Institute seizure precautions, including keeping siderails in the up position and having oxygen and suctioning equipment available. Anticonvulsants may be added to the drug therapy.

Assess the patient with neurologic manifestations for increased intracranial pressure (ICP). If not recognized and managed early, ICP can lead to permanent brain damage and death. Increased ICP in patients with HIV disease is most commonly managed with corticosteroids.

Nursing Safety Priority QSEN

Critical Rescue

Document and report immediately any changes in level of consciousness (one of the earliest signs of increased ICP), vital signs, pupil size or reactivity, or limb strength to the health care provider for appropriate intervention.

Support the family and friends of the patient who has neurologic impairment. There is great trauma in seeing a loved one unable to care for himself or herself or showing childlike behavior. Answer questions honestly and sensitively. Teach UAP, the family, and significant others how to reorient the patient. Encourage them to continue to provide the patient with news of family happenings or current events. Coordinate with the social worker to identify community resources for the patient and family.

Supporting Self-Esteem.

The patient with AIDS may have changes in self-esteem resulting from dramatic changes in appearance. Many patients also have significant changes in their relationships and in day-to-day activities, including a

job. All changes can reduce self-esteem.

Planning: Expected Outcomes.

The patient is expected to identify his or her positive aspects and accept himself or herself. Indicators include that he or she often or consistently demonstrates these behaviors:

- Maintains eye contact
- Accepts compliments from others
- Expresses feelings of self-worth

Interventions.

Provide a climate of acceptance for patients with AIDS by promoting a trusting relationship. Help them express feelings, and identify positive aspects of themselves. Allow for privacy, but do not avoid or isolate the patient. Encourage self-care, independence, control, and decision making by helping him or her set short-term, attainable goals and offering praise when goals are achieved.

Guided imagery is used by many patients to increase their sense of control and enhance self-esteem. Imagery can focus on helping them cope with distressing side effects or painful procedures. Some patients picture battle scenes in which HIV is killed by immune system cells.

Community-Based Care

HIV disease is manageable and chronic (Starr & Bradley-Springer, 2014). The usual course of illness is one of intermittent acute infections and periods of relative wellness over years. This period is often followed by chronic, progressive debilitation. Because of the cyclic nature of HIV disease and AIDS, the patient often spends long periods at home between hospital admissions. In some instances, especially as the illness becomes more severe, he or she may need referral to a long-term care facility, home care agency, or hospice. In collaboration with the social worker, dietitian, and others, work with patients to plan what will be needed and how they will manage at home with self-care and ADLs.

Home Care Management.

Before the patient is discharged to home, assess his or her status, ability to perform self-care activities, and plans to maintain communication with primary care providers. Home care can range from help with ADLs for those with weakness, debility, or limited function to around-the-clock nursing care, drugs, and nutrition support for severely or terminally ill patients. Assess available resources, including family members and

significant others willing and able to be caregivers. Help the family make arrangements for outside caregivers or respite care, if needed. Patients may need referrals or help in planning housing, finances, insurance, legal services, and spiritual counseling. Coordinate with the case manager to ensure these issues are addressed.

Usually a home care nurse makes an initial visit to the patient with AIDS for assessment purposes, and care is followed up by home care aides. If the patient becomes more debilitated, a nurse re-assesses his or her status. Chart 19-7 lists focused assessment areas for the patient with AIDS at home.

Chart 19-7 Focused Assessment

The Person with AIDS

Assess cardiovascular and respiratory status:
- Vital signs
- Presence of acute chest pain or dyspnea
- Presence of cough
- Presence of fever
- Activity tolerance

Assess nutritional status:
- Food intake
- Weight loss or gain
- General condition of skin
- Financial resources

Assess neurologic status:
- Cognitive changes
- Motor changes
- Sensory disturbances

Assess gastrointestinal status:
- Mouth and oropharynx
- Presence of dysphagia
- Presence of abdominal pain
- Presence of nausea, vomiting, diarrhea, constipation

Assess psychological status:
- Presence of anxiety
- Presence of depression

Assess activity and rest:
- Activities of daily living (ADLs)
- Mobility and ambulation

- Fatigue
- Sleep pattern
- Presence of pain

Assess home environment:

- Safety hazards
- Structural barriers affecting functional ability

Assess patient's and caregiver's adherence and understanding of illness and treatment, including:

- Manifestations to report to nurse
- Medication schedule and side or toxic effects

Assess patient's and caregiver's coping skills.

Self-Management Education.

Teaching the patient, family, and friends is a high priority when preparing for discharge. Instruct about modes of transmission and preventive behaviors (e.g., guidelines for safer sex; not sharing toothbrushes, razors, and other potentially blood-contaminated articles). Caregivers also need instruction about best practices for Infection Control Precautions to prevent transmission while caring for the patient in the home (Chart 19-8), nursing techniques to use in the home, and coping or support strategies.

Chart 19-8 Best Practice for Patient Safety & Quality Care QSEN

Infection Control for Home Care of the Person with AIDS

Direct Care

- Follow Standard Precautions and good handwashing techniques.
- Do not share razors or toothbrushes.

Housekeeping

- Wipe up feces, vomitus, sputum, urine, or blood or other body fluids and the area with soap and water. Dispose of solid wastes and solutions used for cleaning by flushing them down the toilet. Disinfect the area by wiping with a 1 : 10 solution of household bleach (1 part bleach to 10 parts water). Wear gloves during cleaning.
- Soak rags, mops, and sponges used for cleaning in a 1 : 10 bleach solution for 5 minutes to disinfect them.
- Wash dishes and eating utensils in hot water and dishwashing soap or detergent.

- Clean bathroom surfaces with regular household cleaners, and then disinfect them with a 1 : 10 solution of household bleach.

Laundry

- Rinse clothes, towels, and bedclothes if they become soiled with feces, vomitus, sputum, urine, or blood. Then dispose of the soiled water by flushing it down the toilet. Launder these clothes with hot water and detergent with 1 cup of bleach added per load of laundry.
- Keep soiled clothes in a plastic bag.

Waste Disposal

- Dispose of needles and other "sharps" in a labeled puncture-proof container such as a coffee can with a lid or empty liquid bleach bottle, using Standard Precautions, to avoid needle stick injuries. Decontaminate full containers by adding a 1 : 10 bleach solution. Then seal the container with tape and place it in a paper bag. Dispose of the container in the regular trash.
- Remove solid waste from contaminated trash (e.g., paper towels or tissues, dressings, disposable incontinence pads, disposable gloves); then flush the solid waste down the toilet. Place the contaminated trash items in tied plastic bags, and dispose of them in the regular trash.

Teach the patient, family, and friends how to protect the patient from infection, how to identify the presence of infections, and what to do if these appear. Teach about the use of self-care strategies, such as good hygiene, balanced rest and exercise, skin care, mouth care, and safe administration and potential side effects of all prescribed drugs. During diet teaching, stress good nutrition; the need to avoid raw or rare fish, fowl, or meat; thorough washing of fruits and vegetables; and proper food refrigeration.

Teach the patient to avoid large crowds, especially in enclosed areas, not to travel to countries with poor sanitation, and to avoid cleaning pet litter boxes. Chart 19-4 lists more strategies to teach the patient and family how to avoid infection.

Psychosocial Preparation.

Patients with AIDS often fear social stigma and rejection. Be aware that this fear is realistic, and help identify ways to avoid problems, as well as identify coping strategies for difficult situations. Support family members and friends in efforts to help the patient and provide

protection from discrimination.

Encourage patients to continue as many usual activities as possible. Except when too ill or too weak, they can continue to work and participate in most social activities. Support them in their selection of friends and relatives with whom to discuss the diagnosis. Stress that sexual partners and care providers should be informed; beyond that, it is up to the patient. Some patients have depression or anxiety about the future. Almost all feel the burden of having a fatal disease widely considered unacceptable and feel compelled to maintain some secrecy about the illness. Referrals to community resources, mental health/behavioral health professionals, and support groups can help the patient verbalize fears and frustrations and cope with the illness.

Health Care Resources.

In many cities, community groups and volunteers assist people with AIDS. The types and number of services vary by agency and city, but many include HIV testing and counseling, clinic services, buddy systems, support groups, respite care, education and outreach, referral services, and housing. Patients may need referrals to other local resources, such as home care agencies, companies that provide home IV therapy, community mental health/behavioral health agencies, Meals on Wheels, transportation services, and others. In addition, educational materials and support groups are available through Internet access.

◆ Evaluation: Outcomes

The overall outcomes for care of patients with AIDS are to maintain the highest possible level of function for as long as possible, reduce infections, and maintain quality of life and dignity during the course of progressive illness. Evaluate the care of the patient with AIDS on the basis of the identified priority problems. Expected outcomes include that he or she should:

- Adhere to the prescribed drug therapy regimen at least 90% of the time
- Practice safer sex techniques all of the time
- Remain free from opportunistic infections
- Have adequate respiratory function
- Achieve an acceptable level of physical comfort
- Attain adequate weight and nutrition and fluid status
- Maintain tissue integrity
- Remain oriented
- Maintain self-esteem
- Maintain a support system and involvement with others

Specific indicators for these outcomes are listed for each patient problem in the Planning and Implementation section (see earlier).

Clinical Judgment Challenge

Ethical/Legal

Mark S. is a 24-year-old man who was diagnosed with HIV 3 years ago. He has been followed in the HIV clinic and has not been adherent to his medication regimen. In addition, he has struggled off and on with substance abuse. He currently lives with his mother and came to the emergency department today with severe pneumocystis pneumonia. He required intubation and admission to the ICU. On his first day in the unit, his mother asked about his condition. She was told that he had a severe pneumonia, but that it was likely he would recover. The staff ask the nurse manager whether Mark's mother has a right to know his HIV status since he lives with her and might be at risk for exposure to the virus.

1. What is the nurse manager's responsibility in this situation?
2. Is Mark's mother likely to be at risk for exposure to HIV? Why or why not?
3. Should the staff inform Mark's mother about his HIV status? Why or why not?
4. If his mother is informed about Mark's HIV status, what, if any, ethical issues/principles would be violated?

Therapy-Induced Immune Deficiencies

Some acquired secondary immune deficiencies may be related to other conditions that cause the loss of immunoglobulins or destruction of lymphocytes. The most common cause of secondary immune deficiency is the use of drugs and other treatment modalities for various diseases. Sometimes immunosuppression is a desired effect, as in organ transplantation or for the treatment of autoimmune disorders. Often immunosuppression is an undesirable, complicating side effect of therapy that is used for another intent, such as cancer chemotherapy, and may even require changing the therapeutic regimen. Various therapies cause different types and degrees of immunosuppression. The challenge is to have maximum therapeutic effect without leaving the patient overly susceptible to serious complications.

Drug-Induced Immune Deficiencies

Several drug classes have major immunosuppressive effects. Some induce general immunosuppression; others are more specific and target one part of the immune system more than another.

Cytotoxic drugs are mostly those used in the treatment of cancer and autoimmune disorders. These drugs interfere with all rapidly dividing cells, especially the white blood cells (WBCs), which are responsible for providing immunity and protection against infection. The result is a decrease in the number of these important cells, especially the neutrophils, greatly increasing the patient's risk for infection. Cytotoxic drugs also interfere with the ability of lymphocytes to produce and release products such as lymphokines and antibodies, causing general immunosuppression.

Corticosteroids are hormones that have both anti-inflammatory and immunosuppressive effects that are used to treat many autoimmune diseases, neoplasms, and endocrine disorders. They inhibit inflammation by blocking the movement of many WBCs. These drugs disrupt the synthesis of arachidonic acid, the main precursor for a variety of inflammatory chemicals.

Corticosteroids reduce the number of circulating T-cells and result in suppressed cell-mediated immunity. They also interfere with immunoglobulin G (IgG) production and reduce antibody-antigen binding. These drugs have many effects that alter disease activity, as well as numerous side effects, including:

- Central nervous system changes, such as euphoria, insomnia, or psychosis
- Cardiovascular changes, such as edema and hypertension
- GI effects, such as gastric irritation, ulcers, and increased appetite (with weight gain)
- Other changes (e.g., hyperglycemia, muscle weakness, delayed wound healing, bone density loss, body fat redistribution, adrenal suppression)

Cyclosporine (Sandimmune, Neoral) is a drug that selectively suppresses the CD4+ T-cells by blocking their growth and development. It is used to prevent organ transplant rejection and graft-versus-host disease and occasionally is used for autoimmune disorders.

Disease-modifying immunosuppressive drugs represent a large group of newer agents that specifically slow the damage caused by a variety of autoimmune diseases. Examples include alefacept (Amevive), etanercept (Enbrel), infliximab (Remicade), and many others. Regardless of their specific action in reducing cell damage, they always decrease the general immune responses to some degree and increase the risk for infection, both newly acquired infections and dormant pre-existing infections. The

health problems for which these drugs are most commonly prescribed are rheumatoid arthritis and psoriasis. Specific disease-modifying drugs are discussed in the chapters presenting the health problems for which they are prescribed.

Radiation-Induced Immune Deficiencies

Although chemotherapy suppresses immunity and inflammation more than radiotherapy does, radiation also is toxic to white blood cells (WBCs), especially lymphocytes and neutrophils. Some radiation exposures can induce profound general immunosuppression. Whether immune deficiency occurs after radiation therapy depends on the location and dose of radiation. Exposure to the ilium and femur in adults can cause generalized immunosuppression because these bone areas are the primary blood cell–producing sites.

Management of the patient with treatment-induced immune deficiency aims to improve immune function and prevent infection. The most severe immunosuppression occurs while he or she is receiving the immunosuppressive drugs or during radiation treatment. The severity and duration of the immunosuppression are related to the dosage of specific drugs. Although this impairment is usually temporary, with good recovery of immunity and inflammation within weeks or months of therapy completion, the potential for severe infections makes this problem a major treatment concern. Common infections occurring during this period include those of fungal origin, especially yeast, residual viral breakthrough, and a variety of bacteria.

