The stress of severe sepsis can cause adrenal insufficiency. Adrenal support may involve providing the patient with low-dose corticosteroids during the treatment period. Drugs used for this purpose are IV hydrocortisone and oral fludrocortisone (Florinef).

Patients with sepsis or septic shock usually have elevated blood glucose levels (>180 mg/dL), which is associated with a poor outcome. Insulin therapy is used to maintain blood glucose levels between 110 mg/dL and 150 mg/dL. Keeping the blood glucose level below

110 mg/dL is associated with increased mortality.

During severe sepsis, patients have microvascular abnormalities and form many small clots. Heparin therapy with fractionated heparin is used to limit inappropriate clotting and to prevent the excessive consumption of clotting factors.

Blood replacement therapy is used when poor clotting with hemorrhage occurs and may include clotting factors, platelets, fresh frozen plasma (FFP), or packed red blood cells. Chapter 40 discusses in detail the care of the patient during blood replacement. The use of platelet transfusion is recommended ahead of other blood products for patients with septic shock to improve clotting (Dellinger et al., 2013).

Community-Based Care

Identified sepsis should be resolved before patients are discharged from the acute care setting. Because more patients are receiving treatment on an ambulatory care basis and are being discharged earlier from acute care settings, more patients at home are at increased risk for sepsis.

Home Care Management.

Evaluate the home environment for safety regarding infection hazards. Note the general cleanliness, especially in the kitchen and bathrooms. Chart 37-6 lists focused patient and environmental assessment data to obtain during a home visit.

Chart 37-6 Home Care Assessment

The Patient at Risk for Sepsis

- Assess the patient for any clinical manifestations of infection, including:
  - Temperature, pulse, respiration, and blood pressure
  - Color of skin and mucous membranes
  - The mouth and perianal area for fissures or lesions
  - Any nonintact skin area for the presence of exudates, redness, increased warmth, swelling
  - Any pain, tenderness, or other discomfort anywhere
  - Cough or any other symptoms of a cold or the flu
  - Urine; or ask patient whether urine is dark or cloudy, has an odor, or causes pain or burning during urination
- Assess patient's and caregiver's adherence to and understanding of infection prevention techniques.

- Assess home environment, including:
  - General cleanliness
  - Kitchen and bathroom facilities, including refrigeration
  - Availability and type of soap for handwashing
  - Presence of pets, especially cats, rodents, or reptiles

Self-Management Education.

Protecting frail patients from infection and sepsis at home is an important nursing function. Teach about the importance of self-care strategies, such as good hygiene, handwashing, balanced diet, rest and exercise, skin care, and mouth care. If patients or family members do not know how to take a temperature or read a thermometer, teach them and obtain a return demonstration. Teach patients and families to notify the health care provider immediately if fever or other signs of infection appear. General recommendations for Infection Precautions for patients at risk for sepsis are listed in Chart 22-4 in Chapter 22.

Evaluation: Outcomes

Evaluate the care of the patient with sepsis or septic shock. The expected outcome is that the patient will maintain normal aerobic cellular metabolism. Specific indicators for these outcomes are listed for the priority patient problem under the *Planning and Implementation* section (see earlier).

Clinical Judgment Challenge

Patient-Centered Care; Evidence-Based Practice; Safety QSEN

The patient is a 70-year-old man undergoing chemotherapy for lymphoma who was brought to the hospital by his wife because he was confused. His vital signs are: T = 95.7° F (35.4° C); P = 112; R = 28; BP = 96/50; Spo_2 = 84%. His health history includes type 2 diabetes, a myocardial infarction 10 years ago (he now has an "on-demand" pacemaker), and hypertension. In addition to chemotherapy, his current oral medications include metformin (Glucophage) 850 mg twice daily, losartan (Cozaar) 50 mg daily, and aspirin 81 mg daily. When you ask whether there have been any changes lately, the wife tells you that he had a "touch" of fungal pneumonia 6 weeks ago and still has a cough with sputum. He has been very uncomfortable for the past week with a "boil" near his rectum. When you assess his perianal region, you find a large raised red bump with an open area draining purulent fluid.

1. What risk factors does this man have for sepsis? Explain why each factor increases his risk.
2. What stage of the sepsis spectrum is he at this time and why?
3. Should you apply oxygen to him before he is seen by the health care provider? Why or why not?

The health care provider evaluates the patient and orders: IV with dextrose 5% in normal saline; IV amikacin (Amikin); cultures of the urine, blood, sputum, his central line, and any open skin areas; complete blood count with differential; and blood values for glucose and lactic acid.

4. Which intervention do you perform first and why?
5. What do you do next and why?

Nursing Concepts and Clinical Judgment Review

What might you NOTICE if the patient is experiencing inadequate oxygenation and tissue perfusion as a result of hypovolemic shock?

- Pulse rapid and thready
- Pulse pressure narrowed
- Respirations rapid and shallow
- Oxygen saturation by pulse oximetry decreased
- Skin cyanosis or pallor (for lighter-skinned patients)
- Skin cool and clammy
- Cyanosis or pallor of the lips and oral mucous membranes (for patients of any skin color)
- Patient is restless or anxious
- Patient has a urine output that is less than expected compared with fluid intake
- Patient states he or she is thirsty

What should you INTERPRET and how should you RESPOND to a patient experiencing inadequate oxygenation and tissue perfusion as a result of hypovolemic shock?

Perform and interpret physical assessment, including:

- Taking vital signs
- Auscultating all lung fields
- Monitoring oxygen saturation by pulse oximetry
- Assessing cognition
- Checking incisions, body orifices, and under the patient for signs of active bleeding

- Assessing the skin for bruises and petechiae
- Examining all body areas for swelling or discoloration that could indicate internal bleeding

Interpret laboratory values:

- Arterial blood gas values: pH lower than 7.35
- Elevated serum lactate levels
- Hemorrhage
  Decreased hematocrit and hemoglobin
  Decreased total red blood cells and platelets
- Dehydration
  Elevated red blood cell count, hematocrit, and hemoglobin
  Elevated white blood cell count

Respond by:

- Applying oxygen
- Assisting the patient to shock position (head and chest flat or elevated to no more than 30 degrees; legs elevated)
- Notifying the Rapid Response Team
- Ensuring placement of venous access
- Increasing IV fluid infusion rate

On what should you REFLECT?

- Observe patient for evidence of improved circulation and oxygenation (see Chapter 33).
- Think about what may have caused the hypovolemia.
- Think about how you may have identified the problem sooner.

Get Ready for the NCLEX® Examination!

Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Ensure vital sign measurements are accurate, and monitor them for changes indicating the presence of shock. **Safety** QSEN
- Identify patients at high risk for infection due to age, disease, or the environment. **Safety** QSEN
- Use the recommended criteria to assess for the presence of sepsis (see Table 37-3). **Evidence-Based Practice** QSEN
- Use strict aseptic techniques when performing invasive procedures, administering IV medications, changing dressings, and handling nonintact skin. **Safety** QSEN
- Use good handwashing techniques before providing any care to a patient who is either immunocompromised or immune deficient. **Safety** QSEN
- Assign a registered nurse rather than a licensed practical nurse/licensed vocational nurse (LPN/LVN) or unlicensed assistive personnel (UAP) to assess the vital signs of a patient who is at risk for or suspected of having hypovolemic shock. **Safety** QSEN
- Use only normal saline for infusion with blood or blood products.

Health Promotion and Maintenance

- Teach all people how to avoid dehydration. **Patient-Centered Care** QSEN
- Teach all people to use safety devices to avoid trauma. **Patient-Centered Care** QSEN
- Instruct all patients going home after surgery or invasive procedures to seek immediate attention for persistent manifestations of early shock. **Patient-Centered Care** QSEN
- Teach all patients who have a local infection to seek medical attention when manifestations of systemic infection appear. **Patient-Centered Care** QSEN

Psychosocial Integrity

- Assess all patients at risk for shock for a change in affect, reduced cognition, altered level of consciousness, and increased anxiety.

Patient-Centered Care QSEN

- Stay with the patient in shock. **Patient-Centered Care** QSEN
- Reassure patients who are in shock that the appropriate interventions are being instituted. **Patient-Centered Care** QSEN

Physiological Integrity

- Be aware of the role of the systemic inflammatory response syndrome (SIRS) in the manifestations and progression of sepsis and septic shock. **Safety** QSEN
- Assess the immunocompromised patient every shift for infection. **Safety** QSEN
- Assess the skin integrity of the patient with reduced immune function at least every shift. **Patient-Centered Care** QSEN
- Immediately assess vital signs of patients who have a change in level of consciousness, increased thirst, or anxiety. **Evidence-Based Practice** QSEN
- Assess for changes in pulse rate and quality or a decrease in urine output rather than blood pressure as an indicator of shock. **Evidence-Based Practice** QSEN
- Give oxygen to any patient in shock. **Evidence-Based Practice** QSEN
- Assess hourly urine output to evaluate the adequacy of treatment for hypovolemic shock. **Evidence-Based Practice** QSEN
- Before administering prescribed antibiotics, obtain blood cultures and cultures of urine, wound drainage, and sputum for any patient suspected to have sepsis. **Evidence-Based Practice** QSEN
- Administer prescribed antibiotics within 1 hour of a diagnosis of sepsis. **Evidence-Based Practice** QSEN

CHAPTER 38

Care of Patients with Acute Coronary Syndromes

Laura M. Dechant

PRIORITY CONCEPTS

- Perfusion
- Pain

Learning Outcomes

Safe and Effective Care Environment

1. Explain the role of the interdisciplinary team in cardiac rehabilitation.

Health Promotion and Maintenance

2. Differentiate between modifiable and nonmodifiable risk factors for coronary artery disease (CAD).

Psychosocial Integrity

3. Assess patient and family responses to acute coronary events, especially myocardial infarction (MI).

Physiological Integrity

4. Compare and contrast the clinical manifestations of stable angina, unstable angina, and MI.
5. Interpret physical and diagnostic assessment findings in patients who have CAD.
6. Prioritize nursing care for patients who have chest pain.
7. Teach patients and families about drug therapy for CAD.

8. Explain the nursing care for patients who have thrombolysis for an MI.
9. Develop a plan of care for the patient who has a percutaneous coronary intervention (PCI) to promote perfusion.
10. Plan postoperative care for the patient who has coronary artery bypass graft (CABG) surgery based on patient preferences, clinical expertise, and current evidence.
11. Identify the postoperative needs of adults having CABG surgery.

http://evolve.elsevier.com/Iggy/

Coronary artery disease (CAD), also called *coronary heart disease (CHD)* or simply *heart disease,* is the single largest killer of American men and women in all ethnic groups. When the arteries that supply the **myocardium** (heart muscle) are diseased, the heart cannot pump blood effectively to adequately perfuse vital organs and peripheral tissues. The organs and tissues need oxygen in arterial blood for survival. When perfusion is impaired, the patient can have life-threatening clinical manifestations and possibly death.

The incidence of CAD has declined over the past decade (Go et al., 2013). This decline is due to many factors, including increasingly effective treatment and an increased awareness and emphasis on reducing major cardiovascular risk factors (e.g., hypertension, smoking, high cholesterol). Some coronary events occur in patients without common risk factors.

❖ Pathophysiology

Coronary artery disease (CAD) is a broad term that includes chronic stable angina and acute coronary syndromes. It affects the arteries that provide blood, oxygen, and nutrients to the myocardium. When blood flow through the coronary arteries is partially or completely blocked, ischemia and infarction of the myocardium may result. Ischemia occurs when *insufficient oxygen* is supplied to meet the requirements of the myocardium. **Infarction** (necrosis, or cell death) occurs when severe ischemia is prolonged and decreased perfusion causes irreversible damage to tissue.

Chronic Stable Angina Pectoris

Angina pectoris is chest pain caused by a temporary imbalance between the coronary arteries' ability to supply oxygen and the cardiac muscle's

demand for *oxygen*. **Ischemia** (lack of oxygen) that occurs with angina is limited in duration and does not cause permanent damage of myocardial tissue.

Angina may be of two main types: stable angina and unstable angina. **Chronic stable angina (CSA)** is chest discomfort that occurs with moderate to prolonged exertion in a pattern that is familiar to the patient. The frequency, duration, and intensity of symptoms remain the same over several months. CSA results in only slight limitation of activity and is usually associated with a *fixed* atherosclerotic plaque. It is usually relieved by nitroglycerin or rest and often is managed with drug therapy. Rarely does CSA require aggressive treatment. *Unstable* angina is discussed in the following Acute Coronary Syndrome section.

Acute Coronary Syndrome

The term **acute coronary syndrome (ACS)** is used to describe patients who have either *unstable* angina or an acute myocardial infarction. In ACS, it is believed that the atherosclerotic plaque in the coronary artery *ruptures,* resulting in platelet aggregation ("clumping"), thrombus (clot) formation, and vasoconstriction (Fig. 38-1). The amount of disruption of the atherosclerotic plaque determines the degree of coronary artery obstruction (blockage) and the specific disease process. The artery has to have at least 40% plaque accumulation before it starts to block blood flow (McCance et al., 2014).

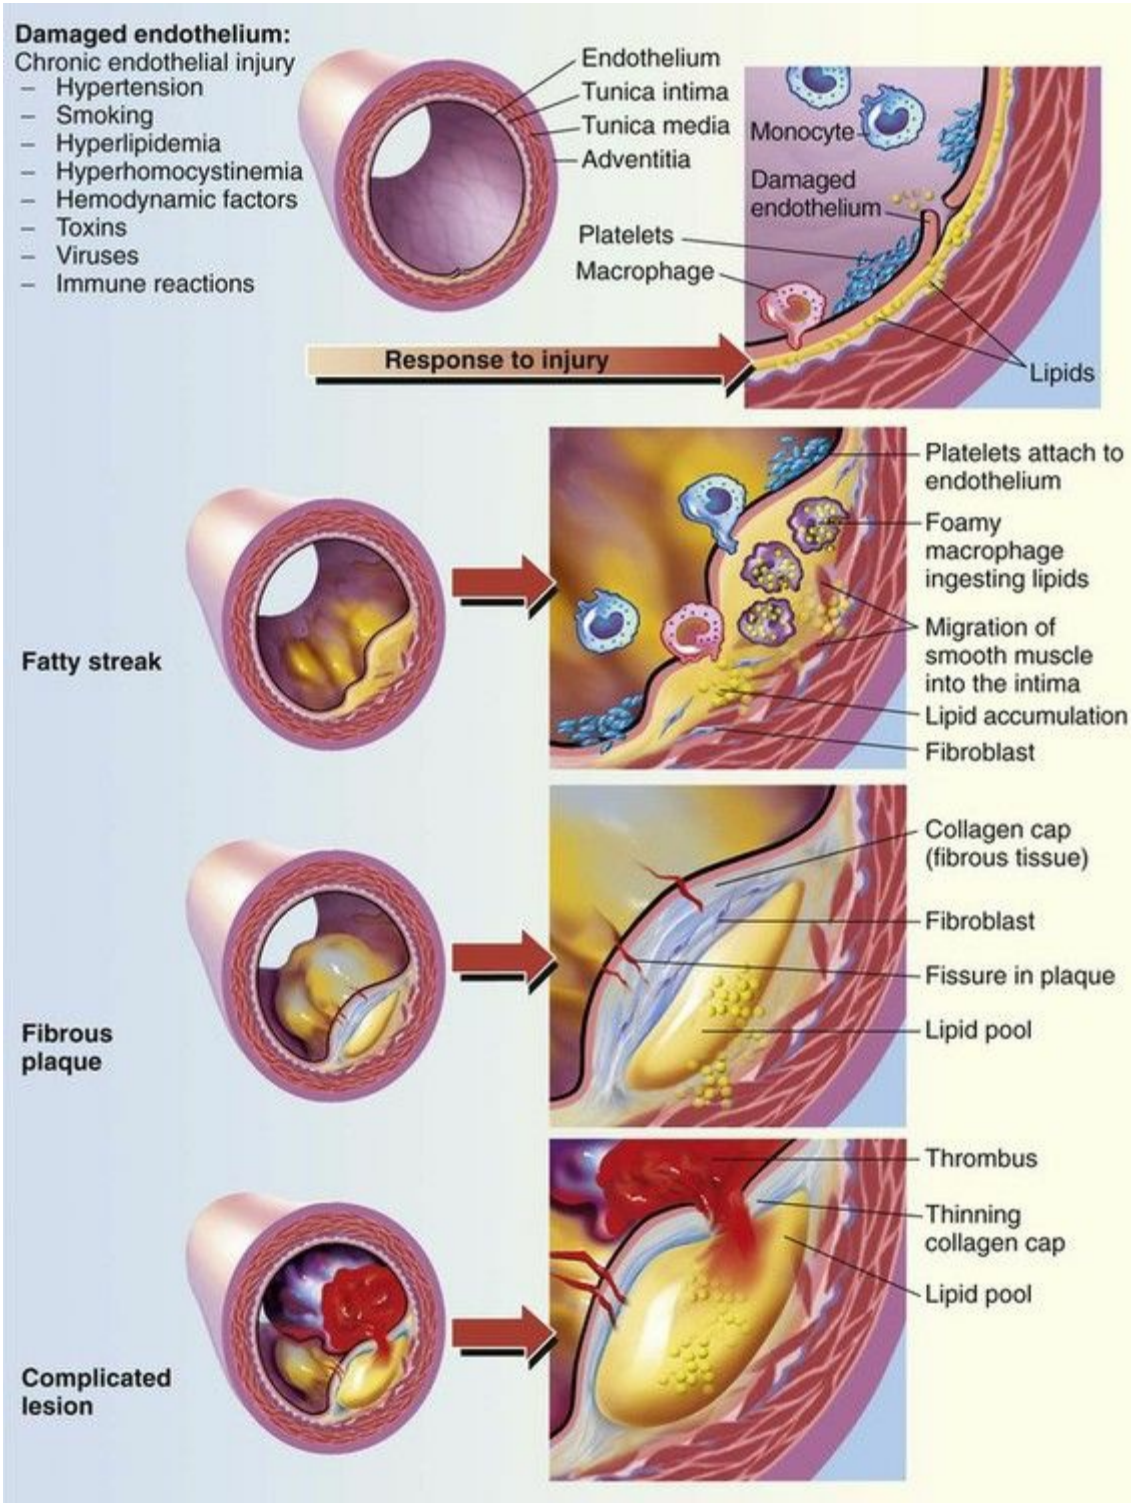

FIG. 38-1 A cross section of an atherosclerotic coronary artery.

Historically, an acute myocardial infarction (MI) was diagnosed by the presence of ST-segment elevation on the 12-lead electrocardiogram (ECG) (see discussion of the normal ECG in Chapter 34). However, all patients do not present with this finding. Instead, they are classified into one of three categories according to the presence or absence of ST-segment elevation on the ECG and positive serum troponin markers:

• ST-elevation MI (STEMI) (traditional manifestation)

- Non–ST-elevation MI (NSTEMI) (common in women)
- Unstable angina pectoris

Unstable Angina Pectoris.

Unstable angina (the most commonly used term) is chest pain or discomfort that occurs at rest or with exertion and causes severe activity limitation. An increase in the number of attacks and in the intensity of the pressure indicates unstable angina. The pressure may last longer than 15 minutes or may be poorly relieved by rest or nitroglycerin. Unstable angina describes a variety of disorders, including *new-onset angina, variant (Prinzmetal's) angina,* and *pre-infarction angina. Patients with unstable angina present with ST changes on a 12-lead ECG but do not have changes in troponin or creatine kinase (CK) levels.*

New-onset angina describes the patient who has his or her first angina symptoms, usually after exertion or other increased demands on the heart. **Variant (Prinzmetal's) angina** is chest pain or discomfort resulting from coronary artery spasm and typically occurs after rest. **Pre-infarction angina** refers to chest pain that occurs in the days or weeks before an MI.

Myocardial Infarction.

The most serious acute coronary syndrome is myocardial infarction (MI), often referred to as *acute MI* or *AMI.* Undiagnosed or untreated angina can lead to this very serious health problem. **Myocardial infarction (MI)** occurs when myocardial tissue is abruptly and severely deprived of oxygen. When blood flow is quickly reduced by 80% to 90%, ischemia develops. Ischemia can lead to injury and necrosis of myocardial tissue if blood flow is not restored. Patients presenting with **non–ST-segment elevation myocardial infarction (NSTEMI)** typically have ST and T-wave changes on a 12-lead ECG. This indicates myocardial ischemia. Cardiac enzymes may be initially normal but elevate over the next 3 to 12 hours. Causes of NSTEMI include coronary vasospasm, spontaneous dissection, and sluggish blood flow due to narrowing of the coronary artery.

Patients presenting with **ST-elevation myocardial infarction (STEMI)** typically have ST elevation in two contiguous leads on a 12-lead ECG. This indicates myocardial infarction/necrosis. STEMI is attributable to rupture of the fibrous atherosclerotic plaque leading to platelet aggregation and thrombus formation at the site of rupture (McCance et al., 2014). *The thrombus causes an abrupt 100% occlusion to the coronary artery, is a medical emergency, and requires immediate revascularization of the blocked coronary artery.*

Often MIs begin with infarction of the subendocardial layer of cardiac

muscle. This layer has the longest myofibrils in the heart, the *greatest* oxygen *demand*, and the *poorest* oxygen *supply.* Around the initial area of infarction (zone of necrosis) in the subendocardium are two other zones: (1) the zone of injury—tissue that is injured but not necrotic; and (2) the zone of ischemia—tissue that is oxygen deprived. This pattern is illustrated in Fig. 38-2.

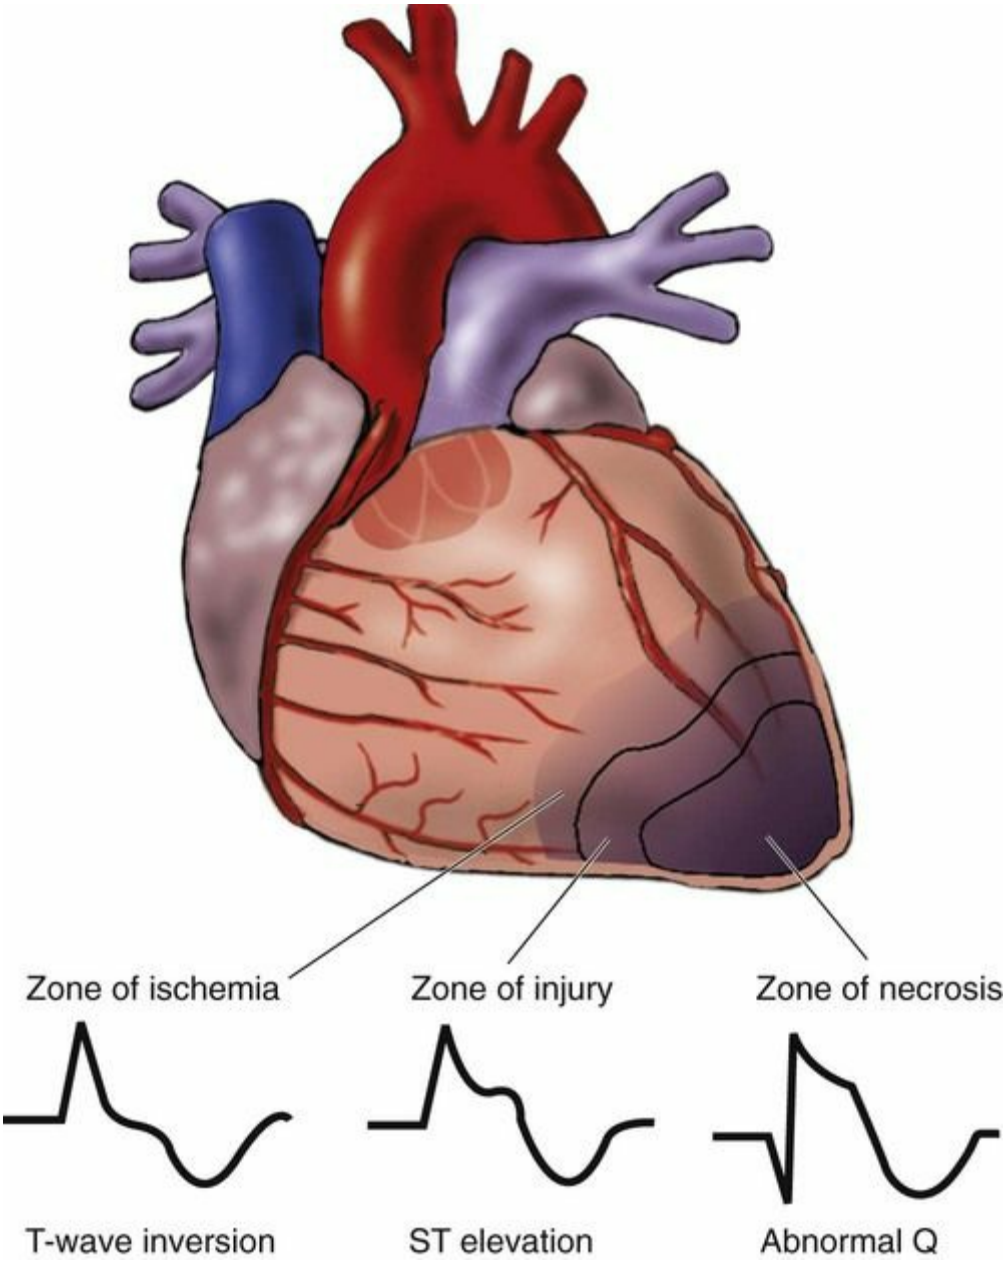

FIG. 38-2 Electrocardiographic changes and patterns associated with myocardial infarction.

Gender Health Considerations

Patient-Centered Care QSEN

Many women with symptomatic ischemic heart disease or abnormal stress testing do not have normal coronary angiography. Studies implicate microvascular disease or endothelial dysfunction or both as the causes for risk for CAD in women. Endothelial dysfunction is the inability of the arteries and arterioles to dilate due to lack of nitric oxide production by the endothelium. Nitric oxide is a relaxant of vascular smooth muscle.

Women typically have smaller coronary arteries and frequently have plaque that breaks off and travels into the small vessels to form an embolus (clot). Positive remodeling, or outward remodeling (lesions that protrude outward), is more common in women (McCance et al., 2014). This outpouching may be missed on coronary angiography.

Infarction is a dynamic process that does not occur instantly. Rather, it evolves over a period of several hours. Hypoxemia from ischemia may lead to local vasodilation of blood vessels and acidosis. Potassium, calcium, and magnesium imbalances, as well as acidosis at the cellular level, may cause changes in normal conduction and contractile functions. Catecholamines (epinephrine and norepinephrine) released in response to hypoxia and pain may increase the heart's rate, contractility, and afterload. These factors increase *oxygen* requirements in tissue that is already oxygen deprived. This may lead to life-threatening ventricular dysrhythmias. The area of infarction may extend into the zones of injury and ischemia. The actual extent of the zone of infarction depends on three factors: collateral circulation, anaerobic metabolism, and workload demands on the myocardium.

Obvious physical changes do not occur in the heart until 6 hours after the infarction, when the infarcted region appears blue and swollen. *These changes explain the need for intervention within the first 4 to 6 hours of symptom onset!* After 48 hours, the infarcted area turns gray with yellow streaks as neutrophils invade the tissue and begin to remove the necrotic cells. By 8 to 10 days after infarction, granulation tissue forms at the edges of the necrotic tissue. Over a 2- to 3-month period, the necrotic area eventually develops into a shrunken, thin, firm scar. Scar tissue permanently changes the size and shape of the entire left ventricle, called **ventricular remodeling.** Remodeling may decrease left ventricular function, cause heart failure, and increase morbidity and mortality. The scarred tissue does not contract, nor does it conduct electrically. Thus this area is often the cause of chronic ventricular dysrhythmias surrounding the infarcted zone (McCance et al., 2014).

The patient's response to an MI also depends on which coronary artery

or arteries were obstructed and which part of the left ventricle wall was damaged: anterior, septal, lateral, inferior, or posterior. Fig. 33-3 in Chapter 33 shows the location of the major coronary arteries.

Obstruction of the left anterior descending (LAD) artery causes *anterior* or *septal* MIs because it perfuses the anterior wall and most of the septum of the left ventricle. Patients with anterior wall MIs (AWMIs) have the highest mortality rate because they are most likely to have left ventricular failure and dysrhythmias from damage to the left ventricle.

The circumflex artery supplies the lateral wall of the left ventricle and possibly portions of the posterior wall or the sinoatrial (SA) and atrioventricular (AV) nodes. Patients with obstruction of the circumflex artery may experience a *posterior* wall MI (PWMI) or a *lateral* wall MI (LWMI) and sinus dysrhythmias.

In most people, the right coronary artery (RCA) supplies most of the SA and AV nodes, as well as the right ventricle and inferior or diaphragmatic portion of the left ventricle. Patients with obstruction of the RCA often have **inferior wall MIs (IWMI).** About half of all inferior wall MIs are associated with an occlusion of the RCA, causing significant damage to the right ventricle. *Thus it is important to obtain a "right-sided" ECG to assess for right ventricular involvement.*

Etiology and Genetic Risk

Atherosclerosis is the primary factor in the development of CAD. Numerous risk factors, both nonmodifiable and modifiable, contribute to atherosclerosis and subsequently to CAD (see Chapter 36).

Nonmodifiable risk factors are personal characteristics that cannot be altered or controlled. These risk factors, which interact with each other, include age, gender, family history, and ethnic background. People with a family history of CAD are at high risk for developing the disease.

Cultural Considerations

Patient-Centered Care QSEN

Several groups have a higher genetic risk for CAD than others. For example, African-American and Hispanic women have higher CAD risk factors than white women of the same socioeconomic status. Of American Indians and Alaskan Natives 18 years of age and older, about 46.7% have one or more CAD risk factors (hypertension [HTN], smoking, high cholesterol, excess weight, or diabetes mellitus). The leading cause of death for both men and women in the Euro-American

population is cardiovascular disease, even though they may not have genetic predispositions to developing cardiovascular risk factors (Go et al., 2013).

Gender Health Considerations

Patient-Centered Care QSEN

Age is the most important risk factor for developing CAD in women. The older a woman is, the more likely she will have the disease. When compared with men, women are usually 10 years older when they have CAD. In addition, women who have MIs have a greater risk for dying during hospitalization. When they are older than 40 years, women are more likely than men to die within 1 year after their MI. If women do survive, they are less likely to participate in cardiac rehabilitation programs (Go et al., 2013).

Modifiable risk factors are lifestyle choices that can be controlled by the patient (with possible medical intervention), such as:

- Elevated serum lipid levels
- Smoking/tobacco use
- Limited physical activity
- Hypertension
- Diabetes mellitus
- Obesity
- Excessive alcohol
- Excessive stress/decreased coping skills

These risk factors are described in more detail in Chapters 33 and 36.

Incidence and Prevalence

The average age of a person having a first MI is 64.7 years for men and 72.2 years for women (Go et al., 2013). Every 34 seconds, a person in the United States has a major coronary event, and every minute, an American will die from CAD (Go et al., 2013). Many people die from coronary heart disease without being hospitalized. Most of these are sudden deaths caused by cardiac arrest.

Gender Health Considerations

Patient-Centered Care QSEN

Premenopausal women have a lower incidence of MI than men.

However, for postmenopausal women in their 70s or older, the incidence of MI equals that of men. Family history is also a risk factor for women; those whose parents had CAD are more susceptible to the disease. Women with abdominal obesity (androidal shape) and metabolic syndrome (described on p. 760) are also at increased risk for CAD. Because lesbian and bisexual women have a higher incidence of overweight and obesity than women who are not lesbian or bisexual, they should be considered an especially high-risk group for CAD. The reasons for these trends are not known (Pettinato, 2012).

Many patients who survive MIs are not able to return to work. CAD is the leading cause of premature, permanent disability in the United States and the world.

Health Promotion and Maintenance

Ninety-five percent of sudden cardiac arrest victims die before reaching the hospital, largely because of ventricular fibrillation ("v fib"). To help combat this problem, automatic external defibrillators (AEDs) are found in many public places, such as in shopping centers and on airplanes. Employees are taught how to use these devices if a sudden cardiac arrest occurs. Some patients with diagnosed CAD have AEDs in their homes or at work. The procedure for using this device is described on p. 671 in Chapter 34.

Health promotion efforts are directed toward controlling or altering modifiable risk factors for CAD. For patients at risk for coronary artery disease (CAD), especially MI, assess specific risk factors and implement an individualized health teaching plan. Teach people who have one or more of these risk factors the importance of modifying or eliminating them to decrease their chances of CAD (Chart 38-1). Chapter 36 describes health teaching and evidence-based interventions for preventing and managing atherosclerosis and hypertension. Smoking cessation is discussed in Chapter 27.

Chart 38-1 Patient and Family Education: Preparing for Self-Management

Prevention of Coronary Artery Disease

Smoking/Tobacco Use

- If you smoke or use tobacco, quit.

- If you don't smoke or use tobacco, don't start.

Diet

- Consume sufficient calories for your body to include:
  - 5% to 6% from saturated fats
  - Avoiding *trans* fatty acids
- Limit your cholesterol intake to less than 200 mg/day.
- Limit your sodium intake as specified by your health care provider, or under 1500 mg/day, if possible.

Cholesterol

- Have your lipid levels checked regularly.
- If your cholesterol and LDL-C levels are elevated, follow your health care provider's advice, including taking statin medications as indicated.

Physical Activity

- If you are middle-aged or older or have a history of medical problems, check with your health care provider before starting an exercise program.
- Exercise periods should be at least 40 minutes long with 10-minute warm-up and 5-minute cool-down periods.
- If you cannot exercise moderately 3 to 4 times each week, walk daily for 30 minutes at a comfortable pace.
- If you cannot walk 30 minutes daily, walk any distance you can (e.g., park farther away from a site than necessary; use the stairs, not the elevator, to go one floor up or two floors down).

Diabetes Mellitus

- Manage your diabetes with your health care provider.

Hypertension

- Have your blood pressure checked regularly.
- If your blood pressure is elevated, follow your health care provider's advice.
- Continue to monitor your blood pressure at regular intervals.

Obesity

- Avoid severely restrictive or fad diets.
- Restrict intake of saturated fats, sweets, sweetened beverages, and cholesterol-rich foods.
- Increase your physical activity.

LDL-C, Low-density lipoprotein–cholesterol.

Using Complementary and Alternative Therapies

Teach patients that adding omega-3 fatty acids from fish and plant sources has been effective for some patients in reducing lipid levels, stabilizing atherosclerotic plaques, and reducing sudden death from an MI. The preferred source of omega-3 acids is from fish 3 times a week or a daily fish oil nutritional supplement (1-2 g/day) containing eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) (American Heart Association [AHA], 2013). Plant sources (flaxseed, flaxseed oil, walnuts, and canola oil) contain α-linolenic acid, and the conversion of α-linolenic acid to EPA and DHA is not as efficient in patients who consume a typical Western diet. Lovaza (omega-3 fatty acids) is a medication used to reduce very high triglycerides (>500 mg/dL) levels. However, it has not been proven to prevent MIs or stroke.

Garlic supplements may also have a small effect on reducing lipid levels, but they have not been shown to prevent MI. Patients often take a number of other supplements, such as vitamin E, coenzyme Q10, Pantesin, and vitamin B complex to decrease the risk for heart disease. However, studies do not show that these substances are helpful in reducing coronary artery disease.

Managing Metabolic Syndrome

Metabolic syndrome, also called *syndrome X,* has been recognized as a risk factor for cardiovascular (CV) disease and is being aggressively researched. Patients who have three of the factors in Table 38-1 are diagnosed with **metabolic syndrome**. This health problem increases the risk for developing diabetes and CAD. About a third of adults older than 20 years in the United States have metabolic syndrome (Go et al., 2013). This increase is likely due to physical inactivity and the current obesity epidemic. Management is aimed at reducing risks, managing hypertension, and preventing complications.

TABLE 38-1

Indicators of Risk Factors for Metabolic Syndrome

RISK FACTOR	INDICATOR
Hypertension	**Either** blood pressure of 130/85 mm Hg or higher **or** taking antihypertensive drug(s)
Decreased HDL-C (usually with high LDL-C) level	**Either** HDL-C <45 mg/dL for men or <55 mg/dL for women **or** taking an anticholesterol drug
Increased level of triglycerides	**Either** 160 mg/dL or higher for men or 135 mg/dL or higher for women **or** taking an anticholesterol drug
Increased fasting blood glucose (due to diabetes, glucose intolerance, or insulin resistance)	**Either** 100 mg/dL or higher **or** taking antidiabetic drug(s)
Large waist size (excessive abdominal fat causing central obesity)	40 inches (102 cm) or greater for men or 35 inches (89 cm) or greater for women

HDL-C, High-density lipoprotein–cholesterol; *LDL-C,* low-density lipoprotein–cholesterol.

NCLEX Examination Challenge

Health Promotion and Maintenance

An older client has a history of coronary artery disease. Which modifiable risk factors will the nurse assess to guide the client's teaching plan? **Select all that apply.**

A Older age
B Tobacco use
C Female
D High-fat diet
E Family history
F Obesity

Patient-Centered Collaborative Care

Assessment

History.

If symptoms of CAD are present at the time of the interview, delay collecting data until interventions for symptom relief, vital sign instability, and dysrhythmias are started and discomfort resolves. If the patient had pain, ask about how he or she has managed the discomfort and other symptoms and which drugs he or she may be taking. When the

patient is pain-free, obtain information about family history and modifiable risk factors, including eating habits, lifestyle, and physical activity levels. Ask about a history of smoking and how much alcohol is consumed each day. Collaborate with the dietitian to assess current body mass index (BMI) and weight as needed.

Physical Assessment/Clinical Manifestations.

Rapid assessment of the patient with chest pain or other presenting symptoms is crucial. It is important to differentiate among the types of chest pain and to identify the source. Question the patient to determine the characteristics of the discomfort. Patients may deny pain, however, and report that they feel "pressure." Appropriate questions to ask concerning the discomfort include onset, location, radiation, intensity, duration, and precipitating and relieving factors.

Cultural Considerations

Patient-Centered Care QSEN

African Americans and women tend to delay seeking treatment for MI and therefore have higher mortality rates than Euro-Americans. One contributing factor to this delay is a greater incidence of dyspnea as an acute symptom among these groups rather than the classic pain more typical of other groups (Go et al., 2013).

If pain is present, ask the patient if the pain is in the chest, epigastric area, jaw, back, shoulder, or arm. Ask him or her to rate the pain on a scale of 0 to 10, with 10 being the highest level of discomfort. Some patients describe the discomfort as tightness, a burning sensation, pressure, or indigestion. A complete pain assessment is described in Chapter 3.

Gender Health Considerations

Patient-Centered Care QSEN

Many women of any age experience atypical angina. **Atypical angina** manifests as indigestion, pain between the shoulders, an aching jaw, or a choking sensation that occurs with exertion. These symptoms typically manifest during stressful circumstances or during activities of daily living. Women may curtail activity as a result of angina, and health care providers need to ask about changes in routine. Symptoms in women

typically include fatigue, sleep disturbance, and dyspnea (Go et al., 2013).

Chart 38-2 compares and contrasts angina and infarction pain. Because angina pain is ischemic pain, it usually improves when the imbalance between oxygen supply and demand is resolved. For example, rest reduces tissue demands and nitroglycerin improves oxygen supply. Discomfort from a myocardial infarction (MI) does not usually resolve with these measures. Ask about any associated symptoms, including *nausea, vomiting, diaphoresis, dizziness, weakness, palpitations, and shortness of breath.*

Chart 38-2 Key Features

Angina and Myocardial Infarction

ANGINA	MYOCARDIAL INFARCTION
• Substernal chest discomfort: ■ Radiating to the left arm ■ Precipitated by exertion or stress (or rest in variant angina) ■ Relieved by nitroglycerin or rest ■ Lasting less than 15 min • Few, if any, associated symptoms	• Pain or discomfort: ■ Substernal chest pain/pressure radiating to the left arm ■ Pain or discomfort in jaw, back, shoulder, or abdomen ■ Occurring without cause, usually in the morning ■ Relieved only by opioids ■ Lasting 30 min or more • Frequent associated symptoms: ■ Nausea/vomiting ■ Diaphoresis ■ Dyspnea ■ Feelings of fear and anxiety ■ Dysrhythmias ■ Fatigue ■ Palpitations ■ Epigastric distress ■ Anxiety ■ Dizziness ■ Disorientation/acute confusion ■ Feeling "short of breath"

Considerations for Older Adults

Patient-Centered Care QSEN

The presence of associated symptoms without chest discomfort is significant. In up to 40% of all patients with MI, primarily older women and patients with diabetes, chest pain or discomfort may be mild or absent. Instead, they have associated symptoms. Some older patients may think they are having indigestion and therefore not recognize that they are having an MI. Others report shortness of breath as the only symptom. The major manifestation of MI in people older than 80 years

may be disorientation or acute confusion because of poor cardiac output and due to inadequate coronary perfusion.

In some older adults with MI, absence of chest pain may be due to cognitive impairment or inability to verbalize pain sensation. However, in most cases it is probably the result of increased collateral circulation. Silent myocardial ischemia increases the incidence of new coronary events and should be treated aggressively.

Assess *blood pressure* and *heart rate.* Interpret the patient's cardiac rhythm and presence of *dysrhythmias.* Sinus tachycardia with premature ventricular contractions (PVCs) frequently occurs in the first few hours after an MI.

Next assess *distal peripheral pulses* and *skin temperature.* The skin should be warm with all pulses palpable. In the patient with unstable angina or MI, poor cardiac output may be manifested by cool, diaphoretic ("sweaty") skin and diminished or absent pulses. *Auscultate for an S_3 gallop, which often indicates heart failure—a serious and common complication of MI.* In adults, the S_3 heart sound is heard with the bell of the stethoscope over the apex of the heart (Jarvis, 2016).

Assess the *respiratory rate* and breath sounds for signs of heart failure. An increased respiratory rate is common because of anxiety and pain, but *crackles or wheezes* may indicate *left-sided* heart failure. Assess for the presence of jugular venous distention and peripheral edema.

The patient with MI may experience a *temperature elevation* for several days after infarction. Temperatures as high as 102° F (38.9° C) may occur in response to myocardial necrosis, indicating the inflammatory response.

Psychosocial Assessment.

Denial is a common early reaction to chest discomfort associated with angina or MI. On average, the patient with an acute MI waits more than 2 hours before seeking medical attention. Often he or she rationalizes that symptoms are due to indigestion or overexertion. In some situations, denial is a normal part of adapting to a stressful event. However, denial that interferes with identifying a symptom such as chest discomfort can be harmful. Explain the importance of reporting any discomfort to the health care provider.

Fear, depression, anxiety, and anger are other common reactions of many patients and their families. Assist in identifying these feelings. Encourage them to explain their understanding of the event, and clarify

any misconceptions.

Laboratory Assessment.

Although there is no single ideal test to diagnose MI, the most common laboratory tests include troponins T and I and creatine kinase-MB (CK-MB). These cardiac markers are specific for MI and cardiac necrosis. Troponins T and I rise quickly. CK-MB is the most specific marker for MI but does not peak until about 24 hours after the onset of pain. These tests are described in more detail in Chapter 33. If serial enzymes are negative, the patient has a nuclear medicine test such as those described in the next section.

Imaging Assessment.

Unless there is associated cardiac dysfunction (e.g., valve disease) or heart failure, a chest x-ray is not diagnostic for angina or MI. A chest x-ray may be performed to assist with ruling out aortic dissection, which may mimic a MI. If the x-ray demonstrates a widened mediastinum, further testing for aortic dissection with either transesophageal echography (TEE) or computed tomography (CT) scan is needed.

Thallium scans use radioisotope imaging to assess for ischemia or necrotic muscle tissue related to angina or myocardial infarction (MI). Areas of decreased or absent perfusion, referred to as *cold spots,* identify ischemia or infarction. Thallium may be used with the exercise tolerance test. Dipyridamole (Persantine) thallium scanning (DTS) may also be used.

Contrast-enhanced cardiovascular magnetic resonance (CMR) imaging may also be done as a noninvasive approach to detect CAD. *Echocardiography* may be used to visualize the structures of the heart.

Use of the 64-slice **computed tomography coronary angiography (CTCA)** has been found to be helpful in diagnosing coronary artery disease in symptomatic patients identified as having a "low- or intermediate-pretest probability" risk for CAD. This new generation of high-speed computed tomography (CT) scanners is becoming a highly reliable, noninvasive way to evaluate CAD (Weustink et al., 2010).

Other Diagnostic Assessment.

Twelve-lead electrocardiograms (ECGs) allow the health care provider to examine the heart from varying perspectives. By identifying the lead(s) in which ECG changes are occurring, the health care provider can identify both the occurrence and the location of ischemia (angina) or necrosis (infarction). In addition to the traditional 12-lead ECG, the health care

provider may request a "right-sided" or 18-lead ECG to determine whether ischemia or infarction has occurred in the right ventricle. *The ECG should be obtained within 10 minutes of patient presentation with chest discomfort!*

An ischemic myocardium does not repolarize normally. Thus 12-lead ECGs obtained during an angina episode reveal ST depression, T-wave inversion, or both. **Variant angina,** caused by coronary vasospasm (vessel spasm), usually causes elevation of the ST segment during angina attacks. These ST and T-wave changes usually subside when the ischemia is resolved and pain is relieved. However, the T wave may remain flat or inverted for a period of time. If the patient is not experiencing angina at the moment of the test, the ECG is usually normal unless he or she has evidence of an old MI.