Coordinate with other health care professionals to provide safe care to patients at risk for infection. Chart 19-5 lists specific actions to prevent infection among patients with any type of immunosuppression. Good handwashing by all health care personnel before contact with the patient is essential for infection prevention. Aseptic technique must be used with any invasive procedure as required by The Joint Commission's National Patient Safety Goals (NPSGs).

In some instances, drug-induced immunosuppression can be reduced or avoided by giving hematopoietic growth factors to stimulate bone marrow production of immune system cells. Although not appropriate for all types of disorders, this treatment can reduce the patient's risk for infection during drug therapy. See Chapters 22 and 40 for discussion about this therapy.

Many patients remain at home during periods of immunosuppression. Teach the patient and family best practices to reduce the patient's risk for infection (see Chart 19-4).

For patients receiving long-term therapy with immunosuppressive drugs, drug dosages are altered according to their responses. The lowest dose that achieves the desired effect is given.

Congenital (Primary) Immune Deficiencies

Congenital, or primary, immune deficiencies are rare disorders in which the person is born with a defect in the development or function of one or more immune components. Thus immunity does not adequately protect him or her from infection or cancer.

Some congenital immune deficiencies are inherited as an X-linked trait (e.g., Bruton's agammaglobulinemia or Wiskott-Aldrich syndrome), and some are recessive (e.g., ataxia-telangiectasia). For many congenital immune deficiencies there is no identified genetic defect.

Congenital immune deficiencies are classified according to the type of immune function that is impaired: antibody-mediated, cell-mediated, or combined. Because cell-mediated and combined immune deficiencies are so severe and rare that the affected person is usually managed in a pediatric setting, only antibody-mediated problems (seen in adults) are discussed in this chapter.

Selective Immunoglobulin a Deficiency

Selective immunoglobulin A (IgA) deficiency is the most common congenital immune deficiency seen in adults, occurring in 1 per 600 to 800 people (McCance et al., 2014). The patient may be asymptomatic or have chronic recurrent infections of the upper respiratory tract, skin, urinary tract, vaginal tract, and GI tract. Selective IgA deficiency does not reduce life span. Because IgA is the major antibody in secretions, bacterial infections are seen mostly in the respiratory, GI, and urogenital tracts.

Treatment for IgA deficiency is limited to vigorous treatment of infections. Unlike other immunoglobulin deficiencies, IgA deficiency is not managed with exogenous immunoglobulin for two reasons. First, exogenous immunoglobulin contains little IgA and would not help boost IgA levels. Second, because patients with IgA deficiency make normal amounts of all other antibodies, they are at high risk for severe allergic reactions to exogenous immunoglobulin.

Nursing Safety Priority QSEN

Drug Alert

Never administer intravenous immunoglobulin (IVIG) to a patient who has selective immunoglobulin A deficiency.

Bruton's Agammaglobulinemia

A classic congenital antibody-mediated immune deficiency is Bruton's disease or Bruton's agammaglobulinemia. Boys born with this disease start to have recurrent infections at about 6 months of age, after maternal antibodies, transferred through the placenta, have been lost. These infections include otitis, sinusitis, pneumonia, furunculosis, meningitis, and septicemia. Laboratory assessment shows an absence of circulating immunoglobulin (antibodies).

The prognosis for many patients with Bruton's disease is good if antibody replacement with immune serum globulin is started early. The globulin is regularly given to these patients, usually about 100 to 400 mg/kg IV every 3 to 4 weeks. The dosage and schedule are individualized. Antibiotics are used for specific infections. Long-term prophylactic antibiotic therapy may be used.

Common Variable Immune Deficiency

The patient with common variable immune deficiency, or hypogammaglobulinemia, has recurrent bacterial infections similar to those seen with Bruton's disease. The patient has low levels of circulating antibodies (immunoglobulins) of all classes.

Hypogammaglobulinemia differs from Bruton's disease in that it usually first appears later (in adolescence or young adulthood), it occurs almost equally in men and women, and the infections are less severe. Common problems include giardiasis (intestinal infection with *Giardia lamblia*), pneumonia, sinusitis, gastric cancer, bronchiectasis, and gallstones.

Treatment is similar to that for Bruton's disease. Regular infusions of immune serum globulin and regular or intermittent use of antibiotics protect the affected person against infection.

Nursing Concepts and Clinical Judgment Review

What might you NOTICE if the patient has impaired protection and increased infection risk as a result of HIV disease and AIDS?

- Chronic or recurrent infections
- History or presence of opportunistic infections

- Decreasing CD4+ T-cell count
- Decreasing CD4+ T-cell to CD8+ T-cell ratio
- Diarrhea
- Report of weight loss and fatigue
- Swollen lymph nodes
- Poor wound healing
- Skin lesions
- Headache
- Fever
- Memory loss

What should you INTERPRET and how should you RESPOND to a patient who has impaired protection and increased infection risk as a result of HIV disease and AIDS?

Perform and interpret focused physical assessment findings including:

- Assess cardiovascular and respiratory status:
  Vital signs
  Presence of acute chest pain or dyspnea
  Presence of cough
  Presence of fever
  Activity tolerance
- Assess nutrition status:
  Food intake
  Weight loss or gain
  General condition of skin
- Assess neurologic status:
  Cognitive changes
  Sensory disturbances
- Assess gastrointestinal status:
  Mouth and oropharynx
  Presence of dysphagia
  Presence of nausea, vomiting, diarrhea
- Assess psychological status:
  Presence of anxiety
  Presence of depression
- Assess activity and rest:
  Activities of daily living (ADLs)
  Fatigue
  Sleep pattern

Presence of pain

Respond:

- Collaborate with members of the health care team to protect the patient from infection.
- Monitor laboratory test results to determine therapy effectiveness, progression of disease, indications of opportunistic infection.
- Teach the patient and significant other about highly active antiretroviral therapy (HAART) including dosages, schedule, side effects, and the need to take all drugs exactly as prescribed.
- Teach the patient and significant other how to avoid infection in the home environment.
- Teach the patient how to avoid transmission of the HIV.
- Continue to assess for changes in the patient's condition, especially indications of infection in any body area.

On what should you REFLECT?

- Consider your personal views on sexuality, lifestyle choices, what constitutes family membership, gender identification, and fear of HIV transmission.
- Evaluate the patient's, family's, and significant other's knowledge of the disease and its management.
- Evaluate the patient's, family's, and significant other's stress levels, use of coping strategies, and knowledge of community resources.
- Assess the knowledge and proficiency of unlicensed assistive personnel (UAP) in carrying out infection control measures.
- Evaluate the degree of compassion and interaction that UAP display toward patients with HIV infection and AIDS.

Get Ready for the NCLEX® Examination!

Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Use Standard Precautions for all patients regardless of age, gender, race or ethnicity, sexual orientation, education level, and profession. **Safety** QSEN
- Follow the best practices outlined in Chart 19-5 to protect the hospitalized immunosuppressed patient from infection. **Evidence-Based Practice** QSEN
- Use good handwashing techniques before providing any care to a patient who is immune deficient.
- Ensure the confidentiality of the patient's HIV status. **Patient-Centered Care** QSEN
- Teach unlicensed assistive personnel (UAP) to use Standard Precautions. **Teamwork and Collaboration** QSEN
- Teach unlicensed assistive personnel (UAP) the differences in care required for a patient with a pathogenic infection versus a patient with an opportunistic infection. **Teamwork and Collaboration** QSEN

Health Promotion and Maintenance

- Identify patients at high risk for infection because of work environment or leisure activities.
- Urge all patients who are HIV positive to use condoms and other precautions during sexual intimacy even if the partner is also HIV positive.
- Teach patients with protein-calorie malnutrition what foods to include in the diet to promote better nutrition.
- Teach the patient and family to protect against infection by following the recommendations in Chart 19-4.
- Teach the patient and family about the manifestations of infection and when to seek medical advice.
- Urge patients to adhere to their antiviral drug regimen.

Psychosocial Integrity

- Treat all patients, regardless of diagnosis, with dignity.
- Do not assume that any visitor or family member knows the patient's

diagnosis.
- Urge all patients who are HIV positive to inform their sexual partners of their HIV status.
- Respect the patient's right to inform or not to inform family members about his or her HIV status. **Patient-Centered Care** QSEN
- Use a nonjudgmental approach when discussing sexual practices, sexual behaviors, and recreational drug use.
- Pace your interview to match the learning needs and energy level of each patient.
- Encourage the patient to express his or her feelings about a change in health status or the diagnosis of an "incurable" disease.
- Refer patients newly diagnosed with HIV infection to local resources and support groups.
- Teach family members reorientation techniques to use when the patient is confused.
- Explain all diagnostic procedures, restrictions, and follow-up care to the patient scheduled for tests.
- Allow patients who have a change in physical appearance to mourn this change.

Physiological Integrity

- Use prescribed oxygen therapy, drug therapy, and respiratory support to improve gas exchange and oxygenation for the patient with respiratory problems related to reduced immunity.
- Use pharmacologic and nonpharmacologic therapies to reduce pain for the patient with HIV disease and AIDS. **Patient-Centered Care** QSEN
- Pace nonurgent health care activities to reduce the risk for fatigue for patients with AIDS.
- Assess the immune-deficient patient every shift for manifestations of infection. Document the assessment findings, and report any manifestation of infection immediately to the health care provider. **Safety** QSEN
- Assess the tissue integrity of the perianal region of a patient with AIDS-related diarrhea after every bowel movement.
- Collaborate with the health care provider, registered dietitian, respiratory therapist, pharmacist, social worker, and case manager to individualize patient care for the person with HIV disease and AIDS in any care setting. **Teamwork and Collaboration** QSEN

CHAPTER 20

Care of Patients with Immune Function Excess

Hypersensitivity (Allergy) and Autoimmunity

M. Linda Workman

PRIORITY CONCEPTS

- Inflammation
- Immunity

Learning Outcomes

Safe and Effective Care Environment

1. Protect the patient who has hypersensitivities from injury related to inflammation.
2. Coordinate with other members of the health care team to ensure a safe environment for the patient with a latex allergy.

Health Promotion and Maintenance

3. Teach patients with allergies how to protect themselves against harm from a hypersensitivity reaction.

Psychosocial Integrity

4. Reduce the psychological impact for patients and families of patients who have immunity or inflammation excess.

Physiological Integrity

5. Assess all patients for the potential to have a severe hypersensitivity reaction.

6. Prioritize care for the patient experiencing anaphylaxis.

 http://www.elsevier.com/Iggy/

Usually, inflammation and immunity are protective and helpful responses. However, when inflammation or immunity is prolonged or excessive or occurs at an inappropriate time, normal tissues are damaged. These responses are "overreactions" to invaders and foreign antigens and are known as *hypersensitivity* or *allergic responses*. When these responses fail to recognize and protect self cells, normal body tissues are attacked and harmed. This type of reaction is known as an *autoimmune response*. Hypersensitivity and autoimmune responses can severely damage cells, tissues, and organs (Abbas et al., 2012).

Hypersensitivities/Allergies

Hypersensitivity or **allergy** is excessive inflammation occurring in response to the presence of an **antigen** (foreign protein or allergen) to which the patient usually has been previously exposed. It can cause problems that range from uncomfortable (e.g., itchy, watery eyes or sneezing) to life threatening (e.g., allergic asthma, anaphylaxis, bronchoconstriction, or circulatory collapse). The terms *hypersensitivity* and *allergy* are used interchangeably. Hypersensitivity reactions are classified into four basic types, determined by differences in timing, pathophysiology, and manifestations (Table 20-1). Each type may occur alone or along with one or more other types (McCance et al., 2014).

TABLE 20-1

Mechanisms and Examples of Types of Hypersensitivities

MECHANISM	CLINICAL EXAMPLES
Type I: Immediate	
Reaction of IgE antibody on mast cells with antigen, which results in release of mediators, especially histamine	Hay fever
	Allergic asthma
	Anaphylaxis
Type II: Cytotoxic	
Reaction of IgG with host cell membrane or antigen adsorbed by host cell membrane	Autoimmune hemolytic anemia
	Goodpasture's syndrome
	Myasthenia gravis
Type III: Immune Complex–Mediated	
Formation of immune complex of antigen and antibody, which deposits in walls of blood vessels and results in complement release and inflammation	Serum sickness
	Vasculitis
	Systemic lupus erythematosus
	Rheumatoid arthritis
Type IV: Delayed	
Reaction of sensitized T-cells with antigen and release of lymphokines, which activates macrophages and induces inflammation	Poison ivy
	Graft rejection
	Positive TB skin tests
	Sarcoidosis

IgE, Immunoglobulin E; *IgG*, immunoglobulin G; *TB*, tuberculosis.

Type I: Rapid Hypersensitivity Reactions

Type I, or rapid hypersensitivity, also called *atopic allergy*, is the most common type of hypersensitivity from excess immunity. This type results from the increased production of the immunoglobulin E (IgE) antibody class. Acute inflammation occurs when IgE responds to an antigen, such as pollen, and causes the release of histamine and other vasoactive amines from basophils, eosinophils, and mast cells. Examples of type I reactions

include anaphylaxis and allergic asthma (discussed in Chapter 30); atopic allergies such as hay fever and allergic rhinitis; and allergies to substances such as latex, bee venom, peanuts, iodine, shellfish, drugs, and thousands of other environmental allergens. Allergens can be contacted in these ways:

- Inhaled (plant pollens, fungal spores, animal dander, house dust, grass, ragweed)
- Ingested (foods, food additives, drugs)
- Injected (bee venom, drugs, biologic substances such as contrast dyes)
- Contacted (latex, pollens, foods, environmental proteins)

Some reactions occur just in the areas exposed to the antigen, such as the mucous membranes of the nose and eyes, causing symptoms of rhinorrhea, sneezing, and itchy, red, watery eyes. Other reactions may involve all blood vessels and bronchiolar smooth muscle causing widespread blood vessel dilation, decreased cardiac output, and bronchoconstriction. This condition is known as **anaphylaxis**, which is a medical emergency and must be treated immediately (see the Anaphylaxis section on p. 351).