When infarction occurs, one of two ECG changes is usually observed: ST-elevation MI (STEMI), or non–ST-elevation MI (NSTEMI). An abnormal Q wave (wider than 0.04 seconds or more than one-third the height of the QRS complex) may develop, depending on the amount of myocardium that has necrosed. Women having an MI often present with an NSTEMI.

The Q wave may develop because necrotic cells do not conduct electrical stimuli. Hours to days after the MI, the ST-segment and T-wave changes return to normal. However, when the Q wave exists, it may become permanent. The Q waves may disappear after a number of years, but their absence does not necessarily mean that the patient has not had an MI.

After the acute stages of an unstable angina episode, the health care provider often requests an *exercise tolerance test (stress test)* on a treadmill to assess for ECG changes consistent with ischemia, evaluate medical therapy, and identify those who might benefit from invasive therapy. Pharmacologic stress-testing agents such as dobutamine (Dobutrex) may be used instead of the treadmill. Treadmill exercise testing is only moderately accurate for women when compared with men. The results are also not as reliable in tall, obese men when compared with short, thinner men. In women with suspected CAD, stress echocardiography or single photon emission computed tomography (SPECT) should be performed.

Cardiac catheterization may be performed to determine the extent and exact location of coronary artery obstructions. It allows the cardiologist and cardiac surgeon to identify patients who might benefit from percutaneous coronary intervention (PCI) or from coronary artery bypass grafting (CABG). Each of these diagnostic tests is described in detail in

Analysis

The patient with coronary artery disease (CAD) may have either stable angina or acute coronary syndrome (ACS). If ACS is suspected or cannot be completely ruled out, the patient is admitted to a telemetry unit for continuous monitoring or to a critical care unit if hemodynamically unstable.

The priority NANDA-I nursing diagnoses and collaborative problems for most patients with CAD include:

1. Acute Pain related to imbalance between myocardial oxygen supply and demand (NANDA-I)
2. Inadequate tissue perfusion (cardiopulmonary) related to interruption of arterial blood flow
3. Activity Intolerance related to fatigue caused by imbalance between oxygen supply and demand (NANDA-I)
4. Ineffective Coping related to effects of acute illness and major changes in lifestyle (NANDA-I)
5. Potential for dysrhythmias
6. Potential for heart failure
7. Potential for recurrent symptoms and extension of injury

Planning and Implementation

Astute assessment skills, timely analysis of troponin, and analysis of the 12-lead ECG (or 18-lead ECG for a suspected right ventricular infarction) are essential to ensure appropriate patient care management. This is particularly important since the average time a patient waits before seeking treatment is over 2 hours. This delay lessens the 4- to 6-hour window of opportunity for the most advantageous treatment with percutaneous intervention.

Managing Acute Pain.

Patients with *diabetes mellitus* and coronary artery disease (CAD) may not experience chest pain or pressure because of diabetic neuropathy. In this patient population, the onset of ACS may be signaled by new onset of atrial fibrillation. With new-onset atrial fibrillation, a cardiac workup should be done to rule out ACS.

Planning: Expected Outcomes.

The expected outcome is that the patient will verbalize a report of

decreased pain and discomfort as a result of prompt collaborative interventions.

Interventions.

The purpose of patient-centered collaborative care is to eliminate discomfort by providing pain relief measures, decreasing myocardial oxygen demand, and increasing myocardial oxygen supply.

Emergency Care: Myocardial Infarction.

Evaluate any report of pain, obtain vital signs, ensure an IV access, and notify the health care provider of the patient's condition. Chart 38-3 summarizes the emergency interventions for the patient with symptoms of CAD.

Chart 38-3 Best Practice for Patient Safety & Quality Care QSEN

Emergency Care of the Patient with Chest Discomfort

- Assess airway, breathing, and circulation (ABCs). Defibrillate as needed.
- ***Provide continuous ECG monitoring.***
- Obtain the patient's description of pain or discomfort.
- Obtain the patient's vital signs (blood pressure, pulse, respiration).
- Assess/provide vascular access.
- Consult chest pain protocol or notify the physician or Rapid Response Team for specific intervention.
- Obtain a 12-lead ECG within 10 minutes of report of chest pain.
- Provide pain-relief medication and aspirin (non–enteric coated) as prescribed.
- Administer oxygen therapy to maintain oxygen saturation ≥95%.
- Remain calm. Stay with the patient if possible.
- Assess the patient's vital signs and intensity of pain 5 minutes after administration of medication.
- Remedicate with prescribed drugs (if vital signs remain stable), and check the patient every 5 minutes.
- Notify the physician if vital signs deteriorate.

ECG, Electrocardiogram.

Pain relief helps increase the oxygen supply and decrease myocardial oxygen demand. The American Heart Association (AHA) recommends

several pain management strategies, including morphine sulfate and oxygen. *Give morphine as the priority in managing pain in patients having an ACS!*

Drug Therapy.

At home or in the hospital, the patient may take nitroglycerin to relieve episodic anginal pain. Aspirin 325 mg, an antiplatelet drug, may also be taken daily to prevent clots that further block coronary arteries.

Nitroglycerin (NTG), a nitrate often referred to as "nitro," increases collateral blood flow, redistributes blood flow toward the subendocardium, and dilates the coronary arteries. In addition, it decreases myocardial oxygen demand by peripheral vasodilation, which decreases both preload and afterload.

Nursing Safety Priority QSEN

Drug Alert

Before administering NTG, ensure that the patient has not taken any phosphodiesterase inhibitors for erectile dysfunction such as sildenafil (Viagra, Revatio) or tadalafil (Cialis) within the past 24 to 48 hours. Concomitant use of NTG with these inhibitors can cause profound hypotension. Remind patients not to take these medications within 24 to 48 hours of one another.

Teach the patient to hold the NTG tablet under the tongue and drink 5 mL (1 teaspoon) of water, if necessary, to allow the tablet to dissolve. NTG spray is also available and is more quickly absorbed. Pain relief should begin within 1 to 2 minutes and should be clearly evident in 3 to 5 minutes. After 5 minutes, recheck the patient's pain intensity and vital signs. If the blood pressure (BP) is less than 100 mm Hg systolic or 25 mm Hg lower than the previous reading, lower the head of the bed and notify the health care provider.

If the patient is experiencing some but not complete relief and vital signs remain stable, another NTG tablet or spray may be used. In 5-minute increments, a total of three doses may be administered in an attempt to relieve angina pain. If the patient uses NTG spray instead of the tablet, teach him or her to sit upright and spray the dose under the tongue. NTG topical patches should be placed below the nipple line to decrease discomfort.

Angina usually responds to NTG. The patient typically states that the pain

is relieved or markedly diminished. When simple measures, such as taking three sublingual nitroglycerin tablets one after the other, do not relieve chest discomfort, the patient may be experiencing an MI.

Nursing Safety Priority QSEN

Critical Rescue

If the patient is experiencing an MI, prepare him or her for transfer to a specialized unit where close monitoring and appropriate management can be provided. If the patient is at home or in the community, call 911 for transfer to the closest emergency department.

In a specialized unit, the health care provider may prescribe IV NTG for management of the chest pain. Begin the drug infusion slowly, checking the BP and pain level every 3 to 5 minutes. The nitroglycerin dose is increased until the pain is relieved, the BP falls excessively, or the maximum prescribed dose is reached (Chart 38-4).

Chart 38-4 Common Examples of Drug Therapy

Coronary Artery Disease (Nitrates, Beta Blockers, and Antiplatelet Agents)

DRUG	USUAL DOSAGE	NURSING INTERVENTIONS	RATIONALES
Nitrates			
Nitroglycerin (Nitrostat, NitroQuick)	0.3-0.4 mg sublingually every 5 min; up to 3 tablets over 15 min	Instruct patients to lie down with the head of the bed at a level of comfort when taking the sublingual form.	Hypotension can be dramatic, immediate, and intensified by the upright position.
Nitrolingual translingual spray	0.4 mg/metered spray	Monitor BP. Pay attention to orthostatic changes.	A decrease in BP occurs with vasodilation.
		Instruct patients to allow the sublingual tablet to dissolve and to avoid swallowing the tablet.	The sublingual dose is absorbed through the sublingual mucous membranes.
		Check the expiration date on sublingual tablets and sprays. Tablets should be replaced every 3-5 mo.	The efficacy of the tablets decreases with time.
		Determine whether pain is relieved.	Additional medication may be required to relieve pain.
		Monitor for headache.	Vasodilation is generalized.
		Do not administer to patients taking drugs used to treat sexual dysfunction (e.g., sildenafil, tadalafil, vardenafil).	Very serious (possibly fatal) interactions may occur.
Isosorbide dinitrate (Isordil, Iso-Bid)	2.5 mg sublingually every 4-6 hr; 5-40 mg orally four times daily 40-80 mg sustained-release tablet every 8-12 hr	Instruct patients taking sublingual forms to lie down before administration.	The hypotensive effect can be dramatic and immediate with sublingual administration.
		Monitor BP, and assess for dizziness.	A decrease in BP occurs with vasodilation.
Isosorbide mononitrate (Imdur)	60-mg extended-release tablet daily	Schedule sustained-release form with an 8- to 12-hr dose-free interval.	Tolerance may develop.
Nitroglycerin patch (Minitran, Nitro-Dur, Nitrek)	Transdermally started at 5 mg/24 hr (10-cm^2 system)	Remove the patch from the patient before defibrillation.	The patient may develop a burn.
		Rotate application sites.	Rotation prevents skin irritation.
		Apply the patch to a clean, dry, hairless area.	The drug is better absorbed when the skin is clean, dry, and hairless.
		Remove patch after 12-14 hr each day.	Removal prevents drug tolerance.
Beta Blockers			
Carvedilol (Coreg, Coreg CR)	12.5-25 mg orally twice daily for Coreg; 40-80 mg orally once daily for Coreg CR	Assess heart rate before administration.	Beta-blocking effects cause a decrease in heart rate.
		Monitor BP.	The hypotensive effect is due to a decrease in cardiac output, suppressed renin activity, and beta-blocking effects.
		Observe for signs of heart failure.	Heart failure may occur as a result of a decrease in cardiac output.
		Assess for shortness of breath and wheezing.	Beta-blocking effects in the lungs can cause bronchoconstriction.
Metoprolol (Lopressor, Toprol XL, Betaloc ✚), a cardioselective beta-adrenergic blocker	*Angina:* 25-100 mg orally daily *MI:* 100 mg orally twice daily; 5 mg IV over 2 min may be repeated twice for a total of 15 mg	Assess heart rate before administration; do not administer if heart rate <50-60 beats/min.	Beta blockers may cause further decreases in heart rate.
		Monitor BP, and hold for systolic <90-100 mm Hg.	Decreased BP pressure is an anticipated effect.
		Assess patients for cough, shortness of breath, edema, and weight gain.	These are indications of heart failure.
Antiplatelet Agents			
Aspirin (Empirin, Apo-ASA ✚, Ecotrin)	81-325 mg orally daily	Suggest that patients take the daily dose with food.	Gastric irritation may occur.
		Question patients about ringing in the ears.	Tinnitus may occur with aspirin toxicity.
		Emphasize to patients that aspirin is an important cardiac medication and should be continued unless they are told to stop.	Studies document significantly better survival rates for patients with coronary artery disease receiving aspirin.
	P2Y12 Platelet Inhibitors		
Clopidogrel (Plavix) ***Do not confuse Plavix with Paxil***	*Acute coronary syndrome or after stent implantation:* 300-600 mg orally loading dose, then 75-150 mg daily	Teach patients to take drug with food.	Drug can cause diarrhea and other GI disturbances.
		Inform patients to report any unusual bleeding or bruising.	Drug prevents platelet aggregation, thus slowing down clot formation.
Prasugrel (Effient)	*Acute coronary syndrome or after stent implantation:* 60 mg orally loading dose, then 10 mg daily	Inform patients to report any unusual bleeding or bruising.	Contraindicated in patients with history of prior stroke or >75 yrs of age, due to increased risk for bleeding. If patient weighs <60 kg, consider lowering dose to 5 mg daily.
Ticagrelor (Brilinta)	*Acute coronary syndrome or after stent implantation:* 180 mg load with 325 mg aspirin, then 90 mg daily with 81 mg of aspirin	Inform patients to report any unusual bleeding or bruising. Teach patients to avoid over-the-counter pain relievers that contain aspirin. Teach patients to take no more than 100 mg of aspirin in a 24 hour period.	May cause dyspnea or bradycardia that is self-limiting. May not work as effectively with high-dose aspirin; use 81 mg of aspirin.

BP, Blood pressure; *MI,* myocardial infarction.

When pain or other symptoms have subsided and the patient is stabilized, the health care provider may change the drug to an oral or

topical nitrate. During administration of long-term oral and topical nitrates, an 8- to 12-hour nitrate-free period should be maintained to prevent tolerance. The patient may initially report a headache. Give acetaminophen (Tylenol, Exdol) before the nitrate to ease some of this discomfort.

The health care provider usually prescribes *morphine sulfate (MS)* to relieve discomfort that is unresponsive to nitroglycerin. Morphine relieves MI pain, decreases myocardial oxygen demand, relaxes smooth muscle, and reduces circulating catecholamines. It is usually administered in 2- to 10-mg doses IV every 5 to 15 minutes until the maximum prescribed dose is reached or the patient experiences relief or signs of toxicity. Monitor for adverse effects of morphine, which include respiratory depression, hypotension, bradycardia, and severe vomiting. Treatment for morphine toxicity is naloxone (Narcan) 0.2 to 0.8 mg IV, vasopressor drugs, IV fluids, and oxygen therapy. Monitor the patient's vital signs and cardiac rhythm every few minutes.

These strategies are often enough to relieve the pain. If they are not adequate, additional interventions identified in the Improving Cardiopulmonary Tissue Perfusion section below may be attempted.

Other Interventions.

Several other interventions may be used with drug therapy to relieve chest pain. Supplemental oxygen increases the amount of oxygen available to myocardial tissue. Therefore oxygen is usually prescribed and administered at a flow of 2 to 4 L/min by nasal cannula titrated to maintain an arterial oxygen saturation (Sa_{O_2}) of 95% or higher. If the BP is stable, assist the patient in assuming any position of comfort. Placing the patient in semi-Fowler's position often enhances comfort and tissue oxygenation. A quiet, calm environment and explanations of interventions often reduce anxiety and help relieve chest pain. If needed, remind the patient to take several deep breaths to increase oxygenation.

Clinical Judgment Challenge

Patient-Centered Care; Evidence-Based Practice; Informatics

QSEN

An 82-year-old man living alone at home had a sudden onset of chest pain. He called 911 and was taken to the emergency department (ED).

1. As his ED nurse, what is your first action in response to his report of chest pain? What evidence supports this decision?

2. The physician prescribes IV nitroglycerin for pain. What assessment will you perform prior to administering this drug and why? For what adverse effects will you monitor during and after morphine administration?
3. What other drugs might the physician prescribe at this time and why?
4. The physician prescribed oxygen at 3 L/min via nasal cannula. What is the purpose of this intervention for managing chest pain?
5. What will you document in the electronic health record about this patient's care?

Improving Cardiopulmonary Tissue Perfusion

Planning: Expected Outcomes.

The primary outcome is that the patient will have increased myocardial perfusion as evidenced by an adequate cardiac output, normal sinus rhythm, and vital signs within normal limits.

Interventions.

Because myocardial infarction (MI) is a dynamic process, restoring perfusion to the injured area (usually within 4 to 6 hours for NSTEMI and 60 to 90 minutes for STEMI) often limits the amount of extension and improves left ventricular function. Complete, sustained reperfusion of coronary arteries after an ACS has decreased mortality rates.

Drug Therapy.

Aspirin (ASA) therapy is recommended by the American College of Cardiology (ACC) and the American Heart Association (AHA) (Cayla et al., 2012). It inhibits both platelet aggregation and vasoconstriction, thereby decreasing the likelihood of thrombosis. *If the patient has new-onset angina at home, teach him or her to chew aspirin 325 mg (4 "baby aspirins" that are 81 mg each) immediately and call 911!* The antiplatelet effect of ASA begins within 1 hour of use and continues for several days. In the hospital setting, The Joint Commission Acute Myocardial Infarction Core Measure Set requires that aspirin be given upon arrival to the emergency department or when an MI occurs in the hospital. Administer 162 to 325 mg non–enteric-coated aspirin every day to all patients with suspected CAD unless absolutely contraindicated. Instruct the patient to chew and swallow the drug and continue taking the drug as prescribed unless adverse effects occur.

Nursing Safety Priority QSEN

Drug Alert

For patients taking aspirin every day, observe for bleeding tendencies, such as nosebleeds or blood in the stool. Aspirin should be discontinued if bleeding occurs.

Glycoprotein (GP) IIb/IIIa inhibitors target the platelet component of the thrombus. Abciximab (ReoPro), eptifibatide (Integrilin), or tirofiban (Aggrastat) may be administered IV to prevent fibrinogen from attaching to activated platelets at the site of a thrombus. These medications are used in unstable angina and NSTEMI. They are also given before and during percutaneous coronary intervention (PCI) to maintain patency of an artery with a large clot and are given with fibrinolytic agents after STEMI. If the GP IIb/IIIa inhibitors are used with a fibrinolytic agent, the dose of the thrombolytic is reduced by 25% to 50% to decrease the risk for bleeding.

Nursing Safety Priority QSEN

Drug Alert

When giving GP IIb/IIIa inhibitors, assess the patient closely for bleeding or hypersensitivity reactions. If either occurs, notify the health care provider or Rapid Response Team immediately. Monitor the platelet level 4 hours after starting the drug and daily after that. Notify the cardiologist if the patient experiences a significant decrease in platelet count per agency protocol.

Once-a-day *beta-adrenergic blocking agents* (e.g., metoprolol XL [Toprol XL], carvedilol CR [Coreg CR]), sometimes just called *beta blockers (BBs)*, decrease the size of the infarct, the occurrence of ventricular dysrhythmias, and mortality rates in patients with MI. The physician usually prescribes a cardioselective beta-blocking agent within the first 1 to 2 hours after an MI if the patient is hemodynamically stable. Beta blockers slow the heart rate and decrease the force of cardiac contraction (see Chart 38-4). Thus these agents prolong the period of diastole and increase myocardial perfusion while reducing the force of myocardial contraction. With beta blockade, the heart can perform more work without ischemia. During beta-blocking therapy, monitor for:

- Bradycardia

• Hypotension
• Decreased level of consciousness (LOC)
• Chest discomfort

Assess the lungs for crackles (indicative of heart failure) and wheezes (indicative of bronchospasm). Hypoglycemia, depression, nightmares, and forgetfulness are also problems with beta blockade, especially in older patients. Many of these side effects decrease with time. Unless contraindicated, all patients experiencing NSTEMI and STEMI should be discharged on beta blocker therapy.

Nursing Safety Priority QSEN

Drug Alert

Do not give beta blockers if the pulse is below 55 or the systolic BP is below 100 without first checking with the health care provider.

Health care providers frequently prescribe *angiotensin-converting enzyme inhibitors (ACEIs)* or *angiotensin receptor blockers (ARBs)* within 48 hours of ACS if ejection fraction is equal to or less than 40% to prevent ventricular remodeling and the development of heart failure. Both ACEIs and ARBs increase survival after an MI. Monitor the patient for decreased urine output, hypotension, and cough. Check for changes in serum potassium, creatinine, and blood urea nitrogen. (Chapter 36 provides a more detailed discussion of ACEIs and ARBs.)

For patients with angina, the health care provider may prescribe calcium channel blockers (CCBs) to promote vasodilation and myocardial perfusion. These drugs are indicated for patients with variant angina or for those who are hypertensive and continue to have angina despite therapy with beta blockers (unstable angina). They are *not* indicated after AMI. Monitor the patient for hypotension and peripheral edema, and review the frequency of angina episodes.

Calcium channel blockers are also used for chronic stable angina (CSA). When they are not successful in managing CSA, *ranolazine (Ranexa)* may be added to the drug regimen. This drug has anti-angina and anti-ischemic properties and is often effective in relieving the pain associated with CSA.

Reperfusion Therapy.

As time passes, myocardial tissue can become increasingly ischemic and necrotic. Therefore, based on the location and skill set within the health

care institution, one of two reperfusion strategies are employed to open a blocked artery in a patient experiencing AMI: thrombolytic therapy or percutaneous coronary intervention (PCI).

Thrombolytic Therapy.

Thrombolytic therapy using **fibrinolytics** dissolves thrombi in the coronary arteries and restores myocardial blood flow. Examples of these agents, which target the fibrin component of the coronary thrombosis, include:

- Tissue plasminogen activator (t-PA, alteplase [Activase]) (IV or intracoronary)
- Reteplase (Retavase) (IV or intracoronary)
- Tenecteplase (TNK) (IV push [IVP])

Intracoronary fibrinolytics may be delivered during cardiac catheterization. Thrombolytic agents are most effective when administered within the first 6 hours of a coronary event. They are used in men and women, young and old.

Thrombolytic therapy is given in a unit where the patient can be continuously monitored. It is indicated for chest pain of longer than 30 minutes' duration that is unrelieved by nitroglycerin, with *indications of STEMI by the ECG.* It is *not* indicated for the NSTEMI patient population. The goal is to start the infusion of fibrinolytics within 30 minutes of ED admission. Contraindications include recent abdominal surgery or stroke, because bleeding may occur when fresh clots are lysed (broken down or dissolved). Table 38-2 lists the current contraindications to thrombolytic therapy.

TABLE 38-2

Contraindications to Thrombolytic Therapy

Absolute
• Any prior intracranial hemorrhage • Known structural cerebral vascular lesion (e.g., arteriovenous malformations) • Known malignant intracranial neoplasm (primary or metastatic) • Ischemic stroke within 3 months EXCEPT acute ischemic stroke within 3 hours • Suspected aortic dissection • Active bleeding or bleeding diathesis (excluding menses) • Significant closed-head or facial trauma within 3 months
Relative
• History of chronic, severe, poorly controlled hypertension • Severe uncontrolled hypertension on presentation (SBP >180 mmHg or DBP >110 mmHg)* • History of prior ischemic stroke within 3 months, dementia, or known intracranial pathology not covered in contraindications • Traumatic or prolonged (≥10 minutes) CPR or major surgery (within 3 weeks) • Recent (within 2–4 weeks) internal bleeding • Noncompressible vascular punctures • For streptokinase/anistreplase: prior exposure (>5 days ago) or prior allergic reaction to these agents • Pregnancy • Active peptic ulcer • Current use of anticoagulants; the higher the INR, the higher risk for bleeding

CPR, Cardiopulmonary resuscitation; *DBP,* diastolic blood pressure; *INR,* international normalized ratio; *MI,* myocardial infarction; *SBP,* systolic blood pressure.

*Could be an absolute contraindication in low-risk patients with MI.

Patients who weigh less than 143 pounds (65 kg) may need to have their dose of thrombolytic adjusted to lessen the likelihood of bleeding.

Nursing Safety Priority QSEN

Drug Alert

During and after thrombolytic administration, immediately report any indications of bleeding to the health care provider or Rapid Response Team. Observe for signs of bleeding by:

- Documenting the patient's neurologic status (in case of intracranial bleeding)
- Observing all IV sites for bleeding and patency
- Monitoring clotting studies
- Observing for signs of internal bleeding (Monitor hemoglobin, hematocrit, and blood pressure.)
- Testing stools, urine, and emesis for occult blood

Percutaneous Coronary Intervention.

For some patients having an ACS, primary percutaneous coronary intervention (PCI) may be used to reopen the clotted coronary artery and restore perfusion. Percutaneous intervention has been associated with excellent return of blood flow through the coronary artery when it can be

performed by an interventional cardiologist within 2 to 3 hours of the onset of symptoms. Many community hospitals can now perform emergent PCI. When primary PCI is not available, patients should receive immediate thrombolytic agents if they are appropriate candidates and then be transferred to a facility that can perform PCI. This procedure is described in detail on p. 772 of this chapter. After PCI with stent placement, the patient requires dual antiplatelet therapy, explained later in the chapter.

Patients who receive fibrinolytics require PCI for more definitive treatment such as stent placement. Therefore, if criteria for PCI are met, it is more advantageous to go directly to the catheterization laboratory where definitive treatment, not just clot resolution, can be performed.

Monitor the patient for indications that the clot has been lysed (dissolved) and the artery reperfused. These indications include:

- Abrupt cessation of pain or discomfort
- Sudden onset of ventricular dysrhythmias
- Resolution of ST-segment depression/elevation or T-wave inversion
- A peak at 12 hours of markers of myocardial damage

After clot lysis with thrombolytics, large amounts of thrombin are released into the system, increasing the risk for vessel reocclusion. To maintain the patency of the coronary artery after thrombolytic therapy, the health care provider usually prescribes aspirin and IV heparin, a *high-alert drug*. Maintain the heparin infusion via pump for 3 to 5 days as prescribed, and monitor the activated partial thromboplastin time (aPTT). The target aPTT range is usually 1½ to 2½ times the control sample. The heparin antifactor Xa assay (heparin assay) test may be used instead of the aPTT in some clinical facilities. Low–molecular-weight heparin (LMWH) (enoxaparin [Lovenox]) may be substituted for IV heparin. Therapeutic dosing of LMWH in this patient population should be based on weight (1 mg/kg). Chapter 36 describes care of the patient receiving heparin or LMWH in detail.

NCLEX Examination Challenge

Physiological Integrity

A client weighing 174 pounds had thrombolytic therapy followed by a one-time dose of IV Lovenox 30 mg. The physician prescribes Lovenox 1 mg/kg subcutaneously after the IV administration. The nurse will give ____ mg of Lovenox to the client.

Increasing Activity Tolerance

Planning: Expected Outcomes.

The patient is expected to increase activity without chest pain and the need for supplemental oxygen as a result of a collaborative cardiac rehabilitation program.

Interventions.

Activity intolerance is reduced by a planned program of cardiac rehabilitation implemented primarily by the nurse and physical therapist and continued after discharge.

Cardiac rehabilitation is the process of actively assisting the patient with cardiac disease in achieving and maintaining a vital and productive life while remaining within the limits of the heart's ability to respond to increases in activity and stress. It can be divided into three phases. *Phase 1* begins with the acute illness and ends with discharge from the hospital. *Phase 2* begins after discharge and continues through convalescence at home. *Phase 3* refers to long-term conditioning.

In the acute phase (phase 1), promote rest and ensure limited mobility. Assistance may be needed for some ADLs, such as ambulation to the bathroom. Patients progress at their own rate to increasing levels of activity depending on their clinical status, age, and physical capabilities.

The next step in phase 1 is independent ambulation of the patient in the room and to the bathroom. Encourage progressive ambulation in the hallway, usually 50, 100, and then 200 feet 3 times a day. In addition, the patient may begin showering for 5 or 10 minutes with warm water. A chair should be available to facilitate rest and maintain balance.

Nursing Safety Priority QSEN

Action Alert

During cardiac rehabilitation, assess the patient's heart rate, blood pressure (BP), respiratory rate, and level of fatigue with each higher level of activity. Decreases greater than 20 mm Hg in the systolic BP, changes of 20 beats per minute in the pulse rate, and/or reports of dyspnea or chest pain indicate intolerance of activity. If these manifestations develop, notify the health care provider and do not advance the patient to the next level. Older adults with CAD often have needs and concerns different from those of younger adults, as described in Chart 38-5.

Chart 38-5 Nursing Focus on the Older Adult

Coronary Artery Disease

- Recognize that chest pain may not be evident in the older patient. Examples of associated symptoms are unexplained dyspnea, confusion, or GI symptoms.
- Although older adults have a greater reduction in mortality rate from myocardial infarction (MI) with the use of thrombolytics, they also have the most severe side effects. Monitor older patients receiving thrombolytics extremely carefully.
- Dysrhythmia may be a normal age-related change rather than a complication of MI. Determine whether the dysrhythmia is causing significant symptoms. Then notify the physician.
- If beta blockers are used, assess the patient carefully for the development of side effects. Exacerbation of the depression some older adults have is a significant problem with beta blockade.
- Plan slow, steady increases in activity. Older adults with minimal previous exercise show particular benefit from a gradual increase in activity.
- Older adults should plan longer warm-up and cool-down periods when participating in an exercise program. Their pulse rates may not return to baseline until 30 minutes or longer after exercise.

All patients with ACS should be referred to a phase 2 cardiac rehabilitation program upon discharge from the hospital. Collaborate with the case manager to plan for the patient's continuing care.

Promoting Effective Coping

Planning: Expected Outcomes.

The patient is expected to learn to cope with the cardiac event and identify effective coping strategies with the help of support systems.

Interventions.

Assess the patient's level of anxiety while allowing expressions of any apprehension, and attempt to define its origin. Simple, repeated explanations of therapies, expectations, and surroundings, as well as patient progress, may help relieve anxiety.

Identify the patient's current *coping* mechanisms. The most common are denial, anger, and depression. Denial allows the patient to decrease a

threat and use problem-focused coping mechanisms. The patient may avoid discussing what has happened and yet comply with treatment regimens. This type of denial decreases anxiety and should not be discouraged. *However, denial that results in a patient who refuses to follow treatment regimens can be harmful.* Because this behavior is usually due to extreme anxiety or fear, threats only worsen the behavior. Remain calm, and avoid confronting the patient. Clearly indicate when a behavior is not acceptable and is potentially harmful as a result of noncompliance.

Anger may represent an attempt to regain control of life. Encourage the patient to verbalize the source of frustration, and provide opportunities for decision making and control. Collaborate with the certified spiritual chaplain or social worker in the hospital to help the patient cope with the situation based on his or her preferences, values, and beliefs. Help the patient identify support systems, such as family, friends, church, or social group.

Depression may be a response to grief and loss of function. Listen as the patient verbalizes feelings of loss, being careful not to offer false or general reassurances. Acknowledge depression, but encourage the patient to perform ADLs and other activities within restrictions.

Identifying and Managing Dysrhythmias

Planning: Expected Outcomes.

The most desired outcome for the patient is that he or she will be free of dysrhythmias. If dysrhythmias occur, they will be identified and managed early to prevent complications or death.

Interventions.

Dysrhythmias are the leading cause of prehospital death in most patients with ACS. Even in the early period of hospitalization, most patients with ACS experience some abnormal cardiac rhythm. When a dysrhythmia develops:

- Identify the dysrhythmia.
- Assess hemodynamic status.
- Evaluate for discomfort.

Dysrhythmias are treated when they cause hemodynamic compromise, increase myocardial oxygen requirements, or predispose the patient to lethal ventricular dysrhythmias.

Typical dysrhythmias for the patient with an *inferior* ACS are bradycardias and second-degree AV blocks resulting from ischemia of the AV node. These rhythms tend to be intermittent. Monitor the cardiac

rhythm and rate and the hemodynamic status. If the patient becomes hemodynamically unstable, a temporary pacemaker may be necessary.

The patient with an *anterior* ACS is likely to exhibit premature ventricular contractions (PVCs) caused by ventricular irritability. Third-degree or bundle branch block is a serious complication in this patient because it indicates that a large portion of the left ventricle is involved. The health care provider may insert a pacemaker. Observe the patient closely to detect the development of heart failure. Appropriate interventions for dysrhythmias are described in Chapter 34.

Monitoring for and Managing Heart Failure

Planning: Expected Outcomes.

The most desired outcome for the patient is that he or she will be free of heart failure. However, if it occurs, the outcome is that the heart failure will be identified and treated early to prevent further complications.

Interventions.

Decreased cardiac output related to heart failure is a relatively common complication after an MI resulting from left ventricular dysfunction, rupture of the intraventricular septum, papillary muscle rupture with valvular dysfunction, or right ventricular infarction. The most severe form of acute heart failure, *cardiogenic shock*, discussed later in this chapter, causes most in-hospital deaths after an ACS. The type of management used to increase cardiac output depends on the location of the ACS and the type of heart failure that resulted from the infarction.

Managing Left Ventricular Failure.

When a patient with ACS experiences damage to the left ventricle, rupture of the intraventricular septum, or tear of a papillary muscle, the amount of blood that the heart can eject is reduced. When volume and pressure are markedly increased in the pulmonary vasculature, pulmonary complications can develop.

Assess for manifestations of left ventricular failure and pulmonary edema by listening for crackles and identifying their location in the lung fields. Wheezing, tachypnea, and frothy sputum may also occur with pulmonary edema. Auscultate the heart, paying particular attention to the presence of an S_3 heart sound.

Nursing Safety Priority QSEN

Critical Rescue

Monitor for, report, and document these signs of inadequate organ perfusion that may result from decreased cardiac output:

- A change in orientation or mental status
- Urine output less than 0.5-1 mL/kg/hr
- Cool, clammy extremities with decreased or absent pulses
- Unusual fatigue
- Recurrent chest pain

In specialized units, hemodynamic monitoring requiring the insertion of a pulmonary artery catheter may be started to assess the patient's preload, afterload, and cardiac output.

Hemodynamic Monitoring.

Hemodynamic monitoring is an invasive system used in critical care areas to provide quantitative information about vascular capacity, blood volume, pump effectiveness, and tissue perfusion. It directly measures pressures in the heart and great vessels. These procedures are usually performed for more seriously ill patients and can provide more accurate measurements of blood pressure, heart function, and volume status. Although medical-surgical nurses do not manage these systems on general hospital units, they should be familiar with the interpretation of some of the major hemodynamic pressures as they relate to patient assessment.

Hemodynamic monitoring does involve significant risks, although complications are uncommon. Therefore informed consent is required. After obtaining consent, the critical care nurse prepares a pressure-monitoring system. The components of this system are a catheter with an infusion system, a transducer, and a monitor. The catheter receives the pressure waves (mechanical energy) from the heart or the great vessels. The transducer converts the mechanical energy into electrical energy, which is displayed as waveforms or numbers on the monitor. Patency of the catheter is maintained with a slow continuous flush of normal saline, usually infused at 3 to 4 mL/hr under pressure to prevent the backup of blood and occlusion of the catheter.

To prepare the transducer, balance and calibrate it according to hospital policy and the manufacturer's specifications. Finally, identify the phlebostatic axis (Chart 38-6) and level the transducer to it. The physician inserts a balloon-tipped catheter percutaneously through a large vein, usually the internal jugular or subclavian, and directs it to the right

atrium (RA). When the catheter tip reaches the RA, the physician inflates the balloon. The catheter advances with the flow of blood through the tricuspid valve, into the right ventricle, past the pulmonic valve, and into a branch of the pulmonary artery. The balloon is deflated after the catheter tip reaches the pulmonary artery. Waveforms are viewed on the monitor as the pulmonary artery catheter is advanced (Fig. 38-3). A chest x-ray is used to check the location of the catheter.

Chart 38-6 Best Practice for Patient Safety & Quality Care QSEN

Identification of the Phlebostatic Axis

1. Position the patient supine.
2. Palpate the fourth intercostal space at the sternum.
3. Follow the fourth intercostal space to the side of the patient's chest.
4. Determine the midway point between anterior and posterior.
5. Find the intersection between the midway point and the line from the fourth intercostal space, and mark it with an X in indelible ink. This is the phlebostatic axis.

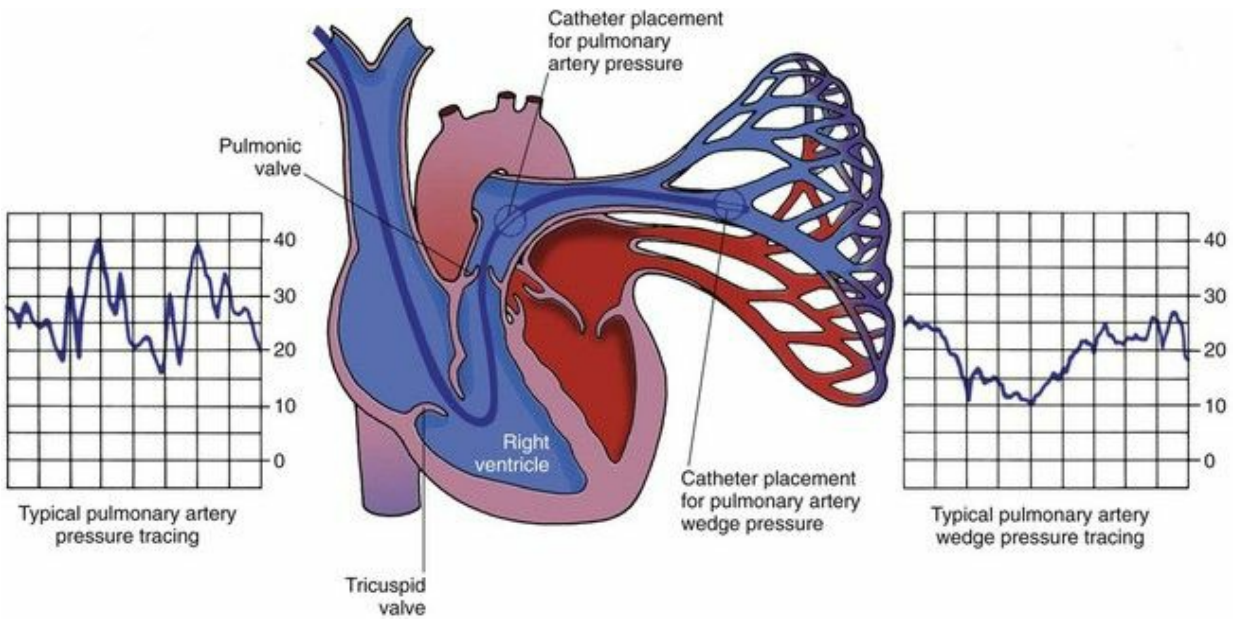

FIG. 38-3 Cardiac pressure waveforms can be seen on the monitor.

A pulmonary artery catheter is a multi-lumen catheter with the capacity to measure right atrial and indirect left atrial pressures or pulmonary artery wedge pressure (PAWP), also known as the **pulmonary artery occlusive pressure (PAOP).** A cardiac output measurement may

also be obtained, as well as cardiac index and systemic and pulmonary vascular resistance.

Right atrial pressure is measured by a pressure sensor on the catheter inside the RA. Normal RA pressure ranges from 1 to 8 mm Hg. *Increased RA pressures may occur with right ventricular failure, whereas low RA pressures usually indicate hypovolemia.*

Normal pulmonary artery pressure (PAP) ranges from 15 to 26 mm Hg systolic/5 to 15 mm Hg diastolic (mean, 15) and is constantly visible on the monitor. When the balloon at the catheter tip is inflated, the catheter advances and wedges in a branch of the pulmonary artery. The tip of the catheter can sense pressures transmitted from the left atrium, which reflect left ventricular end-diastolic pressure (LVEDP). The pressure measured during balloon inflation is called the **pulmonary artery wedge pressure (PAWP).** PAWP closely reflects left atrial pressure and LVEDP in patients with normal left ventricular function, normal heart rates, and no mitral valve disease. The PAWP is a mean pressure and normally ranges between 4 and 12 mm Hg.

Elevated PAWP measurements may indicate left ventricular failure, hypervolemia, mitral regurgitation, or intracardiac shunt. A decreased PAWP is seen with hypovolemia or afterload reduction. Individual values may be less important than the trend in values.

The critical care nurse obtains and records RA pressure, PAP, and PAWP at appropriate intervals (usually every 1 to 4 hours). Single values of these measurements are less significant than the trend of values combined with the patient's clinical manifestations. They help health care providers identify heart failure and guide the administration of fluids and vasoactive drugs. During pressure recording, it is important that the transducer be at the level of the phlebostatic axis. The patient is usually supine with the head elevated up to 45 degrees during hemodynamic readings, although the position may not affect results. If the balloon remains in the wedge position after PAWP measurement, try to change the catheter's position by asking the patient to cough or by changing his or her position. *If these methods are not successful, notify the physician immediately.*

Change the occlusive sterile dressing over the catheter according to hospital policy. Inspect the insertion site for redness, induration, swelling, drainage, and intactness of the sutures. Detailed discussion of the management and care of patients with pulmonary artery catheters can be found in textbooks on critical care nursing.

Be sure to assess for a number of complications associated with pulmonary artery catheters. For example, pulmonary infarction or

pulmonary rupture may occur if the catheter remains in the wedge position. Air embolism is possible if the balloon has ruptured and repeated attempts are made to inflate it. Ventricular dysrhythmias may occur during insertion or if the catheter tip slips back into the right ventricle and irritates the myocardium. Thrombus and embolus formation may occur at the catheter site. Infection may result, and bleeding may be pronounced if the infusion system becomes disconnected.

Direct measurement of *arterial BP* is done by invasive arterial catheter in critically ill patients. The physician or specially trained health care professional inserts an intra-arterial catheter into the radial or femoral artery. After the catheter is inserted, it is attached to pressure tubing. A normal saline flush solution is infused constantly under pressure to maintain the integrity of the system. A transducer attached to the tubing allows continuous direct monitoring of the arterial BP. Direct measurements of BP are usually 10 to 15 mm Hg greater than indirect (cuff) measurements. The arterial catheter may also be used to obtain blood samples for arterial blood gas values and other blood tests.

Because the arterial vasculature is a high-pressure system, frequent assessment of the arterial site and infusion system is essential. *Note any bleeding around the intra-arterial catheter or any loose connections, and correct the situation immediately*. Collateral circulation must be assessed by Doppler before and while the arterial catheter is in place. Carefully monitor color, pulse, and temperature distal to the insertion site for any early signs of circulatory compromise. Complications of systemic intra-arterial monitoring include pain, infection, arteriospasm, or obstruction at the site with the potential for distal infarction, air embolism, and hemorrhage.

Classification of Post–Myocardial Infarction Heart Failure.

Several classification systems may be used to categorize heart failure after an MI. For example, the classic Killip system identifies four classes based on prognosis (Table 38-3). This system complements the ACC/AHA heart failure classification of function assessment discussed in Chapter 35.

TABLE 38-3

Killip Classification of Heart Failure

CLASS	DESCRIPTION
I	Absent crackles and S_3
II	Crackles in the lower half of the lung fields and possible S_3
III	Crackles more than halfway up the lung fields and frequent pulmonary edema
IV	Cardiogenic shock

Patients with *class I* heart failure often respond well to reduction in preload with IV nitrates and diuretics. Monitor the urine output hourly, check vital signs hourly, continue to assess for signs of heart failure, and review the serum potassium level.

Patients with *class II* and *class III* heart failure may require diuresis and more aggressive medical intervention, such as afterload reduction and/or enhancement of contractility. IV nitroprusside or nitroglycerin may be used to decrease both preload and afterload. These drugs are given as continuous infusions in specialized units where the PAWP and BP can be closely monitored. The BP can drop in response to excessive vasodilation.

Patients in *classes II* and *III* are usually started on once-a-day beta blockers (usually Toprol XR or Coreg CR). Dosing is titrated depending on goal achievement and drug tolerance. Other drugs, including ACE inhibitors and ARBs, are commonly prescribed to promote ventricular remodeling. These drugs are described in Chart 38-4 and in Chapter 36.

Positive inotropes, such as dobutamine (Dobutrex) and milrinone (Primacor), increase the force of cardiac contraction. They are administered by continuous IV infusion. The effects of these drugs on the blood vessels and heart rate vary and may be dose dependent. The infusions are titrated to promote cardiac output.

Nursing Safety Priority QSEN

Drug Alert

Use caution when giving positive inotropes because of the potential risk for increasing myocardial oxygen consumption and further decreasing cardiac output. Monitor the patient frequently, paying particular attention to the development of chest pain.

Class IV heart failure is cardiogenic shock. In **cardiogenic shock,** necrosis of more than 40% of the left ventricle occurs. Most patients have a stuttering pattern of chest pain, resulting in piecemeal extension of the

ACS.

Nursing Safety Priority QSEN

Critical Rescue

Monitor for, report, and document manifestations of cardiogenic shock immediately. These signs and symptoms include:

- Tachycardia
- Hypotension
- Systolic BP less than 90 mm Hg or 30 mm Hg less than the patient's baseline
- Urine output less than 0.5-1 mL/kg/hr
- Cold, clammy skin with poor peripheral pulses
- Agitation, restlessness, or confusion
- Pulmonary congestion
- Tachypnea
- Continuing chest discomfort

Early detection is essential because undiagnosed cardiogenic shock has a high mortality rate!

Drug Therapy.

Medical interventions aim to relieve pain and decrease myocardial oxygen requirements through preload and afterload reduction (see Chart 38-4 and Chart 38-7). The health care provider prescribes IV morphine, which is used to decrease pulmonary congestion and relieve pain. Oxygen is administered. Intubation and mechanical ventilation may be necessary.

Chart 38-7 Common Examples of Drug Therapy

Commonly Used Intravenous Vasodilators and Inotropes

DRUG	USUAL DOSAGE	NURSING INTERVENTIONS	RATIONALES
Nitrates			
Nitroprusside sodium (Nipride, Nitropress)	IV only by infusion device Begin with 0.4-0.5 mcg/kg/min May increase gradually to 10 mcg/kg/min	Monitor BP every 2-5 min when initiating therapy. If BP drops excessively, elevate the legs, decrease the dose, and increase fluids per unit policy. Monitor PAWP, SVR, BP, heart rate, urine output frequently. Titrate medication to obtain the desired effect.	This agent is a potent, rapidly reversible vasodilator acting on both peripheral venous and arterial musculature. BP may drop in 2 min.
		Protect from light.	This agent is light sensitive.
		Maintain dose at less than 3 mcg/kg/min if possible.	Doses higher than 3 mcg/kg/min are associated with thiocyanate or cyanide toxicity.
		In patients requiring doses higher than 3 mcg/kg/min for longer than 24-36 hr, monitor for metabolic acidosis, confusion, or hyperreflexia. Examine blood thiocyanate level.	These are indications of the toxic effects of cyanide.
Nitroglycerin (Tridil)	IV only by infusion device Begin with 5 mcg/kg/min and gradually increase in increments of 5 every 3-5 min If no response after 20 mcg/kg/min, increase by 10-20 mcg until desired response	Monitor BP every 1-3 min when initiating therapy. If BP drops excessively, elevate the legs and decrease the dose according to unit policies. Monitor RAP, PAWP, SVR, BP, heart rate, and urine output frequently. Titrate medication to obtain the desired effect.	This agent dilates coronary arteries. It is a more potent systemic vasodilator than an arterial vasodilator. BP may drop in 1 min.
		Intermittent administration of IV nitroglycerin should be considered.	Tolerance may develop rapidly to nitroglycerin administered by continuous IV.
		Monitor patients for headache.	Headache is a frequent side effect of initial nitroglycerin therapy.
Milrinone (Primacor)	IV bolus 50 mcg/kg given over 10 min; start infusion of 0.375-0.75 mcg/kg/min; reduce dose in renal impairment	Assess BP and pulse every 5 min. If systolic BP drops 30 mm Hg, stop infusion and call health care provider.	Hypotension is a common adverse effect.
		Monitor I&O and weight.	The drug causes diuresis.
Fenoldopam (Corlopam)	0.01-1.6 mcg/kg/min IV	Assess BP and pulse every 5 min, then every 1 hr × 2, then every 4 hr, or according to agency policy. Monitor I&O, and assess for signs of dehydration. Observe IV site for extravasation.	Same as for milrinone.
Sympathomimetics			
Dopamine (Intropin)	IV only by infusion device Starting dose 2-5 mcg/kg/min Titrate up to 50 mcg/kg/min	Determine the reason for use and the expected result. Observe the patient's heart rate, ECG, BP, PAWP, SVR, cardiac output, and urine output every 5 min to every 1 hr. Titrate the dose carefully to maintain the dose range and obtain the desired effect. Infuse through a central catheter. Monitor patients for ectopy and angina.	This agent is a dose-dependent activator of alpha, beta, and dopaminergic receptors. 2-5 mcg/kg/min stimulates dopaminergic receptors, which promotes renal and mesenteric blood flow. 5 mcg/kg/min stimulates beta receptors. This increases heart rate and contractility more than 10-15 mcg/kg/min; alpha effects predominate. This causes peripheral constriction. Extravasation can cause tissue necrosis and sloughing. These are adverse effects.
Dobutamine (Dobutrex)	IV only by infusion device, 2-10 mcg/kg/min. May increase to 40 mcg/kg/min.	Observe patients continuously during administration. Titrate the drug on the basis of adequate tissue perfusion: mentation, skin temperature, peripheral pulses, PAWP, cardiac output, SVR, and urine output.	This agent is a very strong $beta_1$-receptor activator and a moderately strong $beta_2$-receptor activator.
		Monitor for atrial and ventricular ectopy.	Dysrhythmias are an adverse effect.

BP, Blood pressure; *ECG,* electrocardiogram; *I&O,* input and output; *PAWP,* pulmonary artery wedge pressure; *RAP,* right atrial pressure; *SVR,* systemic vascular resistance.

Use the information gained from hemodynamic monitoring to titrate drug therapy. Preload reduction may be cautiously attempted with diuretics or nitroglycerin, as described for patients with Killip class III heart failure. (See Chapter 35 for a complete discussion of preload and afterload.) Monitor systolic pressure continuously because vasodilation may result in a further decline in BP. Vasopressors and positive inotropes may be used to maintain organ perfusion, but these drugs increase myocardial oxygen consumption and can worsen ischemia. Use extreme caution in giving drug therapy.

Other Interventions for Left-Sided Heart Failure.

When patients do not respond to drug therapy with improved tissue perfusion, decreased workload of the heart, and increased cardiac contractility, an **intra-aortic balloon pump (IABP)** may be inserted. The IABP is an invasive intervention that is used to improve myocardial perfusion during an acute MI, reduce preload and afterload, and facilitate left ventricular ejection.

The health care provider can insert the device percutaneously or through a surgical cutdown. Inflation of the IABP during diastole augments the diastolic pressure and improves coronary perfusion by increasing blood flow to the arteries. Deflation of the balloon just before systole reduces afterload at the time of systolic contraction. This action facilitates emptying of the left ventricle and improves cardiac output. The balloon catheter is attached to a pump console, which is triggered by an ECG tracing and arterial waveform.

In patients undergoing high-risk percutaneous coronary intervention (PCI) or those at risk for cardiogenic shock, a *percutaneous ventricular assist device* may be used. These devices are temporary to decrease the myocardial workload and oxygen consumption of the heart and increase cardiac output and peripheral perfusion.

Immediate reperfusion is an invasive intervention that shows some promise for managing cardiogenic shock. The patient is taken to the cardiac catheterization laboratory, and an emergency left-sided heart catheterization is performed. If he or she has a treatable occlusion or occlusions, the interventional cardiologist performs a percutaneous coronary intervention in the catheterization laboratory or the patient is transferred to the operating suite for a coronary artery bypass graft (CABG).

Managing Right Ventricular Failure.

Conditions other than left ventricular failure may result in decreased cardiac output after an ACS. In about a third of patients with inferior MIs, right ventricular infarction and failure develop. In this instance, the right ventricle fails independently of the left. Decreased cardiac output with a paradoxical pulse, clear lungs, and jugular venous distention occurs when the patient is in semi-Fowler's position.

A right ventricular MI may be documented by echocardiography and by an ECG using right-sided precordial leads. The desired outcome of management is to improve right ventricular stroke volume by increasing right ventricular fiber stretch or preload. To enhance right ventricular preload, give sufficient fluids (as much as 200 mL/hr) to increase right

atrial pressure to 20 mm Hg. In the critical care unit, *monitor the pulmonary artery wedge pressure (PAWP)—attempting to maintain it below 15 to 20 mm Hg—and auscultate the lungs to assess for left-sided heart failure. If symptoms of this complication occur, notify the health care provider immediately.*

Monitoring for and Managing Recurrent Symptoms and Extension of Injury

Planning: Expected Outcomes.

The most desired outcome is that the patient will not have recurrent symptoms or an extension of myocardial injury. If these problems occur, they will be identified and treated early to prevent further complications or death.

Interventions.

Recurrent discomfort despite medical therapy is one of the major indications for surgical management of CAD. Patients who continue to have chest discomfort despite medical therapy or who have ischemia during a stress test may require invasive correction by PCI or CABG to resolve angina or prevent MI. Before invasive treatment, a left-sided cardiac catheterization with coronary angiogram is performed to document that the lesions are correctable and that left ventricular pump function is adequate.

Percutaneous Coronary Intervention.

Percutaneous coronary intervention (PCI) is an invasive but nonsurgical technique that is performed within 90 minutes of an acute MI (AMI) diagnosis. Hospitals are required to report how many patients with AMI receive a PCI within that time frame per the AMI Core Measure Set. It is performed to reduce the frequency and severity of discomfort for patients with angina and to bridge patients to coronary artery bypass graft (CABG) surgery. It combines clot retrieval, coronary angioplasty, and stent placement. Under fluoroscopic guidance, the cardiologist performs initial coronary angiography. In the STEMI patient, if a clot is seen, a clot retrieval device is inserted over the guidewire and the clot is removed. Once the clot is removed in the STEMI patient or area of narrowing is identified in the NSTEMI patient, a balloon-tipped catheter is introduced through a guidewire to the coronary artery occlusion. The physician activates a compressor that inflates the balloon (angioplasty) to force the plaque against the vessel wall, thus dilating the wall, and reduces or eliminates the occluding clot. Balloon inflation may be

repeated until angiography indicates a decrease in the stenosis (narrowing) to less than 50% of the vessel's diameter (Fig. 38-4). The balloon catheter is then withdrawn, and a balloon catheter with stent is introduced. Once the stent and balloon are in position, the stent is deployed by the balloon inflation. The balloon is deflated and the stent stays in place acting as scaffolding to hold the diseased artery open. **Stents** are expandable metal mesh devices that are used to maintain the patent lumen created by angioplasty or atherectomy. Bare metal or drug-eluting stents (DES) (drug-coated) may be used. By providing a supportive scaffold, these devices prevent closure of the vessel from arterial dissection or vasospasm. Fig. 38-5 shows a stent positioned in a coronary artery.

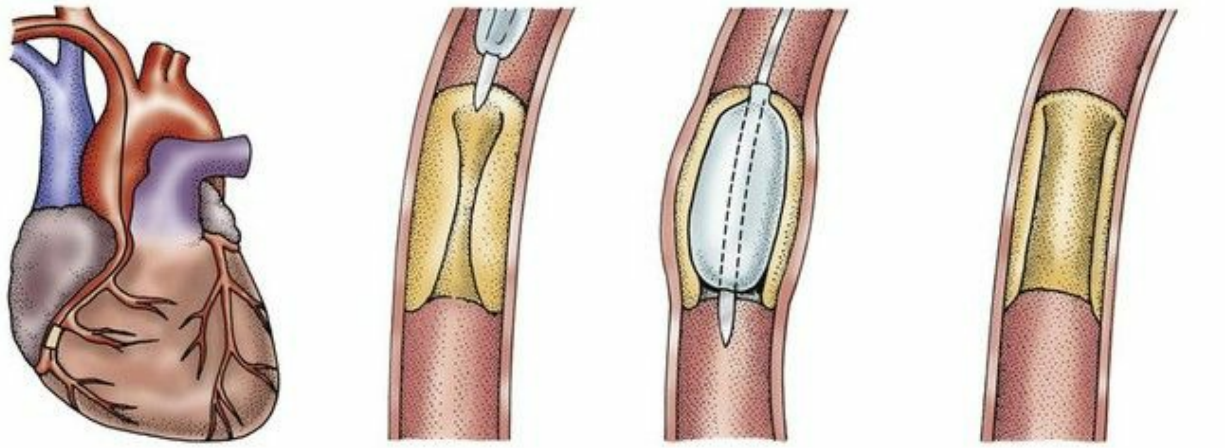

FIG. 38-4 Percutaneous coronary intervention.

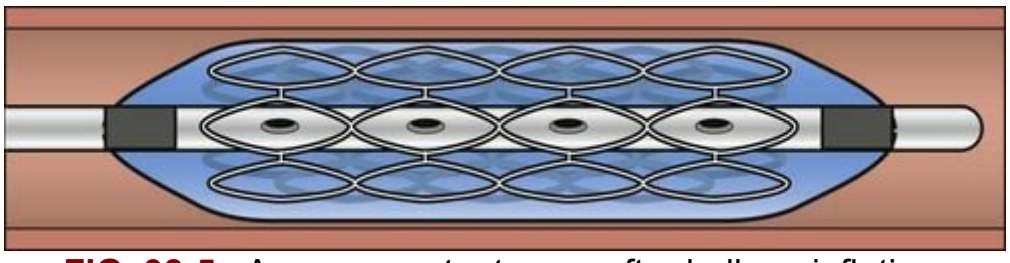

FIG. 38-5 A coronary stent open after balloon inflation.

Patients who are most likely to benefit from PCI have single- or double-vessel disease with discrete, proximal, noncalcified lesions or clots. This procedure often does not work for complex clots. When identifying which lesions are treatable with PCI, the cardiologist

considers the clot's complexity and location, as well as the amount of myocardium at risk. Although treating lesions located in the left main artery places a large amount of myocardial tissue at risk if the vessel closes quickly, these lesions are now being treated more with PCI. In the past, coronary artery bypass grafting (CABG) was the intervention used for these patients. PCI may also be used for the patient with an evolving acute MI, either alone or with thrombolytic therapy or glycoprotein (GP) IIb/IIIa inhibitor, to reperfuse the damaged myocardium.

Without stent placement, the artery often reoccludes due to the artery's normal elasticity and memory. Patients who undergo PCI are required to take dual antiplatelet therapy (DAT) consisting of aspirin and a P2Y12 inhibitor (see Chart 38-4). Before the procedure, the patient receives an initial dose of a P2Y12 platelet inhibitor (clopidogrel [Plavix]) or ticagrelor [Brilinta]) and aspirin. If prasugrel (Effient) is the preferred P2Y12 platelet inhibitor, it is given immediately after PCI. If there are any concerns that the patient may require CABG, the P2Y12 inhibitor may be held until after the procedure. The inhibition of the platelets is permanent and increases the risk for postoperative bleeding. Patients should wait 5 (clopidogrel and ticagrelor) to 7 (prasugrel) days before undergoing CABG. If the patient has received thrombolytic therapy, clopidogrel (Plavix) is the preferred drug.

During the procedure, the patient may receive boluses of IV heparin or a continuous infusion of bivalirudin (Angiomax). Heparin is used to maintain an elevated activated clotting time and prevent clotting on wires and catheters during the procedure. Heparin is discontinued before removal of the catheters. Bivalirudin (Angiomax) is a direct thrombin inhibitor and is frequently used as an alternative to IIb/IIIa inhibitors and heparin. Bivalirudin has a short half-life (25 minutes) and is less dependent on renal function. IV or intracoronary nitroglycerin or diltiazem (Cardizem) is given to prevent coronary vasospasm. PCI initially reopens the vessel in most appropriately selected patients. Within the first 24 hours, however, a small percentage of patients have re-stenosis. At 6 months, a larger number have one or more blockages.

Nursing Safety Priority QSEN

Critical Rescue

After PCI, monitor for potential problems including acute closure of the vessel (causes chest pain), bleeding from the insertion site, and reaction to the contrast medium used in angiography. Also monitor for

and document hypotension, hypokalemia, and dysrhythmias. Document and report any of these findings to the physician or Rapid Response Team immediately!

The health care provider also prescribes a long-term nitrate and beta blocker, and an ACE inhibitor or ARB is added for patients who have had primary angioplasty after an MI. Some patients may experience hypokalemia after the procedure and require careful monitoring and potassium supplements. The nursing interventions for patients receiving these drugs are described in Chart 38-4. Provide careful explanations of drug therapy and any recommended lifestyle changes.

Other Procedures.

Other techniques being used to ensure continued patency of the vessel are laser angioplasty (the laser breaks up the clot) and atherectomy. **Atherectomy** devices can either excise and retrieve plaque or emulsify it. One of the advantages of this procedure is that it creates a less bulky vessel with better elastic recoil. Another procedure that may be performed is rheolytic thrombectomy (e.g., AngioJet, Vortex), which uses low-pressure, high-speed saline jets to break up the clot. The EndiCOR X-SIZER lances and aspirates a clot simultaneously.

Injecting vascular endothelial growth factor (VEGF) during angioplasty has increased perfusion to the wall of the heart. Also, VEGF helps initiate new blood vessel growth and development, which results in increased blood supply to cardiac muscle.

Traditional Coronary Artery Bypass Graft Surgery.

Over 500,000 traditional open **coronary artery bypass graft (CABG)** surgeries are performed in the United States each year (Go et al., 2013). It is the most common type of cardiac surgery and the most common procedure for older adults. Almost half of all CABGs are done for patients older than 65 years. The occluded coronary arteries are bypassed with the patient's own venous or arterial blood vessels or synthetic grafts. The internal mammary artery (IMA) is the current graft of choice because it has an excellent patency rate many years after the procedure.

CABG is indicated when patients do not respond to medical management of CAD or when disease progression is evident. Because of the development of drug-eluting stents (DESs), patients who previously had no option other than CABG have been able to have their vessels revascularized without surgery. The decision for surgery is based on the patient's symptoms and the results of cardiac catheterization. Candidates

for surgery are patients who have:

- Angina with greater than 50% occlusion of the left main coronary artery that cannot be stented
- Unstable angina with severe two-vessel disease, moderate three-vessel disease, or small-vessel disease in which stents could not be introduced
- Ischemia with heart failure
- Acute MI with cardiogenic shock
- Signs of ischemia or impending MI after angiography or percutaneous transluminal coronary angioplasty (PTCA)
- Valvular disease
- Coronary vessels unsuitable for PCI

The vessels to be bypassed should have proximal clots blocking more than 70% of the vessel's diameter but with good distal runoff. Bypass of less occluded vessels may result in poor perfusion through the graft and early obstruction. CABG is most effective when adequate ventricular function remains and the ejection fraction is close to or greater than 50%. Patients with lower ejection fractions are subject to develop more complications.

For most patients, the risk is low and the benefits of bypass surgery are clear. Surgical treatment of CAD does not appear to affect the life span. Left ventricular function is the most important long-term indicator of survival. CABG improves the quality of life for most patients. Most are pain-free at 1 year after surgery and remain so at 5 years after the procedure. The percentage of patients experiencing some pain increases sharply after 5 years.

Preoperative Care.

CABG surgery may be planned as an elective procedure or performed as an emergency. It may be done as a *traditional* operative technique or performed as a *minimally invasive surgical (MIS)* technique, discussed later on p. 777. Patients undergoing elective surgery are admitted on the morning of surgery. Preoperative preparations and teaching are completed during prehospitalization interviews. Teach patients that their drugs will be changed after surgery. Ensure that the necessary drugs have been administered before surgery.

Familiarize the patient and family with the cardiac surgical–critical care unit (sometimes referred to as the "open heart" unit), and prepare them for postoperative care. If the procedure is elective, demonstrate and have the patient return a demonstration of how to splint the chest incision, cough, deep breathe, and perform arm and leg exercises. Stress

that:

- The patient should report any pain to the nursing staff.
- Most of the pain will be in the site where the vessel was harvested. (With the use of endovascular vessel harvesting [EVH] and one or two small incisions, the pain and edema are less than for previously performed procedures.)
- Analgesics will be given for pain.
- Coughing and deep breathing are essential to prevent pulmonary complications.
- Early ambulation is important to decrease the risk for venous thrombosis and possible embolism.

For the traditional surgical procedure, explain that the patient will have a sternal incision; possibly a large leg incision; one, two, or three chest tubes; an indwelling urinary catheter; pacemaker wires; and hemodynamic monitoring. An endotracheal tube will be connected to a ventilator for several hours postoperatively. Tell the patient and family that the patient will not be able to talk while the endotracheal tube is in place. When describing the postoperative course, emphasize that close monitoring and the use of sophisticated equipment are standard treatment.

Preoperative anxiety is common. An appropriate nursing assessment should identify the level of anxiety and the coping methods patients have used successfully in the past. Some patients may find it helpful to define their fears. Common sources of fear include fear of the unknown, fear of bodily harm, and fear of death.

In elective procedures, patients may benefit from detailed information about the surgery, depending on individual preferences and cultural practices. Others may feel overwhelmed by so much material. Some patients need to discuss their feelings in detail or describe the experiences of people they know who have undergone CABG. Assess patients' anxiety level and help them cope.

Operative Procedures.

Coronary artery bypass surgery is performed with the patient under general anesthesia for both cardiopulmonary bypass and off-pump surgery. For the *traditional operative procedure,* the cardiac surgical team begins the procedure with a median sternotomy incision and visualization of the heart and great vessels. Another surgical team may begin harvesting the vein if it is to be used for the graft. Synthetic grafts may be used instead.

Cardiopulmonary bypass (CPB) is used to provide oxygenation,

circulation, and hypothermia during induced cardiac arrest. Blood is diverted from the heart to the bypass machine, where it is heparinized, oxygenated, and returned to the circulation through a cannula placed in the ascending aortic arch or femoral artery (Fig. 38-6). During bypass, the patient's core temperature remains between 95° F (35° C) (cold cardioplegia) and normal temperature (warm cardioplegia). Although cooling decreases the rate of metabolism and demand for oxygen, keeping the heart "warm" decreases postoperative complications that were more common when cold cardioplegia was used. The heart is perfused with a potassium solution, which decreases myocardial oxygen consumption and causes the heart to stop during diastole. This process ensures a motionless operative field and prevents myocardial ischemia.

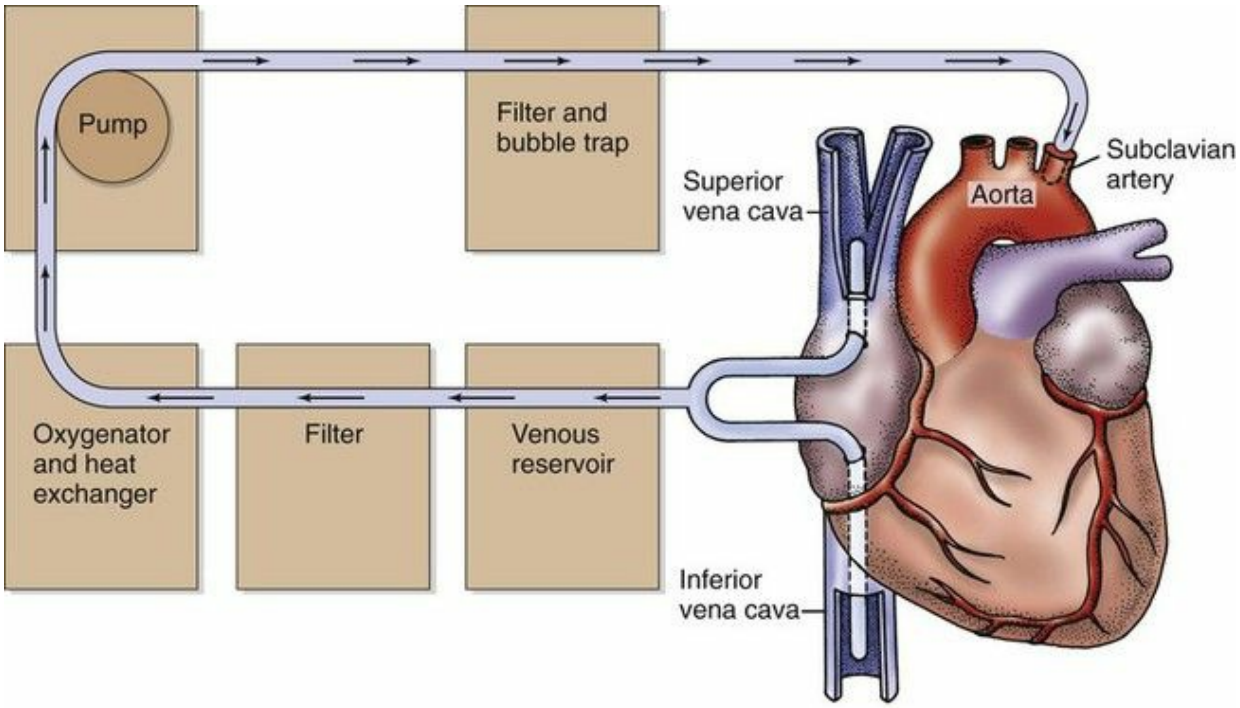

FIG. 38-6 Heart-lung bypass circuitry used during cardiopulmonary bypass.

Once the heart is arrested, the grafting procedure can begin. The surgeon uses the internal mammary artery (IMA), a saphenous vein, and/or a radial artery to bypass blockages in the coronary arteries (Fig. 38-7). The distal end of the vessel graft is dissected and attached below the clot in the coronary artery. If the surgeon uses a venous graft or the radial artery, it is anastomosed (sutured) proximally to the aorta and distally to the coronary artery just beyond the occlusion, thus improving myocardial perfusion. After flow rates through the grafts are measured, the heart is rewarmed slowly. The cardioplegic solution is flushed from

the heart. The heart regains its rate and rhythm, or it may be defibrillated to return it to a normal rhythm. When the procedure is completed, the patient may be rewarmed (if cold cardioplegia was used) and weaned from the bypass machine while the grafts are observed for patency and leakage. The surgeon may place atrial and ventricular pacemaker wires and mediastinal and pleural chest tubes. Finally, the surgeon closes the sternum with wire sutures.

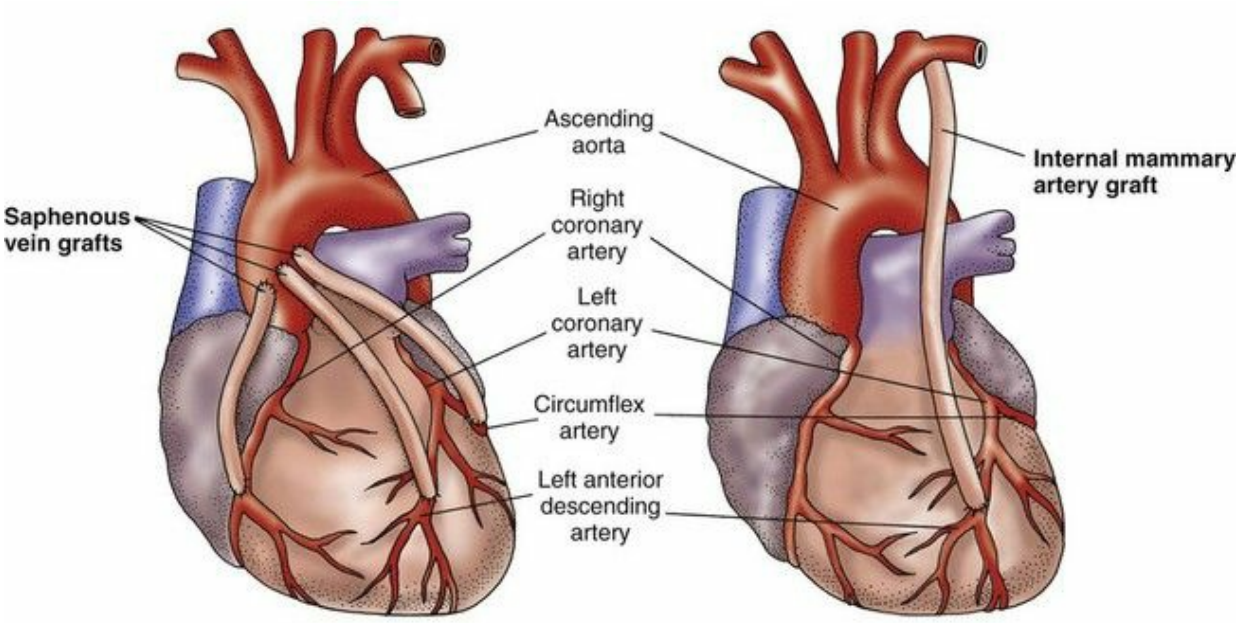

FIG. 38-7 Two methods of coronary artery bypass grafting. The procedure used depends on the nature of the coronary artery disease, the condition of the vessels available for grafting, and the patient's health status.

Postoperative Care.

After traditional surgery, the patient is transported to a post–open heart surgery unit and undergoes mechanical ventilation for 3 to 6 hours. He or she requires highly skilled nursing care from a nurse qualified to provide post–cardiac surgery care, including routine postoperative care described in Chapter 16. *Be sure to use sterile technique when changing sternal or donor-site dressings.*

Connect the mediastinal tubes to water seal drainage systems, and ground the epicardial pacer wires by connecting them to the pacemaker generator. Monitor pulmonary artery and arterial pressures, as well as the heart rate and rhythm, which are displayed on a monitor.

Closely assess the patient for dysrhythmias, such as bradydysrhythmias, atrial fibrillation, or heart block. Manage

symptomatic dysrhythmias according to unit protocol or the health care provider's prescription. Hypoxemia and hypokalemia are frequent causes of ventricular dysrhythmias. If the patient has symptomatic bradydysrhythmias or heart block, turn on the pacemaker and adjust the pacemaker settings as prescribed. Monitor for, report, and document other complications of CABG, including:

- Fluid and electrolyte imbalance
- Hypotension
- Hypothermia
- Hypertension
- Bleeding
- Cardiac tamponade
- Decreased level of consciousness
- Anginal pain

Managing Fluid and Electrolyte Imbalance.

Assessing fluid and electrolyte balance is a high priority in the early postoperative period. Edema is common. However, decisions concerning fluid administration are made on the basis of BP, pulmonary artery wedge pressure (PAWP), right atrial pressure, cardiac output, cardiac index, systemic vascular resistance, blood loss, and urine output. An experienced specialized nurse interprets the assessment findings and adjusts fluid administration on the basis of standing unit policies or specific prescription from the physician.

Serum electrolytes (especially calcium, magnesium, and potassium) may be decreased postoperatively and are monitored carefully. Because the serum potassium level can fluctuate dramatically, electrolyte levels are checked frequently, since imbalances can cause dysrhythmias. Potassium and magnesium depletions are common and may result from hemodilution or diuretic therapy. Calcium replacement is based on the *ionized* serum calcium. The desired potassium level is 4.0 mEq/L, and the magnesium level should be 2.2 mEq/L.

If the serum potassium level is decreased, the health care provider may prescribe IV potassium replacement. The dose of potassium given exceeds the usual recommended level of no more than 20 mEq of potassium per hour. For potassium replacement, as much as 40 to 80 mEq may be mixed in 100 mL of IV solution and given at a rate up to 40 mEq per hour. The drug must be given through a central catheter and controlled by an infusion pump. The patient is placed on a cardiac monitor for intense, focused nursing observation.

Managing Other Complications.

Hypotension (systolic BP <90 mm Hg) is a major problem because it may result in the collapse of the coronary graft. Decreased preload (decreased PAWP) can result from hypovolemia or vasodilation. If the patient is hypovolemic, it might be appropriate to increase fluid administration or administer blood. The health care provider may manage the patient with volume replacement followed by vasopressor therapy to increase the BP. However, if hypotension is the result of left ventricular failure (increased PAWP), IV inotropes might be needed.

Hypothermia is a common problem after surgery. Although warm cardioplegia is now the usual operative procedure used, it is not uncommon for the body temperature to drift downward after the patient leaves the surgical suite. Monitor the body temperature, and institute rewarming procedures if the temperature drops below 96.8° F (36° C). Rewarming may be accomplished with warm blankets, lights, or thermal blankets. The danger of rewarming patients too quickly is that they may begin shivering, resulting in metabolic acidosis, increased myocardial oxygen consumption, and hypoxia. To prevent shivering, rewarming should proceed at a rate no faster than 1.8° F (1° C) per hour. Discontinue the procedure when the body temperature approaches 98.6° F (37° C) and the patient's extremities feel warm.

Hypothermia is a significant risk for the patient after CABG surgery because it promotes vasoconstriction and *hypertension.* Other factors contributing to hypertension in the CABG patient include CPB, drug therapy, and increased sympathetic nervous system activity.

After surgery, many patients experience *hypertension* (hypertension is defined as a systolic BP greater than 140 to 150 mm Hg). Hypertension is dangerous because increased pressure promotes leakage from suture lines and may cause bleeding. Drugs such as nitroprusside (Nipride) or fenoldopam (Corlopam) may be given to decrease afterload, ease the workload of the heart, and prevent heart failure.

Nursing Safety Priority QSEN

Action Alert

Bleeding after CABG surgery occurs to a limited extent in all patients. Measure mediastinal and pleural chest tube drainage at least hourly. Report drainage amounts over 150 mL per hour to the surgeon. Patients with internal mammary artery (IMA) grafts may have more chest drainage than those with saphenous vein grafts (from the leg).

To access the IMA, the pleural space has to be entered and requires a pleural chest tube with the mediastinal tubes, making pulmonary assessment crucial. An autotransfusion of chest drainage to assist with volume management when 500 mL has accumulated or 4 hours has elapsed may be done, depending on the clinical pathway or the health care provider's protocol. Maintain the patency of the mediastinal and pleural chest tubes. One effective way of promoting chest tube drainage is to prevent a dependent loop from forming in the tubing.

If the patient is bleeding and the mediastinal tubes are not kept patent, fluid (blood) may accumulate around the heart. The myocardium is then compressed, and **cardiac tamponade** results. The fluid compresses the atria and ventricles, preventing them from filling adequately and thus reducing cardiac output.

Nursing Safety Priority QSEN

Critical Rescue

Assess for, document, and report manifestations of cardiac tamponade immediately, including:

- Sudden cessation of previously heavy mediastinal drainage
- Jugular venous distention but clear lung sounds
- Pulsus paradoxus (BP more than 10 mm Hg higher on expiration than on inspiration)
- An equalizing of PAWP and right atrial pressure
- Cardiovascular collapse

Prepare the patient for echocardiogram or chest x-ray to confirm the diagnosis. Pericardiocentesis (withdrawal of fluid from the pericardium via a large needle) may not be appropriate for tamponade after coronary artery bypass graft (CABG) because the blood in the pericardium may have clotted. Volume expansion and emergency sternotomy with drainage are the treatments of choice.

The patient may also demonstrate *changes in level of consciousness,* which may be permanent or transient (temporary, short-term). Transient changes related to anesthesia, cardiopulmonary bypass (CPB), air emboli, or hypothermia occur in many patients. Assess for neurologic deficits, which may include slowness to arouse, memory loss, and new-onset confusion.

Patients with transient neurologic deficits usually return to baseline neurologic status within 4 to 8 hours. *Permanent* deficits associated with

an intraoperative stroke may be manifested by:
- Abnormal pupillary response
- Failure to awaken from anesthesia
- Seizures
- Absence of sensory or motor function

Nursing Safety Priority QSEN

Action Alert

After a CABG, check the patient's neurologic status every 30 to 60 minutes until he or she has awakened from anesthesia. Then check every 2 to 4 hours or per agency policy.

NCLEX Examination Challenge

Physiological Integrity

The nurse assesses a client who had a coronary artery bypass graft yesterday. Which assessment finding will the nurse report to the surgeon immediately?
A Incisional pain
B Blood pressure of 136/76
C Decreased level of consciousness
D Apical pulse of 88

Managing Pain.

Differentiate between *sternotomy pain,* which is expected after CABG, and *anginal pain,* which might indicate graft failure. Typical sternotomy pain is localized, does not radiate, and often becomes worse when the patient coughs or breathes deeply. He or she may describe the pain as sharp, aching, or burning. Pain may stimulate the sympathetic nervous system, which increases the heart rate and vascular resistance while decreasing cardiac output. Administer enough of the prescribed analgesic in adequate doses to control pain. During the process of weaning the patient from mechanical ventilation, however, it may be necessary to use short-acting analgesics and to limit pain medication because of the respiratory depressant effects of analgesia.

Transfer from the Special Care Unit.

Mechanical ventilation is usually provided for 3 to 6 hours after surgery

until the patient is breathing adequately and is hemodynamically stable. During the first day, the patient usually has pacemaker wires, hemodynamic monitoring lines, and mediastinal tubes removed. He or she is then transferred to an intermediate care unit. *All CABG patients, especially those with IMA grafts, are at high risk for atelectasis, the number-one complication.* Encourage them to splint, cough, turn, and deep breathe to expectorate secretions. Early ambulation after surgery is essential. Two hours after extubation (removal of the endotracheal tube), patients should be dangled as tolerated and turned side to side. Within 4 to 8 hours after extubation, help patients out of bed into a chair. By the first day after surgery, they should be out of bed in a chair and ambulating 25 to 100 feet 3 times a day as tolerated. Continue to monitor for decreased cardiac output, pain, dysrhythmias, decreased oxygen saturation, and infection during these activities.

Nursing Safety Priority QSEN

Action Alert

Monitor the neurovascular status of the donor arm of patients whose radial artery was used as a graft in CABG. Assess the hand color, temperature, pulse (both ulnar and radial), and capillary refill every hour initially. In addition, check the fingertips, hand, and arm for sensation and mobility at least every 4 hours. IV nitroglycerin is often given for the first 24 hours postoperatively to promote vasodilation in the donor arm and therefore maintain circulation.

Many patients have supraventricular dysrhythmias (especially atrial fibrillation) during the postoperative period, usually on the second or third postoperative day. Examine the monitor pattern for atrial fibrillation. When auscultating the heart, listen for an irregular rhythm.

Sternal wound infections develop between 5 days and several weeks after surgery in a small number of patients and are responsible for increased costs and longer hospital stays. Be alert for **mediastinitis** (infection of the mediastinum) by observing for:

- Fever continuing beyond the first 4 days after CABG
- Instability (bogginess) of the sternum
- Redness, induration, swelling, or drainage from suture sites
- An increased white blood cell count

The health care provider may perform a needle biopsy to confirm a sternal infection. Surgical débridement, antibiotic wound irrigation, and

IV antibiotics are usually indicated. If sternal osteomyelitis has developed, 4 to 6 weeks of IV antibiotics are required. Prophylactic use of mupirocin (Bactroban) intranasally may be prescribed to decrease the incidence of sternal wound infection.

Postpericardiotomy syndrome is a source of chest discomfort for some post–cardiac surgery patients. The syndrome is characterized by pericardial and pleural pain, pericarditis, a friction rub, an elevated temperature and white blood cell count, and dysrhythmias. Postpericardiotomy syndrome may occur days to weeks after surgery and seems to be associated with blood remaining in the pericardial sac. Observe for the development of pericardial or pleural pain. For most patients, the syndrome is mild and self-limiting. However, they may require treatment similar to that for pericarditis. Be prepared to detect acute cardiac (pericardial) tamponade.

Minimally Invasive Direct Coronary Artery Bypass.

The **minimally invasive direct coronary artery bypass (MIDCAB)** (also known as *"keyhole" surgery*) may be indicated for patients with a lesion of the left anterior descending (LAD) artery. In one of the most common MIDCAB procedures, a 2-inch left thoracotomy incision is made and the fourth rib is removed. Then the left internal mammary artery (IMA) is dissected and attached to the still-beating heart below the level of the lesion. Cardiopulmonary bypass (CPB) is not required.

After surgery, assess for chest pain and ECG changes (Q waves and ST-segment and T-wave changes in leads V_2 to V_6) because occlusion of the IMA graft occurs acutely in only a small percentage of patients. *If there is any question of acute graft closure, immediately notify the health care provider.* Patients tend to have more incisional pain after MIDCAB than after traditional CABG surgery, but it can usually be managed with oxycodone or codeine. Because they have a thoracotomy incision and a chest tube or smaller-lumen vacuum chest device, patients are encouraged to cough, deep breathe, and use an incentive spirometer for a week postoperatively. Most patients spend less than 6 hours in a critical care unit and are discharged in 2 or 3 days.

Endovascular (Endoscopic) Vessel Harvesting.

Regardless of whether the traditional CABG or the MIDCAB is performed, the donor vessel may be obtained using an endoscope rather than a large surgical incision. The radial artery or a vein in the leg may be taken using this method. Instead of a large, painful incision, the patient

has one or two very small incisions in the leg or arm. This procedure has decreased hospital length of stay, postoperative complications, and pain.

Transmyocardial Laser Revascularization.

Transmyocardial laser revascularization is a procedure for patients with unstable angina and inoperable CAD with areas of reversible myocardial ischemia. After a single-lung intubation, a left anterior thoracotomy is performed and the heart is visualized. A laser is used to create 20 to 24 long, narrow channels through the left ventricular muscle to the left ventricle. These channels will eventually allow oxygenated blood to flow during diastole from the left ventricle to nourish the muscle. After surgery, the patient is transported to a critical care unit, where hemodynamic monitoring is used to assess for anginal episodes and bleeding disturbances.

Off-Pump Coronary Artery Bypass.

Off-pump coronary artery bypass (OPCAB) is a procedure in which open heart surgery is performed without the use of a heart-lung bypass machine. Advantages include shorter hospital stays and decreased mortality rate, risk for infection, and cost. The disadvantage of OPCAB is that it requires cardiac surgeons to have increased skill to master the technique.

Robotic Heart Surgery.

Robotic heart surgery is a new step toward less invasive open heart surgery. Surgeons operate endoscopically through very small incisions in the chest wall. Use of robotics provides surgeons with capabilities that simplify the surgical process, eliminate tremors that can exist with human hands, increase the ability to reach otherwise inaccessible sites, and improve depth perception and visual acuity.

Other advantages of robotic procedures include shorter hospital stays (average stay is 2 to 3 days), less pain because of smaller incisions, no need for heart-lung bypass machine, less anxiety for the patient, and greater patient acceptance. The use of robotics also allows surgeons to perform telesurgery, performing heart procedures over long distances.

Disadvantages include computer failure, limited numbers of surgeons skilled in these techniques, and the length of surgery time (the time is about 50 minutes longer than the conventional surgery).

Community-Based Care

Home Care Management.

Case management is most appropriate for patients who meet high-cost, high-volume, and high-risk criteria. Patients with coronary artery disease (CAD) clearly meet all these criteria. Clinical pathways and case management programs for those with CAD are used in most U.S. hospitals. By focusing on cardiovascular risk reduction and improving the continuity of care, health care professionals have reduced the length and cost of hospital stays. Posthospital case management should reduce hospital readmission rates and improve patient health.

Patients who have experienced a myocardial infarction (MI), angina, or coronary artery bypass graft (CABG) surgery are usually discharged to home or to a transitional care setting with drug therapy and specific activity prescriptions. Depending on the procedure, hospital stays may be 3 to 5 days for patients with MI or those undergoing CABG and only 1 to 3 days for those undergoing percutaneous coronary intervention (PCI) or newer surgeries. Therefore patients are still recovering when they are discharged from the hospital and need continuing care.

Patients should not be discharged to home alone. Assess whether the patient has family or friends to provide assistance. In some cases, a home care nurse may be needed (Chart 38-8). Older adults are often living alone when coronary events occur and may have a greater need for home assistance after CABG surgery (Chart 38-9). A patient who was a resident in a long-term care facility may be returned there after hospitalization for unstable angina, MI, or CABG surgery.

Chart 38-8 Home Care Assessment

The Patient Who Has Had a Myocardial Infarction

Assess cardiovascular function, including:

- Current vital signs (compare with previous to identify changes)
- Recurrence of discomfort (characteristics, frequency, onset)
- Indications of heart failure (weight gain, crackles, cough, dyspnea)
- Adequacy of tissue perfusion (mentation, skin temperature, peripheral pulses, urine output)
- Indications of serious dysrhythmia (very irregular pulse, palpitations with fainting or near fainting)

Assess coping skills, including:

- Is patient displaying denial, anger, or fear?
- Is caregiver providing adequate support?
- Are patient and caregiver disagreeing about treatment?

Assess functional ability, including:

- Activity tolerance (examine the patient's activity diary: review distance, duration, frequency, and symptoms occurring during exercise)
- Activities of daily living (is any assistance needed?)
- Household chores (who performs them?)
- Does patient plan to return to work? When?

Assess nutritional status, including:

- Food intake (review patient's intake of fats and cholesterol)

Assess patient's understanding of illness and treatment, including:

- How to treat chest discomfort
- Signs and symptoms to report to health care provider
- Dosage, effects, and side effects of medications
- How to advance and when to limit activity
- Modification of risk factors for coronary artery disease

Chart 38-9 Nursing Focus on the Older Adult

Coronary Artery Bypass Graft Surgery

- Be aware that perioperative mortality rates are higher for the older patient than for the patient younger than 60 years.
- Monitor neurologic and mental status carefully because older adults are more likely to have transient neurologic deficits after coronary artery bypass graft (CABG) surgery than younger adults are.
- Observe for side effects of cardiac drugs because older patients are more likely to develop toxic effects from positive inotropes (dobutamine) and potent antihypertensives (nitroglycerin or nitroprusside).
- Monitor the patient closely for dysrhythmias because older adults are more likely to have dysrhythmias such as atrial fibrillation or supraventricular tachycardia after CABG surgery.
- Be aware that recuperation after CABG surgery is slower for older patients and that their average hospital stay is longer.
- Teach the patient and family that during the first 2 to 5 weeks after discharge, fatigue, chest discomfort, and lack of appetite may be particularly bothersome for older adults.
- Teach the patient to let someone know where he or she is walking outside.

Cardiac rehabilitation is available in most communities for patients after an MI or CABG surgery, but only a small percentage participate in

structured rehabilitation programs. Dolansky et al. (2010) found that although post–acute care (PAC) is available for older adults, only 50% of patients who had a myocardial infarction (MI) received PAC. Only 44% of patients who had cardiac surgery participated in post–acute care. Cossette et al. (2012) found that a stepwise nursing intervention post-discharge significantly increased enrollment in cardiac rehabilitation programs over standard of care (see the Evidence-Based Practice box).

Evidence-Based Practice QSEN

Can Nursing Interventions Tailored to the Acute MI Population Increase Enrollment in Cardiac Rehabilitation?

Cossette, S., Frasure-Smith, N., Dupuis, J., Juneau, M., & Guertin, M. (2012). Randomized controlled trial of tailored nursing interventions to improve cardiac rehabilitation enrollment. *Nursing Research, 61*(2), 111-120.