Allergic Rhinitis

Pathophysiology

Allergic rhinitis, or *hay fever,* is triggered by immunity and inflammation reactions to airborne allergens, especially plant pollens, molds, dust, animal dander, wool, food, and air pollutants. Some acute episodes are "seasonal," recurring at the same time each year and lasting only a few weeks. Chronic rhinitis, or perennial rhinitis, occurs intermittently (with no predictable seasonal pattern) or continuously when a person is exposed to certain allergens. In "nonallergic rhinitis," the same manifestations are present although no allergic cause is identified and the immune system does not appear to be involved.

On first exposure to an **allergen** (an antigen that causes allergic sensitization), the person responds by making antigen-specific IgE. This IgE binds to the surface of basophils and mast cells (see Fig. 17-9 on p. 283 in Chapter 17). These cells have many granules containing vasoactive amines (including histamine) that are released when stimulated. Once the antigen-specific IgE is formed, the person is sensitized to that allergen.

In a type I allergic reaction, the already sensitized person is re-exposed to the allergen. The resulting response has a primary phase and a

secondary phase. In the primary phase, the allergen binds to two adjacent IgE molecules on the surface of a basophil or mast cell, which breaks the cell membrane. The membrane opens and releases the vasoactive amines into tissue fluids (Fig. 20-1).

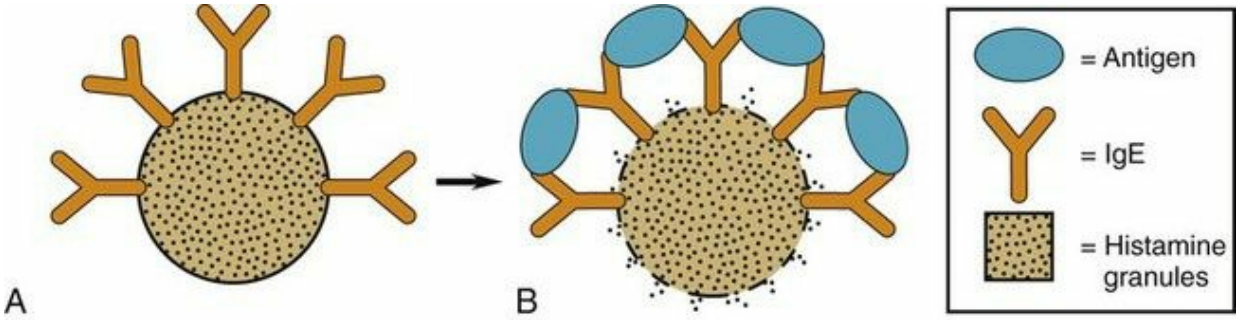

FIG. 20-1 Degranulation and histamine release. **A,** Mast cell with IgE. **B,** Mast cell degranulation and histamine release when allergen binds to IgE.

The most common vasoactive amine is *histamine,* a short-acting biochemical. Histamine causes capillary leak, nasal and conjunctival mucus secretion, and itching (pruritus), often occurring with erythema (redness). These manifestations of inflammation last for about 10 minutes after histamine is first released. When the allergen is continuously present, mast cells continuously release histamine and other proteins, prolonging the response.

The secondary phase results from the release of other cellular proteins. These other proteins draw more white blood cells to the area and stimulate a more general inflammatory reaction through actions of leukotriene and prostaglandins (other mediators of inflammation; see Chapter 17). This reaction occurs in addition to the allergic reaction stimulated in the primary phase. The resulting inflammation increases the clinical manifestations and continues the response.

The production of high IgE levels in response to antigen exposure is genetically based on the inheritance of many genes. Although allergic tendencies are inherited, specific allergies are *not* inherited. For example, a mother who has an allergy to penicillin but not to peanuts may have a child with an allergy to peanuts but not to penicillin. Atopic allergies affect about 10% of the population in North America (McCance et al., 2014).

❖ Patient-Centered Collaborative Care

◆ Assessment

History.

An accurate and detailed history helps identify possible allergic rhinitis (Holmes & Scullion, 2012). Ask the patient to describe the onset and duration of problems in relation to possible allergen exposure. Ask about work, school, and home environments and about possible exposures through hobbies, leisure time, or sports activities. Because a tendency toward type I allergic responses can be inherited, ask about the presence of allergies among parents and siblings.

Physical Assessment/Clinical Manifestations.

The patient with allergic rhinitis has **rhinorrhea** (a "runny" nose), a "stuffy" nose, and itchy, watery eyes. He or she may breathe through the mouth, and the voice has a nasal sound. Drainage from the nose is usually clear or white. The nasal mucosa appears swollen and pink. The patient may have a headache or feel pressure over the frontal and maxillary sinuses. Placing a penlight directly on the skin over the sinuses and observing for a glow *(transillumination)* often shows reduced glow when rhinitis is present. With postnasal drip, the patient has a dry, scratchy throat and pharyngitis. He or she often feels as though a cold is present that has lasted longer than a week. Fever is rare unless an infection occurs with the rhinitis.

Laboratory Assessment.

A white blood cell (WBC) count and differential indicate the presence of excess immunity with an allergic response by an increase in eosinophils. A patient with severe seasonal allergic rhinitis may have an eosinophil count as high as 12% (normal being 1% to 2%). Some patients have an increased total WBC count, but the percentage of neutrophils remains normal (55% to 70%). If an acute infection occurs with allergic rhinitis, both the total WBC count and the neutrophils increase.

Other laboratory tests indicating an allergic reaction include serum immunoglobulin E (IgE) levels measured by enzyme-linked immunosorbent assay (ELISA) and the radioallergosorbent test (RAST) (Pagana & Pagana, 2014). A normal level of IgE for adults is about 39 IU/mL (or less than 100 IU/mL). This level increases greatly with allergies. The usual IgE test does not indicate the specific allergen—only the tendency to have allergic responses. The radioimmunosorbent test (RIST) shows the blood level of IgE directed against a specific antigen and can determine specific allergies. The expense of this study limits its use in allergy testing.

Allergy Testing.

Skin testing can show which specific allergens are the cause of a type I reaction. Skin testing is performed as scratch testing or intradermal testing. Patch testing is often reserved for contact dermatitis.

A scratch or prick test can show an *immediate* hypersensitivity reaction to an allergen and is used in routine allergy testing for type I reactions. Allergens introduced through a scratch or prick cause a localized reaction (wheal) when the test result is positive. Results are usually determined after 15 to 20 minutes.

Patient Preparation.

Systemic glucocorticoids and antihistamines are discontinued 2 weeks before the test to avoid suppressing the test response. Nasal sprays to reduce mucous membrane swelling are permitted, except for sprays that contain an antihistamine.

Procedure.

The best site for scratch testing is the inside of the forearm or on the back. Other sites are used if a rash or skin problem is present on the arms or back. Gently clean the skin with soap and water, and remove surface oils with alcohol.

Small drops of sera containing different known allergens are placed on the skin. The skin is scratched or pricked through the drop with a skin testing needle. Control drops are also applied to determine how a person reacts to substances that do not normally stimulate a reaction (negative control) and to substances that normally should stimulate an excess immunity reaction (positive control). The allergen-tested areas are examined for the presence and size of reactions. These areas are then compared with the control areas. Areas with erythema and wheal formation are positive for that antigen. Degree of sensitivity is estimated by the size of the response.

Although serious reactions in response to scratch testing are rare, ensure that emergency equipment is available during testing. This includes manual resuscitation bag, oxygen, suction equipment, IV infusion set, and drugs for anaphylaxis (epinephrine and diphenhydramine).

Follow-up Care.

After testing is completed, wash the solution from the skin. Topical steroids and oral antihistamines may be given to reduce itching and

increase patient comfort. If an antihistamine that causes sedation is given, another person must drive the patient home.

Intradermal testing is reserved for substances that are strongly suspected of causing allergy but did not test positive with scratch testing. Intradermal testing increases the risk for an adverse reaction, including anaphylaxis. Ensure that emergency equipment is in the room with the patient. Small amounts of testing sera (0.1 mL) are injected intradermally on the upper arm, and the area is observed for erythema and wheal formation. The degree of allergy is estimated by the size of the response. Preparation and follow-up care are the same as for scratch testing.

Oral food challenges are used for patients who have allergic rhinitis when the allergen is eaten rather than inhaled. This type of testing is used to identify specific allergens if skin testing is not conclusive and if keeping a food diary has failed to determine the offending food items. The test requires the patient to eliminate suspected foods for 7 to 14 days before testing. After this time, the patient is directed to eat a specific suspected food for at least 1 day and to monitor for manifestations of allergy. When many food allergies are present, the patient may have to eat only one food type per day of testing. *Oral food challenges are not performed using foods that have previously caused a serious or anaphylactic reaction in the patient being tested.*

◆ Interventions

Interventions for allergy management include avoidance therapy, drug therapy, complementary therapies, and desensitization therapy. Many patients use a combination of these therapies for management of allergic rhinitis and other manifestations of type I allergy.

Avoidance Therapy.

Avoidance therapy can be successful when specific allergens have been identified. Teach the patient to avoid direct or close contact with these agents. Some allergens, such as foods or drugs, may be easy to avoid. Other allergens, such as pollen, mold, or dust mites, may require environmental changes.

Teach patients that airborne allergens can be reduced by air-conditioning and air-cleaning units. Removing cloth drapes, upholstered furniture, and carpeting also reduces airborne allergens. Covering mattresses and pillows with plastic or an ultra-mesh cover reduces exposure to dust mites and mold, as does laundering bed linens weekly in hot water and detergent.

Pet-induced allergies pose special challenges. Simple interventions,

such as keeping pets out of the bedroom and thorough cleaning of the room to remove animal hair and dander, may reduce symptoms. Frequent bathing of the pet or keeping the pet outdoors can decrease allergen exposure. Depending on the severity of the allergy and how well other methods provide relief, pets with fur, feathers, or dander may need to be removed from the household.

Drug Therapy.

Drug therapy for symptom relief can be effective in reducing the allergic response and making the patient more comfortable. This therapy involves the use of steroidal and nonsteroidal agents (to reduce inflammation), vasoconstrictors, antihistamines, mast cell stabilizers, and drugs that inhibit the release or action of leukotrienes.

Decongestants are available as systemic oral drugs or nasal sprays. These drugs do not clear the allergen or prevent the release of mediators such as histamine. They work by causing vasoconstriction in the inflamed tissue, thereby reducing the edema. Decongestants often contain ephedrine, phenylephrine, or pseudoephedrine. Secretions are reduced when vasoconstricting drugs are combined with an anticholinergic drug, such as scopolamine or atropine. Many decongestants are available by prescription and as over-the-counter cold and allergy drugs. Side effects include dry mouth, increased blood pressure, and sleep difficulties.

Nursing Safety Priority QSEN

Drug Alert

Because effects are systemic, teach patients with high blood pressure, glaucoma, or urinary retention to consult with a health care professional before taking any decongestant.

Antihistamines block histamine from binding to the receptor. This action prevents vasodilation and capillary leak. Many antihistamines also decrease secretions. Some antihistamines, such as diphenhydramine (Benadryl, Allerdryl) and chlorpheniramine (Allergy, Aller-Chlor, Chlor-Trimeton), often induce sedation. Others, such as desloratadine (Clarinex), cetirizine (Zyrtec), and fexofenadine (Allegra), are less sedating.

Corticosteroids decrease inflammation and excess immunity in many ways, one of which is by preventing the synthesis of mediators. Corticosteroid nasal sprays (topical intranasal steroids) can prevent the symptoms of

rhinitis. Systemic corticosteroids can produce severe side effects and are used only on a short-term basis for serious problems associated with type I reactions, rarely for rhinitis.

Mast cell stabilizing drugs include nasal sprays, such as cromolyn sodium (Nasalcrom), that prevent mast cell membranes from opening when an allergen binds to IgE. Thus these drugs prevent the symptoms of allergic rhinitis but are not useful during an acute episode.

Leukotriene antagonists may be used to manage and prevent allergic rhinitis. Zileuton (Zyflo) prevents leukotriene synthesis. (See Chapter 17 for a discussion of the role of leukotriene in inflammation and allergy.) Zafirlukast (Accolate) blocks the leukotriene receptor.

Complementary and Alternative Therapies.

Complementary and alternative therapies have helped some patients with rhinitis obtain relief, especially through the use of aromatherapy. Possible mechanisms of action include competition and desensitization. Some patients with pollen allergies report decreased problems after eating unprocessed honey.

Desensitization Therapy.

Desensitization therapy, commonly called "allergy shots," may be needed when allergens are identified and cannot be avoided easily. It involves subcutaneous injections of very dilute solutions of the identified allergen or allergens. A 0.05-mL dose of this solution is injected subcutaneously. Usually an increasing dose is given weekly until the patient is receiving a 0.5-mL dose. The patient is then started on the lowest dose of the next higher concentration of allergen solution. The process is repeated with increasing concentrations of allergen solutions until the patient is receiving the maximum dose of the greatest concentration (usually 1 : 100), depending on his or her response. The recommended full course of treatment is about 5 years.

Desensitization appears to reduce allergic responses by competition. In theory, the very small amounts of allergen first injected are too low to bind to the IgE already present but are enough to induce immunoglobulin G (IgG) production against that allergen. IgG is not attached to either mast cells or basal cells, and allergens that bind to IgG do not trigger allergic responses. IgG then clears the allergen from the body (see Chapter 17). By gradually increasing the allergen injection, large amounts of IgG are produced against the allergen. When the patient is then exposed to the allergen in the environment, the IgG binds to it and clears it from the body before IgE can bind to it and trigger an

allergic reaction. Because so much more IgG can be produced compared with IgE, IgG is successful in the competition to bind the allergen (Abbas et al., 2012).

Anaphylaxis

Pathophysiology

Anaphylaxis, the most life-threatening example of a type I hypersensitivity reaction, occurs rapidly and systemically. It affects many organs within seconds to minutes after allergen exposure. Anaphylaxis is not common, episodes can vary in severity, and *it can be fatal. The major factor in fatal outcomes for anaphylaxis is a delay in the administration of epinephrine* (Simons et al., 2011). Many substances can trigger anaphylaxis in a susceptible person (Table 20-2). Drugs and dyes are more common causes of anaphylaxis in acute care settings; food and insect stings/bites are common causes in community settings.