Cardiac rehabilitation, which is widely available, can reduce recurrence of coronary events by 25%. Due to the decreased length of stay, the nurse has limited time to provide important post-discharge education. In a randomized control trial, adults who experienced acute myocardial infarction (AMI) were contacted at three separate encounters: face to face prior to discharge, telephone call at 3 days post-discharge, and telephone call or face to face meeting at 10 days. The first call focused on the current condition of the patient, symptomology, activity, and patient's concerns. At the second call, the patient's current condition was reviewed and education and discussion about risk factor modification occurred. In addition to cardiac rehabilitation review, risk factor and lifestyle modification were the focus of the third call. The control group received the standard of care that included standard discharge instructions with encouragement to follow up with health care provider.

All participants completed baseline questionnaires: Revised Illness Perception Questionnaire, Family Care Climate Questionnaire—Patient Version, and State-Trait Anxiety Inventory. In addition, all participants received follow-up phone calls from a research assistant at 6 weeks post-discharge. A total of 242 participants were enrolled, and results revealed 45% of patients in the intervention group versus 24% of the control group enrolled in cardiac rehabilitation program (defined as attendance at one session prior to end of 6 weeks post-discharge). The time to mean first visit (day 20 post-discharge) did not differ between the groups. The

intervention did not impact modification of risk factors. Limitations included lack of data on continued attendance, cost-effectiveness of the intervention, and long-term outcomes.

Level of Evidence: 1

The study was a large randomized controlled trial.

Commentary: Implications for Practice and Research

In view of the low percentages of older adults who attend cardiac rehabilitation, nurses can provide the necessary intervention to encourage attendance. Collaborate with the case manager or discharge planner to ensure that follow-up on lifestyle modification occurs after discharge because the patient is focused on immediate discharge needs at the time of discharge. More studies need to be completed to determine the nursing interventions that may be valuable post-discharge in the AMI patient population that not only improve outcomes but also are cost-effective.

MI, Myocardial infarction.

The most frequently cited reasons for nonparticipation are lack of insurance coverage, a physician's decision that it is unnecessary, and the patient's decision that it is not necessary. Those who participate in these programs report greater improvement in exercise tolerance and improved ability to control stress. However, no difference in their return to work has been seen.

Self-Management Education.

The need for health teaching depends in part on the treatment plan or type of procedure that the patient received. Because hospital stays are short and patients are quite ill during hospitalization, most in-hospital education programs concentrate on the skills essential for self-care after discharge.

As part of home visits or a cardiac rehabilitation program, identify the additional educational needs of the patient and family and their readiness to learn. Develop a teaching plan, which usually includes education about the normal anatomy and physiology of the heart, the pathophysiology of angina and MI, risk factor modification, activity and exercise protocols, cardiac drugs, and when to seek medical assistance. Teach patients that myocardial healing after an MI begins early and is usually complete in 6 to 8 weeks. Remind those who have undergone traditional CABG that the sternotomy should heal in about 6 to 8 weeks,

but upper body exercise needs to be limited for several months.

Patients who have undergone CABG require instruction on incision care for the sternum and the graft site. Teach them to inspect the incisions daily for any redness, swelling, or drainage. The leg of a saphenous vein donor site is often edematous. Instruct patients to avoid crossing legs, to wear elastic stockings until the edema subsides, and to elevate the surgical limb when sitting in a chair. Teach patients who have had a radial artery graft to open and close the hand vigorously 10 times every 2 hours.

Risk Factor Modification.

Modification of risk factors is a necessary part of a patient's management and involves changing his or her health maintenance patterns. Such modifications may include tobacco cessation, altered dietary patterns, regular exercise, BP control, and blood glucose control.

For patients who use tobacco, explain its negative effects, especially cigarette smoking. Many patients choose to quit smoking soon after an MI. Chapter 30 also provides information on this lifestyle change.

The mainstays of cholesterol control are nutritional therapy and anti-hyperlipidemic agents, as described in Chapter 36. Teach patients to avoid adding salt when beginning a meal. A reduction of 80 mg/day of sodium can reduce the systolic blood pressure (SBP) by 5 mm Hg and 3 mm Hg for the diastolic blood pressure (DBP). Maintain adequate dietary potassium, calcium, and magnesium intake. Increasing potassium may reduce the SBP by 8 mm Hg. Booklets and cookbooks that can assist the patient in learning to cook with reduced fats, oils, and salt are available from the American Heart Association (AHA).

Collaborate with the physical therapist to establish an activity and exercise schedule as part of rehabilitation, depending on the cardiac procedure that was performed. Instruct the patient to remain near home during the first week after discharge and to continue a walking program. Patients may engage in light housework or any activity done while sitting and that does not precipitate angina. During the second week, they are encouraged to increase social activities and possibly to return to work part-time. By the third week, they may begin to lift objects as heavy as 15 pounds (e.g., 2 gallons of milk) but should avoid lifting or pulling heavier objects for the first 6 to 8 weeks. Chart 38-10 lists suggested instructions for activity level.

Chart 38-10 Patient and Family Education: Preparing

for Self-Management

Activity for the Patient with Coronary Artery Disease

- Begin by walking the same distance at home as in the hospital (usually 400 feet) 3 times each day.
- Carry nitroglycerin with you.
- Check your pulse before, during, and after the exercise.
- Stop the activity for a pulse increase of more than 20 beats/min, shortness of breath, angina, or dizziness.
- Exercise outdoors when the weather is good.
- Gradually increase the walking until the distance is ¼ mile twice daily (usually the end of the second week).
- After an exercise tolerance test and with your physician's approval, walk at least 3 times each week, increasing the distance by ½ mile every other week, until the total distance is 2 miles.
- Avoid straining (lifting, push-ups, pull-ups, and straining at bowel movements).

Patients may begin a simple walking program by walking 400 feet twice a day at the rate of 1 mile/hr the first week after discharge and increasing the distance and rate as tolerated, usually weekly, until they can walk 2 miles at 3 to 4 miles/hr. Teach them to take their pulse reading before, halfway through, and after exercise. Teach the patient to stop exercising if the target pulse rate is exceeded or if dyspnea or angina develops.

After a limited exercise tolerance test, the physical therapist or nurse encourages the patient to join a formal exercise program, ideally one that assists him or her in monitoring cardiovascular progress. The program should include 5- to 7-minute warm-up and cool-down periods, as well as 30 minutes of aerobic exercise. The patient should engage in aerobic exercise a minimum of 3 (and preferably 5) times a week.

Complementary and Alternative Therapies.

Additional therapies can aid in reducing the patient's anxiety about progressive activity both in the immediate postoperative period and during the rehabilitation phase. Many patients who have had cardiac surgery or other invasive procedures use complementary and alternative therapies. However, they often do not share with their health care providers that they use these therapies. Techniques such as progressive muscle relaxation, guided imagery, music therapy, pet therapy, and therapeutic touch may decrease anxiety, reduce depression, and increase

compliance with activity and exercise regimens after heart surgery.

Sexual Activity.

Sexual activity is often a subject of great concern to patients and their partners. Inform the patient and his or her partner that engaging in their usual sexual activity is unlikely to damage the heart. Patients can resume sexual intercourse on the advice of the health care provider, usually after an exercise tolerance assessment. In general, those who can walk one block or climb two flights of stairs without symptoms can usually safely resume sexual activity.

Suggest that initially these patients have intercourse after a period of rest. They might try having intercourse in the morning when they are well rested or wait 1½ hours after exercise or a heavy meal. The position selected should be comfortable for both the patient and his or her partner so that no undue stress is placed on the heart or suture line.

Drug Therapy.

Assess patients with diabetes mellitus for their ability to control hyperglycemia. Review the prescribed dosage of insulin or oral antidiabetic drugs with the patient and family. The patient and/or family should demonstrate accurate testing of blood for glucose levels and the technique for insulin administration, if used.

Teach the patient about the type of prescribed cardiac drugs, the benefit of each drug, potential side effects, and the correct dosage and time of day to take each drug. Drug regimens vary considerably. Many patients with angina are discharged while taking aspirin, a beta blocker, a calcium channel blocker, an anti-hyperlipidemic agent, and a nitrate. Those who have experienced an MI may require aspirin, a beta blocker, an anti-hyperlipidemic agent (statin drug), and an ACEI and/or an ARB. The Joint Commission Acute MI Core Measure Set requires hospitals to report whether patients with an MI are discharged on these drugs. Determine whether the patient can comply with the instructions.

Nursing Safety Priority QSEN

Drug Alert

Use of sublingual or spray nitroglycerin (NTG) deserves special attention. *Teach the patient to carry NTG at all times.* Keep the tablets in a glass, light-resistant container. The drug should be replaced every 3 to 5 months before it loses its potency or stops producing a tingling

sensation when placed under the tongue. Chart 38-11 gives instructions for management of chest discomfort at home.

Chart 38-11 Patient and Family Education: Preparing for Self-Management

Management of Chest Pain at Home

- Keep fresh nitroglycerin available for immediate use.
- At the first indication of chest discomfort, cease activity and sit or lie down.
- Place one nitroglycerin tablet or spray under your tongue, allowing the tablet to dissolve.
- Wait 5 minutes for relief.
- If no relief results, call 911 for transportation to a health care facility.
- While waiting for emergency medical services (EMS), repeat the nitroglycerin and wait 5 more minutes.
- If there is no relief, repeat and wait 5 more minutes.
- Carry a medical identification card or wear a bracelet or necklace that identifies a history of heart problems.

Seeking Medical Assistance.

Teach patients to notify their health care provider if they have:

- Heart rate remaining less than 50 after arising
- Wheezing or difficulty breathing
- Weight gain of 3 pounds in 1 week or 1 to 2 pounds overnight
- Persistent increase in NTG use
- Dizziness, faintness, or shortness of breath with activity

Remind them to always call 911 for transportation to the hospital if they have:

- Chest discomfort that does not improve after 5 minutes or 1 sublingual NTG tablet or spray
- Extremely severe chest or epigastric discomfort with weakness, nausea, or fainting
- Other associated symptoms that are particular to them, such as fatigue and nausea

Health Care Resources.

The American Heart Association (AHA) is an excellent source for booklets, films, CDs, DVDs, cookbooks, and professional service referrals for the patient with coronary artery disease (CAD). Many local

chapters have their own cardiac rehabilitation programs.

Within the community, cardiac rehabilitation programs may be affiliated with local hospitals, community centers, or other facilities, such as clinics. Many shopping malls open before shopping hours to allow a measured walking program indoors. This opportunity is particularly popular with older patients because it provides a good support group and allows for an appropriate place to exercise in inclement weather.

Mended Hearts is a nationwide program with local chapters that provides education and support to coronary artery bypass graft (CABG) patients and their families. Smoking-cessation programs and clinics and weight-reduction programs are located within the community. Many hospitals also sponsor health fairs, BP screening, and risk factor modification programs.

Clinical Judgment Challenge

Teamwork and Collaboration; Safety QSEN

A 55-year-old woman had a MIDCAB surgical procedure and is scheduled to begin cardiac rehabilitation on an ambulatory care basis. Her daughter plans to take her to the physical therapist for this program 3 days a week. The patient wants to return to her job as a nursing educator in a local community college as soon as possible.

1. What are the expected outcomes for this patient as a result of cardiac rehabilitation?
2. What is the role of the physical therapist in cardiac rehabilitation?
3. With what other members of the health care team will the nurse collaborate to ensure the patient's continuity of care?
4. What community resources might this patient use after the completion of her cardiac rehabilitation program?
5. For what surgical complications is she still at risk?

Evaluation: Outcomes

Evaluate the care of the patient with CAD based on the identified priority patient problems. The expected outcomes are that the patient will:

- State that discomfort or other symptoms are alleviated
- Have adequate blood flow through the coronary vasculature to ensure heart function
- Walk 200 feet 4 times a day without discomfort, shortness of breath, or other symptoms of CAD
- Identify support systems and other sources to assist in effective coping

with the cardiac event
- Be free of complications, such as dysrhythmias and heart failure

Nursing Concepts and Clinical Judgment Review

What might you NOTICE if the patient is experiencing inadequate gas exchange and tissue perfusion as a result of coronary artery disease?
- Report of pain (chest, shoulder, arm, jaw, back, or abdomen)
- Report of persistent indigestion
- Dyspnea
- Diaphoresis
- Report of nausea
- Vomiting
- Anxious behavior
- Report of palpitations
- Report of fatigue
- Disorientation or acute confusion (especially in older adults)

What should you INTERPRET and how should you RESPOND to a patient experiencing inadequate gas exchange and tissue perfusion as a result of coronary artery disease?

Perform and interpret physical assessment, including:
- Taking vital signs
- Monitoring oxygen saturation by pulse oximetry
- Taking 12-lead ECG
- Assessing level of consciousness and cognition
- Conducting complete pain assessment
- Drawing blood for laboratory assessment (e.g., troponins)
- Auscultating breath sounds for crackles or wheezes (left-sided heart failure)
- Auscultating heart for abnormal heart sounds
- Assessing for peripheral edema (right-sided heart failure)

Respond by:
- Calling 911 if patient is not in hospital setting OR notifying physician or Rapid Response Team in hospital setting
- Ensuring that patient rests
- Giving oxygen
- Giving nitroglycerin tablet
- Maintaining or starting IV line

- Administering morphine sulfate if MI suspected or diagnosed

On what should you REFLECT?

- Observe patient for decreased report of pain and associated symptoms.
- Continue to monitor oxygen.
- Continue to monitor for dysrhythmias and vital signs.
- Think about what could have precipitated this coronary event.
- Think about how you responded.
- Develop teaching plan for the patient to help prevent further episodes.

Get Ready for the NCLEX® Examination!

Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Collaborate with members of the interdisciplinary health care team members (e.g., physical therapist, case manager, home care providers) when caring for patients preparing for or participating in cardiac rehabilitation. **Teamwork and Collaboration** QSEN

Health Promotion and Maintenance

- Assess the patient for risk factors for coronary artery disease (CAD). Examples of modifiable risk factors that can be managed or controlled include obesity, smoking, high serum lipids, and hypertension; examples of nonmodifiable risk factors that cannot be altered include older age, being African American, and having a family history of CAD.
- Teach patients about the importance of decreasing their risk for CAD (see Chart 38-1). **Safety** QSEN

Psychosocial Integrity

- Allow patients to verbalize and express feelings of fear, anxiety, anger, denial, and grief regarding their CAD.
- Address the needs of the family and significant others, and provide teaching and information regarding the disease process. Clarify any misconceptions.

Physiological Integrity

- Teach patients that angina is the pain associated with decreased blood flow to the heart muscle. An MI indicates necrosis of heart muscle tissue (see Chart 38-2).
- Identify and interpret diagnostic values for cardiac markers, such as troponins and myoglobin, and other indicators of CAD.
- Monitor patients receiving thrombolytics and anticoagulants, such as heparin, for bleeding and bruising. **Safety** QSEN
- For patients undergoing invasive cardiac procedures, assess for signs and symptoms of active bleeding.
- Interpret and assess the patient with CAD for dysrhythmias.

- Evaluate the patient for pain characteristics (e.g., type, location, duration, cause, intensity, and measures taken to relieve symptoms).
- Teach patients and their families about drug therapy, including how to use nitroglycerin if they have chest or other cardiac-related pain (see Chart 38-4).
- After percutaneous cardiac intervention, monitor the patient for potential complications such as chest pain, bleeding from the insertion site, hypotension, hypokalemia, and dysrhythmias. Document and report any of these findings immediately. **Safety** QSEN
- Identify and assess for complications for post–cardiac surgery patients, especially fluid and electrolyte imbalance, bleeding, hypothermia, hypertension, and angina pain.
- Provide emergency care for the patient with chest pain as described in Chart 38-3.
- For patients having coronary artery bypass graft (CABG) surgery, be sure to manage pain adequately, assess fluid and electrolyte balance, and monitor for potential complications. Examples of complications include fluid and electrolyte imbalances (especially hypokalemia), hypothermia, hypertension, bleeding, and neurologic deficits. **Evidence-Based Practice** QSEN

UNIT IX

Problems of Tissue Perfusion: Management of Patients with Problems of the Hematologic System

OUTLINE

CHAPTER 39

Assessment of the Hematologic System

M. Linda Workman

PRIORITY CONCEPTS

- Clotting
- Perfusion

Learning Outcomes

Safe and Effective Care Environment

1. Protect the patient with a potential hematologic problem from injury.

Health Promotion and Maintenance

2. Teach all people how to protect the hematologic system.

Psychosocial Integrity

3. Reduce the psychological impact for the patient and family regarding the assessment and testing of the hematologic system.

Physiological Integrity

4. Explain the relationship between hematologic problems and the concepts of clotting and perfusion.
5. Perform a focused assessment of the hematologic system, incorporating information about genetic risk and age-related changes affecting hematologic function, especially clotting and perfusion.
6. Use knowledge of anatomy, physiology, laboratory analysis, and human development to determine whether hematologic assessment findings are normal or abnormal.

7. Explain the effects of anticoagulants, fibrinolytics, and inhibitors of platelet activity on clotting and perfusion.
8. Prioritize nursing care for the patient after bone marrow aspiration or biopsy.

http://evolve.elsevier.com/Iggy/

The hematologic system includes the blood, blood cells, lymph, and organs involved with blood formation or blood storage. This system is important for oxygenation (gas exchange) and tissue perfusion because the blood is the oxygen delivery system (Fig. 39-1). All systems depend on the blood for oxygen perfusion, and any problem of the hematologic system affects total body health. This chapter, together with Chapter 17, reviews the normal physiology of the hematologic system and assessment of hematologic status.

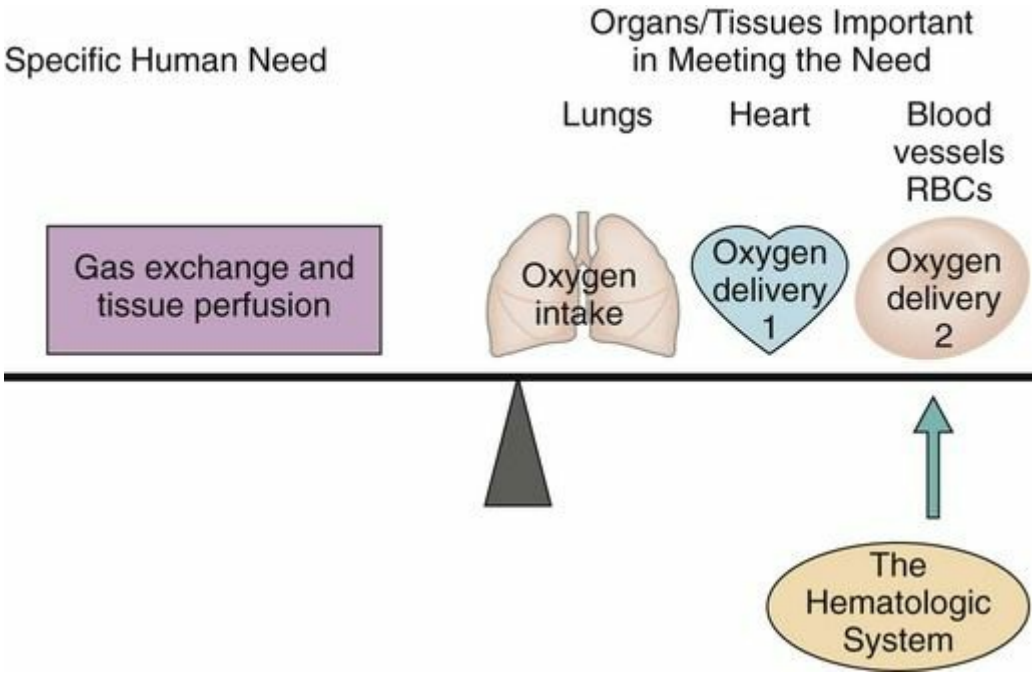

FIG. 39-1 Role of the hematologic system in gas exchange and tissue perfusion. *RBCs,* Red blood cells.

Anatomy and Physiology Review

Bone Marrow

Bone marrow is responsible for blood formation. It produces red blood cells (RBCs, erythrocytes), white blood cells (WBCs, leukocytes), and platelets. Bone marrow also is involved in the immune responses (see Chapter 17).

Each day the bone marrow normally releases about 2.5 billion RBCs, 2.5 billion platelets, and 1 billion WBCs per kilogram of body weight. In adults, cell-producing marrow is present only in flat bones (sternum, skull, pelvic and shoulder girdles) and the ends of long bones. With aging, fatty tissue replaces active bone marrow and only a small portion of the remaining marrow continues to produce blood in older adults (Touhy & Jett, 2014).

The bone marrow first produces **blood stem cells**, which are immature, unspecialized (undifferentiated) cells that are capable of becoming any type of blood cell, depending on the body's needs (Fig. 39-2) (McCance et al., 2014).

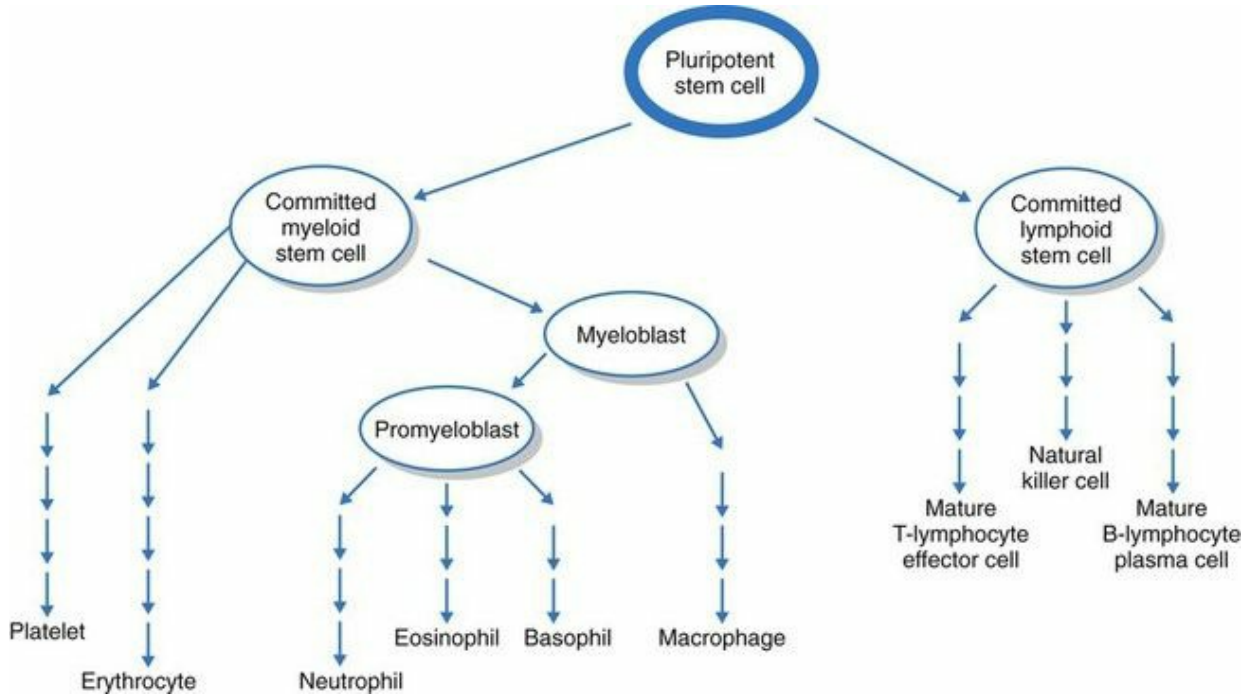

FIG. 39-2 Bone marrow cell growth and blood cell differentiation pathways.

The next stage in blood cell production is the *committed stem cell* (or *precursor* cell). A committed stem cell enters one growth pathway and can at that point specialize (differentiate) into only one cell type. Committed stem cells actively divide but require the presence of a specific growth

factor for specialization. For example, erythropoietin is a growth factor specific for the RBC. Other growth factors control WBC and platelet growth (see Chapters 17, 22, and 40 for discussion of growth factors and cytokines).

Blood Components

Blood is composed of plasma and cells. Plasma is an extracellular fluid. It is similar to the interstitial fluid found between tissue cells, but plasma contains much more protein. The three major types of plasma proteins are albumin, globulins, and fibrinogen.

Albumin maintains the osmotic pressure of the blood, preventing the plasma from leaking into the tissues (see Chapter 11). *Globulins* have many functions, such as transporting other substances and, as antibodies, protecting the body against infection. *Fibrinogen* is activated to form fibrin, which is critical in the blood clotting process.

The blood cells include RBCs, WBCs, and platelets. These cells differ in structure, site of maturation, and function.

Red blood cells **(erythrocytes)** are the largest proportion of blood cells. Mature RBCs have no nucleus and have a biconcave disk shape. Together with a flexible membrane, this feature allows RBCs to change their shape without breaking as they pass through narrow, winding capillaries. The number of RBCs a person has varies with gender, age, and general health, but the normal range is from 4,200,000 to 6,100,000/mm^3.

As shown in Figs. 39-2 and 39-3, RBCs start out as stem cells, enter the myeloid pathway, and progress in stages to mature erythrocytes. Healthy, mature, circulating RBCs have a life span of about 120 days. As RBCs age, their membranes become more fragile. These old cells are trapped and destroyed in the tissues, spleen, and liver. Some parts of destroyed RBCs (e.g., iron, hemoglobin) are recycled and used to make new RBCs.

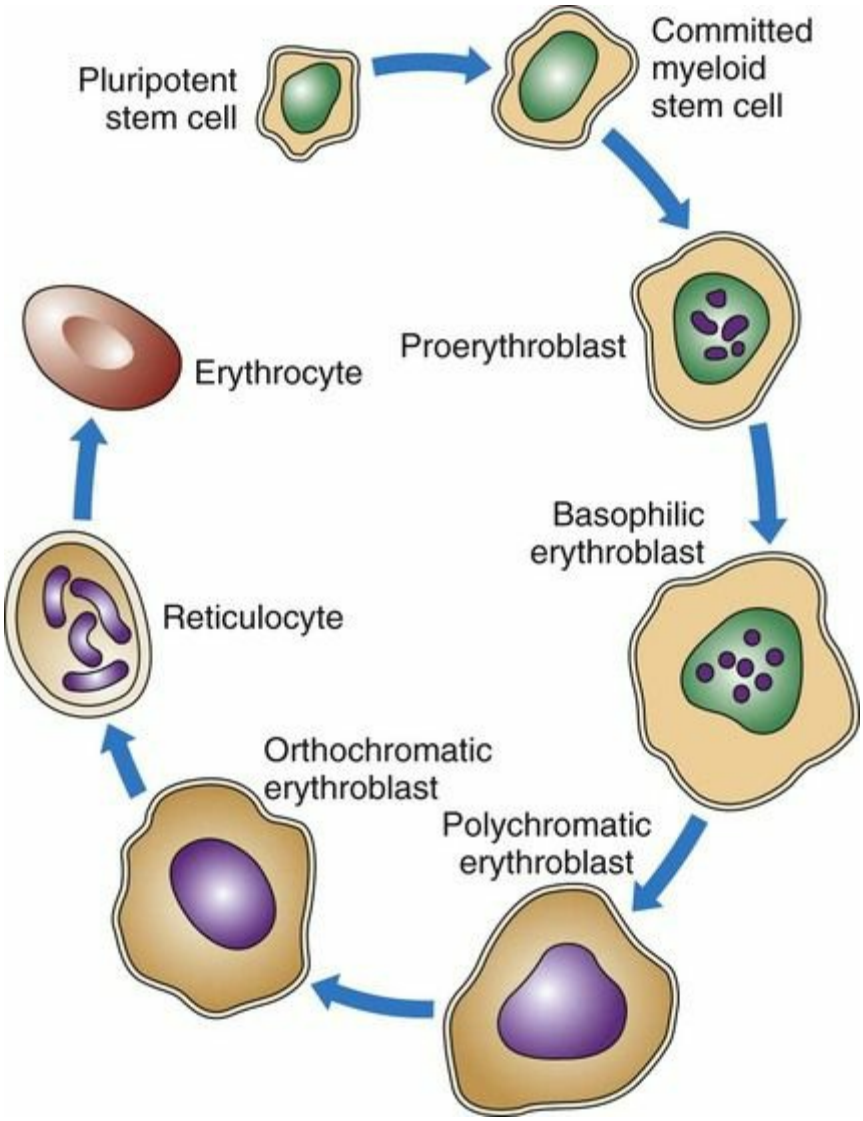

FIG. 39-3 Erythrocyte (red blood cell) growth pathway.

The RBCs produce hemoglobin (Hgb). Each normal mature RBC contains hundreds of thousands of hemoglobin molecules. Each hemoglobin molecule needs iron to be able to transport up to four molecules of oxygen. *Therefore iron is an essential part of hemoglobin.* Hemoglobin also carries carbon dioxide. RBCs also help maintain acid-base balance.

The most important feature of hemoglobin is its ability to combine loosely with oxygen. Only a small drop in tissue oxygen levels increases the transfer of oxygen from hemoglobin to tissues, known as **oxygen dissociation**. See Chapter 27 for a discussion of oxygen dissociation.

The total number of RBCs a person has is carefully controlled to ensure that enough are present for good perfusion with oxygen and for clotting without having too many cells that could "thicken" the blood and slow its flow. RBC production or **erythropoiesis** (selective growth of stem cells into mature erythrocytes) must be properly balanced with RBC destruction or loss. When balanced, this process helps tissue perfusion

by ensuring adequate delivery of oxygen. The trigger for RBC production is an increase in the tissue need for oxygen. The kidney produces the RBC growth factor *erythropoietin* at the same rate as RBC destruction or loss occurs to maintain a constant normal level of circulating RBCs. When tissue oxygen is less than normal **(hypoxia)**, the kidney releases more erythropoietin, which then increases RBC production in the bone marrow. When tissue oxygen is normal or high, erythropoietin levels fall, slowing RBC production. Synthetic erythrocyte stimulating agents (ESAs) such as Procrit, Epogen, and EPO have the same effect on bone marrow as the naturally occurring erythropoietin.

Many substances are needed to form hemoglobin and RBCs, including iron, vitamin B_{12}, folic acid, copper, pyridoxine, cobalt, and nickel. A lack of any of these substances can lead to anemia, which results in unmet tissue oxygen needs because of a reduction in the number or function of RBCs.

White blood cells (WBCs, leukocytes) also are formed in the bone marrow. The many types of WBCs all have specialized functions that provide protection through inflammation and immunity (Table 39-1). WBC function is presented in Chapter 17.

TABLE 39-1

Functions of Specific Leukocytes

LEUKOCYTE	FUNCTION
Inflammation	
Neutrophil	Nonspecific ingestion and phagocytosis of microorganisms and foreign protein
Macrophage	Nonspecific recognition of foreign proteins and microorganisms; ingestion and phagocytosis
Monocyte	Destruction of bacteria and cellular debris; matures into macrophage
Eosinophil	Weak phagocytic action; releases vasoactive amines during allergic reactions
Basophil	Releases histamine and heparin in areas of tissue damage
Antibody-Mediated Immunity	
B-lymphocyte	Becomes sensitized to foreign cells and proteins
Plasma cell	Secretes immunoglobulins in response to the presence of a specific antigen
Memory cell	Remains sensitized to a specific antigen and can secrete increased amounts of immunoglobulins specific to the antigen on re-exposure
Cell-Mediated Immunity	
T-lymphocyte helper/inducer T-cell	Enhances immune activity through the secretion of various factors, cytokines, and lymphokines
Cytotoxic-cytolytic T-cell	Selectively attacks and destroys non-self cells, including virally infected cells, grafts, and transplanted organs
Natural killer cell	Nonselectively attacks non-self cells, especially body cells that have undergone mutation and become malignant; also attacks grafts and transplanted organs

Platelets are the third type of blood cells. They are the smallest blood cells, formed in the bone marrow from megakaryocyte precursor cells. When activated, platelets stick to injured blood vessel walls and form platelet plugs that can stop the flow of blood at the injured site. They also produce substances important to blood clotting and aggregate (clump

together) to perform most of their functions. Platelets help keep small blood vessels intact by initiating repair after damage.

Production of platelets is controlled by the growth factor *thrombopoietin.* After platelets leave the bone marrow, they are stored in the spleen and then released slowly to meet the body's needs. Normally, 80% of platelets circulate and 20% are stored in the spleen.

Accessory Organs of Blood Formation

The spleen and liver are important accessory organs for blood production. They help regulate the growth of blood cells and form factors that ensure proper blood clotting.

The spleen contains three types of tissue: white pulp, red pulp, and marginal pulp. These tissues all help balance blood cell production with blood cell destruction and assist with immunity. White pulp is filled with white blood cells (WBCs) and is a major site of antibody production. As whole blood filters through the white pulp, bacteria and old RBCs are removed. Red pulp is the storage site for RBCs and platelets. Marginal pulp contains the ends of many blood vessels.

The spleen destroys old or imperfect RBCs, breaks down the hemoglobin released from these destroyed cells, stores platelets, and filters antigens. Anyone who has had a splenectomy has reduced immune functions and has an increased risk for infection and sepsis.

The liver produces prothrombin and other blood clotting factors. Also, proper liver function is important in forming vitamin K in the intestinal tract. (Vitamin K is needed to produce clotting factors VII, IX, and X and prothrombin.) Large amounts of whole blood and blood cells can be stored in the liver. The liver also stores extra iron within the protein *ferritin*.

Hemostasis and Blood Clotting

Hemostasis is the multi-stepped process of controlled blood clotting. It results in localized blood clotting in damaged blood vessels to prevent excessive blood loss while blood continues to perfuse all other areas. This complex function balances blood clotting actions with anti-clotting actions. When injury occurs, hemostasis starts the formation of a platelet plug and continues with a series of steps that eventually cause the formation of a fibrin clot. Three sequential processes result in blood clotting: platelet aggregation with platelet plug formation; the blood clotting cascade; and the formation of a complete fibrin clot.

Platelet aggregation begins forming a platelet plug by having platelets

clump together, a process essential for blood clotting. Platelets normally circulate as individual small cells that do not clump together until activated. Activation causes platelet membranes to become sticky, allowing them to clump together. When platelets clump, they form large, semi-solid plugs in blood vessels, disrupting local blood flow. *These platelet plugs are not clots and last only a few hours. Thus they cannot provide complete hemostasis but only start the hemostatic process.*

Substances that activate platelets and cause clumping include adenosine diphosphate (ADP), calcium, thromboxane A_2, and collagen. Platelets secrete some of these substances, and other activating substances are external to the platelet. Platelet plugs start the cascade action that ends with local blood clotting and are important at most steps within the cascade. When too few platelets are present, blood clotting is impaired, increasing the risk for excessive bleeding.

Blood clotting is a cascade triggered by the formation of a platelet plug, which then rapidly amplifies the cascade (Pezzotti & Freuler, 2012). The final result is much larger than the triggering event. Thus the cascade works like a landslide—a few small pebbles rolling down a steep hill can dislodge large rocks, trees, and soil, causing an enormous movement of earth. Just like landslides, cascade reactions are hard to stop once set into motion.

Intrinsic factors are conditions, such as circulating debris or venous stasis, within the blood itself that can activate platelets and trigger the blood clotting cascade (Fig. 39-4). Continuing the cascade to blood clotting requires sufficient amounts of all the clotting factors and cofactors (Table 39-2).

TABLE 39-2
The Clotting Factors

FACTOR	ACTION
I: Fibrinogen	Factor I is converted to fibrin by the enzyme *thrombin.* Individual fibrin molecules form fibrin threads, which are the mesh for clot formation and wound healing.
II: Prothrombin	Factor II is the inactive thrombin. Prothrombin is activated to thrombin by clotting factor X. Activated thrombin converts fibrinogen (clotting factor I) into fibrin and activates factors V and VIII. Synthesis is vitamin K–dependent.
III: Tissue thromboplastin	Factor III interacts with factor VII to initiate the extrinsic clotting cascade.
IV: Calcium	Calcium (Ca^{2+}), a divalent cation, is a cofactor for most of the enzyme-activated processes required in blood clotting. Calcium enhances platelet aggregation and makes red blood cells clump together.
V: Proaccelerin	Factor V is a cofactor for activated factor X, which is essential for converting prothrombin to thrombin.
VI: Discovered to be an artifact	No factor VI is involved in blood clotting.
VII: Proconvertin	Factor VII activates factors IX and X, which are essential in converting prothrombin to thrombin. Synthesis is vitamin K–dependent.
VIII: Antihemophilic factor	Factor VIII together with activated factor IX activates factor X. Factor VIII also combines with another protein (von Willebrand's factor) to help platelets adhere to capillary walls in areas of tissue injury. A lack of factor VIII is the basis for classic hemophilia (hemophilia A).
IX: Plasma thromboplastin component (Christmas factor)	Factor IX, when activated, activates factor X to convert prothrombin to thrombin. A lack of factor IX causes hemophilia B. Synthesis is vitamin K–dependent.
X: Stuart-Prower factor	Factor X, when activated, converts prothrombin into thrombin. Synthesis is vitamin K–dependent.
XI: Plasma thromboplastin antecedent	Factor XI, when activated, assists in the activation of factor IX. However, a similar factor must exist in tissues. People who are deficient in factor XI have mild bleeding problems.
XII: Hageman factor	Factor XII is critically important in the intrinsic pathway for the activation of factor XI.
XIII: Fibrin-stabilizing factor	Factor XIII assists in forming cross-links among the fibrin threads to form a strong fibrin clot.

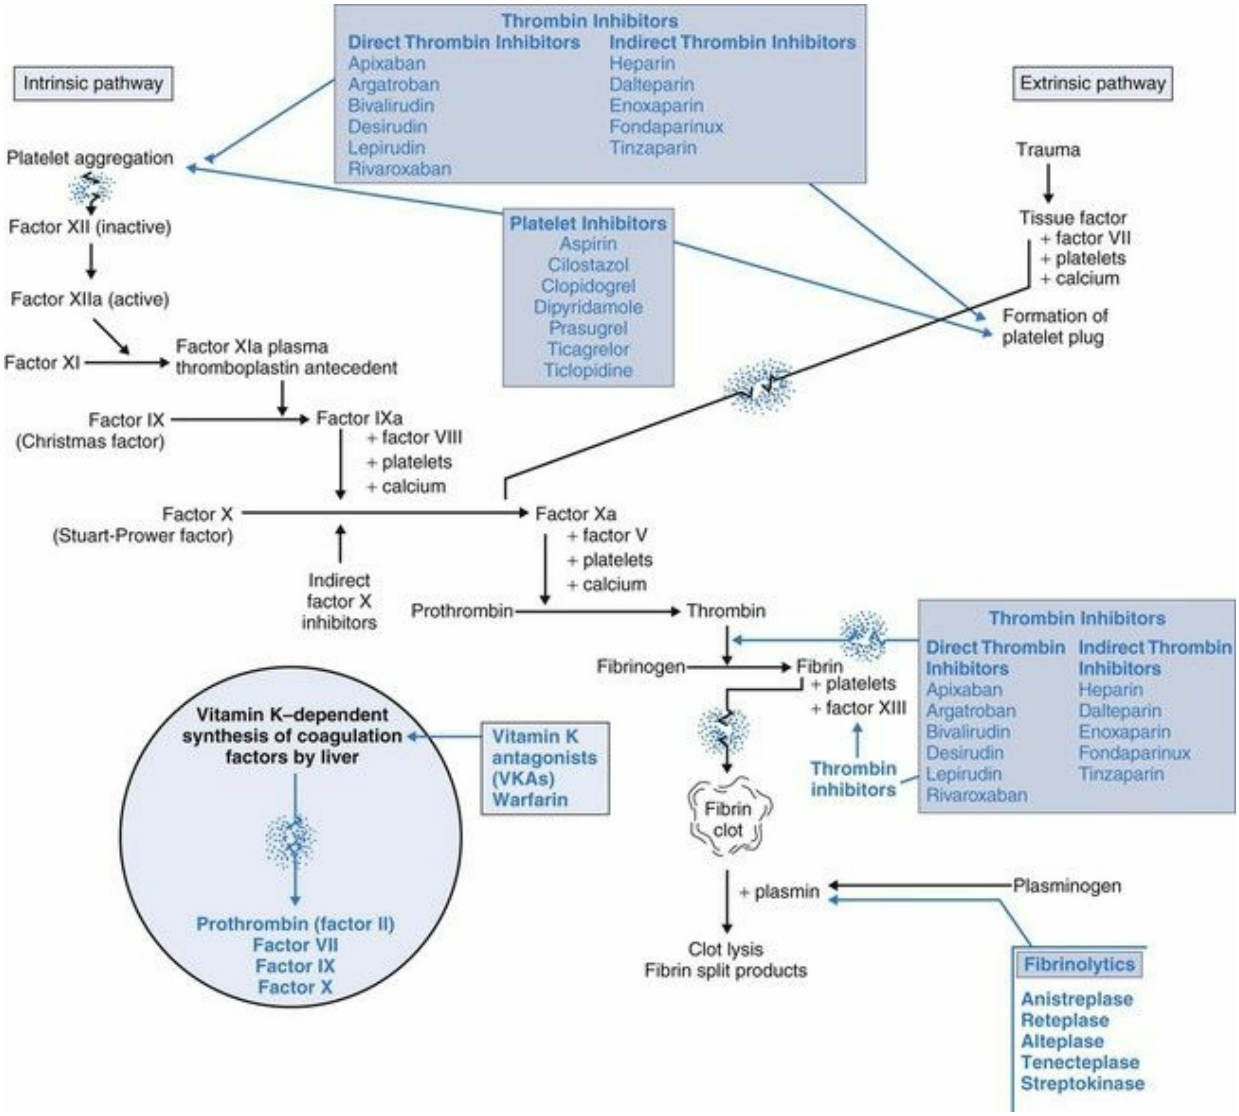

FIG. 39-4 Summary of the blood clotting cascade.

Extrinsic factors outside of the blood can also activate platelets. The most common extrinsic event is trauma that damages blood vessels and exposes collagen. Collagen then activates platelets to form a platelet plug within seconds. The blood clotting cascade is started sooner by this pathway because some intrinsic pathway steps are bypassed. Other blood vessel changes that can activate platelets include inflammation, bacterial toxins, or foreign proteins.

Whether the platelet plugs are formed because of abnormal blood (intrinsic factors) or by exposure to inflamed or damaged blood vessels (extrinsic factors), the end result of the cascade is the same: *formation of a fibrin clot and local blood clotting (coagulation).* The cascade, from the formation of a platelet plug to the formation of a fibrin clot, depends on the presence of specific clotting factors, calcium, and more platelets at every step.

Clotting factors (see Table 39-2) are inactive enzymes that become activated in a sequence. The last part of the sequence is the activation of

fibrinogen into fibrin. At each step, the activated enzyme from the previous step activates the next enzyme. The last two steps in the cascade are the activation of thrombin from prothrombin and the conversion (by thrombin) of fibrinogen into fibrin. Only fibrin molecules can begin the formation of a true clot.

Fibrin clot formation is the last phase of blood clotting. Fibrinogen is an inactive protein made in the liver. The activated enzyme *thrombin* removes the end portions of fibrinogen, converting it to active fibrin that can link together to form fibrin threads. Fibrin threads make a meshlike base to form a blood clot.

After the fibrin mesh is formed, clotting factor XIII tightens up the mesh, making it more dense and stable. More platelets stick to the threads of the mesh and attract other blood cells and proteins to form an actual blood clot. As this clot tightens (retracts), the serum is squeezed out and clot formation is complete.

Anti-Clotting Forces

Because blood clotting occurs through a rapid cascade process, in theory it keeps forming fibrin clots whenever the cascade is set into motion until all blood throughout the entire body has coagulated and perfusion stops. Therefore, whenever the blood clotting cascade is started, anti-clotting forces are also started to limit clot formation only to damaged areas so that normal perfusion is maintained everywhere else. When blood clotting and anti-clotting actions are balanced, clotting occurs only where it is needed and normal perfusion is maintained. The anti-clotting forces both ensure that activated clotting factors are present only in limited amounts and also cause fibrinolysis to prevent over-enlargement of the fibrin clot. **Fibrinolysis** is the process that dissolves fibrin clot edges with special enzymes (Fig. 39-5). The process starts by activating plasminogen to plasmin. Plasmin, an active enzyme, then digests fibrin, fibrinogen, and prothrombin, controlling the size of the fibrin clot.

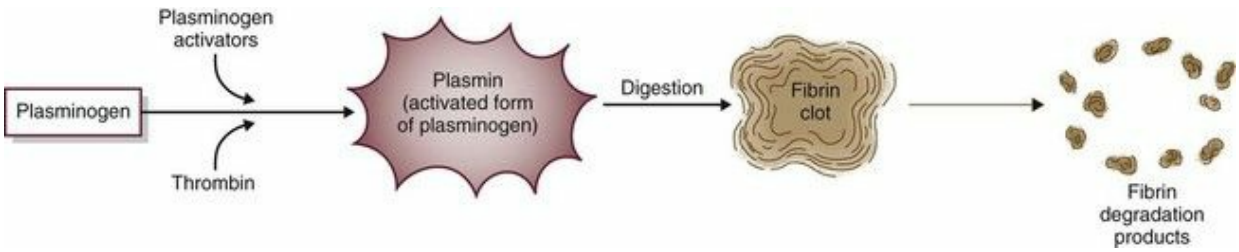

FIG. 39-5 The process of fibrinolysis.

When the blood clotting cascade is activated, certain anti-clotting substances are also activated, such as protein C, protein S, and antithrombin III. Protein C and protein S increase the breakdown of clotting factors V and VIII. Antithrombin III inactivates thrombin and clotting factors IX and X. These actions prevent clots from becoming too large or forming in an area where clotting is not needed. Deficiency of any anti-clotting factor increases the risk for pulmonary embolism, myocardial infarction, and strokes.