TABLE 20-2

Common Agents That Cause Anaphylaxis

Drugs/Foreign Proteins
• Antibiotics (penicillin, cephalosporins, tetracycline, sulfonamides [especially Bactrim and Septra]), streptomycin, vancomycin, chloramphenicol, amphotericin B, others) • Adrenocorticotropic hormone, insulin, vasopressin, protamine* • Allergen extracts, muscle relaxants, hydrocortisone, vaccines, local anesthetics (lidocaine, procaine)* • Angiotensin-converting enzyme (ACE) inhibitors • Angiotensin receptor blockers (ARBs) • Chemotherapy agents (antineoplastic drugs) • Monoclonal antibodies • Whole blood, cryoprecipitate, immune serum globulin* • Radiocontrast media* • Opiates
Foods
• Peanuts • Shellfish • Eggs • Legumes, nuts • Grains • Berries • Preservatives • Bananas
Other Agents
• Pollens • Molds • Latex • Other
Insects/Animals
• Hymenoptera: bees, wasps, hornets • Fire ants • Snake venom

*Anaphylaxis caused by these substances is probably a result of direct mast cell degranulation rather than an immunoglobulin E (IgE)-mediated hypersensitivity event.

Health Promotion and Maintenance

Anaphylaxis has a rapid onset and a potentially fatal outcome (even with appropriate medical intervention); thus prevention and early intervention are critical. *Teach the patient with a history of allergic reactions to avoid allergens whenever possible, to wear a medical alert bracelet, and to alert health care personnel about specific allergies.* Some patients must carry an emergency anaphylaxis kit (e.g., a kit with injectable epinephrine, sometimes called a "bee sting kit") or an epinephrine injector, such as the EpiPen or Twinject automatic injector. The EpiPen device is a spring-loaded injector that delivers 0.3 mg of epinephrine per 2-mL dose directly into the subcutaneous tissue or intramuscularly (Fig. 20-2). Teach patients prescribed the device how to care for and use it (Chart 20-1).

Chart 20-1 Patient and Family Education: Preparing for Self-Management

Care and Use of Automatic Epinephrine Injectors

- Practice assembly of injection device with a non–drug-containing training device provided through the injection device manufacturer.
- Keep the device with you at all times.
- When needed, inject the drug into the top of your thigh, slightly to the outside, holding the device so that the needle enters straight down.
- You can inject the drug right through your pants; just avoid seams and pockets where the fabric is thicker.
- Use the device when *any* symptom of anaphylaxis is present and call 911. It is better to use the drug when it is not needed than to not use it when it is needed!!!
- Whenever you need to use the device, get to the nearest hospital for monitoring for at least the next 4 to 6 hours.
- Have at least two drug-filled devices on hand in case more than one dose is needed.
- Protect the device from light and avoid temperature extremes.
- Carry the device in the case provided by the manufacturer.
- Keep safety cap in place until you are ready to use the device.
- Check the device for:
  - Expiration date—If the date is close to expiring or has expired, obtain a replacement device.*
  - Drug clarity—If the drug is discolored, obtain a replacement device.
  - Security of cap—If the cap is loose or comes off accidently, obtain a replacement device.

*Some manufacturers have an automatic notification service to let you know your device is about to expire.

FIG. 20-2 EpiPen and EpiPen Jr. self-injectors for epinephrine.

The medical records of patients with a history of anaphylaxis should prominently display the list of specific allergens. Ask the patient about drug allergies before giving any drug or agent. If he or she has a known allergy, be sure to document in the medical record the allergen and the typical response produced and communicate the allergy and its response to other members of the health care team. Skin tests should be performed before giving any substance that has a high incidence of causing anaphylactic reactions, such as iodine-containing dyes. Be aware of common cross-reacting agents. For example, a patient who is allergic to penicillin is also likely to react to cephalosporins because both have a similar chemical structure. People who have an allergy to bananas, avocados, and some nuts are more likely to have a latex allergy, although this is not universal.

Take precautionary measures if a drug or agent must be used despite a history of allergic reactions. Start an IV, and place intubation equipment and a tracheostomy set at the bedside. The patient is often premedicated with diphenhydramine (Benadryl, Allerdryl 🍁) or a corticosteroid. The allergy-causing substance is given first intradermally, then subcutaneously, and then intramuscularly in increasing doses at 20- to 30-minute intervals so the initial dose by the next route does not exceed the final dose by the previous route.

❖ Patient-Centered Collaborative Care

◆ Assessment

A major problem with anaphylaxis management is that initial manifestations may be subtle, such as sudden severe abdominal

cramping and diarrhea. A set of three criteria, listed in Chart 20-2, is used for diagnosis of anaphylaxis. A patient is considered to have anaphylaxis whenever any *one* of these three criteria is met.

Chart 20-2

Key Features

Anaphylaxis

Clinical Criteria 1

Onset within minutes to hours of skin or mucous membrane problems involving swollen lips, tongue, soft palate, uvula; widespread hives; pruritus; or flushing along with any *one* of these new onset symptoms:

- Respiratory distress or ineffectiveness:
  - Dyspnea
  - Bronchospasms
  - Wheezes
  - Stridor
  - Hypoxia
  - Cyanosis
  - Peak expiratory rate flow lower than the patient's usual
- Hypotension or any indication of reduced perfusion resulting in organ dysfunction:
  - Loss of consciousness
  - Incontinence
  - Hypotonia
  - Absent deep tendon reflexes

Clinical Criteria 2

Onset within minutes to hours of *two* or more of these symptoms after a patient has been exposed to a potential allergen:

- Skin or mucous membrane problems involving swollen lips, tongue, soft palate, uvula; widespread hives; pruritus; or flushing
- Respiratory distress or ineffectiveness as evidenced by any dyspnea, bronchospasms, wheezes, stridor, hypoxia, cyanosis, or peak expiratory rate flow lower than the patient's usual
- Hypotension or any indication of reduced perfusion resulting in organ dysfunction, such as loss of consciousness, incontinence, hypotonia, or absent deep tendon reflexes
- Persistent GI problems such as nausea or vomiting, cramping, abdominal pain

Clinical Criteria 3

Onset within minutes to hours of hypotension with systolic blood pressure lower than 90 mm Hg or 30% lower than the patient's baseline systolic pressure.

Adapted from Simons, E., Ardusso, L., Bilo, M.B., El-Gamal, Y., Ledford, D., Ring, J., et al. (2011). World Allergy Organization guidelines for the assessment and management of anaphylaxis. *WAO Journal*, *4*(2), 13-37.

A patient having an anaphylactic reaction first has feelings of uneasiness, apprehension, weakness, and impending doom. Often he or she is anxious and frightened. These feelings are followed, often quickly, by generalized itching and urticaria (hives). Erythema and sometimes **angioedema** (diffuse swelling) of the eyes, lips, or tongue occur next (Fig. 20-3). Intensely itchy skin wheals or hives may appear and sometimes merge to form large, red blotches.

FIG. 20-3 Angioedema of the face, lips, and mouth.

Histamine and other mediators cause inflammation, bronchoconstriction, mucosal edema, and excess mucus production. Respiratory symptoms

include congestion, rhinorrhea, dyspnea, and increasing respiratory distress with audible wheezing.

On auscultation, crackles, wheezing, and reduced breath sounds are heard. Patients may have laryngeal edema as a "lump in the throat," hoarseness, and stridor (a crowing sound). Distress increases as the tongue and larynx swell and more mucus is produced. Stridor increases as the airway begins to close. Increasing bronchoconstriction can lead to reduced chest movement and impaired airflow. Respiratory failure may follow from laryngeal edema, suffocation, or lower airway constriction causing hypoxemia (poor blood oxygenation).

The patient is usually hypotensive and has a rapid, weak, irregular pulse from extensive capillary leak and vasodilation. He or she is faint and diaphoretic with increasing anxiety and confusion.

Nursing Safety Priority QSEN

Critical Rescue

Immediately call the Rapid Response Team if you suspect anaphylaxis, because most anaphylactic deaths are related to treatment delay. If the patient is not treated immediately, he or she may lose consciousness. Dysrhythmias, shock, and cardiopulmonary arrest may occur within minutes as intravascular volume is lost and the heart becomes hypoxic.

Interventions

Assess respiratory function first. Emergency respiratory management is critical during an anaphylactic reaction, because the severity of the reaction increases with time. The upper airways and lower airways are affected by bronchoconstriction that quickly impairs airflow and leads to hypoxemic arrest. Immediately establish or stabilize the airway. If an IV drug is suspected to be causing the anaphylaxis, stop the drug immediately but do not remove the venous access because restarting an IV may be very difficult when the patient becomes severely hypotensive. Change the IV tubing and hang normal saline. Additional emergency interventions for patients with anaphylaxis are listed in Chart 20-3.

Chart 20-3 Best Practice for Patient Safety & Quality Care QSEN

Emergency Care of the Patient with Anaphylaxis

- Immediately assess the respiratory status, airway, and oxygen saturation of patients who show any symptom of an allergic reaction.
- Call the Rapid Response Team.
- Ensure that intubation and tracheotomy equipment is ready.
- Apply oxygen using a high-flow, non-rebreather mask at 90% to 100%.
- Immediately discontinue the IV drug or infusing solution of a patient having an anaphylactic reaction to that drug or solution. **Do not** discontinue the IV, but change the IV tubing and hang normal saline.
- If the patient does not have an IV, start one immediately and run normal saline.
- Be prepared to administer epinephrine IV (preferred) or IM.
  - Epinephrine 1 : 1000 concentration, 0.3 to 0.5 mL IV push or IM
  - Repeat drug administration as needed every 5 to 15 minutes until the patient responds
- Keep the head of the bed elevated about 10 degrees if hypotension is present; if blood pressure is normal, elevate the head of the bed to 45 degrees or higher to improve ventilation.
- Raise the feet and legs.
- Stay with the patient.
- Reassure the patient that the appropriate interventions are being instituted.

The patient with anaphylaxis is usually anxious or frightened and often expresses a sense of impending doom. Stay with the patient and reassure him or her that the appropriate interventions are being instituted.

Epinephrine (1 : 1000) 0.3 to 0.5 mL is the first-line drug for anaphylaxis. It is given IM or IV when manifestations appear (see Chart 20-3). This drug constricts blood vessels, improves cardiac contraction, and dilates the bronchioles. The same dose may be repeated every 5 to 15 minutes if needed (Vacca & McMahon-Bowen, 2013). Other drugs used to treat anaphylaxis are listed in Chart 20-4.

Chart 20-4 Common Examples of Drug Therapy

Anaphylaxis

DRUG	MECHANISM	SIDE EFFECTS
Sympathomimetics (First-Line Drugs)		
Epinephrine (Adrenalin)	Rapidly stimulates alpha- and beta-adrenergic receptors of autonomic nervous system (alpha: vasoconstriction; beta: bronchodilation).	Pallor, tachycardia and palpitations, nervousness, muscle twitching, sweating, anxiety, insomnia, hypertension, headache, hyperglycemia.
Isoproterenol (Isuprel)	Stimulates beta-adrenergic receptors, relaxing bronchial smooth muscles and dilating vessels.	Same as for epinephrine.
Ephedrine sulfate (Vatronol)	Similar to isoproterenol but with longer duration of action.	Same as for epinephrine.
Antihistamines (Second-Line Drugs)		
Diphenhydramine HCl (Allerdryl, Benadryl)	Competes with histamine for H_1 receptors on effector cells, thus blocking effects of histamine on bronchioles, gastrointestinal tract, and blood vessels.	Drowsiness, confusion, insomnia, headache, vertigo, photosensitivity, diplopia, nausea, vomiting, dry mouth.
Corticosteroids (Second-Line Drugs)		
Hydrocortisone sodium succinate (Solu-Cortef) (IV/IM) Dexamethasone (Decadron) (IV/IM) Methylprednisolone sodium succinate (Solu-Medrol) (IV/IM) Prednisone (orally)	Anti-inflammatory—inhibits production of many inflammatory mediators; inhibits mast cell degranulation.	Fluid and sodium retention, hypertension, cushingoid state, gastric distress, adrenal suppression, psychosis, osteoporosis, susceptibility to infection.
Vasopressors (Support Drugs)		
Norepinephrine (Levophed)	Raises blood pressure and cardiac output in severely decompensated states.	Headache, tachycardia, fibrillation, decreased urine output, hypertension, metabolic acidosis.
Dopamine (Intropin)	Raises blood pressure and cardiac output in severely decompensated states.	Dysrhythmias, tachycardia, hypertension, dyspnea, nausea and vomiting, azotemia, headache.

Nursing Safety Priority QSEN

Critical Rescue

Administer epinephrine as quickly as possible. Most deaths from anaphylaxis are related to delay in epinephrine administration.

Antihistamines such as diphenhydramine (Benadryl, Allerdryl) 25 to 100 mg are second-line drugs and are given IV or IM for angioedema and urticaria. If needed, an endotracheal tube may be inserted or an emergency tracheostomy may be performed.

If the patient can breathe independently, give oxygen to reduce hypoxemia. Start oxygen therapy via a high-flow non-rebreather facemask at 90% to 100% before arterial blood gas results are obtained. Monitor pulse oximetry to determine oxygenation adequacy. Arterial blood gases may be drawn to determine therapy effectiveness. Use suction to remove excess mucus and other secretions, if indicated. Continually assess the respiratory rate and depth, and assess breath sounds continually for bronchospasm, wheezing, crackles, and stridor. Elevate the bed to 45 degrees unless severe hypotension is present.

For bronchospasms, the patient may be given an inhaled beta-adrenergic agonist such as metaproterenol (Alupent) or albuterol (Proventil) via high-flow nebulizer every 2 to 4 hours. Corticosteroids are added to emergency interventions, but they are not effective

immediately. Oral steroids are continued (at lower doses) after the anaphylaxis is under control to prevent the late recurrence of manifestations.

Continually assess for changes in any body system or for adverse effects of drug therapy. For severe anaphylaxis, the patient is admitted to a critical care unit for cardiac, pulmonary arterial, and capillary wedge pressure monitoring. Observe the patient for fluid overload from the rapid drug and IV fluid infusions, and report changes to the health care provider immediately. The patient is discharged from the hospital when respiratory and cardiovascular systems have returned to baseline.

NCLEX Examination Challenge

Safe and Effective Care Environment

The client having an intravenous injection of radiocontrast material (dye) for an angiogram starts to have skin wheals at the injection site and difficulty breathing. What is the nurse's best first action?
A Administer oxygen by mask or nasal cannula.
B Stop the infusion of the contrast material.
C Prepare an injection of epinephrine.
D Notify the Rapid Response Team.

Latex Allergy

Latex allergy is a type I hypersensitivity reaction in which the specific allergen is a processed natural latex rubber protein. When the allergen enters the body through inhalation or direct contact with blood vessels (e.g., as might occur during surgery), interaction with IgE occurs, leading to a type I reaction and inflammation. For some people, latex allergen contact is limited to the skin or mucous membranes, causing contact dermatitis, a type IV hypersensitivity reaction (see p. 355). Others may have a "mixed" allergic response to latex, with symptoms of both type I and type IV hypersensitivities.

The incidence of latex hypersensitivity in the general population is increasing. People at greatest risk are those with a high exposure to natural latex products, such as patients with spina bifida, people who routinely use latex condoms, and health care workers who use latex gloves, especially gloves that are powdered (Wade, 2012).

Ask all patients about their use of and known reactions to natural latex products. Document all food allergies because some have cross-reactivity for latex allergy. In addition, consider your own exposure and risk for

reactions to natural latex products.

Avoiding products that contain natural latex proteins can prevent reactions and initial sensitivity. Most surgical gloves, tubing, and vial closures are now being made from synthetic substances that do not contain latex proteins. Interventions for the patient who has a type I or a type IV reaction to latex are the same as for reactions caused by other allergens.

Nursing Safety Priority QSEN

Action Alert

Use only latex-free products in the care of a patient with a known latex allergy.

NCLEX Examination Challenge

Safe and Effective Care Environment

With which client is it most important for the nurse to use latex-free gloves?

A 38-year-old woman taking oral contraceptives
B 68-year-old man with total hip replacement
C 38-year-old man allergic to shellfish and nuts
D 28-year-old woman with spina bifida

Type II: Cytotoxic Reactions

In a type II (cytotoxic) reaction, the body makes autoantibodies directed against self cells that have some form of foreign protein attached to them. The autoantibody binds to the self cell and forms an immune complex (see Fig. 17-10 on p. 283 in Chapter 17). The self cell is then destroyed along with the attached protein. Clinical examples of type II reactions include immune hemolytic anemias, immune thrombocytopenic purpura, hemolytic transfusion reactions (when a patient receives the wrong blood type during a transfusion), Goodpasture's syndrome, and drug-induced hemolytic anemia.

Management of type II reactions begins with discontinuing the offending drug or blood product. Plasmapheresis (filtration of the plasma to remove specific substances) to remove autoantibodies may be beneficial. Otherwise, treatment is symptomatic. Complications such as hemolytic crisis and kidney failure can be life threatening.

Type III: Immune Complex Reactions

In a type III reaction, excess antigens cause immune complexes to form in the blood (Fig. 20-4). These circulating complexes usually lodge in small blood vessel walls of the kidneys, skin, and joints. The complexes trigger inflammation, and tissue or vessel damage results.

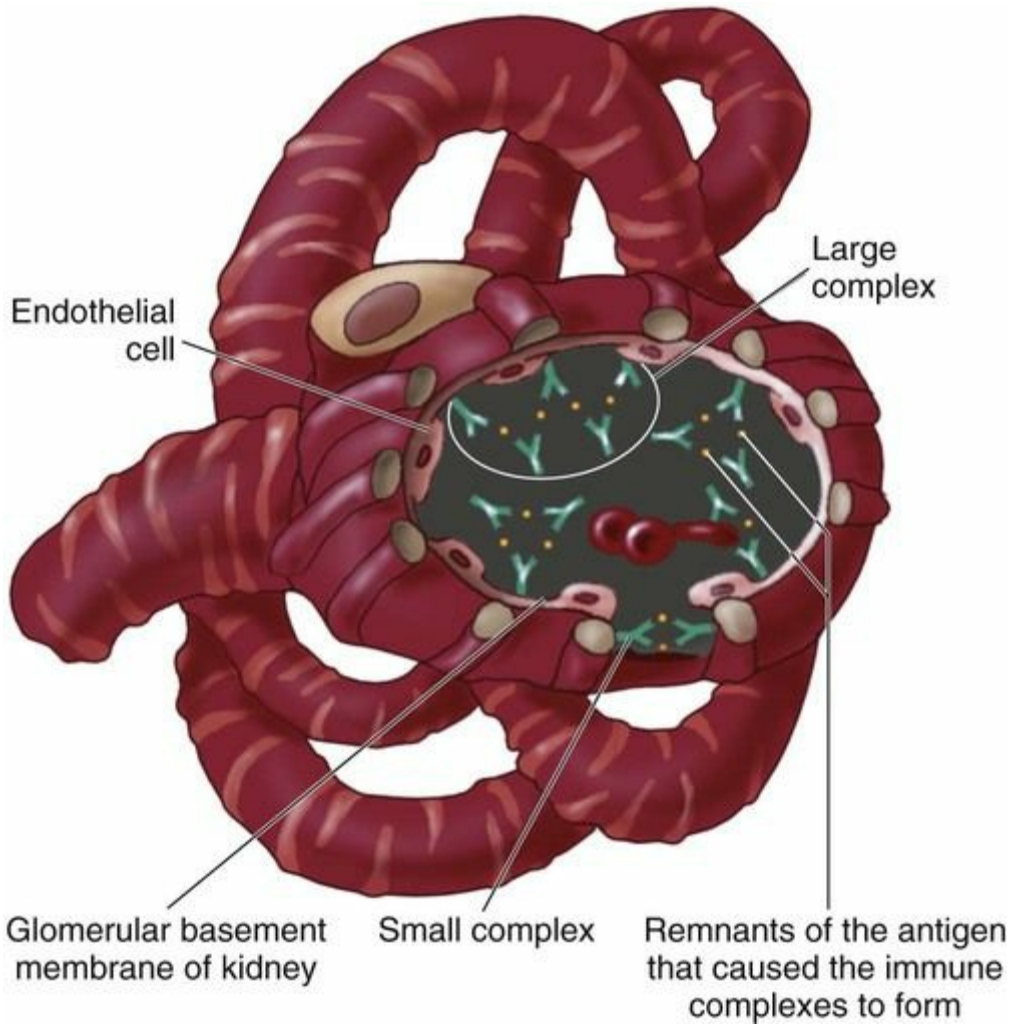

FIG. 20-4 An immune complex in a type III hypersensitivity reaction.

Many immune complex disorders (mostly connective tissue disorders) are caused by type III reactions. For example, the manifestations of rheumatoid arthritis are caused by immune complexes that lodge in joint spaces followed by tissue destruction, scarring, and fibrotic changes. Systemic lupus erythematosus (SLE) has immune complexes lodged in the vessels (vasculitis), the glomeruli (glomerulonephritis), the joints (arthralgia, arthritis), and other organs and tissues. (See Chapter 18 for a discussion of SLE.)

Serum sickness is a group of manifestations that occurs after receiving

serum or certain drugs. Immune complexes are deposited in blood vessel walls of the skin, joints, and kidneys. Common causes of serum sickness are penicillin, other antibiotics, and some animal serum–based drugs. Other agents known to cause serum sickness include antilymphocyte globulin and antithymocyte globulin, used to treat organ transplant rejection.

The patient with serum sickness has fever, arthralgia (achy joints), rash, malaise, lymphadenopathy (enlarged lymph nodes), and possibly polyarthritis and nephritis about 7 to 12 days after receiving the causative agent. Teach him or her about the possibility of serum sickness and what manifestations to look for whenever you give a foreign serum. Also keep emergency equipment and drugs close at hand in case he or she has an anaphylactic reaction.

Serum sickness is usually self-limiting, and manifestations subside after several days. Management is symptomatic; antihistamines are given for itching and aspirin for arthralgias. Prednisone is given if manifestations are severe.

Type IV: Delayed Hypersensitivity Reactions

In a type IV reaction, the reactive cell is the T-lymphocyte (T-cell). Antibodies and complement are not involved. Sensitized T-cells (from a previous exposure) respond to an antigen by releasing chemical mediators and triggering macrophages to destroy the antigen. A type IV response typically occurs hours to days after exposure. It consists of edema, induration, ischemia, and tissue damage at the site.

An example of a small type IV reaction is a positive purified protein derivative (PPD) test for tuberculosis (TB). In a patient previously exposed to TB, an intradermal injection of this agent causes sensitized T-cells to clump at the injection site, release lymphokines, and activate macrophages. Induration and erythema at the injection site appear after about 24 to 72 hours.

Other examples of type IV reactions include contact dermatitis, poison ivy skin rashes, local response to insect stings, tissue transplant rejections, and sarcoidosis.

Patch testing for type IV hypersensitivity involves applying test chemicals that contain the allergen(s) to which the patient has been exposed. The patches remain in place for 48 hours. After removal, the skin areas in contact with the chemical are examined for localized redness, swelling, and blisters.

Removal of the offending antigen is the major focus of management.

The reaction is self-limiting in 5 to 7 days, and the patient is treated symptomatically. Monitor the reaction site and sites distal to the reaction for circulation adequacy. Diphenhydramine (Benadryl) is not useful for type IV reactions because histamine is not the main mediator. Because IgE does not cause this type of reaction, desensitization does not reduce the response. Corticosteroids can reduce the discomfort and help resolve the reaction more quickly.

Autoimmunity

Autoimmunity is a process whereby a person develops an inappropriate immunity. In this response, antibodies or lymphocytes are directed against healthy normal cells and tissues. (Antibodies directed against self tissues or cells are known as **autoantibodies**.) For unknown reasons, the immune system fails to recognize certain body cells or tissues as self and thus triggers immune reactions. The responses, both antibody- and cell-mediated responses, are directed against normal body cells (McCance et al., 2014).

Examples of diseases that have an autoimmune cause include systemic lupus erythematosus (SLE), polyarteritis nodosa, scleroderma, rheumatoid arthritis, autoimmune hemolytic anemia, rheumatic fever, and Hashimoto's thyroiditis (Table 20-3). Other diseases, such as type 1 diabetes mellitus, may have multiple causes, one of which is autoimmune.

TABLE 20-3

Known or Probable Autoimmune Disorders

DISORDER	AUTOANTIGEN
Systemic or Non–Organ Specific	
Systemic lupus erythematosus	DNA, DNA proteins
Rheumatoid arthritis	IgG, possibly cartilage
Progressive systemic sclerosis	DNA proteins
Mixed connective tissue disorder	DNA proteins
Scleroderma	Endothelial cells; epithelial cells
Organ Specific	
Autoimmune hemolytic anemia	Erythrocytes
Autoimmune thrombocytopenic purpura	Platelets
Crohn's disease	Crypt epithelial cells
Diabetes mellitus, type I	Islet cells, insulin, insulin receptor
Dermatomyositis	Unknown
Glomerulonephritis	Glomerular basement membranes
Goodpasture's syndrome	Glomerular basement membranes, pulmonary basement membranes
Graves' disease	Thyroid-stimulating hormone receptor
Hashimoto's thyroiditis	Thyroid cell surface
Idiopathic Addison's disease	Adrenal cell
Myasthenia gravis	Acetylcholine receptor, acetylcholine
Pernicious anemia	Intrinsic factor, parietal cell, B_{12} complexes
Psoriasis	Stratum corneum
Reiter's syndrome	Possibly collagen, conjunctival cells
Sjögren's syndrome	Salivary gland cells, vaginal mucous cells, lacrimal gland cells
Uveitis	Uveal tract cells (eye)
Vasculitis	Unknown, possibly collagen or endothelial cells

IgG, Immunoglobulin G.

Management of autoimmunities depends on the organ or organs affected. *There is no cure.* Anti-inflammatory drugs and immunosuppressive drugs are commonly used along with symptomatic treatment to suppress the excess immunity.

Gender Health Considerations

Patient-Centered Care QSEN

Virtually all autoimmune disorders, especially rheumatic disorders, occur much more commonly among women than men (McCance et al., 2014). The risk for autoimmune disease among women compared with men ranges from 5 : 1 to 20 : 1.

Sjögren's Syndrome

Pathophysiology

Sjögren's syndrome (SS) is a group of problems that often appear with other autoimmune disorders. Problems include dry eyes, dry mucous membranes of the nose and mouth (xerostomia), and vaginal dryness. These problems are caused by autoimmune destruction (excess immunity) of the lacrimal, salivary, and vaginal mucus-producing glands. Often, the patient with SS also has rheumatoid arthritis or fibromyalgia.

Most patients with SS are women 35 to 45 years old. SS occurs more frequently among patients with certain tissue types, specifically HLA-DRW52, HLA-DR3, and HLA-B8. Although an exact triggering agent has not been identified, viral infection is strongly suspected, especially human immunodeficiency virus type 1 (HIV-1), human T-cell lymphotrophic virus type 1 (HTLV-1), and Epstein-Barr virus (EBV).

Insufficient tears cause inflammation and ulceration of the cornea. Insufficient saliva decreases digestion of carbohydrates, promotes tooth decay, and increases the risk for oral and nasal infections. Vaginal dryness increases the risk for infection and causes painful sexual intercourse.

Patient-Centered Collaborative Care

The patient with Sjögren's syndrome (SS) usually has blurred vision, burning and itching of the eyes, and thick mattering in the conjunctiva. Difficulty swallowing food is common, as are changes in taste. Ask about nosebleeds (**epistaxis**) and frequent upper respiratory infections (Catanzaro & Dinkel, 2014).