Hematologic Changes Associated with Aging

Aging changes the blood components (Touhy & Jett, 2014). The older adult has a decreased blood volume with lower levels of plasma proteins. The lower plasma protein level may be related to a low dietary intake of proteins, as well as to reduced protein production by the older liver. Chart 39-1 lists assessment tips for older adults.

Chart 39-1 Nursing Focus on the Older Adult

Hematologic Assessment

FINDINGS IN HEMATOLOGIC DISORDERS	NORMAL CHANGES IN THE OLDER ADULT	SIGNIFICANCE/ALTERNATIVES
Nail Beds (for Capillary Refill)		
Pallor or cyanosis may indicate a hematologic disorder.	Thickened or discolored nails make viewing color of nail beds impossible.	Use another body area, such as the lip, to assess central capillary refill.
Hair Distribution		
Thin or absent hair on the trunk or extremities may indicate poor circulation to a particular area.	Progressive loss of body hair is a normal facet of aging.	A relatively even pattern of hair loss that has occurred over an extended period is not significant.
Skin Moisture		
Skin dryness may indicate any of a number of hematologic disorders.	Skin dryness is a normal result of aging.	Skin moisture is not usually a reliable indicator of an underlying pathologic condition in the older adult.
Skin Color		
Skin color changes, especially pallor and jaundice, are associated with some hematologic disorders.	Pigment loss and skin yellowing are common changes associated with aging.	Pallor in an older adult may not be a reliable indicator of anemia. Laboratory testing is required. Yellow-tinged skin in an older adult may not be a reliable indicator of increased serum bilirubin levels. Laboratory testing is required.

As bone marrow ages, it produces fewer blood cells. Total red blood cell (RBC) and white blood cell (WBC) counts are lower among older adults, although platelet counts do not change. Lymphocytes become less reactive to antigens and lose immune function. Antibody levels and responses are lower and slower in older adults. The WBC count does not rise as high in response to infection in older people as it does in younger people.

Hemoglobin levels in men and women fall after middle age. Iron-deficient diets may play a role in this reduction.

Assessment Methods

Patient History

Age and gender are important to consider when assessing the patient's hematologic status. Bone marrow function and immune activity decrease with age.

Gender Health Considerations

Patient-Centered Care QSEN

At all ages, women have lower blood cell counts than do men. This difference is greater during menstrual years because menstrual blood loss may occur faster than blood cell production. This difference also may be related to blood dilution caused by fluid retention from female hormones. Always assess for RBC adequacy in a woman hospitalized for any reason.

Liver function, the presence of known immunologic or hematologic disorders, current drug use, dietary patterns, and socioeconomic status are important to assess. Because the liver makes clotting factors, ask about manifestations that may indicate liver problems, such as jaundice, anemia, and gallstones. Previous radiation therapy for cancer may impair hematologic function if marrow-forming bones were in the radiation path.

Ask about the patient's occupation and hobbies and whether the home is located near an industrial setting. This information may identify exposure to agents that affect bone marrow and hematologic function.

Check all drugs that the patient is using or has used in the past 3 weeks. Ask about the use of drugs listed in Table 39-3 that are known to change hematologic function. Check a drug handbook to determine whether other drugs the patient takes can affect hematologic function.

TABLE 39-3

Drugs Impairing the Hematologic System

Drugs Causing Bone Marrow Suppression	Drugs Causing Hemolysis	Drugs Disrupting Platelet Action
• Altretamine • Amphotericin B • Azathioprine • Chemotherapeutic agents • Chloramphenicol • Chromic phosphate • Colchicine • Didanosine • Eflornithine • Foscarnet sodium • Ganciclovir • Interferon alfa • Pentamidine • Sodium iodide • Zalcitabine • Zidovudine	• Acetohydroxamic acid • Amoxicillin • Chlorpropamide • Doxapram • Glyburide • Mefenamic acid • Menadiol diphosphate • Methyldopa • Nitrofurantoin • Penicillin G benzathine • Penicillin V • Primaquine • Procainamide hydrochloride • Quinidine polygalacturonate • Quinine • Sulfonamides • Tolbutamide • Vitamin K	• Aspirin • Carbenicillin • Carindacillin • Dipyridamole • Ibuprofen • Meloxicam • Naproxen • Oxaprozin • Pentoxifylline • Sulfinpyrazone • Ticarcillin • Ticlopidine • Valproic acid

Ask the patient about use of blood "thinners" and NSAIDs, which change blood clotting activity. Such drugs include anticoagulants, fibrinolytics, and platelet inhibitors. Many patients refer to these drugs as "blood thinners" although they do not change blood thickness (viscosity) (Karch, 2012). Fig. 39-4 shows where in the blood clotting cascade these agents work.

Anticoagulant drugs work by interfering with one or more steps involved in the blood clotting cascade. Thus these agents *prevent* new clots from forming and limit or prevent extension of formed clots. *Anticoagulants do not break down existing clots.* These drugs are classified as direct thrombin inhibitors, indirect thrombin inhibitors, and vitamin K antagonists.

Direct thrombin inhibitors (DTIs) can be given by the parenteral route and orally. The parenteral drugs include lepirudin (Refludan), desirudin (Iprivask), bivalirudin (Angiomax), argatroban (ARGATROBAN, Acova), rivaroxaban (Xarelto), and apixaban (Eliquis). The drugs prevent the conversion of prothrombin (factor X) to its active form, thrombin (factor Xa). Less thrombin disrupts the clotting cascade by reducing the amount of fibrinogen that is converted to active fibrin (Karch, 2012; Straznitskas & Giarratano, 2014).

Indirect thrombin inhibitors include the heparins and heparinoids. These drugs include enoxaparin (Lovenox), dalteparin (Fragmin), tinzaparin (Innohep), and fondaparinux (Arixtra). All are given parenterally. The lower molecular weight drugs are preferred for home use. The drugs cause anticoagulation by binding to and increasing the activity of antithrombin III (AT III). By activating antithrombin III,

coagulation factor Xa (thrombin) is indirectly inhibited (Karch, 2012).

Vitamin K antagonists (VKAs) decrease the synthesis of vitamin K in the intestinal tract, which then reduces the production of vitamin K–dependent clotting factors II, VII, IX, and X, along with the anticoagulant proteins C and S (Karch, 2012). When the clotting factors are reduced, anticoagulation results. The most commonly used VKA is warfarin (Coumadin, Jantoven), an oral agent.

Fibrinolytic drugs (also known as *thrombolytic drugs* or "clot busters") selectively break down fibrin threads present in formed blood clots. The mechanism to start fibrin degradation is activation of the inactive tissue protein *plasminogen* to its active form, *plasmin*. Plasmin directly attacks and degrades the fibrin molecule. Common fibrinolytic drugs include alteplase (Activase), reteplase (Retavase), tenecteplase (TNKase), and urokinase (Abbokinase, Kinlytic). All are administered by the IV route. Urokinase is approved for use only in patients who have a massive pulmonary embolism.

The use of fibrinolytic drugs results in the best clot breakdown with less disruption of blood clotting. These drugs are the first-line therapy for problems caused by small, localized formed clots such as myocardial infarction (MI), limited arterial thrombosis, and thrombotic strokes. For some problems, such as MI, these drugs are usually given only within the first 6 hours after the onset of symptoms. This time limitation is not related to drug activity because fibrinolytic agents can break down clots older than 6 hours. Rather, the tissue that has been anoxic for more than 6 hours as a result of an acute event is not likely to benefit from this therapy, making the risks to the patient greater than the advantages.

Platelet inhibitors or antiplatelet drugs prevent either platelet activation or aggregation (clumping). The most widely used drug for this effect is aspirin, which inhibits the production of substances that activate platelets, such as thromboxane. Other drugs change the platelet membrane, reducing its "stickiness," or prevent activators from binding to platelet receptors by inhibiting a variety of enzymes important to platelet activation (Karch, 2012). These drugs include cilostazol (Pletal), clopidogrel (Plavix), dipyridamole (Persantine), prasugrel (Effient), ticagrelor (Brilinta), and ticlopidine (Ticlid). Another group of drugs that inhibits platelets by binding to certain membrane proteins include abciximab (ReoPro), eptifibatide (Integrilin), and tirofiban (Aggrastat), which are all administered parenterally. In addition, many complementary therapy agents, such as St. John's wort and *Ginkgo biloba*, inhibit platelet activity.

Nutrition Status

Diet can alter cell quality and affect clotting. Ask patients to recall what they have eaten during the past week. Use this information to assess possible iron, protein, mineral, or vitamin deficiencies. Diets high in fat and carbohydrates and low in protein, iron, and vitamins can cause many types of anemia and decrease the functions of all blood cells. Diets high in vitamin K, found in leafy green vegetables, may increase the rate of blood clotting. Assess the amount of salads and other raw vegetables that the patient eats and whether supplemental vitamins and calcium are used.

Ask about alcohol consumption because chronic alcoholism causes nutrition deficiencies and impairs the liver, both of which reduce blood clotting.

Ask about personal resources, such as finances and social support. A person with a low income may have a diet deficient in iron and protein because foods containing these substances are more expensive.

Family History and Genetic Risk

Assess family history because many disorders affecting blood and blood clotting are inherited. Ask whether anyone in the family has had hemophilia, frequent nosebleeds, postpartum hemorrhages, excessive bleeding after tooth extractions, or heavy bruising after mild trauma. Ask whether any family member has sickle cell disease or sickle cell trait. Although sickle cell disease is seen most often among African Americans, anyone can have the trait.

NCLEX Examination Challenge

Health Promotion and Maintenance

Why is it important for the nurse to teach the client starting on the anticoagulant *warfarin* (Coumadin) to limit his or her intake of leafy green vegetables?

A These foods contain vitamin K, which can increase the effects of warfarin.

B These foods contain vitamin K, which can reduce the effects of warfarin.

C These foods enhance aspirin activity and increase the risk for bleeding in the person who also takes warfarin.

D These foods reduce aspirin activity and increase the risk for pulmonary

embolism in the person who also takes warfarin.

Current Health Problems

Ask about lymph nodes swelling, excessive bruising or bleeding, and whether the bleeding was spontaneous or induced by trauma. Ask about the amount and duration of bleeding after routine dental work. Ask women to estimate the number of pads or tampons used during the most recent menstrual cycle and whether this amount represents a change from the usual pattern of flow. Ask whether clots are present in menstrual blood. If menstrual clots occur, ask her to estimate clot size using coins or fruit for comparison.

Assess and record whether the patient has shortness of breath on exertion, palpitations, frequent infections, fevers, recent weight loss, headaches, or paresthesias. Any or all of these symptoms may occur with hematologic disease.

The most common manifestation of anemia is fatigue as a result of decreased oxygen delivery to cells. Cells use oxygen to produce the high-energy chemical *adenosine triphosphate (ATP)* needed to perform most cellular work. When oxygen delivery to cells is reduced, cellular work decreases and fatigue increases. Ask patients about feeling tired, needing more rest, or losing endurance during normal activities. Ask them to compare their activities during the past month with those of the same month a year ago. Determine whether other manifestations of anemia, such as vertigo, tinnitus, and a sore tongue, are present.

Physical Assessment

Assess the whole body because blood problems may reduce oxygen delivery and tissue perfusion to all systems (Jarvis, 2016). Some assessment findings associated with hematologic problems are less reliable when seen in the older adult (see Chart 39-1). Equipment needed for hematologic assessment includes gloves, a stethoscope, a blood pressure cuff, and a penlight. Remember to gently handle the patient suspected of having a hematologic problem to avoid causing bruising, petechiae, or excessive bleeding.

Skin Assessment

Inspect the skin and mucous membranes for pallor or jaundice. Assess nail beds for pallor or cyanosis. Pallor of the gums, conjunctivae, and palmar creases (when the palm is stretched) indicates decreased

hemoglobin levels and poor tissue oxygenation. Assess the gums for active bleeding in response to light pressure or brushing the teeth with a soft-bristled brush, and assess any lesions or draining areas. Inspect for petechiae and large bruises *(ecchymoses)*. **Petechiae** are pinpoint hemorrhagic lesions in the skin. Bruises may cluster together. For hospitalized patients, determine whether there is bleeding around nasogastric tubes, endotracheal tubes, central lines, peripheral IV sites, or Foley catheters. Check the skin turgor, and ask about itching because dry skin from poor perfusion itches. Assess body hair patterns. Areas with poor circulation, especially the lower legs and toes, may have sparse or absent hair, although this may be a normal finding in an older adult.

Cultural Considerations

Patient-Centered Care QSEN

Pallor and cyanosis are more easily detected in people with darker skin by examining the oral mucous membranes and the conjunctiva of the eye. Jaundice can be seen more easily on the roof of the mouth. Petechiae may be visible only on the palms of the hands or the soles of the feet. Bruises can be seen as darker areas of skin and palpated as slight swellings or irregular skin surfaces. Ask the patient about pain when skin surfaces are touched lightly or palpated. (Chapter 24 provides tips for assessing darker skin.)

Head and Neck Assessment

Check for pallor or ulceration of the oral mucosa. The tongue is smooth in pernicious anemia and iron deficiency anemia or smooth and beefy red in other nutrition deficiencies. These manifestations may occur with fissures at the corners of the mouth. Assess for scleral jaundice.

Inspect and palpate all lymph node areas. Document any lymph node enlargement, including whether palpation of the enlarged node causes pain and whether the enlarged node moves or remains fixed with palpation.

Respiratory Assessment

When blood problems reduce oxygen delivery, the lungs work harder to make adjustments that can maintain tissue perfusion. Assess the rate and depth of respiration while the patient is at rest and during and after mild physical activity (e.g., walking 20 steps in 10 seconds). Note whether the patient can complete a 10-word sentence without stopping for a breath.

Assess whether the patient is fatigued easily, has shortness of breath at rest or on exertion, or needs extra pillows to breathe well at night. Anemia can cause these manifestations as a result of respiratory changes made as adjustments to the reduced tissue oxygen levels.

Cardiovascular Assessment

When blood problems reduce oxygen delivery, the heart works harder to make adjustments to maintain tissue perfusion. Pulses may become weak and thready. Observe for distended neck veins, edema, or indications of phlebitis. Use a stethoscope to listen for abnormal heart sounds and irregular rhythms. Assess blood pressure (BP). Systolic BP tends to be lower than normal in patients with anemia and higher than normal when the patient has excessive red blood cells.

Kidney and Urinary Assessment

The kidneys have many blood vessels, and bleeding problems may cause gross or occult *hematuria* (blood in the urine). Inspect urine for color. Hematuria may appear as grossly bloody red or dark brownish gold urine. Test the urine for proteins with a urine test dipstick because blood contains protein and blood in the urine increases its protein content. Keep in mind that the person with chronic kidney disease (CKD) produces less natural erythropoietin and often is anemic.

Musculoskeletal Assessment

Rib or sternal tenderness may occur with leukemia (blood cancer) when the bone marrow overproduces cells, increasing the pressure in the bones. Examine the skin over superficial bones, including the ribs and sternum, by applying firm pressure with the fingertips. Assess the range of joint motion, and document any swelling or joint pain.

Abdominal Assessment

The normal adult spleen is usually *not* palpable, but an enlarged spleen occurs with many hematologic problems. An enlarged spleen may be detected by palpation, but this is usually performed by the health care provider because an enlarged spleen is tender and ruptures easily.

Nursing Safety Priority QSEN

Action Alert

Do not palpate the splenic area of the abdomen for any patient with a suspected hematologic problem. An enlarged spleen ruptures easily and can lead to hemorrhage and death.

Palpating the edge of the liver in the right upper quadrant of the abdomen can detect enlargement, which often occurs with hematologic problems. The normal liver may be palpable as much as 4 to 5 cm below the right costal margin but is usually not palpable in the epigastrium.

A common cause of anemia among older adults is a chronically bleeding GI ulcer or intestinal polyp. If the ulcer is located in the stomach or the small intestine, obvious blood may not be visible in the stool or such a small amount is passed each day that the patient is not aware of it. Obtain a stool specimen for occult blood testing.

Central Nervous System Assessment

Assessing cranial nerves and testing neurologic function are important in hematologic assessment because some problems cause specific changes. Vitamin B_{12} deficiency impairs nerve function, and severe chronic deficiency may cause permanent neurologic degeneration. Many neurologic problems can develop in patients who have leukemia, because leukemia can cause bleeding, infection, or tumor spread within the brain. When the patient with a suspected bleeding disorder has any head trauma, expand the assessment to include frequent neurologic checks and checks of cognitive function (see Chapter 41).

Psychosocial Assessment

Regardless of the type of hematologic problem, each person brings his or her own coping style to the illness. Develop a rapport with the patient and learn what coping mechanisms he or she has used successfully in the past.

Ask the patient and family members about social support networks and financial resources. A problem in these areas can interfere with the patient's adherence to therapy.

Diagnostic Assessment

Laboratory Tests

Laboratory test results often provide the most definitive information about hematologic problems. Chart 39-2 lists laboratory data used to assess hematologic function. When a venipuncture is necessary, apply

pressure to the site for at least 5 minutes on a patient suspected of having a hematologic problem to prevent bleeding and hematoma formation.

Chart 39-2

Laboratory Profile

Hematologic Assessment

TEST	REFERENCE RANGE	INTERNATIONAL REFERENCE UNITS	SIGNIFICANCE OF ABNORMAL FINDINGS
Red blood cell (RBC) count	*Females:* 4.2-5.4 million/μL	4.2-5.4 × 10^{12} cells/L	*Decreased levels* indicate possible anemia or hemorrhage. *Increased levels* indicate possible chronic hypoxia or polycythemia vera.
	Males: 4.7-6.1 million/μL	4.7-6.1 × 10^{12} cells/L	
Hemoglobin (Hgb)	*Females:* 12-16 g/dL	7.4-9.9 mmol/L	Same as for RBC.
	Males: 14-18 g/dL	8.7-11.2 mmol/L	
Hematocrit (Hct)	*Females:* 37%-47%	0.37-0.47 fraction	Same as for RBC.
	Males: 42%-52%	0.42-0.52 fraction	
Mean corpuscular volume (MCV)	80-95 fL	Same as reference range	*Increased levels* indicate macrocytic cells, possible anemia. *Decreased levels* indicate microcytic cells, possible iron deficiency anemia.
Mean corpuscular hemoglobin (MCH)	27-31 pg	Same as reference range	Same as for MCV.
Mean corpuscular hemoglobin concentration (MCHC)	32-36 g/dL	32%-36%	*Increased levels* may indicate spherocytosis or anemia. *Decreased levels* may indicate iron deficiency anemia or a hemoglobinopathy.
White blood cell (WBC) count	5000-10,000/mm^3	5.0-10.0 × 10^9 cells/L	*Increased levels* are associated with infection, inflammation, autoimmune disorders, and leukemia. *Decreased levels* may indicate prolonged infection or bone marrow suppression.
Reticulocyte count	0.5%-2.0% of RBCs	0.005-0.20 fraction	*Increased levels* may indicate chronic blood loss. *Decreased levels* indicate possible inadequate RBC production.
Total iron-binding capacity (TIBC)	250-460 mcg/dL	45-82 μmol/L	*Increased levels* indicate iron deficiency. *Decreased levels* may indicate anemia, hemorrhage, hemolysis.
Iron (Fe)	*Females:* 60-160 mcg/dL	11-29 μmol/L	*Increased levels* indicate iron excess, liver disorders, hemochromatosis, megaloblastic anemia. *Decreased levels* indicate possible iron deficiency anemia, hemorrhage.
	Males: 80-180 mcg/dL	14-32 μmol/L	
Serum ferritin	*Females:* 10-150 ng/mL	10-150 mcg/L	Same as for iron.
	Males: 12-300 ng/mL	12-300 mcg/L	
Platelet count	150,000-400,000/mm^3	150-400 × 10^9/L	*Increased levels* may indicate polycythemia vera or malignancy. *Decreased levels* may indicate bone marrow suppression, autoimmune disease, hypersplenism.
Hemoglobin electrophoresis	Hgb A_1: 95%-98% Hgb A_2: 2%-3% Hgb F: 0.8%-2% Hgb S: 0% Hgb C: 0% Hgb E: 0%	Same as reference range	*Variations* indicate hemoglobinopathies.
Direct Coombs' and indirect Coombs' test	Negative	Negative	*Positive findings* indicate antibodies to RBCs.
Prothrombin time (PT)	11-12.5 sec 85%-100%	Patient PT/normal PT INR 0.8-1.1	*Increased time* indicates possible deficiency of clotting factors V and VII.
			Decreased time may indicate vitamin K excess.

fL, Femtoliter; *INR*, international normalized ratio; *pg*, picograms.

Data from Pagana, K., & Pagana, T. (2014). *Mosby's manual of diagnostic and laboratory tests* (5th ed.). St. Louis: Mosby.

Tests of Cell Number and Function.

A peripheral blood smear is made by taking a drop of blood and spreading

it over a slide. It can be read by an automated calculator or by a technologist with a microscope. This rapid test provides information on the sizes, shapes, and proportions of different blood cell types within the peripheral blood.

A complete blood count (CBC) includes a number of studies: red blood cell (RBC) count, white blood cell (WBC) count, hematocrit, and hemoglobin level. The RBC count measures circulating RBCs in 1 mm^3 of blood. The WBC count measures all leukocytes present in 1 mm^3 of blood. To determine the percentages of different types of leukocytes circulating in the blood, a WBC count with differential leukocyte count is performed (see Chapter 17). The hematocrit (Hct) is the percentage of red blood cells in the total blood volume. The hemoglobin (Hgb) level is the total amount of hemoglobin in blood.

The CBC can measure other features of the RBCs. The mean corpuscular volume (MCV) measures the average volume or size of individual RBCs and is useful for classifying anemias. When the MCV is elevated, the cell is larger than normal *(macrocytic),* as seen in megaloblastic anemias. When the MCV is decreased, the cell is smaller than normal *(microcytic),* as seen in iron deficiency anemia. The mean corpuscular hemoglobin (MCH) is the average amount of hemoglobin by weight in a single RBC. The mean corpuscular hemoglobin concentration (MCHC) measures the average amount of hemoglobin by percentage in a single RBC. When the MCHC is decreased, the cell has a hemoglobin deficiency and is *hypochromic* (a lighter color), as in iron deficiency anemia. These three tests can help determine possible causes of low RBC counts that are not related to blood loss (Rauen, 2012).

Reticulocyte count is helpful in determining bone marrow function. A reticulocyte is an immature RBC that still has its nucleus. An elevated reticulocyte count indicates that RBCs are being produced and released by the bone marrow before they mature. Normally only about 2% of circulating RBCs are reticulocytes. An elevated reticulocyte count is desirable in an anemic patient or after hemorrhage because this indicates that the bone marrow is responding to a decrease in the total RBC level. An elevated reticulocyte count without a precipitating cause usually indicates health problems, such as polycythemia vera (a malignant condition in which the bone marrow overproduces RBCs).

A platelet count, also known as a *thrombocyte count,* reflects the number of platelets in circulation. The normal range is 150,000 to 400,000/mm^3. When this value is low *(thrombocytopenia),* the person is at greater risk for bleeding because platelets are critical for blood clotting. Patients who

have values between 40,000/mm^3 and 80,000/mm^3 may have prolonged bleeding from trauma, dental work, and surgery. Patients who have platelet values below 20,000/mm^3 may have spontaneous bleeding that is very difficult to stop.

Hemoglobin electrophoresis detects abnormal forms of hemoglobin, such as hemoglobin S in sickle cell disease. Hemoglobin A is the major type of hemoglobin in an adult.

Leukocyte alkaline phosphatase (LAP) is an enzyme produced by normal mature neutrophils. Elevated LAP levels occur during episodes of infection or stress. An elevated neutrophil count without an elevation in LAP level occurs with some types of leukemia.

Coombs' tests, both direct and indirect, are used for blood typing. The direct test detects antibodies against RBCs that may be attached to a person's RBCs. Although healthy people can make these antibodies, in certain diseases (e.g., systemic lupus erythematosus, mononucleosis) these antibodies are directed against the patient's own RBCs. Excessive amounts of these antibodies can cause hemolytic anemia (Pagana & Pagana, 2014).

The indirect Coombs' test detects the presence of circulating antiglobulins. The test is used to determine whether the patient has serum antibodies to the type of RBCs that he or she is about to receive by blood transfusion (Pagana & Pagana, 2014).

Serum ferritin, transferrin, and the total iron-binding capacity (TIBC) tests measure iron levels. Abnormal levels of iron and TIBC occur with problems such as iron deficiency anemia.

The serum ferritin test measures the amount of free iron present in the plasma, which represents 1% of the total body iron stores. Therefore the serum ferritin level provides a means to assess total iron stores. People with serum ferritin levels within 10 g of the normal range for their gender have adequate iron stores; people with levels 10 g or more lower than the normal range have inadequate iron stores and have difficulty recovering from any blood loss.

Transferrin is a protein that transports dietary iron from the intestines to cell storage sites. Measuring the amount of iron that can be bound to serum transferrin indirectly determines whether an adequate amount of transferrin is present. This test is the total iron-binding capacity (TIBC) test. Normally, only about 30% of the transferrin is bound to iron in the blood. TIBC increases when a person is deficient in serum iron and stored iron levels. Such a value indicates that an adequate amount of transferrin is present but less than 30% of it is bound to serum iron.

Tests Measuring Bleeding and Coagulation.

Tests that measure bleeding and coagulation provide information that reflects the effectiveness of different aspects of blood clotting. These tests are used to diagnose specific hematologic health problems, determine drug therapy effectiveness, and identify risk for excessive bleeding or clotting.

Prothrombin time (PT) measures how long blood takes to clot, reflecting the level of clotting factors II, V, VII, and X and how well they are functioning. When enough of these clotting factors are present and functioning, the PT shows blood clotting between 11 and 12.5 seconds or within 85% to 100% of the time needed for a control sample of blood to clot. PT is prolonged when one or more of these clotting factors are deficient.

The PT test is now used less often to assess how fast blood clots, because control blood is taken from different people and may not be the same even in one laboratory from one day to the next. To reduce PT errors as a result of control blood variation or in some of the chemicals used in the test, the international normalized ratio is used to assess clotting time.

International normalized ratio (INR) measures the same process as the PT by establishing a normal mean or standard for PT. The INR is calculated by dividing the patient's PT by the established standard PT. A normal INR ranges between 0.7 and 1.8. When using the INR to monitor warfarin therapy, the desired outcome is usually to maintain the patient's INR between 2.0 and 3.0 regardless of the actual PT in seconds. The desired INR range for any patient, however, is individualized for specific patient factors and medical conditions.

The partial thromboplastin time (PTT) assesses the intrinsic clotting cascade and the action of factors II, V, VIII, IX, XI, and XII. PTT is prolonged whenever any of these factors is deficient, such as in hemophilia or disseminated intravascular coagulation (DIC). Because factors II, IX, and X are vitamin K–dependent and are produced in the liver, liver disease can prolong the PTT. Desired therapeutic ranges for anticoagulation are usually between 1.5 and 2.0 times normal values but can be greater depending on the reason the person is receiving anticoagulation therapy.

The anti-factor Xa test measures the amount of anti-activated factor X (anti-Xa) in blood, which is affected by heparin. It is used mainly to monitor heparin levels in patients treated with either standard unfractionated heparin or low–molecular-weight heparin. For people not receiving heparin in any form, the reference range is less than 0.1 IU/mL.

The usual therapeutic range for patients receiving standard heparin is 0.5 to 1.0 IU/mL, and the usual therapeutic range for patients receiving low–molecular-weight heparin is 0.3 to 0.7 IU/mL. Test results are affected by age, gender, health history, and the specific laboratory technique used for the test.

Platelet aggregation, or the ability to clump, is tested by mixing the patient's plasma with an agonist substance that should cause clumping. The degree of clumping is noted. Aggregation can be impaired in von Willebrand's disease and during the use of drugs such as aspirin, anti-inflammatory agents, psychotropic agents, and platelet inhibitors.

NCLEX Examination Challenge

Physiological Integrity

Which blood test result for a client being assessed for a hematologic problem indicates to the nurse that chronic anemia is likely?

A International normalized ratio (INR) is 0.9

B Platelet count of 180,000/mm^3

C Reticulocyte value of 14%

D Hematocrit of 27%

Imaging Assessment

Assessment of the patient with a suspected hematologic problem can include radioisotopic imaging. Isotopes are used to evaluate the bone marrow for sites of active blood cell formation and sites of iron storage. Radioactive colloids are used to determine organ size and liver and spleen function.

The patient is given a radioactive isotope by IV about 3 hours before the procedure. Once in the nuclear medicine department, he or she must lie still for about an hour during the scan. No special patient preparation or follow-up care is needed for these tests.

Standard x-rays may be used to diagnose some hematologic problems. For example, multiple myeloma causes classic bone destruction, with a "Swiss cheese" appearance on x-ray.

Bone Marrow Aspiration and Biopsy

Bone marrow aspiration or biopsy, which are similar invasive procedures, helps evaluate the patient's hematologic status when other tests show abnormal findings that indicate a possible problem in blood cell

production or maturation. Results provide information about bone marrow function, including the production of all blood cells and platelets. In a bone marrow aspiration, cells and fluids are suctioned from the bone marrow. In a bone marrow biopsy, solid tissue and cells are obtained by coring out an area of bone marrow with a large-bore needle.

A health care provider's order and a signed informed consent are obtained before either procedure is performed. Bone marrow aspiration may be performed by a physician, an advanced practice nurse, or a physician assistant, depending on the agency's policy and regional law. The procedure may be performed at the patient's bedside, in an examination room, or in a laboratory.

After learning what specific tests will be performed on the marrow, check with the hematology laboratory to determine how to handle the specimen. Some tests require that heparin or other solutions be added to the specimen.

Patient Preparation.

Most patients are anxious before a bone marrow aspiration, even those who have had one in the past. You can help reduce anxiety and allay fears by providing accurate information and emotional support. Some patients like to have their hand held during the procedure.

Explain the procedure, and reassure the patient that you will stay during the entire procedure. Occasionally a friend or family member is permitted to be present to provide emotional support. Tell the patient that the local anesthetic injection will feel like a stinging or burning sensation. Tell him or her to expect a heavy sensation of pressure and pushing while the needle is being inserted. Sometimes a crunching sound can be heard or scraping sensation felt as the needle punctures the bone. Explain that a brief sensation of painful pulling will be experienced as the marrow is being aspirated by mild suction in the syringe. If a biopsy is performed, the patient may feel more discomfort as the needle is rotated into the bone.

Assist the patient onto an examining table, and expose the site (usually the iliac crest). If this site is not available or if more marrow is needed, the sternum may be used. If the iliac crest is the site, place the patient in the prone or side-lying position. Depending on the tests to be performed on the specimen, a laboratory technician may also be present to ensure proper handling of the specimen.

Procedure.

The procedure usually lasts from 5 to 15 minutes. The type and the amount of anesthesia or sedation depend on the physician's preference, the patient's preference and previous experience with bone marrow aspiration and biopsy, and the setting.

A local anesthetic agent is injected into the skin around the site. The patient may also receive a mild tranquilizer or a rapid-acting sedative, such as midazolam (Versed), lorazepam (Ativan, Apo-Lorazepam, Novo-Lorazem), or etomidate (Amidate). Some patients do well with guided imagery or autohypnosis.

Nursing Safety Priority QSEN

Action Alert

Aspiration or biopsy procedures are invasive, and sterile technique must be observed.

The skin over the site is cleaned with a disinfectant. For an aspiration, the needle is inserted with a twisting motion and the marrow is aspirated by pulling back on the plunger of the syringe. When sufficient marrow has been aspirated to ensure accurate analysis, the needle is rapidly withdrawn while the tissues are supported at the site. For a biopsy, a small skin incision is made and the biopsy needle is inserted through the skin opening. Pressure and several twisting motions are needed to ensure coring and loosening of an adequate amount of marrow tissue. Apply external pressure to the site until hemostasis is ensured. A pressure dressing or sandbags may be applied to reduce bleeding at the site.

Follow-Up Care.

The nursing priority after a bone marrow aspiration or biopsy is prevention of excessive bleeding. Cover the site with a dressing after bleeding is controlled, and closely observe it for 24 hours for manifestations of bleeding and infection. A mild analgesic (aspirin-free) may be given for discomfort, and ice packs can be placed over the site to limit bruising. Instruct the patient to inspect the site every 2 hours for the first 24 hours and to note the presence of active bleeding or bruising. Advise him or her to avoid contact sports or any activity that might result in trauma to the site for 48 hours.

Information obtained from bone marrow aspiration or biopsy reflects the degree and quality of bone marrow activity present. The counts made

on a marrow specimen can indicate whether different cell types are present in the expected quantities and proportions. In addition, bone marrow aspiration or biopsy can confirm the spread of cancer cells from other tumor sites.

Clinical Judgment Challenge

Safety; Patient-Centered Care QSEN

A 52-year-old man is scheduled for a bone marrow aspiration because his white blood cell count has been persistently abnormal and his father died from chronic lymphocytic leukemia (CLL). He is very anxious this morning, and you remember him from one of his earlier visits in which you drew his blood. At that visit, he started vomiting when you placed the needle in his vein. He tells you that he is very worried about the results and the pain of the procedure. He also tells you that his daughter has a dance recital tonight and he very much wants to attend this event.

1. Is this patient a candidate for autohypnosis? Why or why not?
2. Is there any reason(s) for him to think he may also have CLL? If so, what might this be?
3. What will you tell him about attending the dance recital?

Nursing Concepts and Clinical Judgment Review

What might you NOTICE in a patient with adequate tissue perfusion related to normal hematologic function?

Vital signs:

- Heart rate and respiratory rate within normal range
- Blood pressure within normal range

Physical assessment:

- Able to speak a sentence of 12 words without stopping for breath
- Able to walk and talk without stopping for breath
- Skin color normal (no cyanosis, pallor, or jaundice)
- Oral mucous membrane and nail beds pink with rapid capillary refill
- Gums pink, no petechiae or bleeding
- Appropriate distribution of body hair, especially on legs and feet
- Warm hands and feet, no dependent edema
- Skin clear with no large bruises or petechiae
- Lower eyelid conjunctivae red

- Urine output just about equal to fluid intake
- Urine clear and yellow

Psychological assessment:

- Oriented and not confused
- Energy level good; able to engage in desired work, recreational, and personal activities

Laboratory assessment:

- Red blood cell, hemoglobin, hematocrit, white blood cell, and platelet levels within normal limits for age and gender
- Reticulocyte count less than 2%

Get Ready for the NCLEX® Examination!

Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Verify that a patient having a bone marrow aspiration or biopsy has signed an informed consent statement. **Safety** QSEN
- Handle patients with suspected hematologic problems gently to avoid bleeding or bruising. **Safety** QSEN
- Do not palpate the splenic area of any patient suspected of having a hematologic problem. **Safety** QSEN
- Maintain pressure over a venipuncture site for at least 5 minutes to prevent excessive bleeding. **Safety** QSEN

Health Promotion and Maintenance

- Teach people to avoid unnecessary contact with environmental chemicals or toxins. If contact cannot be avoided, teach people to use safety precautions.
- Instruct patients about the importance of eating a diet with adequate amounts of foods that are good sources of iron, folic acid, and vitamin B_{12}. **Patient-Centered Care** QSEN

Psychosocial Integrity

- Teach patients and family members about what to expect during procedures to assess hematologic function, including restrictions, drugs, and follow-up care. **Patient-Centered Care** QSEN
- Ask patients about their activity level and whether they are satisfied with the energy they have for activities. **Patient-Centered Care** QSEN
- Support the patient during a bone marrow aspiration or biopsy. **Patient-Centered Care** QSEN

Physiological Integrity

- Interpret blood cell counts and clotting tests to assess hematologic status. **Evidence-Based Practice** QSEN
- Be aware of these facts for hematologic function:
  - Tissue oxygenation and perfusion rely on normal hematologic function for oxygen delivery.

- The most common manifestation of a hematologic problem is fatigue.
- A platelet plug and a fibrin clot are not the same.
- Both clotting forces and anti-clotting forces are needed to maintain adequate perfusion.
- Women have reduced red blood cell, hematocrit, and hemoglobin levels at all ages compared with men.

- Use the lip rather than nail beds to assess capillary refill on older adults. **Evidence-Based Practice** QSEN
- Rely on laboratory tests rather than skin color changes in older adults to assess anemia or jaundice. **Evidence-Based Practice** QSEN
- Assess the patient's endurance in performing ADLs. **Patient-Centered Care** QSEN
- Apply an ice pack to the needle site after a bone marrow aspiration or biopsy. **Patient-Centered Care** QSEN
- Check the needle insertion site at least every 2 hours after a bone marrow aspiration or biopsy. If the patient is going home, teach the patient and family how to assess the site for bleeding and when to seek help. **Patient-Centered Care** QSEN
- Instruct patients to avoid activities that may traumatize the site after a bone marrow aspiration or biopsy.

CHAPTER 40

Care of Patients with Hematologic Problems

Katherine I. Byar

PRIORITY CONCEPTS

- Gas Exchange
- Perfusion
- Clotting
- Immunity
- Infection

Learning Outcomes

Safe and Effective Care Environment

1. Use principles of infection control to prevent infection when caring for a patient with a hematologic problem who also has reduced immunity.
2. Protect patients who have a hematologic problem with impaired clotting from injury.

Health Promotion and Maintenance

3. Teach all people to take measures to protect the hematologic system from damage and cancer, including the avoidance of known environmental causative agents.
4. Teach the patient with hematologic problems and the family how to avoid injury and complications in the home.
5. Use assessment information to identify people at increased genetic risk for a hematologic problem.

Psychosocial Integrity

6. Reduce the psychological impact for the patient and family regarding

changes in the function of the hematologic system.

7. Work with other members of the health care team to ensure that the values, preferences, and expressed needs of patients with a hematologic problem are respected.

Physiological Integrity

8. Assess and reassess the manifestations of patients being managed for a hematologic problem.
9. Use appropriate strategies to relieve pain and promote comfort for patients experiencing a hematologic problem.
10. Use laboratory data and clinical manifestations to prioritize nursing care for the patient who has an acute or chronic hematologic problem.
11. Collaborate with other health care professionals who help patients and families experiencing an acute or chronic hematologic problem achieve desired health outcomes.
12. Coordinate nursing interventions for the patient with a hematologic disorder in the community.
13. Prioritize nursing responsibilities during transfusion therapy.

 http://evolve.elsevier.com/Iggy/

Any condition that impairs the production or function of blood cells or that causes the abnormal destruction of any type of blood cell can result in a hematologic problem. Problems of the hematologic system can affect many tissues and organs by interfering with gas exchange and tissue perfusion. The type and severity of the disorder determine the impact it has on patient health. This chapter discusses mild hematologic disorders and those that are potentially life threatening, such as sickle cell disease and hematologic malignancies.

Red Blood Cell Disorders

Red blood cells (RBCs), also known as **erythrocytes**, are the major cell in the blood. As discussed in Chapter 39, tissue gas exchange for oxygenation depends on keeping the circulating number of RBCs within the normal range for the person's age and gender and on maintaining normal RBC function. RBC disorders include problems in production, function, and destruction. Problems may result in poor function of RBCs, decreased numbers of RBCs (anemia), or an excess of RBCs (polycythemia).

Anemia is a reduction in either the number of RBCs, the amount of hemoglobin, or the **hematocrit** (percentage of packed RBCs per deciliter of blood). It is a clinical indicator, not a specific disease, because it occurs with many health problems. Anemia can result from dietary problems, genetic disorders, bone marrow disease, or excessive bleeding. GI bleeding is the most common reason for anemia in adults.

There are many types and causes of anemia (Table 40-1). Some are caused by a deficiency in one of the components needed to make fully functional RBCs. Other anemias are caused by decreased RBC production or increased RBC destruction. Despite the many causes, manifestations (Chart 40-1) and the nursing care needed are similar for all types of anemia.

Chart 40-1 Key Features

Anemia

Integumentary Manifestations

- Pallor, especially of the ears, the nail beds, the palmar creases, the conjunctivae, and around the mouth
- Cool to the touch
- Intolerance of cold temperatures
- Nails become brittle and become concave over time

Cardiovascular Manifestations

- Tachycardia at basal activity levels, increasing with activity and during and immediately after meals
- Murmurs and gallops heard on auscultation when anemia is severe
- Orthostatic hypotension

Respiratory Manifestations

- Dyspnea on exertion

- Decreased oxygen saturation levels

Neurologic Manifestations

- Increased somnolence and fatigue
- Headache

TABLE 40-1

Common Causes of Anemia

TYPE OF ANEMIA	COMMON CAUSES
Sickle cell disease	Autosomal recessive inheritance of two defective gene alleles for hemoglobin synthesis
Glucose-6-phosphate dehydrogenase (G6PD) deficiency anemia	X-linked recessive deficiency of the enzyme *G6PD*
Autoimmune hemolytic anemia	Abnormal immune function in which a person's immune reactive cells fail to recognize his or her own red blood cells as self cells
Iron deficiency anemia	Inadequate iron intake caused by: • Iron-deficient diet • Chronic alcoholism • Malabsorption syndromes • Partial gastrectomy Rapid metabolic (anabolic) activity caused by: • Pregnancy • Adolescence • Infection
Vitamin B_{12} deficiency anemia	Dietary deficiency Failure to absorb vitamin B_{12} from intestinal tract as a result of: • Partial gastrectomy • Pernicious anemia • Malabsorption syndromes
Folic acid deficiency anemia	Dietary deficiency Malabsorption syndromes Drugs: • Oral contraceptives • Anticonvulsants • Methotrexate
Aplastic anemia	Exposure to myelotoxic agents: • Radiation • Benzene • Chloramphenicol • Alkylating agents • Antimetabolites • Sulfonamides • Insecticides Viral infection (unproven): • Epstein-Barr virus • Hepatitis B • Cytomegalovirus

Anemias Resulting From Increased Destruction of Red Blood Cells

Sickle Cell Disease

Pathophysiology

Sickle cell disease (SCD), which used to be called *sickle cell anemia*, is a genetic disorder that results in chronic anemia, pain, disability, organ damage, increased risk for infection, and early death. There is great

variation among patients in how severe the disease is and when complications start.

This disorder results in the formation of abnormal hemoglobin chains. In healthy adults, the normal hemoglobin **(hemoglobin A [HbA])** molecule has two alpha chains and two beta chains of amino acids. Normal adult red blood cells usually contain 98% to 99% HbA, with a small percentage of a fetal form of hemoglobin (HbF).

In SCD, at least 40% (and often much more) of the total hemoglobin is composed of an abnormal beta chain **(hemoglobin S [(HbS])**. HbS is sensitive to low oxygen content of the RBCs. When RBCs having large amounts of HbS are exposed to decreased oxygen conditions, the abnormal beta chains contract and pile together within the cell, distorting the cell into a sickle shape. Sickled cells become rigid and clump together, causing the RBCs to become "sticky" and fragile. The clumped masses of sickled RBCs block blood flow (Fig. 40-1), known as a *vaso-occlusive event (VOE).* VOE leads to further tissue **hypoxia** (reduced oxygen supply) and more sickle-shaped cells, which then leads to more blood vessel obstruction and ischemia in the affected tissues. Repeated episodes of ischemia cause progressive organ damage from anoxia and infarction. Conditions that cause sickling include hypoxia, dehydration, infection, venous stasis, pregnancy, alcohol consumption, high altitudes, low or high environmental or body temperatures, acidosis, strenuous exercise, emotional stress, and anesthesia.

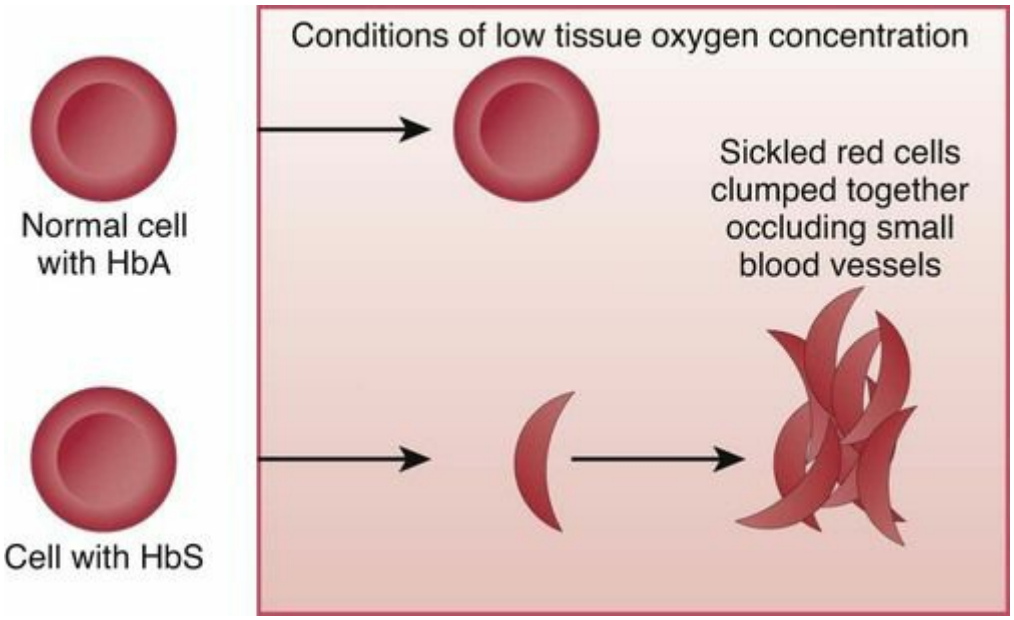

FIG. 40-1 Red blood cell actions under conditions of low tissue oxygenation. (*HbA*, Hemoglobin A; *HbS*, hemoglobin S.)