Examination reveals enlarged lymph nodes. If rheumatoid arthritis (RA) accompanies SS, the patient has swollen, painful joints and limited joint mobility (see Chapter 18 for a discussion of RA). Laboratory assessment may show increased amounts of general antinuclear antibodies, anti–SS-A or anti–SS-B antibodies, and elevated levels of IgM rheumatoid factor.

There is no cure for SS. The intensity and the progression of the disorder can be slowed by suppressing immunity and inflammation. Drugs used to modulate the immune system in patients with SS include low-dose chemotherapy with methotrexate (Rheumatrex) or cyclophosphamide (Cytoxan). Both drugs have serious long-term side effects, especially on liver and bone marrow function. Other immunosuppressive drugs used to manage SS are corticosteroids,

cyclosporine (Gengraf, Neoral, Sandimmune), and hydroxychloroquine (Plaquenil). The monoclonal antibody *rituximab* (Rituxan) has been beneficial for patients with severe inflammatory manifestations of SS (Poetzsch, 2012).

A variety of artificial tears and artificial saliva can help reduce the dry eye and dry mouth manifestations. Teach patients to use humidifiers in the home to increase environmental moisture. Use of water-soluble vaginal lubricants and moisturizers can increase patient comfort and reduce vaginitis. Some patients relieve dry mouth with drugs that increase salivation, such as systemic pilocarpine (Salagen). A drug that increase tears production is cyclosporine (Restasis) eyedrops.

Another intervention for dry eyes is to block the tear outflow channel with small plugs or close it surgically. Then, tears produced remain in contact with the eye longer.

Clinical Judgment Challenge

Patient-Centered Care; Evidence-Based Practice QSEN

The patient is a 49-year-old secretary who has just been diagnosed with Sjögren's syndrome (SS) when her health care provider investigated possible causes for her sudden increase in dental caries (15 in 1 year). Upon hearing about the possible dry eyes and vaginal dryness that often accompany SS, she tells you that she has noticed the dry eyes and thought it was just "old age" catching up with her. She also says that she has noticed some vaginal dryness but is not concerned about it because she is not sexually active. She then tells you that she feels bad about this diagnosis because it means that she probably has a poor immune system and is at a greater risk for infections and cancer.

1. Is she correct about her assessment of her immune function? Why or why not?
2. What should you tell her about the vaginal dryness even though she is not concerned?
3. In addition to follow-up by her primary health care provider for the SS, what other health promotion activities would be important for her?

Goodpasture's Syndrome

Pathophysiology

Goodpasture's syndrome is an autoimmune disorder in which autoantibodies attack the glomerular basement membrane and

neutrophils. The two organs with the most damage are the lungs and the kidneys. A person with the disorder may have lung and/or kidney problems. Lung damage is manifested as pulmonary hemorrhage. Kidney damage shows as glomerulonephritis that may rapidly progress to complete kidney failure (see Chapters 67 and 68). Goodpasture's syndrome is most common in adolescent males or young men (McCance et al., 2014).

Patient-Centered Collaborative Care

Goodpasture's syndrome often is not diagnosed until serious lung or kidney problems are present. Manifestations include shortness of breath, hemoptysis (bloody sputum), decreased urine output, weight gain, generalized edema, hypertension, and tachycardia. Chest x-rays show areas of consolidation. The most common cause of death is uremia as a result of kidney failure.

Spontaneous resolution of Goodpasture's syndrome has occurred but is rare. Interventions focus on reducing damage from excess immunity and performing some type of renal replacement therapy.

Drug therapy is the mainstay of treatment for Goodpasture's syndrome. High-dose corticosteroids are most often used. Other drug therapy to suppress the autoimmune response is the same as that for Sjögren's syndrome (SS).

Additional therapy to reduce the excessive immunity involves plasmapheresis (filtration of the plasma to remove some proteins) to remove the autoantibodies. If the lungs and kidneys do not have permanent damage, patients undergoing plasmapheresis have shown clinical improvement. Some patients using plasmapheresis need infusions of intravenous immunoglobulin (IVIG) to maintain antibody protection against infection.

Depending on the level of kidney function remaining, the patient may need ongoing renal replacement therapy. Peritoneal dialysis or hemodialysis may be used, depending on the patient's health status, ability to self-manage the therapy, and lifestyle (see Chapter 68).

Kidney transplantation is an option for some patients with Goodpasture's syndrome. After transplantation, kidney function is normal and a few patients have been completely disease-free. In others, the kidney problems are improved but the lung destruction continues. Some of the drugs used to prevent kidney rejection also suppress the autoimmune response.

What might you NOTICE if the patient is experiencing excess immunity and loss of protective response in the form of a severe allergic reaction?

- Possible skin rash, blisters, wheals, especially on the skin at the IV site
- Swelling of the face, lips, tongue (angioedema)
- Difficulty breathing, hoarseness, stridor, wheezing
- Cyanosis
- Increasing anxiety

What should you INTERPRET and how should you RESPOND to a patient experiencing excess immunity and loss of protection as a result of a severe allergic reaction?

Perform and interpret physical assessment, including:

- Taking vital signs, especially respiratory rate and depth and blood pressure
- Auscultating all lung fields
- Monitoring oxygen saturation by pulse oximetry
- Assessing cognition
- Assessing for the use of accessory muscles
- Assessing for the presence of thick or excessive secretions
- Assessing the patient's ability to cough and clear the airway

Respond by:

- Removing or discontinuing the offending agent
- Ensuring a patent airway
- Notifying the Rapid Response Team
- Applying oxygen, and assessing the patient's responses to this intervention
- Maintaining IV access, changing IV tubing, hanging normal saline
- Keeping the patient's head elevated between 10 and 45 degrees
- Preparing to administer IV diphenhydramine and epinephrine
- Staying with the patient

On what should you REFLECT?

- Observe patient for evidence of drug therapy and oxygen therapy effectiveness (adequate tissue perfusion and oxygenation [see Chapter 27]).
- Think about what may have precipitated this episode and what steps could be taken to either prevent a similar episode or identify it earlier.
- Think about what additional resources could improve the nursing

response to this situation.

Get Ready for the NCLEX® Examination!

Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Ensure that only latex-free products are used for a patient who has a known latex allergy. **Safety** QSEN
- Verify that all allergies are documented in a prominent place in the patient's medical record.
- Keep emergency equipment and drugs (epinephrine, Benadryl, cortisol) in or near the room of a patient with known severe allergies or a history of anaphylaxis. **Safety** QSEN

Health Promotion and Maintenance

- Urge all patients with severe allergies or those who have a history of anaphylaxis to wear a medical alert bracelet.
- Teach the patient and family about the manifestations of allergic reactions and when to seek medical help. **Patient-Centered Care** QSEN
- Teach the patient who has a known drug allergy about which other drugs are likely to stimulate the same reactions. **Patient-Centered Care** QSEN
- Teach the patient who carries an automatic epinephrine injector how to care for, assemble, and use the device. Obtain a return demonstration. **Patient-Centered Care** QSEN

Psychosocial Integrity

- Explain all diagnostic procedures, restrictions, and follow-up care to the patient scheduled for tests related to hypersensitivities.
- Stay with the patient in anaphylaxis.
- Reassure patients who are in anaphylaxis that the appropriate interventions are being instituted.

Physiological Integrity

- Identify patients at risk for hypersensitivity reactions, especially anaphylaxis. **Safety** QSEN
- Communicate a patient's allergies to all members of the health care team.
- Immediately assess the respiratory status and airway of patients who

show any manifestations of an allergic reaction. **Evidence-Based Practice** QSEN

- Immediately discontinue the IV drug or solution of a patient having an anaphylactic reaction to that drug or solution. **Do not** discontinue the IV, but change the IV tubing and hang normal saline. **Evidence-Based Practice** QSEN
- Hold the dose of any prescribed drug when a patient develops angioedema. **Safety** QSEN
- Give oxygen to any patient in anaphylaxis.

CHAPTER 21

Cancer Development

M. Linda Workman

PRIORITY CONCEPTS

- Cellular Regulation

Learning Outcomes

Health Promotion and Maintenance

1. Help people identify behaviors that reduce the risk for cancer development and cancer death.
2. Teach the recommended screening practices and schedules for specific cancer types.

Physiological Integrity

3. Explain why causes of specific cancers can be hard to establish.
4. Use knowledge of basic biology to understand how normal cells can lose cellular regulation and become malignant.
5. Distinguish the features of normal cells from those of benign tumors and cancer cells.
6. Discuss the roles of oncogenes and suppressor genes in cancer development.
7. Compare the cancer development processes of initiation and promotion.
8. Interpret cancer grading, ploidy, and staging reports.
9. Explain how cancer metastasis occurs and the expected sites of distant metastasis for common cancers.
10. Discuss the role of immunity in protection against cancer.
11. Assess the individual patient's need for genetic testing for cancer predisposition based on family history.

http://evolve.elsevier.com/Iggy/

Abnormal cell growth includes moles or skin tags, which are **benign** (harmless) and do not require intervention, as well as **malignant cell growth** (cancer). Cancer is serious and without intervention leads to death. It is a common health problem in the United States and Canada. Over 1.8 million people are newly diagnosed with cancer each year (American Cancer Society [ACS], 2014; Canadian Cancer Society, 2014). Some types of cancer can be prevented; others have better cure rates if diagnosed early. As a nurse, you can have a vital impact in educating the public about cancer prevention and early detection methods.

Although cancer is common today, it is not a new disorder. Some types of cancer are more common today, especially among more affluent societies, than in centuries past. Two reasons for this increase are the longer life expectancy of people in more affluent countries and increased exposure to substances that cause cancer.

Cancer will occur in about 1 of every 3 people currently living in North America (ACS, 2014; Canadian Cancer Society, 2014), although cancer risk differs for each person. More than 13 million Americans with a history of cancer are alive today (ACS, 2014).

Pathophysiology

During infancy and childhood, growth of cells and tissues is normal, and many body cells continue to "grow" by **mitosis** (cell division) long after maturation is complete. Such cells are located in tissues in which constant damage or wear is likely and continued cell growth is needed to replace dead tissues. Cells of the skin, hair, mucous membranes, bone marrow, and linings of organs such as the lungs, stomach, intestines, bladder, and uterus, among others have the ability to divide throughout a person's life span. The growth is well controlled through cellular regulation, ensuring that the right number of cells is always present in any tissue or organ.

Some tissues and organs stop growing by cell division after development is complete. For example, heart muscle cells no longer divide after fetal life; the number of heart muscle cells is fixed at birth. The size of the heart increases as the person grows because each cell gets larger, but the number of heart muscle cells does not increase. Growth that causes tissue to increase in size by enlarging each cell is **hypertrophy**. Growth that causes tissue to increase in size by increasing the number of cells is **hyperplasia** (Fig. 21-1).

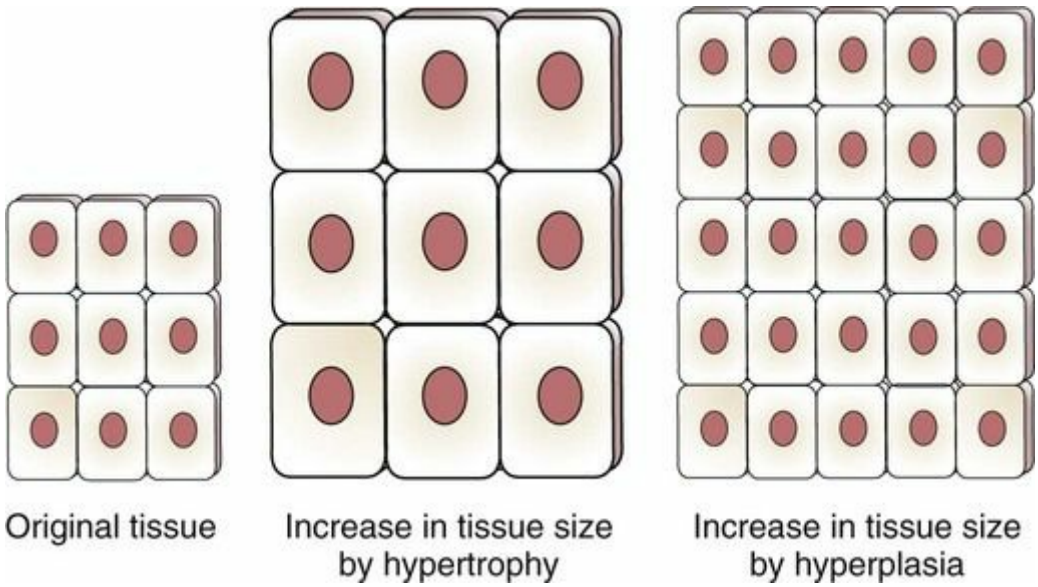

FIG. 21-1 Tissue growth by hypertrophy and hyperplasia.

Any new or continued cell growth not needed for normal development or replacement of dead and damaged tissues is called **neoplasia**. This cell growth is always abnormal even if it causes no harm. Whether the new cells are benign or cancerous, neoplastic cells develop from normal cells *(parent cells).* Thus cancer cells were once normal cells but underwent

genetic mutations to no longer look, grow, or function normally. The strict processes controlling normal growth and function, cellular regulation, have been lost (Beery & Workman, 2012). To understand how cancer cells grow, it is helpful to first understand the regulation and function of normal cells.

Biology of Normal Cells

Many different normal cells work together to make the whole person function at an optimal level. For optimal function, each cell must perform in a predictable manner.

Specific morphology is the feature in which each normal cell type has a distinct and recognizable appearance, size, and shape, as shown in Fig. 21-2.

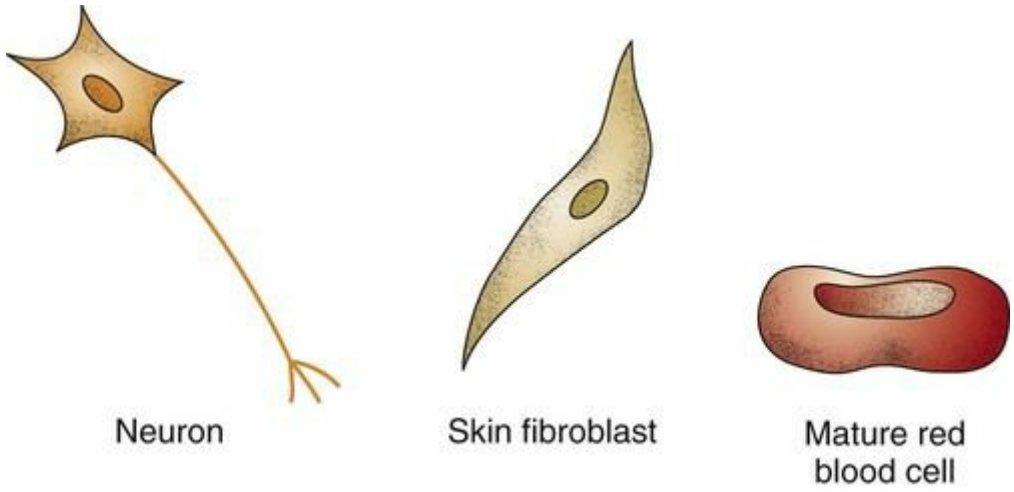

FIG. 21-2 Distinctive morphology of some normal cells.

A smaller nuclear-to-cytoplasmic ratio means that the nucleus of a normal cell does not take up much space inside the cell. As shown in Fig. 21-2, the size of the normal cell nucleus is relatively small compared with the size of the rest of the cell, including the cytoplasm.

Differentiated function means that every normal cell has at least one function it performs to contribute to whole-body function. For example, skin cells make keratin, liver cells make bile, cardiac muscle cells contract, and red blood cells make hemoglobin.

Tight adherence occurs because normal cells make proteins that protrude from the membranes, allowing cells to bind closely and tightly together. One such protein is fibronectin, which keeps most normal tissues bound tightly to each other. Exceptions are blood cells. Red blood cells and white blood cells produce no fibronectin and do not

usually adhere together.

Nonmigratory means that normal cells do not wander throughout the body (except for blood cells). This occurs in normal cells because they are tightly bound together, which prevents cell wandering from one tissue into the next.

Orderly and well-regulated growth or cellular regulation is a very important feature of normal cells. They divide (undergo mitosis) for only two reasons: (1) to develop normal tissue or (2) to replace lost or damaged normal tissue. Even when they are capable of mitosis, normal cells divide only when body conditions are just right. Cell division **(mitosis)**, occurring in a well-recognized pattern, is described by the cell cycle. Fig. 21-3 shows the phases of the cell cycle. Living cells not actively reproducing are in a reproductive resting state termed G_0. During the G_0 period, cells actively carry out their functions but do not divide. Normal cells spend most of their lives in the G_0 state rather than in a reproductive state.

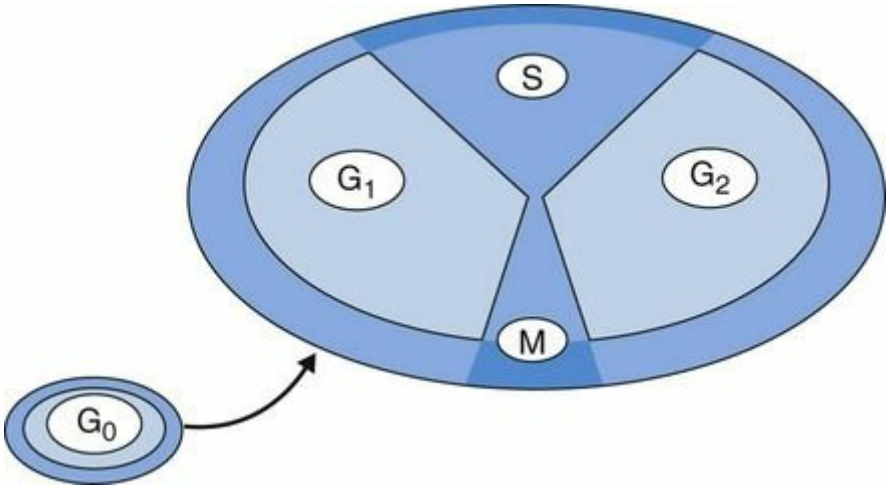

FIG. 21-3 The cell cycle.

Mitosis makes one cell divide into two new cells that are identical to each other and to the cell that began mitosis. The steps of entering and completing the cell cycle are tightly controlled. This cellular regulation occurs through proteins produced by "suppressor genes."

Whether a cell enters and completes the cell cycle to form two new cells depends on the presence and absence of specific cellular regulation proteins. Proteins that promote cells to enter and complete cell division are produced by oncogenes and are known as *cyclins*. When cyclins are activated, they allow a cell to leave G_0 and enter the cycle. These activated cyclins then drive the cell to progress through the different phases of the

cell cycle and divide. Proteins produced by suppressor genes control the amount of cyclins present and ensure that cell division occurs only when it is needed. *Thus cellular regulation of division is a balance between the proteins that promote cell division (cyclins) and the proteins that limit cell division (suppressor gene products).*

Fig. 21-4 shows the activities of the phases of the cell cycle (described below):

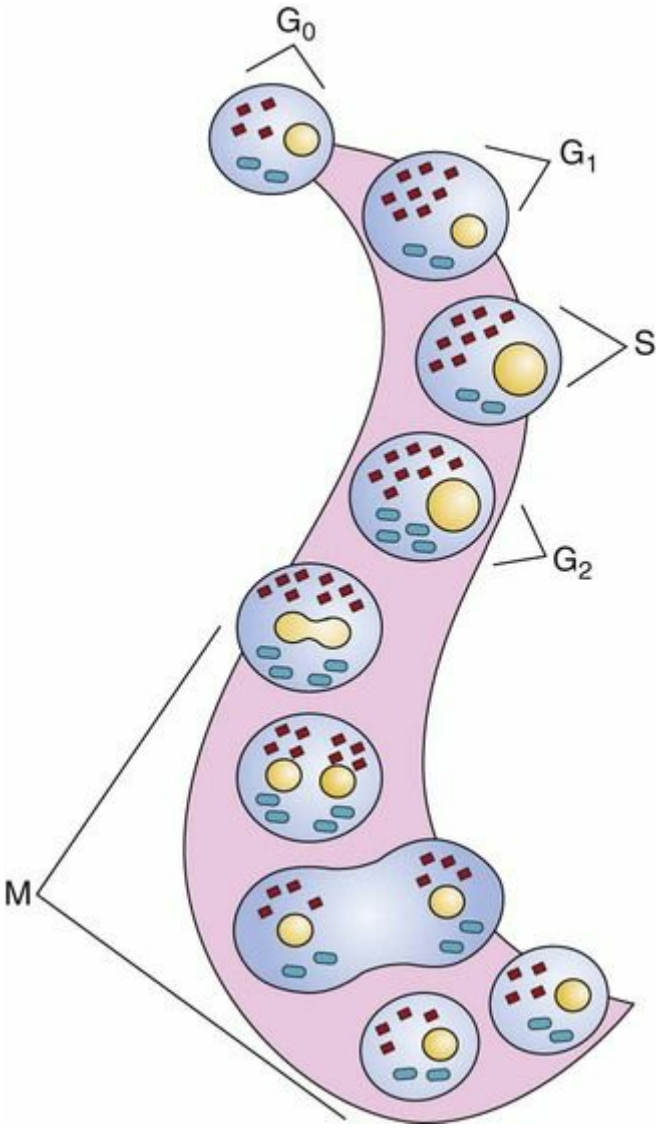

FIG. 21-4 Cellular events during mitotic cell division.

- **G_1.** In this phase, the cell is getting ready for division by taking on extra nutrients, making more energy, and growing extra membrane. The amount of cytoplasm also increases.
- **S.** Because making one cell into two cells requires twice as much of everything, including DNA, the cell must double its DNA content through DNA synthesis. This process occurs in S phase.

- **G_2.** In this phase, the cell makes important proteins that will be used in actual cell division and in normal physiologic function after cell division is complete.
- **M.** The single cell splits apart into two cells (actual mitosis) during M phase.

Contact inhibition is cellular regulation that stops further rounds of cell division when the dividing cell is completely surrounded and touched (contacted) by other cells. Of the normal cells that can divide, each cell divides only when some of its surface is not in direct contact with another cell. Once a normal cell is in direct contact on all surface areas with other cells, it no longer undergoes mitosis. Thus normal cell division is contact inhibited.

Apoptosis is programmed cell death. Not only do normal cells have to divide only when needed and perform their specific differentiated functions, to ensure optimum body function, some cells also have to die at the appropriate time. Thus normal cells have a finite life span. With each cell division, the telomeric DNA at the ends of the cell's chromosomes shortens (see Chapter 4). When this DNA is gone, the cell responds to cellular regulation signals for apoptosis. This ensures that each organ has an adequate number of cells at their functional peak.

Normal chromosomes (known as **euploidy**) is a feature of most normal human cells. These cells have 23 pairs of chromosomes, the correct number for humans.

Biology of Abnormal Cells

Body cells are exposed to a variety of conditions that can alter how the cells grow or function. When either cell growth or cell function is changed, the cells are considered abnormal. Table 21-1 compares features of normal, benign tumor, and cancer (malignant) cells.

TABLE 21-1

Characteristics of Normal and Abnormal Cells

CHARACTERISTIC	NORMAL CELL	BENIGN TUMOR CELL	MALIGNANT CELL
Cell division	None or slow	Continuous or inappropriate	Rapid or continuous
Appearance	Specific morphologic features	Specific morphologic features	Anaplastic
Nuclear-to-cytoplasmic ratio	Smaller	Smaller	Larger
Differentiated functions	Many	Many	Some or none
Adherence	Tight	Tight	Loose
Migratory	No	No	Yes
Growth	Well regulated	Expansion	Invasion
Chromosomes	Diploid (euploid)	Diploid (euploid)	Aneuploid*
Mitotic index	Low	Low	High*

*Depends on the degree of malignant transformation.

Features of Benign Tumor Cells

Benign tumor cells are normal cells growing in the wrong place or at the wrong time as a result of a small problem with cellular regulation. Examples include moles, uterine fibroid tumors, skin tags, endometriosis, and nasal polyps. Benign tumor cells have these characteristics:

- *Specific morphology* occurs with benign tumors. They look like the tissues they come from, retaining the specific morphology of parent cells.
- *A smaller nuclear-to-cytoplasmic ratio* is a feature of benign tumors just like completely normal cells.
- *Specific differentiated functions* continue to be performed by benign tumors. For example, in endometriosis, a type of benign tumor, the normal lining of the uterus (endometrium) grows in an abnormal place (e.g., on an ovary or in the chest cavity). This displaced endometrium acts just like normal endometrium by changing each month under the influence of estrogen. When the hormone level drops and the normal endometrium sheds from the uterus, the displaced endometrium, wherever it is, also sheds.
- *Tight adherence* of benign tumor cells to each other occurs because they continue to make fibronectin.
- *No migration* or wandering of benign tissues occurs because they remain tightly bound and do not invade other body tissues.
- *Orderly growth* with normal growth patterns occurs in benign tumor cells even though their growth is not needed. The fact that growth continues beyond an appropriate time or occurs in the wrong place

indicates some problem with cellular regulation, but the rate of growth is normal. The benign tumor grows by hyperplastic expansion. *It does not invade.*

- *Normal chromosomes* are usually found in benign tumor cells, with a few exceptions. Most of these cells have 23 pairs of chromosomes, the correct number for humans.

Features of Cancer Cells

Cancer **(malignant)** cells are abnormal, serve no useful function, and are harmful to normal body tissues. Cancers commonly have these features:

- *Anaplasia* is the cancer cells' loss of the specific appearance of their parent cells. As a cancer cell becomes more malignant, it becomes smaller and rounded. Thus many different types of cancer cells look alike under the microscope.
- *A larger nuclear-cytoplasmic ratio* occurs because the cancer cell nucleus is larger than that of a normal cell and the cancer cell is smaller than a normal cell. The nucleus occupies much of the space within the cancer cell, creating a larger nuclear-to-cytoplasmic ratio.
- *Specific functions are lost* partially or completely in cancer cells. *Cancer cells serve no useful purpose.*
- *Loose adherence* is typical for cancer cells because they do not make fibronectin. As a result, cancer cells easily break off from the main tumor.
- *Migration* occurs because cancer cells do not bind tightly together and have many enzymes on their cell surfaces. These features allow the cells to slip through blood vessel walls and between tissues, spreading from the main tumor site to many other body sites. The ability to spread **(metastasize)** is unique to cancer cells and a major cause of death. Cancer cells invade other tissues, both close by and more remote from the original tumor. Invasion and persistent growth make untreated cancer deadly.
- *Contact inhibition does not occur* in cancer cells because of lost cellular regulation, even when all sides of these cells are in continuous contact with the surfaces of other cells. This persistence of cell division makes the disease difficult to control.
- *Rapid or continuous cell division* occurs in many types of cancer cells because they re-enter the cell cycle for mitosis almost continuously because cellular regulation is lost. These cells also do not respond to signals for apoptosis. Most cancer cells have a lot of the enzyme *telomerase,* which maintains telomeric DNA. As a result, cancer cells do not

respond to apoptotic signals and have an unlimited life span (are "immortal").

- *Abnormal chromosomes* **(aneuploidy)** are common in cancer cells as they become more malignant. Chromosomes are lost, gained, or broken; thus cancer cells can have more than 23 pairs or fewer than 23 pairs. Cancer cells also may have broken and rearranged chromosomes.

Cancer Development

Carcinogenesis/Oncogenesis

Carcinogenesis and **oncogenesis** are other names for cancer development. The process of changing a normal cell into a cancer cell is called **malignant transformation**, occurring through loss of cellular regulation leading to the steps of initiation, promotion, progression, and metastasis (Beery & Workman, 2012).