Usually sickled cells go back to normal shape when the precipitating condition is removed, the blood oxygen level is normalized, and proper tissue perfusion resumes. Although the cells then appear normal, some of the hemoglobin remains twisted, decreasing cell flexibility. The cell membranes are damaged over time, and cells are permanently sickled. The membranes of cells with HbS are more fragile and more easily broken. The average life span of an RBC containing 40% or more of HbS is about 10 to 20 days, much less than the 120-day life span of normal RBCs. This reduced RBC life span causes **hemolytic** (blood cell–destroying) anemia in patients with sickle cell disease.

The patient with SCD has periodic episodes of extensive cellular sickling, called **crises.** The crises have a sudden onset and can occur as often as weekly or as seldom as once a year. Many patients are in good health much of the time, with crises occurring only in response to conditions that cause local or systemic **hypoxemia** (deficient oxygen in the blood).

Repeated VOEs in large blood vessels cause long-term damage to tissues and organs. Most damage results from tissue hypoxia, anoxia, ischemia, and cell death. Organs begin to have small infarcted areas and scar tissue formation, and eventually organ failure results. Tissues most often affected are the spleen, liver, heart, kidney, brain, joints, bones, and retina.

Etiology and Genetic Risk

Sickle cell disease (SCD) is a genetic disorder with an autosomal recessive pattern of inheritance (see Chapter 4). A specific mutation in the hemoglobin gene alleles on chromosome 11 leads to the formation of HbS instead of HbA (Parsh & Kumar, 2012). In sickle cell disease, the patient has two HbS gene alleles, one inherited from each parent, usually resulting in 80% to100% of the hemoglobin being HbS. Because both hemoglobin alleles are S, sickle cell disease is sometimes abbreviated "SS." Patients with SCD often have severe manifestations even when triggering conditions are mild. If a patient with SCD has children, each child will inherit one of the two abnormal gene alleles and at least have sickle cell trait.

Sickle cell trait occurs when one normal gene allele and one abnormal gene allele for hemoglobin are inherited and only half of the hemoglobin chains are abnormal. Sickle cell trait is abbreviated "AS." The patient is a carrier of the HbS gene allele (Fig. 40-2) and can pass the trait on to his or her children. However, the patient has only mild manifestations of the disease when precipitating conditions are present because less than 40%

of the hemoglobin is abnormal.

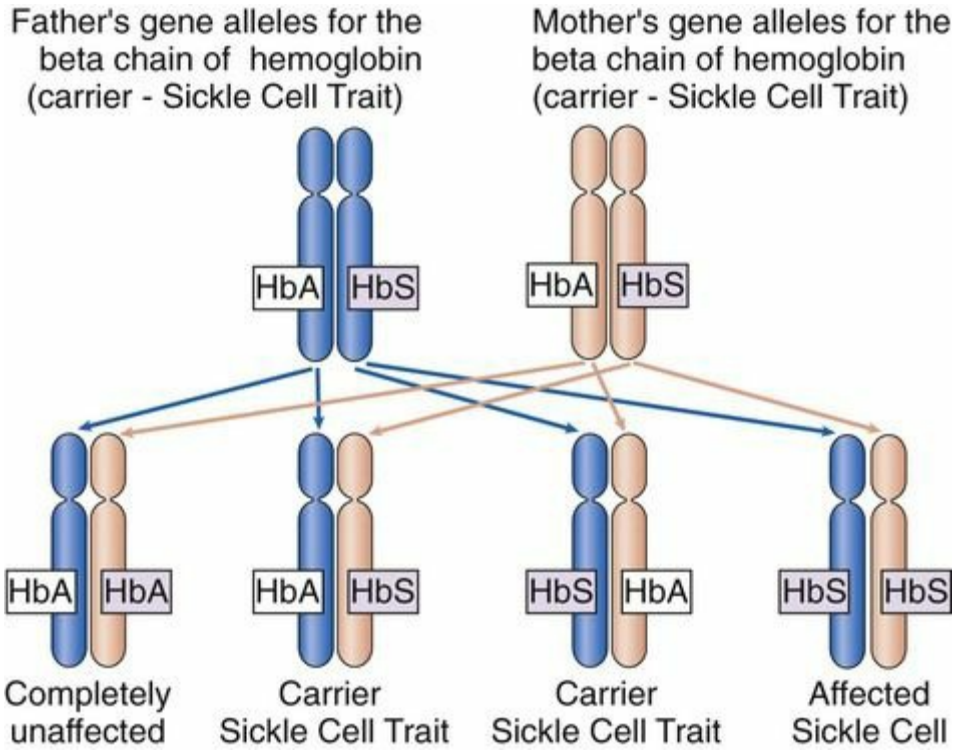

FIG. 40-2 Possible transmission of sickle cell disease and sickle cell trait when both parents are carriers. (*HbA*, Hemoglobin A; *HbS*, hemoglobin S.)

Incidence and Prevalence

Sickle cell trait and different forms of SCD occur in people of all races and ethnicities but is most common among African Americans in the United States. About 72,000 people have SCD, occurring in 1 in 500 African Americans. About 1 in 12 to 1 in 15 (8%) African Americans are carriers of one sickle cell gene allele and have AS (United States National Library of Medicine, 2014).

❖ Patient-Centered Collaborative Care

◆ Assessment

History.

An adult with sickle cell disease (SCD) usually has a long-standing diagnosis of the disorder. Those with sickle cell trait usually have no manifestations or abnormal laboratory findings other than the presence of hemoglobin S. This person may be unaware that he or she has a hematologic problem until an acute illness is present or when anesthesia

is administered.

Ask about previous crises, what led to the crises, severity, and usual management. Explore recent contact with ill people and activities to determine what caused the current crisis. Ask about manifestations of infection.

Review all activities and events during the past 24 hours, including food and fluid intake, exposure to temperature extremes, drugs taken, exercise, trauma, stress, recent airplane travel, and ingestion of alcohol or other recreational drugs. Ask about changes in sleep and rest patterns, ability to climb stairs, and any activity that induces shortness of breath. Determine the patient's perceived energy level using a scale ranging from 0 to 10 (0 = not tired with plenty of energy; 10 = total exhaustion) to assess the degree of fatigue.

Physical Assessment/Clinical Manifestations.

Pain is the most common manifestation of SCD crisis. Others vary with the site of tissue damage.

Cardiovascular changes, including the risk for high-output heart failure, occur because of the anemia. Assess the patient for shortness of breath and general fatigue or weakness. Other problems may include murmurs, the presence of an S_3 heart sound, and increased jugular-venous pulsation or distention. Assess the cardiovascular status by comparing peripheral pulses, temperature, and capillary refill in all extremities. Extremities distal to blood vessel occlusion are cool to the touch with slow capillary refill and may have reduced or absent pulses. Heart rate may be rapid and blood pressure may be low to average with anemia.

Priapism is a prolonged penile erection that can occur in men who have SCD. The cause is excessive vascular engorgement in erectile tissue. The condition is very painful and can last for hours. During the priapism episode, the patient usually cannot urinate.

Skin changes include pallor or cyanosis because of poor gas exchange from decreased perfusion and anemia. Examine the lips, tongue, nail beds, conjunctivae, palms, and soles of the feet at least every 8 hours for subtle color changes. With cyanosis, the lips and tongue are gray and the palms, soles, conjunctivae, and nail beds have a bluish tinge.

Another skin manifestation of SCD is jaundice. Jaundice results from RBC destruction and release of bilirubin. To assess for jaundice in patients with darker skin, inspect the roof of the mouth for a yellow appearance. Examine the sclera closest to the cornea to assess jaundice more accurately. Jaundice often causes intense itching.

Many adults with SCD have ulcers on the lower legs that are caused by

poor perfusion, especially on the outer sides and inner aspect of the ankle or the shin (Ladizinski et al., 2012). These lesions often become necrotic or infected, requiring débridement and antibiotic therapy. Inspect the legs and feet for ulcers or darkened areas that may indicate necrotic tissue.

Abdominal changes include damage to the spleen and liver, which often occurs early from many episodes of hypoxia and ischemia. In crisis, abdominal pain is diffuse and steady, involving the back and legs. The liver or spleen may feel firm and enlarged with a nodular or "lumpy" texture in later stages of the disease.

Kidney and urinary changes are common as a result of poor perfusion and decreased tissue gas exchange. Chronic kidney disease occurs as a result of anoxic damage to the kidney nephrons. Early damage makes the kidneys less effective at filtration and reabsorption. The urine contains protein, and the patient may not concentrate urine. Eventually, the kidneys fail, resulting in little or no urine output.

Musculoskeletal changes occur because arms and legs are often sites of blood vessel occlusion. Joints may be damaged from hypoxic episodes and have necrotic degeneration. Inspect the arms and legs, and record any areas of swelling, temperature, or color difference. Ask patients to move all joints. Record the range of motion and any pain with movement.

Central nervous system (CNS) changes may occur in SCD. During crises, patients may have a low-grade fever. If the CNS has infarcts or repeated episodes of hypoxia, patients may have seizures or manifestations of a stroke. Assess for the presence of "pronator drift," bilateral hand grasp strength, gait, and coordination. See Chapter 41 for details of neurologic assessment.

Psychosocial Assessment.

Often behavioral changes are early manifestations of cerebral hypoxia from poor perfusion. Observe the patient, and document behavior. Ask family members whether the current behavior and mental status are usual for the patient.

SCD is a painful, life-limiting disorder that can be passed on to one's children. Assess the patient's psychosocial needs in terms of new factors that might contribute to a crisis, established support systems, use of coping patterns, and disease progression.

Laboratory Assessment.

The diagnosis of SCD is based on the percentage of hemoglobin S (HbS) on electrophoresis. A person who has AS usually has less than 40% HbS,

and the patient with SCD may have 80% to 100% HbS. This percentage does not change during crises. Another indicator of SCD is the number of RBCs with permanent sickling. This value is less than 1% among people with no hemoglobin disease, is 5% to 50% among people with AS, and may be 90% among patients with SCD.

Other laboratory tests can indicate complications of the disease, especially during crises. The hematocrit of patients with SCD is low (between 20% and 30%) because of RBC shortened life span and RBC destruction. This value decreases even more during crises or during stress (aplastic crisis). The reticulocyte count is high, indicating anemia of long duration. The total bilirubin level may be high because damaged RBCs release iron and bilirubin.

The total white blood cell (WBC) count is usually high in patients with SCD. This elevation is related to chronic inflammation caused by tissue hypoxia and ischemia.

Imaging Assessment.

Bone changes occur as a result of chronically stimulated marrow and low bone oxygen levels. The skull may show changes on x-ray as a result of bone surface cell destruction and new growth, giving the skull a "crew cut" appearance on x-ray. X-rays of joints may show necrosis and destruction. Ultrasonography, CT, positron emission tomography (PET), and MRI may show soft-tissue and organ changes from poor perfusion and chronic inflammation.

Other Diagnostic Assessment.

Electrocardiographic (ECG) changes document cardiac infarcts and tissue damage. Specific ECG changes are related to the area of the heart damaged. Echocardiograms may show cardiomyopathy and decreased cardiac output (low ejection fraction).

NCLEX Examination Challenge

Safe and Effective Care Environment

Which new assessment finding in a client with sickle cell disease who currently is in crisis does the nurse report immediately to the health care provider?

A Pain in the right hip with limited range of motion
B Slow capillary refill in the toes of the right foot
C Yellow appearance of the roof of the mouth

D Facial drooping on the right side

Analysis

The priority NANDA-I nursing diagnoses and collaborative problems for patients with sickle cell disease include:
1. Acute Pain and Chronic Pain related to poor tissue oxygenation and joint destruction (NANDA-I)
2. Potential for infection, sepsis, multiple organ dysfunction, and death

Interventions

Managing Pain.

The pain with sickle cell crisis is the result of tissue injury caused by poor perfusion and tissue gas exchange from obstructed blood flow. Mild pain episodes can be managed at home. However, pain is often severe enough to require hospitalization and opioid analgesics. Acute pain episodes have a sudden onset, usually involving the chest, back, abdomen, and extremities. Complications of SCD can cause severe, chronic pain, requiring large doses of opioid analgesics.

Ask whether the pain is typical of past pain episodes. If not, other pain causes or disease complications must be explored. Ask the patient to rate pain on a scale ranging from 0 to 10, and evaluate the effectiveness of interventions based on the ratings.

Concerns about substance abuse can lead to inadequate pain treatment in these patients. Opioid addiction is rare, occurring in only 2% to 5% of patients with SCD. Pain management is based on past pain history, previous drug use, disease complications, and current pain assessment. Health care providers need to be aware of their own attitudes when caring for this population. If substance abuse occurs, management of addiction is incorporated into the overall treatment plan. Addicted patients in acute pain crisis still need opioids (Jenerette & Leak, 2012).

Drug therapy for patients in acute sickle cell crisis often starts with at least 48 hours of IV analgesics. (Chart 40-2 lists best practices for nursing care of the patient in sickle cell crisis.) Morphine and hydromorphone (Dilaudid) are given IV on a routine schedule or by infusion pump using patient-controlled analgesia (PCA) (Myers & Eckes, 2012). Once relief is obtained, the IV dose can be tapered and the drug given orally. Avoid "as needed" (PRN) schedules because they do not provide adequate relief. Moderate pain may be managed with oral doses of opioids or NSAIDs. (See Chapter 3 for more information on pain management.)

Chart 40-2 Best Practice for Patient Safety & Quality Care QSEN

Care of the Patient in Sickle Cell Crisis

- Administer oxygen.
- Administer prescribed pain medication.
- Hydrate the patient with normal saline IV and with beverages of choice (without caffeine) orally.
- Remove any constrictive clothing.
- Encourage the patient to keep extremities extended to promote venous return.
- Do not raise the knee position of the bed.
- Elevate the head of the bed no more than 30 degrees.
- Keep room temperature at or above 72° F (22.2° C).
- Avoid taking blood pressure with external cuff.
- Check circulation in extremities every hour:
  - Pulse oximetry of fingers and toes
  - Capillary refill
  - Peripheral pulses
  - Toe temperature

Hydroxyurea (Droxia) may reduce the number of sickling and pain episodes by stimulating fetal hemoglobin (HbF) production. Increasing the level of HbF reduces sickling of red blood cells in patients with sickle cell disease. However, this drug is associated with an increased incidence of leukemia. Long-term complications should be discussed with the patient before this therapy is started. Hydroxyurea also suppresses bone marrow function including immunity, and regular follow-up to monitor complete blood counts (CBCs) for drug toxicity is important.

Nursing Safety Priority QSEN

Action Alert

Hydroxyurea is **teratogenic** (can cause birth defects). Teach sexually active women of childbearing age using this drug to adhere to strict contraceptive measures while taking hydroxyurea and for 1 month after the drug is discontinued.

Hydration by the oral or IV route helps reduce the duration of pain episodes. Urge the patient to drink water or juices. Because the patient is

often dehydrated and his or her blood is hypertonic, hypotonic fluids are usually infused at 250 mL/hr for 4 hours. Once the patient's blood osmolarity is down to the normal range of 270 to 300 mOsm, the IV rate is reduced to 125 mL/hr if more hydration is needed.

Complementary therapies and other measures, such as keeping the room warm, using distraction and relaxation techniques, positioning with support for painful areas, aroma therapy, therapeutic touch, and warm soaks or compresses, all help reduce pain perception.

Clinical Judgment Challenge

Ethical/Legal

A 27-year-old African-American man in sickle cell crisis is a patient on your unit. During report, one of the nurses from the previous shift mentions that she withheld the IV opioid pain medication during the night because she had taken care of this patient a year ago and feels that he is a "drug seeker."

1. What is your first action?
2. How should you approach your colleague?
3. Can a patient with sickle cell disease become addicted to opioids?
4. What can you do to prevent an incident like this one from happening again?

Preventing Sepsis, Multiple Organ Dysfunction, and Death.

The patient with SCD is at greater risk for bacterial infection because of decreased spleen function resulting from anoxic damage. Interventions focus on preventing infection, controlling infection, and starting treatment early for specific infections. The patient with a fever should have diagnostic testing for sepsis including CBC with differential, blood cultures, reticulocyte count, urine culture, and a chest x-ray. Usually these patients are started on prophylactic antibiotics.

Prevention and early detection strategies are used to protect the patient in sickle cell crisis from infection. Frequent, thorough handwashing is of the utmost importance. Any person with an upper respiratory tract infection who enters the patient's room must wear a mask. Use strict aseptic technique for all invasive procedures.

Continually assess the patient for infection, and monitor the daily CBC with differential WBC count. Inspect the mouth every 8 hours for lesions indicating fungal or viral infection. Listen to the lungs every 8 hours for crackles, wheezes, or reduced breath sounds. Inspect voided urine for

odor and cloudiness, and ask about urgency, burning, or pain on urination. Take vital signs at least every 4 hours to assess for fever, or supervise this action when performed by others.

Drug therapy by prophylaxis with twice-daily oral penicillin reduces the number of pneumonia and other streptococcal infections. Urge the patient to receive yearly influenza vaccinations and to receive the pneumonia vaccine. Drug therapy for an actual infection depends on the sensitivity of the specific organism, as well as on the extent of the infection.

Continued blood vessel occlusion by clumping of sickled cells increases the risk for multiple organ dysfunction. Acute chest syndrome, in which a vaso-occlusive event (VOE) causes infiltration and damage to the pulmonary system, is a major cause of death in adults with SCD. Thus preventing heart and lung damage is a priority. Management focuses on prevention of VOEs and promotion of perfusion.

Assess the patient admitted in sickle cell crisis for adequate perfusion to all body areas. Remove restrictive clothing, and instruct the patient to avoid flexing the knees and hips.

Hydration is needed because dehydration increases cell sickling and must be avoided. Assist him or her in maintaining adequate hydration. The patient in acute crisis needs an oral or IV fluid intake of at least 200 mL/hr.

Oxygen is given during crises because lack of oxygen is the main cause of sickling. Ensure that oxygen therapy is nebulized to prevent dehydration. Monitor oxygen saturation. If saturation is low, evaluation of arterial blood gases (ABGs) and a chest x-ray may be needed.

Transfusion with RBCs can be helpful to increase HbA levels and dilute HbS levels, although they must be prescribed cautiously to prevent iron overload from repeated transfusions. Monitor the patient for transfusion complications (discussed on pp. 822-823 in the Acute Transfusion Reactions section).

In some treatment centers, hematopoietic stem cell transplantation (HSCT) is performed to correct abnormal hemoglobin permanently. Because HSCT is expensive and may result in life-threatening complications, its risks and benefits need to be considered for each patient.

Community-Based Care

Sickle cell disease (SCD) becomes worse over time, and a true remission is rare, although the number of crisis episodes may be reduced. Care focuses on teaching the patient and family how to prevent crises and

complications (Chart 40-3). The patient with SCD may receive care in acute care, subacute care, extended or assistive care, and home care settings.

Chart 40-3 Patient and Family Education: Preparing for Self-Management

Prevention of Sickle Cell Crisis

- Drink at least 3 to 4 liters of liquids every day.
- Avoid alcoholic beverages.
- Avoid smoking cigarettes or using tobacco in any form.
- Contact your health care provider at the first sign of illness or infection.
- Be sure to get a "flu shot" every year.
- Ask your health care provider about taking the pneumonia vaccine.
- Avoid temperature extremes of hot or cold.
- Be sure to wear socks and gloves when going outside on cold days.
- Avoid planes with unpressurized passenger cabins.
- Avoid travel to high altitudes (e.g., cities like Denver and Santa Fe).
- Ensure that any health care professional who takes care of you knows you have sickle cell disease, especially the anesthesia provider and radiologist.
- Consider genetic counseling.
- Avoid strenuous physical activities.
- Engage in mild, low-impact exercise at least 3 times a week when you are not in crisis.

Teach the patient to avoid specific activities that lead to hypoxia and hypoxemia. Stress the recognition of the early manifestations of crisis so that interventions can be started early to prevent pain, complications, and permanent tissue damage. Teach the patient and family about the correct use of opioid analgesics at home. Counsel patients about the hereditary aspects of SCD, and provide information about birth control methods and pregnancy options. Many patients and family members can be helped by local support groups. Provide information about the closest local chapter of the Sickle Cell Foundation. Often local children's hospitals have sickle cell support groups that include adults with the disease.

Gender Health Considerations

Patient-Centered Care QSEN

Pregnancy in women with SCD may be life threatening. Barrier methods of contraception (cervical cap, diaphragm, or condoms with or without spermicides) are often recommended for women with SCD. The use of hormone-based contraceptives is controversial, because these drugs may increase clot formation, especially among smokers, predisposing them to crises. Urge women using hormone-based contraceptives to not smoke.

Glucose-6-Phosphate Dehydrogenase Deficiency Anemia

Pathophysiology

More than 200 forms of **hemolytic** (blood cell–destroying) anemia are present from birth as a result of defects or deficiencies of one or more enzymes in red blood cells (RBCs). Most of these enzymes are needed to complete some critical step in RBC energy production. The most common type of inherited hemolytic anemia is the deficiency of the enzyme *glucose-6-phosphate dehydrogenase* (G6PD). This disease is inherited as an X-linked recessive disorder with more severe expression in males and mild partial expression in carrier females. It affects about 10% of all African Americans and also may occur in Sephardic Jews, Greeks, Iranians, Chinese, Filipinos, and Indonesians (McCance et al., 2014).

G6PD stimulates reactions in glucose metabolism important for energy in RBCs because they contain no other way to produce adenosine triphosphate (ATP). Cells with reduced amounts of G6PD break more easily during exposure to some drugs (e.g., sulfonamides, aspirin, quinine derivatives, chloramphenicol, dapsone, high doses of vitamin C, and thiazide diuretics) and exposure to benzene and other toxins.

New RBCs have some G6PD, but the enzyme diminishes as the cells age. The patient usually does not have manifestations until exposed to triggering agents or until a severe infection develops. After exposure to a precipitating cause, acute RBC breakage begins and lasts 7 to 12 days. During this acute phase, anemia and jaundice develop. The hemolytic reaction is limited because only older RBCs, containing less G6PD, are destroyed.

Patient-Centered Collaborative Care

Prevention is the most important therapeutic measure. Men who belong to the high-risk groups should be tested for this problem before being

given drugs that can cause the hemolytic reaction.

Hydration is important during an episode of hemolysis to prevent debris and hemoglobin from collecting in the kidney tubules, which can lead to acute kidney injury (AKI). Osmotic diuretics, such as mannitol (Osmitrol), may help prevent this complication. Transfusions are needed when anemia is present and kidney function is normal (see Transfusion Therapy section, p. 819).

Immunohemolytic Anemia

The most common types of hemolytic anemias in North America are the immunohemolytic anemias, also referred to as *autoimmune hemolytic anemias* (McCance et al., 2014). The pathophysiology is abnormal immunity that results in the excessive destruction of red blood cell membranes *(lysis)* followed by accelerated erythropoiesis. Acquired hemolytic syndromes result from increased RBC destruction occurring from trauma, viral infection, malaria, exposure to certain chemicals or drugs, and autoimmune reactions.

In immunohemolytic anemia, immune system products (e.g., antibodies) attack a person's own RBCs for unknown reasons. Regardless of the cause, RBCs are viewed as non-self by the immune system and then are attacked and destroyed.

The two types of immunohemolytic anemia are warm antibody anemia and cold antibody anemia. **Warm antibody anemia** occurs with immunoglobulin G (IgG) antibody excess. These antibodies are most active at 98.6° F (37° C) and may be triggered by drugs, chemicals, or other autoimmune problems. **Cold antibody anemia** has complement protein fixation on immunoglobulin M (IgM) and occurs most at 86° F (30° C). This problem often occurs with a Raynaud's-like response in which the arteries in the hands and feet constrict profoundly in response to cold temperatures or stress.

Management depends on disease severity. Steroid therapy to suppress immunity is temporarily effective in most patients. Splenectomy and more intense immunosuppressive therapy with chemotherapy drugs may be used if steroid therapy fails. Plasma exchange therapy with antibody removal is effective for patients who do not respond to chemotherapy drugs.

Anemias Resulting From Decreased Production of Red Blood Cells

Anemias caused by decreased RBC production occur in response to many

problems. Some are caused by failure of the bone marrow to produce healthy RBCs. Anemias also are caused by failure of the body to make or absorb a substance needed for RBC production. Many substances needed for RBC production are ingested as part of a healthy diet. For some patients with anemia resulting from a dietary deficiency, diet therapy is sufficient to manage anemia.

Considerations for Older Adults

Patient-Centered Care QSEN

Older patients often have restricted diets and may be unable to eat meat because of tooth loss or economic reasons and thus are at risk for iron deficiency anemia. Ask about a family history of anemia. B_{12} deficiency anemia often occurs in patients 50 to 80 years of age and may result from an inherited genetic mutation. Because manifestations are vague, the disorder can easily be overlooked (Orton, 2012).

Iron deficiency anemia is the most common anemia worldwide, especially among women, older adults, and people with poor diets. It can result from blood loss, poor GI absorption of iron, and an inadequate diet (McCance et al., 2014). The problem is a decreased iron supply for the developing RBC.

Adults usually have between 2 and 6 g of iron, depending on the size of the person and the amount of hemoglobin in the cells. With chronic iron deficiency, RBCs are small **(microcytic)** and the patient has mild symptoms of anemia, including weakness and pallor. Other manifestations include fatigue, reduced exercise tolerance, and fissures at the corners of the mouth. Serum ferritin values are less than 10 ng/mL (normal range is 12 to 300 ng/mL).

Any adult with iron deficiency should be evaluated for abnormal bleeding, especially from the GI tract. Management of iron deficiency anemia involves increasing the oral intake of iron from food sources (e.g., red meat, organ meat, egg yolks, kidney beans, leafy green vegetables, and raisins). If iron losses are mild, oral iron supplements, such as ferrous sulfate, are started until the hemoglobin level returns to normal. Instruct patients to take the iron supplement between meals for better absorption and to reduce GI distress. When iron deficiency anemia is severe, iron solutions (iron dextran [Dexferrum, INFeD, Pri-Dextra]; ferumoxytol [Feraheme]) can be given parenterally.

Vitamin B_{12} deficiency anemia results in failure to activate the enzyme

that moves folic acid into precursor RBC cells so that cell division and growth into functional RBCs can occur. These precursor cells then undergo improper DNA synthesis and increase in size. Only a few are released from the bone marrow. This type of anemia is called *megaloblastic* or **macrocytic anemia** because of the large size of these abnormal cells.

Causes of vitamin B_{12} deficiency include vegan diets or diets lacking dairy products, small bowel resection, chronic diarrhea, diverticula, tapeworm, or overgrowth of intestinal bacteria. Anemia resulting from failure to absorb vitamin B_{12} **(pernicious anemia)** is caused by a deficiency of **intrinsic factor** (a substance normally secreted by the gastric mucosa), which is needed for intestinal absorption of vitamin B_{12}.

Vitamin B_{12} deficiency anemia may be mild or severe, usually develops slowly, and manifestations include pallor and jaundice, **glossitis** (a smooth, beefy-red tongue) (Fig. 40-3), fatigue, and weight loss. Patients with pernicious anemia may also have **paresthesias** (abnormal sensations) in the feet and hands and poor balance (Simmons, 2012).

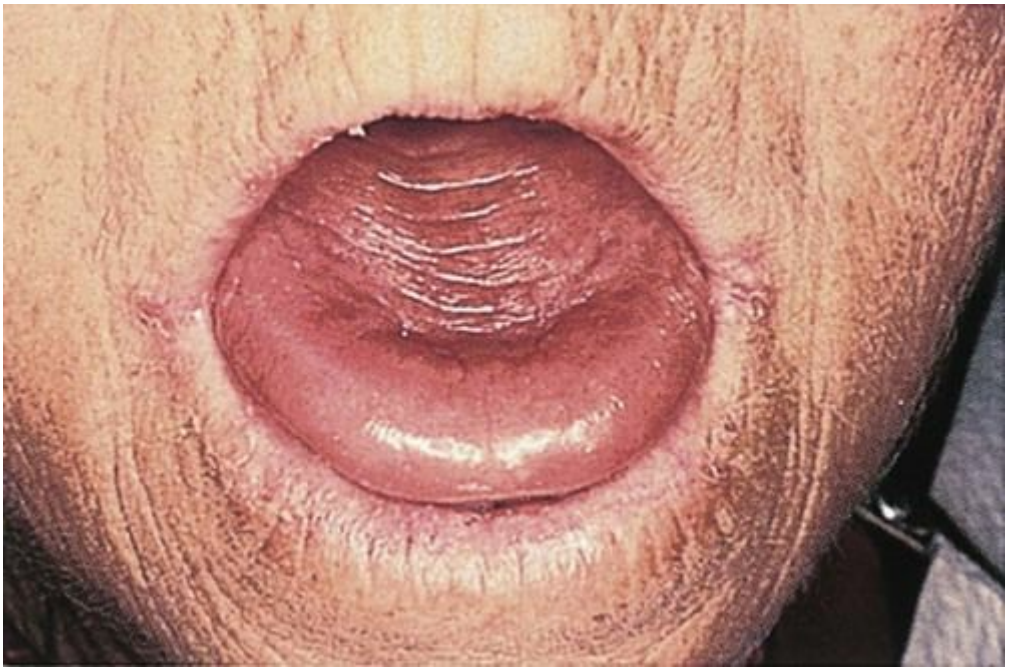

FIG. 40-3 Glossitis, a smooth tongue as a result of vitamin B_{12} deficiency anemia.

When anemia is caused by a dietary deficiency, the focus of management is to increase the intake of foods rich in vitamin B_{12} (animal proteins, fish, eggs, nuts, dairy products, dried beans, citrus fruit, and leafy green vegetables). Vitamin supplements may be prescribed when

anemia is severe. Patients who have pernicious anemia are given vitamin B_{12} injections weekly at first and then monthly for the rest of their lives. Oral B_{12} preparations and nasal spray or sublingual forms of cobalamin may be used to maintain vitamin levels after the patient's deficiency has first been corrected by the traditional injection method (Orton, 2012).

Folic acid deficiency can also cause anemia with manifestations similar to those of vitamin B_{12} deficiency. However, nervous system functions remain normal because folic acid deficiency does not affect nerve function. The disease develops slowly.

Common causes of folic acid deficiency are poor nutrition, malabsorption, and drugs. Poor nutrition, especially a diet lacking green leafy vegetables, liver, yeast, citrus fruits, dried beans, and nuts, is the most common cause. Malabsorption syndromes, such as Crohn's disease, are the second most common cause. Anticonvulsants and oral contraceptives can contribute to folic acid deficiency and anemia.

Prevention begins by identifying high-risk patients, such as older, debilitated patients with alcoholism; patients at risk for malnutrition; and those with increased folic acid requirements. A diet rich in foods containing folic acid and vitamin B_{12} prevents a deficiency. This type of anemia is managed with scheduled folic acid replacement therapy.

Aplastic anemia is a deficiency of circulating red blood cells (RBCs) because of failure of the bone marrow to produce these cells. It is caused by an injury to the immature precursor cell for red blood cells. Although aplastic anemia sometimes occurs alone, it usually occurs with **leukopenia** (a reduction in white blood cells [WBCs]) and **thrombocytopenia** (a reduction in platelets), a condition known as **pancytopenia.** Disease onset may be slow or rapid.

The most common type of the disease is caused by long-term exposure to toxic agents, drugs (see Table 39-3 in Chapter 39), ionizing radiation, or infection, but often the cause is unknown. The disease also may follow viral infection. The most common hereditary form of the disease is Fanconi's anemia.

The patient has manifestations of severe anemia. A complete blood count (CBC) shows severe macrocytic anemia, leukopenia, and thrombocytopenia. A bone marrow biopsy may show replacement of cell-forming marrow with fat. Infection is common.

Blood transfusions are used only when the anemia causes disability or when bleeding is life threatening because of low platelet counts. Unnecessary transfusion increases the chances for developing immune reactions to platelets and shortens the life span of the transfused cell.

This therapy is discontinued as soon as the bone marrow begins to produce RBCs.

Hematopoietic stem cell transplantation with donor cells is the most successful method of treatment for aplastic anemia that does not respond to other therapies. Cost, availability, and complications limit this treatment. For those patients who are unable to undergo such treatment or lack a suitable donor, immunosuppressive therapy remains the treatment of choice.

Immunosuppressive therapy helps patients who have the types of aplastic anemia with a disease course similar to that of autoimmune problems. Drugs such as prednisone, antithymocyte globulin (ATG), and cyclosporine A (Sandimmune) have resulted in partial or complete remissions. For moderate aplastic anemia, daclizumab (Zenapax) has improved both blood counts and transfusion requirements. Splenectomy may be needed for patients with an enlarged spleen that is either destroying normal RBCs or suppressing their development. (See discussion of surgical management for autoimmune thrombocytopenic purpura on p. 818.)

Disorders of Excess Red Blood Cells or Iron

Polycythemia Vera

Pathophysiology

In polycythemia, the number of red blood cells (RBCs) in the blood is *greater* than normal. The blood of a patient with polycythemia is **hyperviscous** (thicker than normal blood). The problem may be temporary (because of other conditions) or chronic.

Polycythemia vera (PV) is a disease with a sustained increase in blood hemoglobin levels to 18 g/dL, an RBC count of 6 million/mm^3, or a hematocrit of 55% or greater. PV is a cancer of the RBCs with three major hallmarks: massive production of RBCs, excessive leukocyte production, and excessive production of platelets. More than 90% of patients with PV show a mutation of the *JAK2* kinase gene in the affected cells (McCance et al., 2014). Extreme **hypercellularity** (cell excess) of the peripheral blood occurs in people with PV.

The patient's facial skin and mucous membranes have a dark, purple or cyanotic, flushed **(plethoric)** appearance with distended veins. Intense itching caused by dilated blood vessels, and poor perfusion is common. The thick blood moves more slowly and places increased demands on the heart, resulting in hypertension. In some areas, blood flow may be so

slow that stasis occurs. Vascular stasis causes **thrombosis** (clotting) within the smaller vessels, occluding them, which leads to tissue hypoxia, anoxia and, later, to infarction and necrosis. Tissues most at risk for this problem are the heart, spleen, and kidneys, although damage can occur in any organ or tissue.

Because the actual number of cells in the blood is greatly increased and the cells are not completely normal, cell life spans are shorter. The shorter life spans and increased cell production cause a rapid turnover of circulating blood cells. This rapid turnover increases the amount of cell debris (released when cells die) in the blood, adding to the general "sludging" of the blood. This debris includes uric acid and potassium, which cause the manifestations of gout and hyperkalemia (elevated serum potassium level).

Even though the number of RBCs is greatly increased, their oxygen-carrying capacity is impaired, and patients have poor gas exchange with severe hypoxia. Bleeding problems are common because of platelet impairment.

Patient-Centered Collaborative Care

Polycythemia vera is a malignant disease that progresses in severity over time. If left untreated, few people with PV live longer than 2 years after diagnosis. With management by repeated phlebotomy with apheresis (2 to 5 times per week), the patient may live 10 to 15 years or longer. (**Apheresis** is the withdrawal of whole blood and removal of some of the patient's blood component, in this case RBCs. The plasma is then reinfused back into the patient.) Increasing hydration and promoting venous return help prevent clot formation. Therapy for PV also includes the use of anticoagulants. Chart 40-4 lists health tips for patients with PV.

Chart 40-4 Patient and Family Education: Preparing for Self-Management

Polycythemia Vera

- Drink at least 3 liters of liquids each day.
- Avoid tight or constrictive clothing, especially garters and girdles.
- Wear gloves when outdoors in temperatures lower than 50° F (10° C).
- Keep all health care–related appointments.
- Contact your health care provider at the first sign of infection.
- Take anticoagulants as prescribed.
- Wear support hose or stockings while you are awake and up.

- Elevate your feet whenever you are seated.
- Exercise slowly and only on the advice of your physician.
- Stop activity at the first sign of chest pain.
- Use an electric shaver.
- Use a soft-bristled toothbrush to brush your teeth.
- Do not floss between your teeth.

Aggressive IV chemotherapy is no longer recommended because of its increased risk for inducing leukemia. Aspirin therapy may be used to decrease clot formation but increases the risk for GI bleeding. Hydroxyurea, an oral chemotherapy drug, may be prescribed for severe manifestations of the disease. Interferon-alfa therapy has also shown some benefit in controlling RBC production.

NCLEX Examination Challenge

Health Promotion and Maintenance

Which intervention is most important for the nurse to teach the client with polycythemia vera to prevent injury as a result of the increased bleeding tendency?

A Use a soft-bristled toothbrush.
B Drink at least 3 liters of liquids per day.
C Wear gloves and socks outdoors in cool weather.
D Exercise slowly and only on the advice of the physician.

Hereditary Hemochromatosis

Hereditary hemochromatosis is an autosomal recessive disorder in which a mutation in both alleles of the *HFE* gene cause increased intestinal absorption of dietary iron (Beery & Workman, 2012). The excess iron is deposited in a variety of tissues and organs, including the liver, spleen, heart, joints, skin, and pancreas. The iron deposits can damage the organs, leading to organ failure. Usually the disease is more common in men and manifestations appear in men during their 40s. Women have manifestations later because the loss of menstrual blood before menopause helps remove excess iron. The most common clinical manifestations are abdominal pain, liver enlargement, hyperglycemia, and a gradual darkening of the skin. Later problems include diabetes, liver cirrhosis, endocrine gland failure, heart disease, and death.

The disorder is usually diagnosed on the basis of clinical manifestations and altered iron levels. Genetic testing is available to

determine carrier status. When the disorder is identified early before organ damage, management is simple and can prevent severe organ damage and early death. Phlebotomy and removal of 500 mL of blood at a time, occurring as often as twice weekly at first, is performed to reduce the overall iron load of the blood. The desired outcome is to reduce blood ferritin levels to less than 9 to 50 micrograms per liter. Once this level has been achieved, phlebotomy frequency can be reduced to once every 2 to 4 months for maintenance.

Myelodysplastic Syndromes

Pathophysiology

Myelodysplastic syndromes (MDS) are a group of disorders caused by the formation of abnormal cells in the bone marrow. These abnormal cells are usually destroyed shortly after they are released into the blood. As a result, patients with MDS have a decrease in all blood cell types. Anemia is the most common problem with MDS, although **neutropenia** (low white blood cell count [WBC]) and **thrombocytopenia** (low platelets) are also often present.

MDS most often occurs in people ages 60 years or older. MDS has cancer-like features and is considered to be a *precancerous* state. Like cancer, it arises from a single population of abnormal cells. About 30% of all patients with MDS do eventually develop acute leukemia (McCance et al., 2014). There are a number of subtypes of MDS with different prognoses and responses to therapy. Patients are categorized into risk groups (i.e., low, intermediate [1 and 2], high) based on the severity of **pancytopenia** (low counts of all blood cell types), cytogenetic abnormalities, and numbers of blast cells (immature WBC cells) found in the bone marrow (Kurtin, 2012).

The exact cause of MDS is not clear. Risk factors include normal physiologic changes associated with aging, chemical exposures (pesticides, benzene), tobacco smoke, and exposure to radiation or chemotherapy drugs. Diagnosis is made by examination of the chromosomes and the genes within the chromosomes (cytogenetic testing) of the bone marrow cells. Peripheral blood smears are used to assess the level of cell maturation and the proportion of abnormal cells.

Patient-Centered Collaborative Care

The only potentially curative treatment for MDS is an allogeneic hematopoietic stem cell transplantation, which is often not an option

because of the advanced age of many patients (Kurtin, 2012). Several alternate management strategies have demonstrated some promise. For low-risk and intermediate-1–risk MDS, the antitumor immunomodulatory agent *lenalidomide* (Revlimid) is approved for patients whose dysplastic cells have the chromosome abnormality of a deleted *5q*. Two other agents approved for intermediate-2–risk and high-risk MDS are azacitidine (Vidaza) and decitabine (Dacogen) (Kurtin, 2012). These drugs often require at least 3 to 6 months to achieve a clinical response; therefore supportive care is necessary.

Supportive care includes blood transfusions for anemia and platelet transfusions when platelet levels are very low. Erythropoiesis-stimulating agents (ESAs), such as epoetin alfa (Epogen, Procrit) or darbepoetin alfa (Aranesp), may be given in addition to transfusions.

White Blood Cell Disorders

As discussed in Chapter 17, white blood cells (WBCs), or **leukocytes,** provide protection from infection and cancer development. This protection depends on maintaining normal numbers and ratios of the different mature circulating WBCs. When any one type of WBC is present in either abnormal amounts (too high or too low), immunity, gas exchange, and clotting are altered to some degree, placing patients at risk for many complications. This section covers the changes and nursing care for patients with disorders involving overgrowth of specific types of WBCs. (See Chapter 19 for the problems and care needs for patients with immune deficiency.)

Leukemia

Pathophysiology

Leukemia is cancer with uncontrolled production of immature WBCs ("blast" cells) in the bone marrow. As a result, the bone marrow becomes overcrowded with immature, nonfunctional cells and production of normal blood cells is greatly decreased. Leukemia may be **acute**, with a sudden onset, or **chronic**, with a slow onset and manifestations that persist for years.

Leukemias are classified by cell type. Leukemic cells coming from the lymphoid pathways (see Fig. 17-3 in Chapter 17) are typed as **lymphocytic** or **lymphoblastic.** Leukemic cells coming from the myeloid pathways are typed as **myelocytic** or **myelogenous.** Several subtypes exist for each of these diseases, which are classified according to the degree of maturity of the abnormal cell and the specific cell type involved. These are identified as M0 through M8. M3 is a subtype (referred to as *acute promyelocytic leukemia* [APL]) that has a specific treatment different from other AMLs. It is identified by a translocation of chromosomes 15 and 17. *Biphenotypic leukemia* is acute leukemia that shows both lymphocytic and myelocytic features.

With leukemia, cancer most often occurs in the stem cells or early precursor leukocyte cells, causing excessive growth of a specific type of immature leukocyte. In some chronic leukemias, the cancerous cells may be more mature. These cells are abnormal, and their excessive production in the bone marrow stops normal bone marrow production, leading to anemia, thrombocytopenia, and leukopenia. Often the number of immature, abnormal WBCs ("blasts") in the blood is greatly elevated, and these cells cannot provide infection protection. Leukemic cells can

also be found in the spleen, liver, lymph nodes, and central nervous system. Without treatment, the patient will die of infection or hemorrhage. For patients with acute leukemia, these changes occur rapidly and, without intervention, progress to death. Chronic leukemia may be present for years before changes appear.

Etiology and Genetic Risk

The exact cause of leukemia is unknown, although many genetic and environmental factors are involved in its development. The basic problem involves damage to genes controlling cell growth. This damage then changes cells from a normal to a **malignant** (cancer) state. Analysis of the bone marrow of a patient with acute leukemia shows abnormal chromosomes about 50% of the time (McCance et al., 2014). Possible risk factors for the development of leukemia include ionizing radiation, viral infection, exposure to chemicals and drugs, disorders such as myelodysplastic syndrome or Fanconi's anemia, genetic factors, immunologic factors, environmental factors, and the interaction of these factors.

Ionizing radiation exposures such as radiation therapy for cancer treatment or heavy accidental exposures increase the risk for leukemia development, particularly acute myelogenous leukemia (AML). Chemicals and drugs have been linked to leukemia development because of their ability to damage DNA. Previous treatment for cancer with some chemotherapy drugs (e.g., melphalan, doxorubicin, etoposide, and cyclophosphamide) poses risks for leukemia development about 5 to 8 years after treatment. Table 39-3 in Chapter 39 lists chemicals and drugs that damage the hematologic system.

Genetic and immunity factors influence leukemia development. There is an increased incidence of the disease among patients with genetic conditions such as Down syndrome, Bloom syndrome, Klinefelter syndrome, and Fanconi's anemia. Immune deficiencies may promote the development of leukemia. Chronic lymphocytic leukemia appears to have a familial or genetic predisposition.

Incidence and Prevalence

Leukemia accounts for 2% of all new cases of cancer and 4% of all deaths from cancer (American Cancer Society [ACS], 2014). The incidence depends on many factors, including the type of WBC affected, age, gender, race, and geographic locale.

In the United States, about 49,000 new cases of leukemia occur each year (ACS, 2014). Leukemia is classified into four different types based

on the cell type affected and how fast the disease progresses (Table 40-2).

TABLE 40-2

Classification of Leukemia Types

LEUKEMIA TYPE	FEATURES
Acute myelogenous leukemia (AML)	Most common in adults Has 8 subtypes
Acute promyelocytic leukemia (APL)	Subtype of AML Most curable of adult leukemias
Acute lymphocytic leukemia (ALL)	Forms about 10% of adult-onset leukemias Often is Philadelphia chromosome–positive
Chronic myelogenous leukemia (CML)	Forms about 20% of adult-onset leukemias Occurs most often after age 50 years Usually is Philadelphia chromosome–positive Has three phases: • *Chronic*—slow growing with mild manifestations that respond to therapy • *Accelerated*—more rapid growing with more severe manifestations, increased blast cells, and failure to respond to therapy • *Blast*—very aggressive leukemia with high percentage of blast and promyelocytes that spread to other organs
Chronic lymphocytic leukemia (CLL)	Most common chronic leukemia in adults; occurs most often after age 50 years Is associated with a genetic predisposition Survival time can extend to 10 years or more in patients diagnosed with early-stage disease

Patient-Centered Collaborative Care

Assessment

History.

Ask the patient about exposure to risk factors and related genetic factors. Age is important because the risk for adult-onset leukemia increases with age. Occupation and hobbies may reveal exposure to agents that increase the risk for leukemia. Previous illnesses and the medical history may reveal exposure to ionizing radiation or drugs that increase risk.

Changes in immunity increase the risk for infection in the patient with leukemia. Even when the blood count shows a normal or high level of WBCs, these cells are immature and cannot protect the patient from infection. Ask about the frequency and severity of infections, such as colds, influenza, pneumonia, bronchitis, or unexplained fevers, during the past 6 months.

Platelet function is reduced with leukemia, interfering with clotting. Ask about any excessive bleeding episodes, such as:

- A tendency to bruise easily or longer after minor trauma
- Nosebleeds
- Increased menstrual flow
- Bleeding from the gums
- Rectal bleeding
- Hematuria (blood in the urine)

If the patient has experienced such an episode, ask whether this type and extent of bleeding is his or her usual response to injury or represents a change.

The patient with leukemia often has weakness and fatigue from anemia and from the increased metabolism of the leukemic cells. Ask whether any of these problems have occurred:

- Headaches
- Behavior changes
- Increased somnolence; decreased alertness; fatigue
- Decreased attention span
- Muscle weakness
- Loss of appetite
- Weight loss

A 24-hour activity history may reveal activity intolerance, changes in behavior, and unexplained fatigue. Determine how long the patient has had any of these debilitating problems.

Physical Assessment/Clinical Manifestations.

Leukemia affects all blood cells, and blood influences the health and function of all organs and systems. Thus many body areas and systems may be affected (Chart 40-5). The following manifestations occur with acute leukemia and chronic leukemia in the blast phase.

Chart 40-5 Key Features

Acute Leukemia

Integumentary Manifestations
• Ecchymoses • Petechiae • Open infected lesions • Pallor of the conjunctivae, nail beds, palmar creases, and around the mouth
Gastrointestinal Manifestations
• Bleeding gums • Anorexia • Weight loss • Enlarged liver and spleen
Renal Manifestations
• Hematuria
Musculoskeletal Manifestations
• Bone pain • Joint swelling and pain
Cardiovascular Manifestations
• Tachycardia at basal activity levels • Orthostatic hypotension • Palpitations
Respiratory Manifestations
• Dyspnea on exertion
Neurologic Manifestations
• Fatigue • Headache • Fever

Cardiovascular changes often are related to adjustments needed when perfusion and gas exchange are reduced from anemia. The heart rate is increased, and blood pressure is decreased. **Murmurs** (abnormal blood flow sounds in the heart) and **bruits** (abnormal blood flow sounds over arteries) may be heard. Capillary refill is slow. When the WBC count is greatly elevated and blood is highly viscous, blood pressure is elevated with a bounding pulse.

Respiratory changes are related to reduced gas exchange from anemia and to infection. Respiratory rate increases as anemia becomes more severe. If a respiratory infection is present, the patient may have coughing and dyspnea. Abnormal breath sounds are heard on auscultation.

Skin changes include pallor and coolness to the touch as a result of reduced perfusion from anemia. Pallor is most evident on the face, around the mouth, and in the nail beds. The conjunctiva of the eye also is pale, as are the creases on the palm of the hand. Petechiae may be present on any area of skin surface, especially the legs and feet. The petechiae may be unrelated to any obvious trauma. Inspect for skin infections or injured areas that have failed to heal. Inspect the mouth for gum bleeding and any sore or lesion that may indicate infection.

Intestinal changes may be related to an increased bleeding tendency

and to fatigue. Weight loss, nausea, and anorexia are common. Examine the rectal area for fissures, and test stool for occult blood. Many patients with leukemia have reduced bowel sounds and are constipated because reduced blood flow to intestinal tissue leads to decreased peristalsis. Enlargement of the liver and spleen and abdominal tenderness also may be present from leukemic cells trapped in these organs.

Central nervous system (CNS) changes include cranial nerve problems, headache, and papilledema from leukemic invasion of the CNS. Seizures and coma also may occur.

Miscellaneous changes can include bone and joint tenderness as the marrow is damaged and the bone reabsorbs. Leukemic cells invade lymph nodes, causing enlargement.

Psychosocial Assessment.

The patient with newly diagnosed leukemia is very anxious and fearful of the disease outcome. Spend time with the patient and family to assess what the diagnosis means to them and what they expect in the future (Albrecht, 2014).

A diagnosis of leukemia has serious consequences for a person's lifestyle. Hospitalization for initial treatment often lasts weeks and may result in boredom, loneliness, isolation, and financial stress. Assess coping patterns, including activities that the patient finds enjoyable and methods that help him or her relax. After initial therapy, the patient may resume work, depending on the occupation. Often the patient must make adjustments for changes in functional status. He or she usually is hospitalized repeatedly for complications.

Laboratory Assessment.

The patient with acute leukemia usually has decreased hemoglobin and hematocrit levels, a low platelet count, and an abnormal white blood cell (WBC) count. The WBC count may be low, normal, or elevated. The patient with a high WBC count consisting of mostly blast cells at diagnosis has a poorer prognosis.

The definitive test for leukemia is an examination of cells obtained from bone marrow aspiration and biopsy (Fig. 40-4). The bone marrow is full of leukemic **blast phase cells** (immature cells that are dividing). The proteins **(antigens)** on the surfaces of the leukemic cells are "markers" that help diagnose the type of leukemia and may indicate prognosis. These include the T11 protein, terminal deoxynucleotidyl transferase (TDT), the common acute lymphoblastic leukemia antigen (CALLA), and the CD33 antigen.

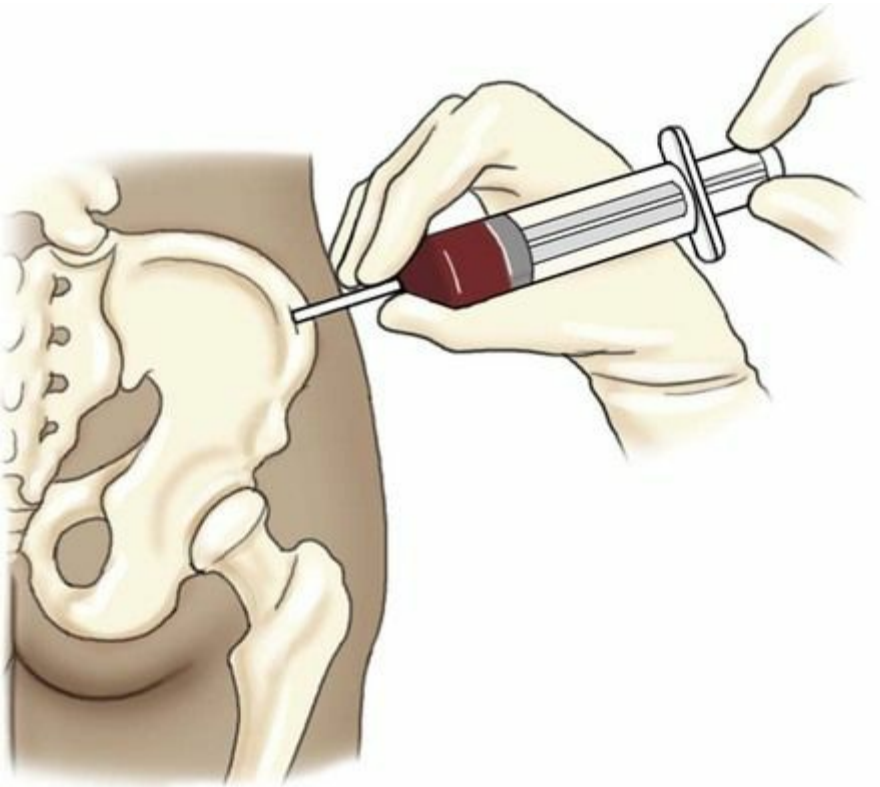

FIG. 40-4 Bone marrow aspiration from the posterior iliac crest. (*GVHD*, Graft-versus-host disease.)

Blood clotting times and factors are usually abnormal with acute leukemia. Reduced levels of fibrinogen and other clotting factors are common. Whole-blood clotting time (Lee-White clotting test) is prolonged, as is the activated partial thromboplastin time (aPTT).

Chromosome analysis (cytogenetic studies) of the leukemic cells may identify marker chromosomes to help diagnose the type of leukemia, predict the prognosis, and determine therapy effectiveness. An example is the Philadelphia chromosome, which is important in the diagnosis and treatment of some chronic myelogenous leukemia (CML) and adult acute lymphocytic leukemia (ALL). The Philadelphia chromosome is an abnormal chromosome caused by a translocation of the *ABL* gene from chromosome 9 onto the *BCR* gene of chromosome 22. The new protein produced by this mutation inhibits cell apoptosis and DNA repair, leading to further genetic abnormality (Simoneau, 2013).

Imaging Assessment.

Specific manifestations determine the need for specific tests. In a patient with dyspnea, a chest x-ray is needed to determine whether leukemic infiltrates are present in the lung. Skeletal x-rays may help determine whether loss of bone minerals and bone density is present.

NCLEX Examination Challenge

Physiological Integrity

The blood of a client who has chronic myelogenous leukemia shows a high percentage of blast cells and promyelocytes. What is the nurse's correct interpretation of this test result?
A The client's risk for infection is decreasing.
B The disease has become more aggressive.
C The drug therapy for the disease is effective.
D The type of leukemia is now lymphocytic rather than myelogenous.

Analysis

The priority NANDA-I nursing diagnoses and collaborative problems for patients with acute myelogenous leukemia (AML), the most common type of acute leukemia seen in adults, include:
1. Risk for Infection related to decreased immune response and chemotherapy (NANDA-I)
2. Risk for Injury related to thrombocytopenia and chemotherapy (NANDA-I)
3. Fatigue related to decreased tissue oxygenation and increased energy demands (NANDA-I)

Planning and Implementation

Preventing Infection

Planning: Expected Outcomes.

The patient with leukemia is expected to remain free from infection. Indicators include:
- Absence of fever and foul-smelling or purulent drainage
- Absence of cough, chest pain, and dyspnea
- Absence of urinary frequency, urgency, or pain and burning
- Intact skin and mucous membranes

Interventions.

Infection is a major cause of death in the patient with leukemia because the white blood cells are immature and cannot function or the cells are depleted from chemotherapy, and sepsis is a common complication. Infection occurs through both **auto-contamination** (normal flora overgrows and penetrates the internal environment) and **cross-**

contamination (organisms from another person or the environment are transmitted to the patient). The most common sources of infection are the skin, respiratory tract, and intestinal tract.

Gram-negative bacteria are the most common cause of infection, although infections from other causes do occur. Interventions aim to halt infection and control infections early. Chart 40-6 lists areas to assess for the patient at risk for infection.

Chart 40-6 Focused Assessment

Patients at Risk for Infection

General Condition

- Age
- History of allergies
- History of chemotherapy, radiation therapy, or other immunosuppressive therapies, such as steroid use
- Chronic diseases
- History of febrile neutropenia and associated symptoms
- Nutrition status
- Functional status—problems with immobility
- Tobacco use—cigarettes, pipe, cigars, oral
- Recreational drug use
- Alcohol use
- Prescribed and over-the-counter drug use
- Baseline and ongoing vital signs—blood pressure, heart rate, respiratory rate, and temperature

Skin and Mucous Membranes

- Thorough inspection of all skin surfaces with attention to axillae, anorectal area, and under breasts; inspection of skin for color, vascularity, bleeding, lesions, edema, moist areas, excoriation, irritation, erythema; general condition of hair and nails, pressure areas, swelling, pain, tenderness, biopsy or surgical sites, wounds, enlarged lymph nodes, catheters, or other devices
- Inspection of oral cavity, including lips, tongue, mucous membranes, gingiva, teeth, and throat—color, moisture, bleeding, ulcerations, lesions, exudate, mucositis, stomatitis, plaque, swelling, pain, tenderness, taste changes, amount and character of saliva, ability to swallow, changes in voice, dental caries, patient's oral hygiene routine
- History of current skin or mucous membrane problems

Head, Eyes, Ears, Nose

- Pain, tenderness, exudate, crusting, enlarged lymph nodes

Cardiopulmonary

- Respiratory rate and pattern, breath sounds (presence/absence, adventitious sounds), quantity and characteristics of sputum, shortness of breath, use of accessory muscles, dysphagia, diminished gag reflex, tachycardia, blood pressure

Gastrointestinal

- Pain, diarrhea, bowel sounds, character and frequency of bowel movements, constipation, rectal bleeding, hemorrhoids, change in bowel habits, sexual practices, erythema, ulceration

Genitourinary

- Dysuria, frequency, urgency, hematuria, pruritus, pain, vaginal or penile discharge, vaginal bleeding, burning, lesions, ulcerations, characteristics of urine

Central Nervous System

- Cognition, level of consciousness, personality, behavior

Musculoskeletal

- Tenderness, pain, loss of function

Drug Therapy for Acute Leukemia.

Drug therapy for patients with AML is divided into three distinctive phases: induction, consolidation, and maintenance.

Induction therapy is intense and consists of combination chemotherapy started at the time of diagnosis. The purpose of this therapy is to achieve a rapid, complete remission of all manifestations of disease. A combination of chemotherapeutic agents is usually prescribed. However, agencies and physicians differ in drugs used and the treatment schedule. One example of aggressive induction therapy is continuous IV cytosine arabinoside for 7 days together with an anthracycline for the first 3 days, sometimes referred to as a "7 plus 3" regimen. This therapy results in severe bone marrow suppression with neutropenia, making the patient even more at risk for infection. For acute promyelocytic leukemia, the agent *tretinoin* (Vesanoid) is added to the chemotherapy regimen.

Prolonged hospitalizations are common while the patient is neutropenic. Recovery of bone marrow function requires at least 2 to 3

weeks, during which the patient must be protected from life-threatening infections. Other side effects of drugs used for induction therapy include nausea, vomiting, diarrhea, **alopecia** (hair loss), **stomatitis** (mouth sores), kidney toxicity, liver toxicity, and cardiac toxicity. (See Chapter 22 for information on effects of anticancer agents.) Older patients have a greater infection-related death rate during this phase than do younger patients. Patients with APL are at greater risk for sepsis with disseminated intravascular coagulation (DIC) during induction therapy than are patients with other subtypes of AML.

Consolidation therapy consists of another course of either the same drugs used for induction at a different dosage or a different combination of chemotherapy drugs. This treatment occurs early in remission, and its intent is to cure. Consolidation therapy may be either a single course of chemotherapy or repeated courses. Hematopoietic stem cell transplantation also may be considered, depending on the disease subtype and the patient's response to induction therapy.

Maintenance therapy may be prescribed for months to years after successful induction and consolidation therapies for acute lymphocytic leukemia (ALL) and acute promyelocytic leukemia (APL). The purpose is to maintain the remission achieved through induction and consolidation. Not all types of leukemia respond to maintenance therapy.

Drug Therapy for Chronic Leukemia.

Imatinib mesylate (Gleevec) is a common first-line drug therapy for CML that is Philadelphia chromosome–positive. This oral drug is well tolerated and has been effective at inducing remission for early stages of CML. Other drugs approved for first-line therapy or for patients whose disease is resistant or intolerant to imatinib are dasatinib (Sprycel) or nilotinib (Tasigna) (Byar & Workman, 2012). Other drugs used to treat CML include interferon-alfa, which reduces the growth of leukemic cells, but its use is limited because of side effects, such as flu-like manifestations and fevers. Patient responses to therapy are evaluated on the basis of hematologic, cytogenetic, and molecular criteria.

Chronic lymphocytic leukemia (CLL) is the most prevalent form of leukemia in adults, affecting women more often than men. Cytogenetic testing is important in the prognosis. Partial deletion of chromosome 13 is associated with a benign disease course, whereas a deletion of chromosome 11 or of chromosome 17 (*p53* mutation) is associated with a poor prognosis. Treatment of CLL with standard chemotherapy can cause remissions but does not cure the disease. The decision to initiate therapy is based on disease stage, manifestations, and disease activity. Rituximab

(Rituxan) is often combined with standard chemotherapy drugs or used as a single agent. Another drug approved for CLL is bendamustine (Treanda), which may be used alone or along with rituximab. Other monoclonal antibodies approved for CLL are ofatumumab (Arzerra) and alemtuzumab (Campath). Current investigational therapies for CLL include ibrutinib, oblimersen (Genasense), flavopiridol (Alvocidib), and lenalidomide (Revlimid).

Hematopoietic stem cell transplantation in patients with CLL is an option that offers curative potential or prolonged disease-free survival. However, it comes with considerable risk for mortality and is not an appropriate alternative for all patients.

Drug Therapy for Infection.

Drug therapy is the main defense against infections that develop in patients undergoing therapy for AML. Drugs used depend on the sensitivity of the organism causing the infection, as well as infection severity. Drugs for infection include antibacterial, antiviral, and antifungal agents.

Infection Protection.

A major focus in caring for the patient with leukemia is protection from infection. All personnel must use extreme care during all nursing procedures. Frequent, thorough handwashing is of the utmost importance. Anyone with an upper respiratory tract infection who enters the patient's room must wear a mask. Observe strict asepsis when changing dressings or accessing a central venous catheter. Maintain strict aseptic technique in the care of these catheters at all times.

If possible, ensure that the patient is in a private room to reduce cross-contamination. Other precautions are used, such as not allowing standing water in vases, denture cups, or humidifiers in the patient's room, because they are breeding grounds for organisms.

Some facilities place the immunosuppressed patient in a room with a high-efficiency particulate air (HEPA) filtration or laminar airflow system. These systems decrease the number of airborne pathogens. It is not known whether these systems benefit patients.

Continually assess the patient for the presence of infection. This task is difficult because manifestations are not obvious in the patient with leukopenia. The patient with leukopenia may have a severe infection without pus and with only a low-grade fever.

Monitor the patient's daily CBC with differential WBC count and absolute neutrophil count (ANC). Inspect the mouth during every shift for lesions and mucosa breakdown. Assess the lungs every 8 hours for

crackles, wheezes, and reduced breath sounds. Assess urine for odor and cloudiness. Ask about any urgency, burning, or pain on urination. Take vital signs at least every 4 hours to assess for fever.

Nursing Safety Priority QSEN

Critical Rescue

A temperature elevation of even 1° F (or 0.5° C) above baseline is significant for a patient with leukopenia and indicates infection until it has been proven otherwise. Report this finding to the health care provider at once.

Many hospital units that specialize in the care of patients with neutropenia have specific protocols for antibiotic therapy if infection is suspected. Usually the health care provider is notified immediately and specific specimens are obtained for culture. Obtain blood for bacterial and fungal cultures from peripheral IV sites and from the central venous catheter (Myers & Reyes, 2011). Obtain urine specimens, sputum specimens, and specimens from open lesions for culture. Chest x-rays are taken. After the specimens are obtained, the patient begins IV antibiotics.

Skin care is important for preventing infection in the patient with leukemia because the skin may be the only intact defense. Teach him or her about hygiene, and urge daily bathing. If the patient is immobile, turn him or her every hour and apply skin lubricants.

Perform pulmonary hygiene every 2 to 4 hours. Listen to the lungs for crackles, wheezes, and reduced breath sounds. Urge the patient to cough and deep breathe or to perform sustained maximal inhalations every hour while awake.

Hematopoietic Stem Cell Transplantation.

Hematopoietic stem cell transplantation (HSCT), sometimes called *bone marrow transplantation (BMT),* is standard treatment for the patient with leukemia who has a closely matched donor and who is in temporary remission after induction therapy. It is used also for lymphoma, multiple myeloma, aplastic anemia, sickle cell disease, and many solid tumors.

The bone marrow is the actual site of production of leukemic cells. It can be difficult to ensure that all leukemic cells have been eradicated during induction therapy. Therefore before an HSCT, additional chemotherapy with or without total body irradiation is given to purge

(condition or clean) the marrow of leukemic cells. *These treatments are lethal to the bone marrow, and without replacement of stem cells by transplantation, the patient would die of infection or hemorrhage.*

After conditioning, new healthy stem cells are given to the patient. The new cells go to the marrow and then begin the process of hematopoiesis, which results in normal, properly functioning blood cells and, ideally, a permanent cure.

Many hospitals have transplant units. With long-term survival increasing after HSCT, nurses can expect to be caring for these people—if not during the actual transplantation or recovery period, then after the recovery period—in a variety of health care settings.

HSCT started with the use of **allogeneic bone marrow transplantation** (transplantation of bone marrow from a sibling or matched unrelated donor) and has advanced to the use of human leukocyte antigen (HLA)–matched stem cells from the umbilical cords of unrelated donors. Transplants are classified by the source of stem cells (Table 40-3). Stem cells for transplantation may be obtained by bone marrow harvest, peripheral stem cell apheresis, or umbilical cord blood stem cell banking. Transplantation has five phases: stem cell obtainment, conditioning regimen, transplantation, engraftment, and post-transplantation recovery.

TABLE 40-3

Classification of Transplants

TYPE OF TRANSPLANT	SOURCES OF STEM CELLS
Autologous	
Self-donation	Bone marrow harvest
	Peripheral stem cell pheresis
	Umbilical cord blood
Syngeneic	
Patient's HLA identical twin	Bone marrow harvest
	Peripheral stem cell pheresis
Allogeneic	
HLA-matched relative	Bone marrow harvest
Unrelated HLA-matched donor	Peripheral stem cell pheresis
Mismatched or partially HLA-matched family member or unrelated donor (donor registries)	Umbilical cord blood

HLA, Human leukocyte antigen.

Obtaining the Stem Cells.

Stem cells are taken either from the patient directly (*autologous stem cells*), an HLA-identical twin (*syngeneic stem cells*), or from an HLA-matched person (*allogeneic stem cells*). For allogeneic transplant, the best results occur when the donor is an HLA-identical sibling; however, transplant also can be successful between those with closely but not perfectly matched HLA types. The chance of matching with any given sibling is 25%. Donor registries keep records of potential donors who can provide stem cells for patients who do not have a family member HLA match. The chance of matching with an unrelated donor is 1 in 5000.

Cultural Considerations

Patient-Centered Care QSEN

About 70% of people on the bone marrow donor lists are white. The chance of finding an HLA-matched unrelated donor is estimated at 30% to 40% for white people, but for African Americans the chance is less than 20% because there are fewer African Americans among registered donors. Although blood types are common in all racial groups, tissue types can be very different among racial and ethnic groups. Nationally, efforts are made to publicize the need for donors from all cultural backgrounds. Help in this effort by providing accurate information and dispelling myths.

Bone marrow harvesting occurs after a suitable donor is identified by tissue typing. The procedure occurs in the operating room, where marrow is removed through multiple aspirations from the iliac crests, although this technique is used less often today. About 500 to 1000 mL of marrow is aspirated, and the donor's marrow regrows within a few weeks. The marrow is then filtered and, if autologous, is treated to rid the marrow of any remaining cancer cells. Allogeneic marrow is transfused into the recipient immediately. Autologous marrow is frozen for later use.

Monitor the donor for fluid loss, assess for complications of anesthesia, and manage pain. During surgery, donors may lose a large amount of fluid in addition to the volume of marrow taken. Donors are hydrated with saline infusions before and immediately after surgery. Occasionally the donor may need an RBC transfusion. Assess the harvest sites to ensure that the dressings are dry and intact and that the donor is not bleeding excessively.

Marrow donation is usually a same-day surgical procedure. Teach the

donor to inspect the harvest sites for bleeding and to take analgesics for pain. Pain at the harvest sites (hips) is common and is managed with oral non–aspirin-containing analgesics. Some donors may require opioid analgesics for pain control.

Peripheral blood stem cell (PBSC) harvesting requires three phases: mobilization, collection by apheresis, and reinfusion. **PBSCs** are stem cells that have been released from the bone marrow and circulate within the blood. Although there are fewer stem cells in peripheral blood than in bone marrow, their numbers can be artificially increased. During the mobilization phase, chemotherapy or hematopoietic growth factors are given to the patient for an autologous collection, depending on the cancer type, and hematopoietic growth factors alone are given to the donor for an allogeneic or syngeneic collection. These agents increase the numbers of stem cells and WBCs in the peripheral blood. A new agent approved for some other types of hematologic malignancies to mobilize stem cells before harvesting in combination with hematopoietic growth factors is plerixafor (Mozobil). This drug has been shown to decrease the number of apheresis collections needed (Slater, 2012).

After mobilization, the stem cells are then collected by **apheresis** (withdrawing whole blood, filtering out the cells, and returning the plasma to the patient). One to five apheresis procedures, each lasting 2 to 4 hours, are needed to obtain enough stem cells for transplantation. The cells are frozen and stored for reinfusion after the patient's conditioning regimen is completed.

Monitor the patient or donor closely during apheresis. Complications include catheter clotting and hypocalcemia (caused by anticoagulants). Low calcium levels may cause numbness or tingling in the fingers and toes, abdominal or muscle cramping, or chest pain. Oral calcium supplements may be used to manage these symptoms. Monitor vital signs at least every hour during apheresis. The patient may become hypotensive from fluid loss during the procedure.

Cord blood harvesting involves obtaining stem cells from umbilical cord blood of newborns. This blood has a high concentration of stem cells. These cells are obtained through a simple blood draw from the placenta after birth and before the placenta detaches. The blood is then sent to the Cord Blood Registry for processing and storage. The stem cells may be used later for an unrelated recipient or stored in case the infant develops a serious illness later in life and needs them.

Conditioning Regimen.

Fig. 40-5 outlines the timing and steps involved in transplantation. The

day the patient receives the stem cells is day T-0. Before transplantation, the conditioning days are counted in reverse order from T-0, just like a rocket countdown. After transplantation, days are counted in order from the day of transplantation.

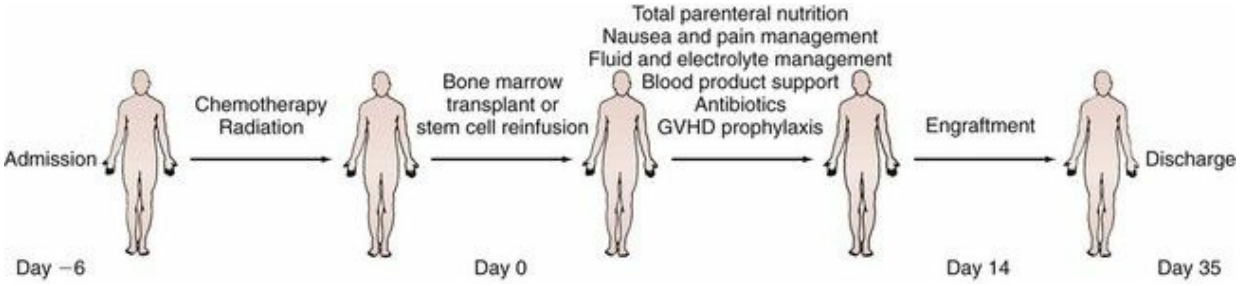

FIG. 40-5 Timing and steps of allogeneic bone marrow transplantation.

The patient first undergoes a conditioning regimen, which varies with the diagnosis and type of transplant to be received. The conditioning regimen serves two purposes: (1) to "wipe out" the patient's own bone marrow, thus preparing him or her for optimal graft take; and (2) to give higher-than-normal doses of chemotherapy and/or radiotherapy to rid the person of cancer cells *(myeloablation).* Usually a period of 5 to 10 days is required. The regimen usually includes high-dose chemotherapy and, less commonly, total-body irradiation (TBI). Each conditioning regimen is individually tailored, with the patient's specific disease, overall health, and previous treatment considered.

Because of the problems and risk for death associated with this conditioning regimen, a non-myeloablative approach may be used instead. Non-myeloablative regimens use lower doses of chemotherapy and/or lower dose of TBI that allow for recovery of a recipient's own immune system. The use of non-myeloablative conditioning regimens decreases the chemotherapy side effects but relies on the development of graft-versus-host disease (GVHD) for the control of the cancer. There are many variations of non-myeloablative conditioning regimens. In contrast, myeloablative conditioning regimens use high doses of chemotherapy with or without radiation therapy to completely destroy a recipient's bone marrow, allowing for replacement by a new immune system.

During conditioning, bone marrow and normal tissues respond immediately to the chemotherapy and radiation. *The patient has all of the expected side effects associated with both therapies (see Chapter 22). When chemotherapy is given in high doses, these side effects are more intense than those seen with standard doses.*

Late effects from the conditioning regimen may occur as late as 3 to 10 years after transplantation. These problems include veno-occlusive disease (VOD), skin toxicities, cataracts, lung fibrosis, second cancers, cardiomyopathy, endocrine complications, and neurologic complications.

Transplantation.

Day T-0 is the day of transplantation. The transplantation itself is very simple. Frozen marrow, PBSCs, or umbilical cord blood cells are thawed and then infused through the patient's central catheter like an ordinary blood transfusion.

Nursing Safety Priority QSEN

Action Alert

Do not use blood administration tubing to infuse stems cells because the cells could get caught in the filter, resulting in the patient receiving fewer stem cells.

Side effects of all types of stem cell transfusions are similar. The patient may have fever and hypertension in response to the preservative used in stem cell storage. To prevent these reactions, acetaminophen (Tylenol), hydrocortisone, and diphenhydramine (Benadryl) are given before the infusion. Antihypertensives or diuretics may be needed to treat fluid volume changes.

Engraftment.

The transfused PBSCs and marrow cells circulate briefly in the peripheral blood. The stems cells find their way to the marrow-forming sites of the patient's bones and establish residency there.

Engraftment, the successful "take" of the transplanted cells in the patient's bone marrow, is key to the whole transplantation process. For the stem cells to "rescue" the patient after his or her own bone marrow have been wiped out, the stem cells must survive and grow in the patient's bone marrow sites. The average time to engraftment for PBSC cells is 14 days. For bone marrow, the average time is 21 days. To aid engraftment, growth factors, such as granulocyte colony-stimulating factor or granulocyte-macrophage colony-stimulating factor, may be given. When engraftment occurs, the patient's WBC, RBC, and platelet counts begin to rise. Engraftment syndrome (ES) with fever and weight gain may occur at this time (Thoele, 2014).

Monitoring of engraftment involves checking the patient's blood for *"chimerism,"* which is the presence of blood cells that show a different genetic profile or marker from those of the patient. Mixed chimerism is the presence of both the patient's cells and those from the donor. Progressive chimerism with increasing percentages of donor cells indicates engraftment. Regressive chimerism with increasing percentages of the patient's cells indicates graft failure. When engraftment is successful, only the donor's cells are present.

Prevention of Complications.

The period after transplantation is difficult. Infection and poor clotting with bleeding are severe problems because the patient remains without any immunity until the transfused cells grow and engraft. Care for this patient is the same as for the patient during induction therapy for AML. Helping the patient maintain hope through this long recovery period is difficult. Complications are often severe and life threatening. Help the patient have a positive attitude and be involved in his or her own recovery.

In addition to the problems related to the period of **pancytopenia** (too few circulating blood cells), other complications of HSCT include failure to engraft, development of graft-versus-host disease (GVHD), and veno-occlusive disease (VOD).

Failure to engraft occurs when the donated stem cells fail to grow in the bone marrow and function properly. This issue is discussed in advance with the patient and the donor. Failure to engraft occurs more often with transplants using allogeneic stem cells than with those using autologous stem cells. The causes include too few cells transplanted, attack or rejection of donor cells by the recipient's remaining immune system cells, infection of transplanted cells, and unknown biologic factors. *If the transplanted cells fail to engraft, the patient will die unless another transplant with stem cells is successful.*

Graft-versus-host disease (GVHD) occurs mostly in allogeneic transplants but also can occur in autologous transplants (Baker & McKiernan, 2011). The immunocompetent cells of the donated marrow recognize the patient's (recipient) cells, tissues, and organs as foreign and start an immunologic attack against them. The graft is actually trying to attack the host tissues and cells.

Although all host tissues can be attacked and harmed, the tissues usually damaged are the skin, eyes, intestinal tract, liver, female genitalia, lungs, immune system, and musculoskeletal system (Johnson, 2013). Fig. 40-6 shows the typical skin appearance of GVHD. About 25% to 50% of all allogeneic HSCT recipients have some degree of GVHD, and

more than 15% of the patients who develop GVHD die of its complications. The presence of some GVHD indicates successful engraftment.

FIG. 40-6 Typical skin manifestations of graft-versus-host disease (GVHD).

Management of GVHD involves limiting the activity of donor T-cells by using drugs to suppress immunity such as cyclosporine, tacrolimus, methotrexate, corticosteroids, mycophenolate mofetil (Cellcept, MMF), and antithymocyte globulin (ATG) (Baker & McKiernan, 2011). Care is taken to avoid suppressing the new immune system to the extent that either infection risk increases or the new cells stop engrafting.

Veno-occlusive disease (VOD) is the blockage of liver blood vessels by clotting and inflammation (phlebitis) and occurs in about one fifth of patients with HSCT. Problems usually begin within the first 30 days after transplantation. Patients who received high-dose chemotherapy,

especially with alkylating agents, are at risk for life-threatening liver complications. Manifestations include jaundice, pain in the right upper quadrant, ascites, weight gain, and liver enlargement.

Because there is no way of opening the liver vessels, treatment is supportive. Early detection improves the chance for survival. Fluid management is also crucial. Assess the patient daily for weight gain, fluid retention, increases in abdominal girth, and hepatomegaly.

Clinical Judgment Challenge

Safety; Teamwork and Collaboration QSEN

The patient is a 44-year-old chemical plant foreman who developed acute myelogenous leukemia 6 months ago. His initial therapy was successful, and he is scheduled to have a stem cell transplant with his identical twin brother as the donor. His brother lives in the same city and is a professor at a local university. The patient is very grateful that his brother will donate bone marrow and states that he is certain that he has no risk for infection during the procedure because his brother is his identical twin.

1. What type of class of stem cell transplant would this procedure be considered?
2. Is the patient correct in assuming that he has no risk for infection because the donor is his twin brother? Provide a rationale for your response.
3. Which, if any, complications of stem cell transplantation are reduced or eliminated by having an identical sibling donate the stem cells?
4. Which, if any, complications (and why) are still possible even with a donor who is an identical sibling?

Minimizing Injury.

Bone marrow production of platelets is severely limited with acute myelogenous leukemia (AML), leading to thrombocytopenia. The patient is at great risk for poor clotting with excessive bleeding in response to minimal trauma. Thrombocytopenia can also be caused by induction therapy for AML or high-dose chemotherapy for transplantation.

Planning: Expected Outcomes.

The patient with leukemia is expected to remain free from bleeding. Indicators include:

- Maintenance of hematocrit and hemoglobin within normal limits

- Absence of visible bleeding, petechiae, or ecchymosis
- Absence of evidence of occult bleeding (e.g., abdominal swelling, tarry stools)

Interventions.

The platelet count is decreased as a side effect of chemotherapy. During the period of greatest bone marrow suppression (the **nadir**), the platelet count may be less than 10,000/mm^3. The patient is at extreme risk for bleeding once the platelet count falls below 50,000/mm^3, and spontaneous bleeding may occur when the count is lower than 20,000/mm^3.

Bleeding Precautions are used to protect the patient at increased risk for injury from bleeding (Chart 40-7). Assess at least every 4 hours for evidence of bleeding: oozing, enlarging bruises, petechiae, or purpura. Inspect all stools, urine, drainage, and vomit for blood, and test for occult blood. Measure any blood loss as accurately as possible, and measure the abdominal girth daily. Increases in abdominal girth can indicate internal hemorrhage. Institute the Bleeding Precautions listed in Chart 40-7. Platelet levels return to normal more slowly than do either WBCs or RBCs, and the patient remains at bleeding risk for weeks after discharge.

Chart 40-7 Best Practice for Patient Safety & Quality Care QSEN

The Patient with Thrombocytopenia

- Handle the patient gently.
- Use a lift sheet when moving and positioning in bed.
- Avoid IM injections and venipunctures.
- When injections or venipunctures are necessary, use the smallest-gauge needle for the task.
- Apply firm pressure to the needle stick site for 10 minutes or until the site no longer oozes blood.
- Apply ice to areas of trauma.
- Test all urine and stool for the presence of occult blood.
- Observe IV sites every 2 hours for bleeding.
- Avoid trauma to rectal tissues:
  - Do not give enemas.
  - Administer well-lubricated suppositories with caution.
  - Advise patient not to have anal intercourse.
- Measure abdominal girth daily.

- Advise the patient to use an electric shaver.
- Teach the patient to avoid mouth trauma:
  - Use soft-bristled toothbrush or tooth sponges.
  - Do not floss between teeth.
  - Avoid dental work, especially extractions.
  - Avoid hard foods.
  - Make sure that dentures fit and do not rub.
- Encourage the patient not to blow the nose or insert objects into the nose.
- Advise the patient to avoid contact sports.
- Teach the patient to wear shoes with firm soles when ambulating.

Monitor laboratory values daily, especially CBC results, to assess bleeding risk, as well as actual blood loss. The patient with a platelet count below 10,000/mm^3 may need a platelet transfusion. For the patient with severe blood loss, packed RBCs may be prescribed (see discussion on p. 822 in the Red Blood Cell Transfusions section).

Conserving Energy.

Production of red blood cells is limited in leukemia, causing anemia and fatigue. Also, leukemic cells have high rates of metabolism, increasing fatigue in the anemic patient. Anemia may also occur as a side effect of chemotherapy.

Planning: Expected Outcomes.

The patient with leukemia is expected to have no increase in fatigue. Indicators include that the patient consistently demonstrates these behaviors:

- Participates in self-care
- Recognizes manifestations of fatigue
- Changes activity level to match energy level

Interventions.

Interventions to reduce fatigue focus on conserving energy and improving RBC counts.

Nutrition therapy is needed to assist the patient to eat enough calories to meet at least basal energy requirements. However, increasing food intake can be difficult with fatigue. Collaborate with a dietitian to provide small, frequent meals high in protein and carbohydrates.

Blood transfusions are sometimes indicated for the patient with fatigue.

Transfusions with packed RBCs increase the blood's oxygen-carrying capacity and replace missing RBCs. (See Chart 40-12 on p. 820 for nursing care during transfusions.)

Drug therapy with colony-stimulating growth factors may reduce the severity and duration of anemia and neutropenia after intensive chemotherapy. For anemia, erythropoiesis-stimulating agents (ESAs) that boost production of RBCs may be used. These agents now carry a warning for causing hypertension and increasing the risk for myocardial infarction. ESAs must be given with care and should be avoided in patients with myeloid malignancies. They are not used unless the hemoglobin level is lower than 10 mg/dL and are stopped when this level is reached. Assess for side effects such as hypertension, headaches, fever, **myalgia** (muscle aches), and rashes. (See Chapter 22 for information on hematopoietic growth factors.)

Activity management helps conserve the patient's energy (Chart 40-8). Examine the patient's schedule of prescribed and routine activities. Assess those activities that do not have a direct positive effect on the patient's condition in terms of their usefulness. If the benefit of an activity is less than its worsening of fatigue, coordinate with other members of the health care team about eliminating or postponing it. Activities that may be postponed include physical therapy and invasive diagnostic tests not needed for assessment or treatment of current problems.

Chart 40-8 Best Practice for Patient Safety & Quality Care QSEN

Conserving Energy

- Reassure the patient that fatigue is temporary and energy levels will improve over a period of weeks to months. Stress that a return to previous energy levels may take as long as a year.
- Teach the patient that shortness of breath and palpitations are symptoms of over-activity.
- Instruct the patient to stop activity when shortness of breath or palpitations are present.
- Space care activities at least an hour apart, and avoid the time right before or right after meals.
- Schedule care activities at times when the patient has more energy (e.g., immediately after naps).
- Perform complete bed bath only every other day. In between complete

baths, ensure cleansing of face, hands, axillae, and perineum.
- In collaboration with other members of the health care team, cancel or reschedule non-essential tests and activities.
- Provide four to six small, easy-to-eat meals instead of three larger ones.
- Urge the patient to drink small amounts of protein shakes or other nutritional supplements.
- During periods of extreme fatigue, encourage the patient to allow others to perform personal care.
- Help the patient identify one or two lead visitors (those designated as allowed to visit at any time and who do not disturb the patient).
- Selectively limit non–lead visitors when the patient is resting or sleeping.
- Remind families that, although independence is important, independence in ADLs during extreme fatigue can be detrimental to the patient's health.
- Monitor oxygen saturation and respiratory rate during any activity to determine patient responses and activity tolerance.

NCLEX Examination Challenge

Safe and Effective Care Environment

The client is 3 weeks post-transplant from an allogeneic stem cell transplantation for acute lymphocytic leukemia. There is now some peeling of the client's skin on the palms of the hands and the soles of the feet. Which additional assessment data support the nurse's suspicion of possible graft-versus-host disease (GVHD)?

A The client's temperature is slightly below normal.

B Today's platelet count is 5,000/mm^3 and the WBCs are low.

C The client has had 6 to 10 watery stools daily for 3 days.

D The client's urine output is less than 800 mL in 24 hours.

Community-Based Care

The patient with leukemia is discharged after induction chemotherapy and recovery of blood cell production. Follow-up care continues on an ambulatory care basis. Although many transplant centers discharge patients after engraftment, some centers also give high-dose chemotherapy and stem cell infusion on an ambulatory care basis. This plan involves daily clinic visits and frequent follow-up by nurses in the home care setting.

Home Care Management.

Planning for home care for the patient with leukemia begins as soon as remission is achieved. Assess the available support systems. Many patients need a visiting nurse to assist with dressing changes for central venous catheters, infusions, and to answer questions. Home transfusion therapy for blood components may be needed.

Coordination of the home care team is critical for the patient receiving stem cell transplantation in the home setting. Potential candidates are evaluated in advance. Criteria include a knowledgeable caregiver, a clean home environment, location near the hospital, telephone access, and emotional stability of the patient and caregiver.

Home care nurses give chemotherapy and monitor for complications. Nurses visit the patient once or twice per day and spend between 4 and 8 hours per day in the home. The patient receives the stem cell transplant infusion in the ambulatory care clinic. Nursing care is similar to that provided in the hospital. If complications such as sepsis or veno-occlusive disease (VOD) occur, the patient is admitted to the inpatient facility.

Self-Management Education.

Instruct the patient and family about the importance of continuing therapy and medical follow-up. Many patients go home with a central venous catheter in place and need instructions about its care. Chart 40-9 lists guidelines for central venous catheter care at home. These guidelines may be altered depending on the home setting, assistance available, and agency policy.

Chart 40-9 Patient and Family Education: Preparing for Self-Management

Home Care of the Central Venous Catheter

- To maintain patency, flush the catheter briskly with saline once a day and after completing infusions.
- Change the Luer-Lok cap on each catheter lumen weekly.
- Change the dressing as often as prescribed:
  - Use clean technique with thorough handwashing.
  - Clean the exit site with alcohol and povidone-iodine (Betadine) or with chlorhexidine.
  - Apply antibacterial ointment to the site, if prescribed.
  - Cover the site with dry sterile gauze dressing, taped securely, or with

transparent adherent dressing.
- To prevent tension, always tape the catheter to yourself.
- Look for and report any signs of infection (redness, swelling, or drainage at the exit site).
- In case of a break or puncture in the catheter lumen, immediately clamp the catheter between yourself and the opening. *Notify your physician immediately.*

Protecting the patient from infection at home is just as important as it was during hospitalization. (See Chart 40-6 for focused assessment for the patient at risk for infection.) Teach about proper hygiene and the need to avoid crowds or others with infections. Neither the patient nor any household member should receive live virus immunization (poliomyelitis, measles, or rubella) for 2 years after transplantation. Instruct the patient to continue mouth care regimens at home. Stress to the patient that he or she should immediately notify the physician if a fever or any other indications of infection develop. Chart 40-10 lists guidelines for infection prevention.

Chart 40-10 Patient and Family Education: Preparing for Self-Management

Prevention of Infection

- Avoid crowds and other gatherings of people who might be ill.
- Do not share personal toilet articles, such as toothbrushes, toothpaste, washcloths, or deodorant sticks, with others.
- If possible, bathe daily.
- Wash the armpits, groin, genitals, and anal area at least twice a day with an antimicrobial soap.
- Clean your toothbrush daily by either running it through the dishwasher or rinsing it in liquid laundry bleach and then rinsing it with running water.
- Wash your hands thoroughly with an antimicrobial soap before you eat or drink, after touching a pet, after shaking hands with anyone, as soon as you come home from any outing, and after using the toilet.
- Eat a low-bacteria diet, and avoid salads, raw fruits and vegetables, and undercooked meat.
- Wash dishes between uses with hot, sudsy water, or use a dishwasher.
- Do not drink water that has been standing for longer than 15 minutes.
- Do not reuse cups and glasses without washing.