Initiation is the first step in carcinogenesis. Normal cells can become cancer cells if they lose cellular regulation by having their genes promoting cell division, **oncogenes**, turn on excessively (overexpressed). Initiation is a change in gene expression caused by anything that can penetrate a cell, get into the nucleus, and mutate the DNA, leading to loss of cellular regulation. Such changes can activate oncogenes that should have only limited expression and can damage suppressor genes, which normally limit oncogene activity. Thus initiation leads to excessive cell division through DNA damage that results in loss of cellular regulation by either loss of suppressor gene function or enhancement of oncogene function.

Initiation is an irreversible event that can lead to cancer development. After initiation, a cell can become a cancer cell if the cellular regulation loss that occurred during initiation continues. *If growth conditions are right, widespread metastatic disease can develop from just one cancer cell.*

Substances that change the activity of a cell's genes so that the cell becomes a cancer cell are **carcinogens**. Carcinogens may be chemicals, physical agents, or viruses. More than 100 agents, substances, mixtures, and exposures are known or reasonably anticipated to cause cancer in humans, and about another 200 are suspected to be carcinogens. The National Toxicology Program's website (http://ntp.niehs.nih.gov/) lists these substances (U.S. Department of Health and Human Services [USDHHS], 2011). Chapters presenting the care of patients with specific cancers discuss specific known carcinogens within the Etiology sections.

Promotion is the enhanced growth of an initiated cell by substances known as **promoters**. Once a normal cell has been initiated by a carcinogen and is a cancer cell, it can become a tumor if its growth is enhanced. Many normal hormones and body proteins, like insulin and estrogen, can act as promoters and make cells divide more frequently. The time between a cell's initiation and the development of an overt tumor is called the **latency period**, which can range from months to years. Exposure to promoters can shorten the latency period.

Progression is the continued change of a cancer, making it more malignant over time. After cancer cells have grown to the point that a

detectable tumor is formed (a 1-cm tumor has at least 1 billion cells in it), other events must occur for this tumor to become a health problem. First, the tumor must develop its own blood supply. The tumor makes vascular endothelial growth factor (VEGF) that triggers nearby capillaries to grow new branches into the tumor, ensuring the tumor's continued nourishment and growth.

As tumor cells continue to divide, some of the new cells change features from the original, initiated cancer cell and form different groups. Some of the differences provide these cell groups with advantages *(selection advantages)* that allow them to live and divide no matter how the conditions around them change. These tumor changes may allow it to become more malignant. Over time, the tumor cells have fewer and fewer normal cell features.

The original tumor is called the **primary tumor**. It is usually identified by the tissue from which it arose *(parent tissue),* such as in breast cancer or lung cancer. When primary tumors are located in vital organs, such as the brain or lungs, they can grow and either lethally damage the vital organ or interfere with that organ's ability to perform its vital function. At other times, the primary tumor is located in soft tissue that can expand without damage as the tumor grows. One such site is the breast. The breast is not a vital organ, and even with a large tumor, the primary tumor alone would not cause the patient's death. When the tumor spreads from the original site into vital areas, life functions can be disrupted and death may follow.

Metastasis occurs when cancer cells move from the primary location by breaking off from the original group and establishing remote colonies. These additional tumors are called **metastatic** or **secondary tumors**. *Even though the tumor is now in another organ, it is still a cancer from the original altered tissue. For example, when breast cancer spreads to the lung and the bone, it is still breast cancer in the lung and bone—not lung cancer and not bone cancer.* Metastasis occurs through many steps, as shown in Fig. 21-5.

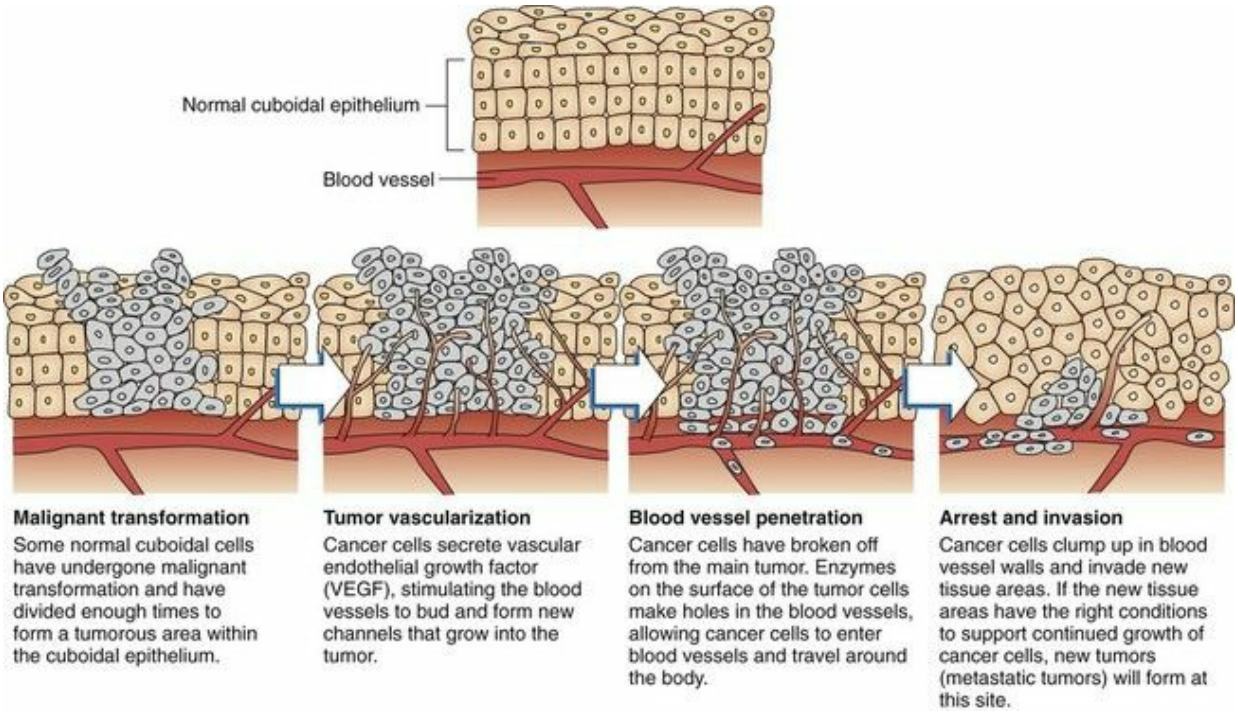

FIG. 21-5 The steps of metastasis.

Tumors first extend into surrounding tissues by secreting enzymes that open up areas of surrounding tissue. Pressure, created as the tumor increases in size, forces tumor cells to invade new territory.

Spread to distant organs and tissues requires cancer cells to penetrate blood vessels. **Bloodborne metastasis** (tumor cell release into the blood) is the most common cause of cancer spread. Enzymes secreted by tumor cells also make large pores in the patient's blood vessels, allowing tumor cells to enter the blood and circulate. Because tumor cells are loosely held together, clumps of cells break off of the primary tumor into blood vessels for transport.

Tumor cells circulate through the blood and enter tissues at remote sites. Clumps of cancer cells can become trapped in capillaries. These clumps damage the capillary wall and allow cancer cells to leave the capillary and enter the surrounding tissue.

When conditions in the remote site can support tumor cell growth, the cells stop circulating (arrest) and invade the surrounding tissues, creating secondary tumors. Table 21-2 lists the common sites of metastasis for specific tumor types.

TABLE 21-2

Common Sites of Metastasis for Different Cancer Types

Breast Cancer
Bone* Lung* Liver Brain
Lung Cancer
Brain* Bone Liver Lymph nodes Pancreas
Colorectal Cancer
Liver* Lymph nodes Adjacent structures
Prostate Cancer
Bone (especially spine and legs)* Pelvic nodes
Melanoma
GI tract Lymph nodes Lung Brain
Primary Brain Cancer
Central nervous system

*Most common site of metastasis for the specific malignant neoplasm.

Another way cancers metastasize is by *lymphatic spread*. Lymphatic spread is related to the number, structure, and location of lymph nodes and vessels. Primary sites that are rich in lymphatics have more early metastatic spread than areas with few lymphatics.

Cancer Classification

Cancers are classified by the type of tissue from which they arise (e.g., glandular, connective) (McCance et al., 2014), as described in Table 21-3. Other ways to classify cancer include biologic behavior, anatomic site, and degree of differentiation.

TABLE 21-3

Classification of Tumors By Tissue of Origin

PREFIX	TISSUE OF ORIGIN	BENIGN TUMOR	MALIGNANT TUMOR*
Adeno	Epithelial glands	Adenoma	Adenocarcinoma
Chondro	Cartilage	Chondroma	Chondrosarcoma
Fibro	Fibrous connective	Fibroma	Fibrosarcoma
Glio	Glial cells (brain)	Glioma	Glioblastoma
Hemangio	Blood vessel	Hemangioma	Hemangiosarcoma
Hepato	Liver	Hepatoma	Hepatocarcinoma
			Hepatoblastoma
Leiomyo	Smooth muscle	Leiomyoma	Leiomyosarcoma
Lipo	Fat/adipose	Lipoma	Liposarcoma
Lympho	Lymphoid tissues		Malignant lymphomas Hodgkin's lymphoma Non-Hodgkin's lymphoma Burkitt's lymphoma Cutaneous T-cell
Melano	Pigment-producing skin		Melanoma
Meningioma	Meninges	Meningioma	Malignant meningioma
			Meningioblastoma
Neuro	Nerve tissue	Neuroma Neurofibroma	Neurosarcoma Neuroblastoma
Osteo	Bone	Osteoma	Osteosarcoma
Renal	Kidney		Renal cell carcinoma
Rhabdo	Skeletal muscle	Rhabdomyoma	Rhabdomyosarcoma
Squamous	Epithelial layer of skin, mucous membranes, and organ linings	Papilloma	Squamous cell carcinoma of skin, bladder, lungs, cervix

*Carcinomas are tumors of glandular tissue; sarcomas are tumors of connective tissue; blastomas are tumors of less differentiated, embryonal tissues.

About 100 different types of cancer arise from various tissues or organs. Fig. 21-6 compares cancer distribution by site and gender. Cancers are either solid or hematologic. Solid tumors develop from specific tissues (e.g., breast cancer and lung cancer). Hematologic cancers arise from blood cell–forming tissues (e.g., leukemias and lymphomas).

(Data from American Cancer Society, 2014 and Canadian Cancer Statistics, 2014.)

Cancer Grading, Ploidy, and Staging

Systems of grading and staging have been developed to help standardize cancer diagnosis, prognosis, and treatment. **Grading** of a tumor classifies cellular aspects of the cancer. **Ploidy** classifies tumor chromosomes as normal or abnormal. **Staging** classifies clinical aspects of the cancer.

Grading is needed because some cancer cells are "more malignant" than others, varying in their aggressiveness and sensitivity to treatment. Some cancer cells barely resemble the tissue from which they arose, are aggressive, and spread rapidly. These cells are a "high-grade" cancer. On the basis of cell appearance and activity, grading compares the cancer cell with the normal parent tissue from which it arose. It is a means of evaluating the patient with cancer for prognosis and appropriate therapy. Grading also allows health care professionals to evaluate the results of management.

Different clinical groups have established different grading systems for different types of cancer cells, but overall, they resemble the standard

system listed in Table 21-4. This system rates cancer cells with the lowest rating given to those cells that closely resemble normal cells and the highest rating given to cancer cells that barely resemble normal cells. Grading systems for different cancers are presented in the clinical chapters in which care is discussed.

TABLE 21-4

Grading of Malignant Tumors

GRADE	CELLULAR CHARACTERISTICS
G_x	Grade cannot be determined.
G_1	Tumor cells are well differentiated and closely resemble the normal cells from which they arose.
	This grade is considered a low grade of malignant change.
	These tumors are malignant but are relatively slow growing.
G_2	Tumor cells are moderately differentiated; they still retain some of the characteristics of normal cells but also have more malignant characteristics than do G_1 tumor cells.
G_3	Tumor cells are poorly differentiated, but the tissue of origin can usually be established.
	The cells have few normal cell characteristics.
G_4	Tumor cells are poorly differentiated and retain no normal cell characteristics.
	Determination of the tissue of origin is difficult and perhaps impossible.

Ploidy is the description of cancer cells by chromosome number and appearance. Normal human cells have 46 chromosomes (23 pairs), the normal diploid number **(euploidy)**. When malignant transformation occurs, changes in the genes and chromosomes also occur. Some cancer cells gain or lose whole chromosomes and may have structural abnormalities of the remaining chromosomes, a condition called **aneuploidy**. The degree of aneuploidy usually increases with the degree of malignancy. Some specific chromosome changes are associated with specific cancers, and their presence is used for diagnosis and prognosis. One example is the "Philadelphia" chromosome abnormality often present in chronic myelogenous leukemia cells (see Chapter 40).

Staging determines the exact location of the cancer and its degree of metastasis at diagnosis. Cancer stage influences selection of therapy. Staging is done by clinical staging, surgical staging, and pathologic staging. *Clinical staging* assesses the patient's clinical manifestations and evaluates them for tumor size and possible spread. *Surgical staging* assesses the tumor size, number, sites, and spread by inspection at surgery. *Pathologic staging* is the most definitive type, determining the tumor size, number, sites, and spread by pathologic examination of tissues obtained at surgery.

The **tumor, node, metastasis (TNM)** system is used to describe the anatomic extent of cancers. The TNM staging systems have specific prognostic value for each solid tumor type. Table 21-5 shows a basic TNM

staging system. TNM staging is not useful for leukemia or lymphomas (see Chapter 40). Additional specific staging systems include Dukes' staging of colon and rectal cancer and Clark's levels method of staging skin cancer.

TABLE 21-5

Staging of Cancer—TNM Classification

Primary Tumor (T)	
T_x	Primary tumor cannot be assessed
T_0	No evidence of primary tumor
T_{is}	Carcinoma in situ
T_1, T_2, T_3, T_4	Increasing size and/or local extent of the primary tumor
Regional Lymph Nodes (N)	
N_x	Regional lymph nodes cannot be assessed
N_0	No regional lymph node metastasis