- Avoid changing pet litter boxes. If unavoidable, use gloves or wash hands immediately.
- Avoid keeping turtles and reptiles as pets.
- Do not feed pets raw or undercooked meat.
- Take your temperature at least twice a day.
- Report any of these manifestations of infection to your physician immediately:
  - Temperature greater than 100° F (38° C)
  - Persistent cough (with or without sputum)
  - Pus or foul-smelling drainage from any open skin area or normal body opening
  - Presence of a boil or abscess
  - Urine that is cloudy or foul smelling, or burning on urination
- Take all drugs as prescribed.
- Do not dig in the garden or work with houseplants.
- Avoid travel to areas of the world with poor sanitation or inadequate health care facilities.

Many patients return home still at risk for bleeding because platelet recovery is slower than recovery of other cells. Reinforce safety and bleeding precautions, and emphasize that these precautions must be followed until the platelet count remains above 50,000/mm^3. Teach the patient and family to assess for petechiae, avoid trauma and sharp objects, apply pressure to wounds for 10 minutes, and report blood in the stool or urine or headache that does not respond to acetaminophen. Chart 40-11 lists guidelines for patients at risk for bleeding.

Chart 40-11 Patient and Family Education: Preparing for Self-Management

The Patient at Risk for Bleeding

- Use an electric shaver.
- Use a soft-bristled toothbrush, and do not floss.
- Do not have dental work done without consulting your doctor.
- Do not take aspirin or any aspirin-containing products. Read the label to be sure the products do not contain aspirin or salicylates.
- Wear shoes or slippers with a sole to avoid foot injury.
- Do not participate in contact sports or any activity likely to result in your being bumped, scratched, or scraped.
- If you are bumped, apply ice to the site for at least 1 hour.

- Notify your physician if you:
  - Experience an injury and persistent bleeding results
  - Have excessive menstrual bleeding
  - See blood in your urine or bowel movement
  - Have a headache that does not respond to acetaminophen
- Avoid anal intercourse.
- Take a stool softener to prevent straining during a bowel movement.
- Do not use enemas or rectal suppositories.
- Avoid bending over at the waist.
- Do not wear clothing or shoes that are tight or that rub.
- Avoid blowing your nose or placing objects in your nose. If you must blow your nose, do so gently without blocking either nasal passage.

Psychosocial Preparation.

A diagnosis of leukemia threatens self-esteem and the family role. The patient faces the possibility of death, and treatment causes major changes in self-image. Changes occur in body image, level of independence, and lifestyle. Some feel threatened by the environment, seeing everything as infectious. Patients who are cared for in protective isolation may feel lonely and isolated. Help the patient and family define priorities, understand the illness and its treatment, and find hope. Make referrals to support groups sponsored by organizations such as the American Cancer Society or the Leukemia and Lymphoma Society of America.

One problem that lasts for a long period after transplantation is severe fatigue. Although the acute period after transplantation requires energy conservation with reduced activity, in the later recovery period, exercise provides benefits and fatigue reduction (see the Evidence-Based Practice box) (Albrecht, 2014; Chiffelle & Kenny, 2013). Help the patient and family understand the benefits of low-impact exercise.

Evidence-Based Practice QSEN

Exercise for Less Fatigue

Chiffelle, R., & Kenny, K. (2013). Exercise for fatigue management in hematopoietic stem cell transplantation recipients. *Clinical Journal of Oncology Nursing, 17*(3), 241-242.

Fatigue associated with cancer therapy has been recognized as one of the most distressing and debilitating side effects. The fatigue experienced by patients after hematopoietic stem cell transplantation

(HSCT) has been found to be more severe and persist much longer than that associated with more standard therapy. Exercise, even during the treatment period, has been shown to reduce the perception of fatigue and its negative effects on performance of desired activities in patients undergoing standard chemotherapy or radiation. It is not known whether exercise would be beneficial in reducing the long-term fatigue frequently experienced after HSCT or even could have harmful effects.

Level of Evidence: 1

The results are based on a systematic review and meta-analysis of 25 previous studies related to assessing the evidence for recommending an exercise intervention for relief of cancer-related fatigue (CRF) in patients receiving traditional cancer treatments and those whose treatment additionally involved HSCT. The studies analyzed included 6 other systematic reviews, 16 randomized controlled clinical trials, 6 nonrandomized controlled trials, and 1 qualitative study. Results of this analysis do indicate that exercise for patients after HSCT is at least not harmful and has some benefit in reducing the distress of fatigue. Although not all patients universally had fatigue reduction, none experienced an increase in fatigue with exercise.

Commentary: Implications for Practice and Research

For best practice, interventions must be both effective and not harmful. Therefore this meta-analysis contributes substantial evidence that some exercise in patients after HSCT is not harmful and does provide some reduction of the distress associated with CRF. Because many patients and their families believe that the patient is much more fragile after HSCT, some are hesitant to increase activity in any way. Nurses can be instrumental in helping patients and families get past the mental barrier of fear regarding activity and can recommend low-impact exercise. However, the type of exercise (e.g., walking, cycling, low-impact aerobics) and the best timing for implementing an exercise intervention to have maximum benefit have yet to be determined.

Health Care Resources.

The patient with limited social support may need help at home until strength and energy return. A home care aide may suffice for some patients, whereas for others a visiting nurse may be needed. The patient may also need equipment for ADLs and ambulation. Assess financial resources. Cancer treatment is expensive, and you will need to coordinate with the social services department to ensure that insurance is adequate.

If the patient is uninsured, explore other sources, such as drug company–sponsored compassionate aid programs. The Leukemia and Lymphoma Society of America also offers limited financial help.

Prolonged outpatient contact and follow-up are necessary, and patients need transportation to the outpatient facility. Many local units of the American Cancer Society offer free transportation to patients with cancer, including leukemia.

Evaluation: Outcomes

Evaluate the care of the patient with leukemia based on the identified priority patient problems. The expected outcomes include that the patient will:

- Remain free of infection and sepsis
- Not experience episodes of bleeding
- Be able to balance activity and rest
- Use energy conservation techniques

Specific indicators for these outcomes are listed for each priority patient problem in the Planning and Implementation section (see earlier).

Malignant Lymphomas

Lymphomas are cancers of the lymphoid tissues with abnormal overgrowth of lymphocytes. Lymphomas are cancers of committed lymphocytes rather than stem cell precursors (as in leukemia). This growth occurs as solid tumors in lymphoid tissues scattered throughout the body, especially the lymph nodes and spleen, rather than in the bone marrow. The two major adult forms of lymphoma are Hodgkin's lymphoma (HL) and non-Hodgkin's lymphoma (NHL).

Hodgkin's Lymphoma

Pathophysiology

Hodgkin's lymphoma (HL) is a cancer that can affect any age-group. However, it appears to peak in two different age-groups: (1) teens and young adults, and (2) adults in their 50s and 60s (McCance et al., 2014). HL affects younger men and women equally, but the disease is more prevalent in men in the older group.

The exact cause of HL is uncertain. Possible causes of HL include viral infections (i.e. Epstein-Barr virus [EBV], human T-cell leukemia/lymphoma virus [HTLV], and human immune deficiency virus

[HIV]) and exposure to chemicals. Most cases of the disease, however, occur in people without known risk factors.

This cancer usually starts in a single lymph node or a single chain of nodes. These nodes contain a specific cancer cell type, the **Reed-Sternberg cell,** a marker for HL. HL often spreads predictably from one group of lymph nodes to the next, unlike non-Hodgkin's lymphoma.

Patient-Centered Collaborative Care

Assessment

The most common assessment finding is a large but painless lymph node or nodes. The patient may also have constitutional manifestations ("B symptoms") that include: fevers (>101.5° F [>38.6° C]); heavy night sweats; and unplanned weight loss (>10% of normal body weight). The presence of these manifestations often means a poorer prognosis. Many patients have no manifestations at time of diagnosis, and specific manifestations often depend on the site and extent of disease.

Diagnosis and subtype are established when biopsy reveals Reed-Sternberg cells (McCance et al., 2014). HL is then classified into one of several different subtypes.

After diagnosis, staging is performed to determine the extent of disease. This process is detailed and must be accurate because the treatment regimen is determined by the extent of disease. Staging usually includes a history and physical examination, CBC, electrolyte panel, kidney and liver function tests, erythrocyte sedimentation rate (ESR), bone marrow aspiration and biopsy, and computed tomography (CT) of the neck, chest, abdomen, and pelvis. Positron emission tomography (PET) may be used to assess for disease not detected by CT. PET scans are helpful after treatment to assess disease response to therapy. After staging procedures are complete, the stage of the disease is determined by the Ann Arbor Staging Criteria (Table 40-4).

TABLE 40-4

Ann Arbor Staging Criteria for Hodgkin's Lymphoma

STAGE	MANIFESTATION CRITERIA
Ia	Disease is present only in a single lymph node region or in only one non–lymph node site.
Ib	Disease location is the same as Ia. In addition, the patient has some or all of these manifestations: persistent fever, night sweats, weight loss of more than 10% of normal body weight.
IIa	Disease is present in two or more separate lymph node regions on the same side of the diaphragm or in two non–lymph node sites on the same side of the diaphragm.
IIb	Disease location is the same as IIa. In addition, the patient has some or all of these manifestations: persistent fever, night sweats, weight loss of more than 10% of normal body weight.
IIIa	Disease extends to lymph node regions on both sides of the diaphragm.
IIIb	Disease location is the same as IIIa. In addition, the patient has some or all of these manifestations: persistent fever, night sweats, weight loss of more than 10% of normal body weight.
IIIc	Same as IIIb along with disease present in the spleen.
IV	Disease is present in many body areas, including in one or more non-nodal tissues and organs.

Interventions

HL is one of the most treatable types of cancer. For stages I and II disease, the treatment is external radiation of involved lymph node regions. With more extensive disease, radiation and combination chemotherapy are used to achieve remission. (See Chapter 22 on general care of patients receiving radiation and chemotherapy.)

Nursing management of the patient undergoing treatment for HL focuses on the acute side effects of therapy, especially:

- Drug-induced pancytopenia with increased risk for infection, anemia, and bleeding
- Severe nausea and vomiting
- Skin problems at the site of radiation
- Constipation or diarrhea
- Permanent sterility for male patients receiving radiation to the lower abdomen or pelvic region in combination with specific chemotherapy drugs (The patient is informed and given the option to store sperm in a sperm bank *before* treatment.)
- Secondary cancer development and the need for long-term follow-up

Non-Hodgkin's Lymphoma

Pathophysiology

Non-Hodgkin's lymphoma (NHL) includes all lymphoid cancers that do not have the Reed-Sternberg cell. There are over 60 subtypes of NHL divided into either indolent or aggressive lymphomas. NHL generally spreads through the lymphatic system in a less orderly fashion than HL. About 70,000 new cases are diagnosed each year in North America (ACS, 2014). The disease is more common in men and older adults.

The exact cause of NHL is unknown although the incidence is higher among patients with solid organ transplantation, immunosuppressive drug therapy, and HIV disease. Chronic infection from *Helicobacter pylori* is associated with a type of lymphoma called *mucosa-associated lymphoid tissue (MALT) lymphoma,* and Epstein-Barr viral infection has been associated with Burkitt's lymphoma. There is an increased incidence of NHL among people exposed to pesticides, insecticides, and dust.

Patients usually have swollen lymph nodes (lymphadenopathy) or tumor spread to other organs (e.g., GI tract, skin, bone marrow, sinuses, thyroid, central nervous system) at the time of diagnosis. Enlarged lymph nodes may be the only manifestation of lymphoma. Painless swelling of the cervical, axillary, inguinal, and femoral nodes is most often seen. The diagnosis of NHL is made only after the biopsy of an involved lymph node is reviewed by a hematopathologist.

Lymphoma is not a single disease but, rather, a group of diseases. The specific subtype of lymphoma must be classified because management varies with the subtype. Classification is based on cytology, immunophenotyping by flow cytometry, and genetic (chromosomal changes and molecular rearrangements) and clinical features. NHLs are broadly classified as B-cell or T-cell lymphomas, depending on the lymphocyte type that gave rise to the cancer. B-cell lymphomas are most common.

Classification of NHL is more complicated than that for Hodgkin's lymphoma and is based on the World Health Organization (WHO) classification system. In addition, lactate dehydrogenase (LDH) levels and beta-2 microglobulin levels are also evaluated to measure tumor growth rates and calculate prognosis. (High LDH levels and high beta-2 microglobulin levels are associated with a poorer prognosis.) Cerebrospinal fluid is evaluated when lymphoma is present in the CNS, around the spinal column, brain, or testes, and when HIV-related lymphoma is diagnosed.

Patients with **indolent** (slow-growing) lymphomas usually have painless lymph node swelling at diagnosis. Those with more aggressive

B-cell lymphomas may have large masses at diagnosis and manifestations. Constitutional manifestations ("B symptoms"), as seen in Hodgkin's lymphoma, occur in about one third of patients with aggressive lymphomas and rarely in indolent lymphomas. Bone marrow involvement in indolent lymphomas is common.

Patient-Centered Collaborative Care

Treatment options for patients with NHL vary based on the subtype of the tumor, international prognostic index (IPI) score, stage of the disease, performance status, and overall tumor burden. Special consideration for patients with additional health problems is important, especially among older adult patients. Many new therapies have evolved over the past decade for various subtypes of NHL. These therapies include combinations of chemotherapy drugs alone or in combination with monoclonal antibodies (e.g., rituximab and alemtuzumab), localized radiation therapy, radiolabeled antibodies (^{131}I tositumomab and ^{90}Y ibritumomab tiuxetan), hematopoietic stem cell transplantation, and investigational agents (Byar & Workman, 2012).

Nursing care needs are similar to those for patients with HL, with additional organ-specific problems if the disease is widespread. With the use of biotherapy for NHL, close monitoring for infusion-related reactions is needed during and after the delivery of monoclonal antibodies (see Chapter 22 for general care of patients undergoing treatment with biotherapy). Patient and family education are important in the management and prevention of complications.

Clinical Judgment Challenge

Prioritization, Delegation, and Supervision QSEN

The patient is a 52-year-old woman who has undergone an autologous stem cell transplantation for non-Hodgkin's lymphoma. She is recovering, and her white blood cell count is improving but is still very low. She remains on neutropenic precautions. The LPN reports that the patient's heart rate, respiratory rate, temperature, and blood pressure are elevated.

1. Which vital sign finding would you report to the health care provider immediately and why?
2. You must assign an unlicensed assistive personnel (UAP) to help care for this patient. Of the four UAP available, one is newly pregnant and has worked on this unit for 3 years, one has had cold symptoms for 3

days, one has not yet cared for a patient on neutropenic precautions, and one has a fear of people with cancer. Which UAP should you avoid assigning to this patient? Provide a rationale for your choice.
3. A nursing student tearfully reports to you, "I took some flowers into the patient's room to cheer him up and he told me that he didn't think he was supposed to have flowers. I took them out of the room right away and then I realized I had made a mistake." How should you respond to this student?
4. The student asks you whether a book still wrapped in shrink wrap just now brought in by a friend of the patient can be taken to the patient's room. How will you help the student know what to do in this situation?

Multiple Myeloma

Pathophysiology

Multiple myeloma is a white blood cell (WBC) cancer that involves a mature B-lymphocyte called a *plasma cell*, which secretes antibodies. These cells are overgrown in the bone marrow. When these cells become cancerous, they produce excessive antibodies (gamma globulins). Thus the disorder is called a "gammopathy." When myeloma cells are overproduced, fewer red blood cells (RBCs), WBCs, and platelets are produced, leading to anemia and increased risk for infection and bleeding.

In addition to the excess antibodies, multiple myeloma cells also produce excess cytokines (see Chapter 17) that increase cancer cell growth and destroy bone. The excess antibodies are in the blood, increasing the serum protein levels and clogging blood vessels in the kidney and other organs. Without treatment, the disease causes progressive bone destruction, bleeding problems, kidney failure, immunosuppression, and death.

Multiple myeloma accounts for about 11,000 deaths per year in the United States (ACS, 2014). The disease is most common in people older than 65 years. The incidence is higher in American blacks than in whites, with a much higher incidence in men.

The cause of multiple myeloma is unknown. Possible risk factors include radiation exposure, chemical exposure, and infection with human herpes virus-8 (HHV-8). This cancer can be distinguished by changes in immunoglobulin structure that begin within a single clone of cells even before transformation to cancer occurs. When the specifically altered immunoglobulin is present in a high enough quantity, the type can be recognized as a unique "spike" pattern on a serum electrophoresis test of

plasma proteins. Because one clone of cells develops into cancer cells, the abnormal immunoglobulin produced by these cells is a *monoclonal* paraprotein.

Patient-Centered Collaborative Care

Assessment

Some patients have no symptoms at time of the diagnosis. An elevation of serum total protein or a detection of a monoclonal protein (also known as *paraprotein*) in the blood or urine may be the only finding. Other common manifestations include fatigue, anemia, bone pain, pathologic fractures, recurrent bacterial infections, and kidney dysfunction.

A positive finding of a serum monoclonal protein is not sufficient to make a diagnosis of multiple myeloma. About 1% of the population produce a monoclonal protein in the blood but do not have multiple myeloma. This condition is labeled ***m****onoclonal* ***g****ammopathy of* ***u****ndetermined* ***s****ignificance* or *MGUS,* which is a premalignant condition. Follow-up of patients with MGUS is important because a small percentage eventually will develop multiple myeloma. Multiple myeloma is distinguished from MGUS by having more than 10% of the bone marrow infiltrated with plasma cells, the presence of a monoclonal protein in the serum or urine, and the presence of osteolytic bone lesions.

The staging system for multiple myeloma divides patients into stages and prognostic groups on the basis of the serum beta-2 microglobulin and albumin levels. Other factors that help determine prognosis include age, performance status, serum creatinine, serum albumin, serum calcium, lactate dehydrogenase (LDH) level, C-reactive protein, hemoglobin level, platelet count, quantitative immunoglobulins, beta-2 microglobulin, serum free light chains, serum protein electrophoresis (SPEP) with immunofixation, 24-hour urine for SPEP, and cytogenetic abnormalities found in the bone marrow biopsy (Kurtin & Faiman, 2013).

The patient usually first notices fatigue, easy bruising, and bone pain. Bone fractures, hypertension, infection, hypercalcemia, and fluid imbalance may occur as the disease progresses. Diagnosis is made by x-ray findings of bone thinning with areas of bone loss that resemble Swiss cheese, high immunoglobulin and plasma protein levels, and the presence of Bence-Jones protein (protein composed of incomplete antibodies) in the urine. A bone marrow biopsy is performed to diagnose the disease and to determine chromosome changes. An abnormality of chromosome 11 predicts a longer survival, and absence of chromosome 13 is a poor

prognostic factor.

Interventions

Treatment options vary. For minimal disease, watchful waiting may be an option instead of chemotherapy. Standard treatment for multiple myeloma is the use of proteasome inhibitors, such as bortezomib (Velcade) or carfilzomib (Kyprolis), and immunomodulating drugs, such as thalidomide (Thalomid) or lenalidomide (Revlimid). All these agents, which are types of targeted cancer therapy (see Chapter 22), may be used alone or in combination with steroids, such as dexamethasone (Decadron). Drug selection is based on whether the patient is eligible for an autologous stem cell transplant. If eligible, drug therapy is used to reduce tumor burden before transplantation. For patients who are not eligible for an autologous stem cell transplantation, standard chemotherapy drugs such as melphalan, prednisone, vincristine, cyclophosphamide, doxorubicin, and carmustine are usually effective in controlling but not curing the disease.

Side effects and severe toxicities can occur with these agents. Myelosuppression is an expected side effect of many myeloma therapies. A nursing priority is to teach the patient about the manifestations. The risk for thromboembolic events is increased with the use of thalidomide and lenalidomide. Peripheral neuropathy can be challenging, causing pain and poor quality of life. GI side effects, such as nausea, vomiting, diarrhea, and constipation, are severe and can be life threatening if not managed properly.

Despite therapy, multiple myeloma remains largely incurable (Kurtin & Faiman, 2013). Best outcomes are seen with autologous hematopoietic stem cell transplantation, although few patients are able to pursue this option (Mangan et al., 2013). Because most patients with multiple myeloma have bone pain, analgesics and alternative approaches for pain management, such as relaxation techniques, aromatherapy, or hypnosis, are used for pain relief. The bone disease of multiple myeloma is treated with bisphosphonates (pamidronate [Aredia], zoledronic acid [Zometa], denosumab [Xgeva]), which inhibit bone resorption and can help reduce the skeletal complications.

Coagulation Disorders

Coagulation disorders are bleeding disorders with increased bleeding resulting from defects in one or more components regulating blood clotting. Bleeding disorders may be spontaneous or traumatic, localized or generalized, lifelong or acquired. They can arise from a defect in the clotting processes at the vascular, platelet, or clotting factor level.

Platelet Disorders

As discussed in Chapter 39, clotting always starts with platelets sticking together (aggregation) and forming a platelet plug. Any condition that either reduces the number of platelets or interferes with their ability to adhere (stick to one another, blood vessel walls, collagen, or fibrin threads) can result in increased bleeding. Platelet disorders are inherited, acquired, or temporarily induced by drugs that limit platelet production or inhibit aggregation.

Platelet numbers below that needed for blood clotting is called **thrombocytopenia**. It may occur as a result of other conditions or treatments that suppress general bone marrow activity. The problem also can occur from limited platelet formation or an increased rate of platelet destruction in the spleen. The two thrombocytopenic conditions affecting adults are *autoimmune thrombocytopenic purpura* and *thrombotic thrombocytopenic purpura*.

Autoimmune Thrombocytopenic Purpura

Pathophysiology

Autoimmune thrombocytopenic purpura is also called *idiopathic thrombocytopenic purpura (ITP)*. The number of circulating platelets is greatly reduced in ITP, even though platelet production is normal.

Patients with this disorder make an antibody against the surface of their own platelets (an antiplatelet antibody). This antibody coats the platelet surfaces, making destruction by macrophages easier (see Chapter 17). The spleen has many macrophages, and the blood vessels of the spleen are long and twisted. These conditions increase destruction of antibody-coated platelets in the spleen. When platelet destruction exceeds platelet production, the number of circulating platelets decreases and clotting is impaired.

The trigger for the production of autoantibodies is unknown, but viral infection is suspected. ITP is most common among women between the

ages of 20 and 50 years and among people who have other autoimmune disorders (McCance et al., 2014; Radovich, 2011).

Patient-Centered Collaborative Care

Assessment

Manifestations of ITP are at first seen in the skin and mucous membranes: large **ecchymoses** (bruises) or a petechial rash on the arms, legs, upper chest, and neck; mucosal bleeding occurs easily. If the patient has had significant blood loss, anemia may also be present.

A rare complication is intracranial bleeding–induced stroke. Assess for neurologic function and mental status (see Chapter 41).

ITP is diagnosed by a low platelet count and increased megakaryocytes in the bone marrow. Antiplatelet antibodies may be detected in the blood. If the patient has any episodes of bleeding, hematocrit and hemoglobin levels may be low.

Interventions

As a result of the decreased platelet count, the patient is at great risk for poor clotting and increased bleeding. Interventions include therapy for the underlying condition and protection from bleeding episodes. Management is often limited to those patients with platelet counts lower than 50,000/mm^3, those who are bleeding, and those who are at high risk for bleeding.

Drug therapy to control ITP includes drugs that suppress immune function. Drugs such as corticosteroids, azathioprine (Imuran), eltrombopag, rituximab (Rituxan), and romiplostim are used to inhibit production of antiplatelet autoantibodies. IV immunoglobulin and IV anti-Rho can help prevent the destruction of antibody-coated platelets, although anti-Rho carries a Black Box Warning for increased risk for intravascular hemolysis and death. Aggressive therapy involves low doses of chemotherapy drugs.

Platelet transfusions are used when platelet counts are less than 10,000/mm^3 or the patient has an acute life-threatening bleeding episode. Transfusions are not performed routinely because the donated platelets are just as rapidly destroyed by the spleen as the patient's own platelets. (See discussion on p. 822 in the Platelet Transfusions section.)

Maintaining a safe environment helps protect the patient from bleeding. Closely monitor the amount of bleeding that is occurring. (For nursing care actions, see the discussion of Minimizing Injury on p. 812 in the

Leukemia section.)

Surgical management with a splenectomy may be needed for the patient who does not respond to drug therapy. (The spleen is the site of excessive platelet destruction.)

Depending on the size of the spleen and the risk for bleeding, splenectomy may be performed as an open abdominal surgery or as minimally invasive surgery by laparoscopy. Nursing care after surgery is the same as for any other abdominal surgery (see Chapter 16). After splenectomy, the patient is at increased risk for infection because the spleen performs many protective immune functions, especially antibody generation. For this reason, vaccinations against pneumococcal, meningococcal, and *Haemophilus influenzae* are recommended either 2 weeks before a planned splenectomy or 2 weeks after the surgery. Teaching patients about their increased risk for infection, avoiding crowds and people who are ill, and consulting with the health care provider is a nursing priority.

Thrombotic Thrombocytopenic Purpura

In thrombotic thrombocytopenic purpura (TTP), platelets clump together abnormally in the capillaries and too few platelets remain in circulation. The patient has inappropriate clotting, yet the blood fails to clot when trauma occurs. The cause of TTP appears to be an autoimmune reaction in small blood vessel cells (endothelial cells) that starts platelet aggregation and clotting there. Tissues become ischemic, leading to kidney failure, myocardial infarction, and stroke. Untreated, this disorder is often fatal within 3 months.

Management of the patient with TTP focuses on preventing platelet clumping and stopping the autoimmune process. Plasma removal and the infusion of fresh frozen plasma reduce the clumping caused by elements of the patient's blood. Drugs that inhibit platelet clumping, such as aspirin, alprostadil (Prostin), and plicamycin, also may be helpful. Immunosuppressive therapy reduces the intensity of this disorder.

Clotting Factor Disorders

Coagulation or bleeding disorders can result from a clotting factor defect. Defects include the inability to produce a specific clotting factor, production of low quantities of a clotting factor, or production of a less active form of a clotting factor.

Most clotting factor disorders are genetic problems of one clotting

factor. A damaged liver also leads to a clotting disorder by reducing the amount of clotting factors produced. Common disorders that result from defects at the clotting factor level include hemophilias A and B and von Willebrand's disease. Disseminated intravascular coagulation (DIC) often occurs with septic shock (see Chapter 37).

Hemophilia

Pathophysiology

Hemophilia is a hereditary bleeding disorder with two forms resulting from different clotting factor deficiencies. Hemophilia A (classic hemophilia) is a deficiency of factor VIII and accounts for 80% of cases of hemophilia. Hemophilia B (Christmas disease) is a deficiency of factor IX and accounts for 20% of cases. The incidence of both disorders is 1 in 10,000 (Hitch, 2013; McCance et al., 2014).

Genetic/Genomic Considerations

Patient-Centered Care QSEN

Hemophilia is an X-linked recessive trait. Women who are **carriers** (can pass on the gene without expressing bleeding problems) have a 50% chance of passing the hemophilia gene to their daughters (who then are carriers) and to their sons (who then have hemophilia). Hemophilia A affects mostly males, none of whose sons will have the gene for hemophilia and all of whose daughters will be carriers. About 30% of patients with hemophilia have no family history and their disease may be the result of a new gene mutation (Beery & Workman, 2012). Ensure that the family is referred to the appropriate level of genetic counseling.

The clinical pictures of hemophilias A and B are identical. The patient has abnormal bleeding in response to any trauma because of a deficiency of the specific clotting factor. Hemophiliacs form platelet plugs at the bleeding site, but the clotting factor deficiency impairs the formation of stable fibrin clots. This allows excessive bleeding, which may be mild, moderate, or severe, depending on the degree of factor deficiency.

Patient-Centered Collaborative Care

Assessment of the patient with hemophilia shows:

- Excessive bleeding from minor cuts, bruises, or abrasions (from abnormal platelet function)

- Joint and muscle hemorrhages that lead to disabling long-term problems and may require joint replacement
- A tendency to bruise easily
- Prolonged and potentially fatal hemorrhage after surgery

The laboratory test results for a patient with hemophilia show a prolonged activated partial thromboplastin time (aPTT), a normal bleeding time, and a normal prothrombin time (PT). The most common problem that occurs with hemophilia is degenerating joint function as a result of chronic bleeding into the joints, especially the hip and knee.

The bleeding problems of hemophilia A are managed by either regularly scheduled infusions of synthetic factor VIII or the infusion of this substance only when injury or bleeding occurs. The cost of factor VIII replacement is prohibitive for many people with hemophilia. The source of factor VIII varies (Table 40-5), and the traditional sources, derived from pooled human serum, are no longer recommended because of the risk for transfusion-related infections (National Hemophilia Foundation, 2014).

TABLE 40-5

Antihemophilic Drugs

DRUG TYPES	SOURCES
High purity antihemophilic factor • Alphanate • Humate-P • Koate-DIV	Pooled human serum
Monoclonal antibody purified antihemophilic factor • Hemofil-M • Monarc-M • Monoclate-P	Pooled human serum
Recombinant antihemophilic factor • Helixate FS • Kogenate FS • Recombinate	Recombinant DNA technology
B-domain deleted (BDD) recombinant antihemophilic factor • ReFacto	Recombinant DNA technology
Recombinant antihemophilic factor plasma/albumin-free method (rAHF-PFM) • Advate	Recombinant DNA technology
Recombinant antihemophilic factor plasma/albumin-free method • Xyntha	Recombinant DNA technology
Porcine factor VIII • Hyate: C	Animal serum

Heparin-Induced Thrombocytopenia

Heparin-induced thrombocytopenia (HIT) is a serious immunity-mediated clotting disorder with an unexplained drop in platelet count after heparin treatment. The occurrence is increasing because of the increased use of heparin. Unlike other clotting disorders, HIT is an immune-mediated drug reaction that is caused by heparin-dependent platelet-activating immunoglobulin G (IgG) antibodies in which heparin binds with platelet factor 4 (PF4). This drug binding leads to the development of a highly reactive immune complex that activates the platelets. Once activated, platelets release procoagulants and PF4, which neutralizes heparin and increases thrombin generation from prothrombin.

HIT can occur in patients receiving any type of heparin, although it is more common after exposure to unfractionated heparin. The incidence is higher among patients with risk factors of (1) duration of heparin use longer than 1 week, (2) exposure to unfractionated heparin, (3) postsurgical thromboprophylaxis, and (4) being female.

Manifestations of HIT include venous thromboembolism (VTE) such as deep vein thrombosis and pulmonary embolism. The diagnosis is based on the patient's exposure to heparin, which can be up to 100 days before the event. Thrombocytopenia after heparin exposure is the hallmark sign of HIT. Clinical, as well as laboratory, findings need to be interpreted to properly diagnose this disorder.

Once HIT is diagnosed, anticoagulation therapy is started. Drug management for HIT management is with a direct thrombin inhibitor such as argatroban (Argatroban), lepirudin (Refludan), and bivalirudin (Angiomax).

Transfusion Therapy

Any blood component may be removed from a donor and transfused into a recipient. Blood components may be transfused individually or collectively, with varying degrees of benefit to the recipient. Table 40-6 lists indications for transfusion therapy.

TABLE 40-6

Indications for Treatment with Blood Components

COMPONENT	VOLUME	INFUSION TIME	INDICATIONS
Packed red blood cells (PRBCs)	200-250 mL	2-4 hr	Anemia; hemoglobin <6 g/dL, 6-10 g/dL, depending on symptoms
Washed red blood cells (WBC-poor PRBCs)	200 mL	2-4 hr	History of allergic transfusion reactions Hematopoietic stem cell transplant patients
Platelets			
Pooled	About 300 mL	15-30 min	Thrombocytopenia, platelet count <20,000 Patients who are actively bleeding with a platelet count <50,000
Single donor	200 mL	30 min	History of febrile or allergic reactions
Fresh frozen plasma	200 mL	15-30 min	Deficiency in plasma coagulation factors Prothrombin or partial thromboplastin time 1.5 times normal
White blood cells (WBCs)	400 mL	1 hr	Sepsis, neutropenic infection not responding to antibiotic therapy

Pretransfusion Responsibilities

Nursing actions during transfusions focus on prevention or early recognition of adverse transfusion reactions. Preparation of the patient for transfusion is critical, and blood product administration procedures must be carefully followed. Before infusing any blood product, review the agency's policies and procedures. Chart 40-12 lists best practices for transfusion therapy.

Chart 40-12 Best Practice for Patient Safety & Quality Care QSEN

Transfusion Therapy

NURSING ACTIONS	RATIONALES
Before Infusion	
1. Assess laboratory values.	Many institutions have specific guidelines for blood product transfusions (e.g., platelet count <20,000 or hemoglobin <6 g/dL).
2. Verify the medical prescription.	Legally, a physician's prescription is required for transfusions. The prescription should state the type of product, dose, and transfusion time.
3. Assess the patient's vital signs, urine output, skin color, and history of transfusion reactions.	Determine whether the patient can tolerate infusion. Baseline information may be needed to help identify transfusion reactions.
4. Obtain venous access. Use a central catheter or at least a 19-gauge needle if possible.	The larger-bore needle allows cells to flow more easily without occluding the lumen of the catheter.
5. Obtain blood products from a blood bank. Transfuse as soon as possible after first performing **all the required safety checks.** QSEN	Once a blood product has been released from the blood bank, the product should be transfused as soon as possible (e.g., red blood cell transfusions should be completed within 4 hours of removal from refrigeration).
6. With another registered nurse, verify the patient by name and number, check blood compatibility, and note expiration time.	Human error is the most common cause of ABO incompatibility reactions.
During Infusion	
7. Administer the blood product using the appropriate filtered tubing.	Filters are needed to remove aggregates and possible contaminants.
8. Dilute blood products with only normal saline solution.	Hemolysis occurs if some other IV solution is used.
9. Remain with the patient during the first 15 to 30 minutes of the infusion.	Hemolytic reactions occur most often within the first 50 mL of the infusion.
10. Infuse the blood product at the prescribed rate.	Fluid overload is a potential complication of rapid infusion.
11. Monitor vital signs.	Vital sign changes often indicate transfusion reactions.
After Infusion	
12. When the transfusion is completed, discontinue infusion and dispose of the bag and tubing properly.	Bloodborne pathogens may be spread inadvertently through improper disposal.
13. Document.	The patient record should indicate the type of product infused, product number, volume infused, time of infusion, and any adverse reactions.

A health care provider's prescription is needed to administer blood components. The prescription specifies the type of component, the volume, and any special conditions. Verify the prescription for accuracy and completeness. In many hospitals, a separate consent form must be obtained from the patient before a transfusion is performed.

A blood specimen is obtained for type and crossmatch (testing of the donor's blood and the recipient's blood for compatibility). The procedures for obtaining this specimen are specified by hospital policy. Usually a new type-and-crossmatch specimen is required at least every 72 hours.

Both Y-tubing and straight tubing sets are used for blood component infusion (Fig. 40-7). A blood filter (about 170 μm) to remove sediment from the stored blood products is included with blood administration sets and must be used to transfuse most, but not all, blood products.

FIG. 40-7 Blood administration setup.

Use normal saline as the solution to administer with blood products, although this practice is not evidence-based (Kessler, 2013). Ringer's lactate and dextrose in water are not used for infusion with blood products because they may cause clotting or hemolysis of blood cells, although there is not sufficient evidence of hemolysis when using hypotonic fluids (Elgin et al., 2011; Kessler, 2013; Kessler et al., 2012; Tolich et al., 2013).

Nursing Safety Priority QSEN

Action Alert

Never add to or infuse other drugs with blood products because they may clot the blood during transfusion.

Before the transfusion, in compliance with recommendations by The Joint Commission's National Patient Safety Goals (NPSGs), the priority action is to determine that the blood component delivered is correct and that identification of the patient is correct. Check the physician's prescription together with another registered nurse to determine the patient's identity and whether the hospital identification band name and number are identical to those on the blood component tag. According to The Joint Commission's National Patient Safety Goals, *the patient's room number is not an acceptable form of identification*. Some facilities use a bar code–point of care (BC-POC) system, similar to drug dispensing systems, in an attempt to improve patient safety and reduce identification errors.

Nursing Safety Priority QSEN

Action Alert

The nurse who will be actually administering the blood products must be one of the two professionals comparing the patient's identification with the information on the blood component bag.

Examine the blood bag label, the attached tag, and the requisition slip to ensure that the ABO and Rh types are compatible with those of the patient. Check the expiration date, and inspect the product for discoloration, gas bubbles, or cloudiness, which are all indicators of bacterial growth or hemolysis.

Transfusion Responsibilities

Before starting the transfusion, explain the procedure to the patient. Assess vital signs and temperature immediately before starting the infusion. Begin the infusion slowly. *Remain with the patient for the first 15 to 30 minutes.* Any severe reaction usually occurs with infusion of the first 50 mL of blood. Ask the patient to report unusual sensations such as chills, shortness of breath, hives, or itching. Assess vital signs 15 minutes after starting the infusion for indications of a reaction. If there are none, the rate can be increased to transfuse 1 unit in 2 hours (depending on the patient's cardiac status and the facility's policy for rate of administration). Take vital signs every hour during the transfusion or as

specified by the agency's policy. Some facilities are now continuously monitoring patients during transfusions using a wireless remote monitoring device (Card et al., 2012).

Blood components without large amounts of RBCs can be infused more quickly. The identification checks are the same as for RBC transfusions. It may be necessary to infuse blood products at a slower rate for older patients. Best practices related to the nursing care needs of older patients during transfusion therapy are listed in Chart 40-13.

Chart 40-13 Best Practice for Patient Safety & Quality Care QSEN

The Older Adult Receiving a Transfusion

- Assess the patient's circulatory, kidney, and fluid status before initiating the transfusion.
- Use no larger than a 19-gauge needle.
- Try to use blood that is less than 1 week old. (Older blood cell membranes are more fragile, break easily, and release potassium into the circulation.)
- Take vital signs (especially pulse, blood pressure, and respiratory rate) every 15 minutes throughout the transfusion. Changes in these parameters can indicate fluid overload and may also be the only indicators of adverse transfusion reactions.
  - Overload
    - Rapid bounding pulse
    - Hypertension
    - Swollen superficial veins
  - Transfusion Reaction
    - Rapid thready pulse
    - Hypotension
    - Increased pallor, cyanosis
- Administer blood slowly, taking 2 to 4 hours for each unit of whole blood, packed red blood cells, or plasma.
- Avoid concurrent fluid administration into any other IV site.
- If possible, allow 2 full hours after the administration of 1 unit of blood before administering the next unit.

Electrolyte imbalances are possible as a result of transfusions, especially with packed red blood cells or with whole blood. During transfusions, some cells are damaged, releasing potassium and raising

the patient's serum potassium level above normal (hyperkalemia). This problem is more likely when the blood being transfused has been frozen or is several weeks old.

Types of Transfusions

At one time, transfusion with whole blood was the most common form of transfusion therapy. Today, whole-blood transfusions are extremely rare (AABB [formerly called the American Association of Blood Banks], 2013). When a whole-blood donation is made, it is centrifuged on arrival at the blood-banking facility and separated in to various components. The individual components are then transfused according to patients' specific needs.

Red Blood Cell Transfusions

RBCs are given to replace cells lost from trauma or surgery. Patients with problems that destroy RBCs or impair RBC maturation also may receive RBC transfusions. Packed RBCs, supplied in 250-mL bags, are a concentrated source of RBCs and are the most common component given to RBC-deficient patients.

Blood transfusions are actually transplantations of tissue from one person to another. Therefore the donor and recipient blood must be carefully checked for compatibility to prevent lethal reactions (Table 40-7). Compatibility is determined by two different antigen systems (cell surface proteins): the ABO system antigens and the Rh antigen, present on the membranes of RBCs.

TABLE 40-7

Compatibility Chart for Red Blood Cell Transfusions

DONOR	RECIPIENT			
	A	B	AB	O
A	X		X	
B		X	X	
AB			X	
O	X	X	X	X

RBC antigens are inherited. For the ABO system, a person inherits one of these:

- A antigen (type A blood)
- B antigen (type B blood)
- Both A and B antigens (type AB blood)

• Neither A nor B antigens (type O blood)

People develop circulating antibodies against the blood type antigens they did not inherit. For example, a person with type A blood forms antibodies against type B blood. A person with type O blood has not inherited either A or B antigens and will form antibodies against RBCs with either A or B antigens. If RBCs that have an antigen are infused into a recipient who does not share that antigen, the infused blood is recognized by the recipient's antibodies as non-self and the recipient then has a reaction to the transfused products.

The Rh antigen system is slightly different. An Rh-negative person is born without the Rh-antigen on his or her RBCs and does not form antibodies unless specifically sensitized to it. Sensitization can occur with RBC transfusions from an Rh-positive person or from exposure during pregnancy and birth. Once an Rh-negative person has been sensitized and antibodies develop, any exposure to Rh-positive blood can cause a transfusion reaction. Antibody development can be prevented by giving anti-Rh-immunoglobulin (RHoGAM) as soon as exposure to the Rh antigen is suspected. *People who have Rh-positive blood can receive an RBC transfusion from an Rh-negative donor, but Rh-negative people should not receive Rh-positive blood.*

Platelet Transfusions

Platelets are given to patients with platelet counts below 10,000/mm^3 and to patients with thrombocytopenia who are actively bleeding or are scheduled for an invasive procedure. Platelet transfusions are pooled from as many as 10 donors and do not have to be of the same blood type as the patient has. For patients who are having a hematopoietic stem cell transplantation (HSCT) or who need multiple platelet transfusions, platelets from a single donor may be prescribed, which reduces the chances of allergic reactions.

Platelet infusion bags usually contain 300 mL for pooled platelets and 200 mL for single-donor platelets. Platelets are fragile and must be infused immediately after being brought to the patient's room, usually over a 15- to 30-minute period. A special transfusion set with a smaller filter and shorter tubing is used. Additional platelet filters help remove white blood cells (WBCs) from the platelets for patients who have a history of febrile reactions or who need multiple platelet transfusions.

Nursing Safety Priority QSEN

Action Alert

When infusing platelets, do not use the standard blood administration set because the filter traps the platelets and the longer tubing increases platelet adherence to the lumen.

Take the vital signs before the infusion, 15 minutes after the infusion starts, and at its completion. A patient who has had a transfusion reaction in the past may be given diphenhydramine (Benadryl) and acetaminophen (Tylenol) before the transfusion to reduce the fever and severe chills (rigors) that often occur during platelet transfusions.

Plasma Transfusions

Plasma infusions may be given fresh to replace blood volume and clotting factors. More often, plasma is frozen immediately after donation, forming **fresh frozen plasma (FFP)**. Infuse FFP immediately after thawing while the clotting factors are still active.

ABO compatibility is required for transfusion of plasma products because the plasma contains the donor's ABO antibodies that could react with the recipient's RBC antigens. The infusion bag contains about 200 mL. Infuse FFP as rapidly as the patient can tolerate, generally over a 30- to 60-minute period, through a regular Y set or straight filtered tubing.

Granulocyte (White Blood Cell) Transfusions

Rarely, neutropenic patients with infections receive white blood cell (WBC) replacement transfusions. WBC surfaces have many antigens that can cause severe reactions when infused into a patient whose immune system recognizes these antigens as non-self.

WBCs are suspended in 400 mL of plasma and should be infused slowly, usually over a 45- to 60-minute period depending on the concentration of cells being infused. Agency policies often require stricter monitoring of patients receiving WBCs because reactions are more common. A physician may need to be present in the hospital unit, and vital signs may need to be taken every 15 minutes throughout the transfusion. Amphotericin B infusion should be separated from WBC transfusions by 4 to 6 hours.

Acute Transfusion Reactions

Patients can develop any of these transfusion reactions: febrile, hemolytic, allergic, or bacterial reactions; circulatory overload; or

transfusion-associated graft-versus-host disease (GVHD). To prevent complications, remain alert during transfusions to detect early reactions and initiate appropriate management.

Febrile transfusion reactions occur most often in the patient with anti-WBC antibodies, which can develop after multiple transfusions, white blood cell transfusions, and platelet transfusions. The patient develops chills, tachycardia, fever, hypotension, and tachypnea. Giving leukocyte-reduced blood or single-donor HLA-matched platelets reduces the risk for this type of reaction. WBC filters may be used to trap WBCs and prevent their infusion into the patient.

Hemolytic transfusion reactions are caused by blood type or Rh incompatibility. When blood containing antigens different from the patient's own antigens is infused, antigen-antibody complexes are formed in his or her blood. These complexes destroy the transfused cells and start inflammatory responses in the blood vessel walls and organs. The reaction may be mild, with fever and chills, or life threatening, with disseminated intravascular coagulation (DIC) and circulatory collapse (McCance et al., 2014). Other manifestations include:

- Apprehension
- Headache
- Chest pain
- Low back pain
- Tachycardia
- Tachypnea
- Hypotension
- Hemoglobinuria
- A sense of impending doom

The onset of a hemolytic reaction may be immediate or may not occur until subsequent units have been transfused (Kessler et al., 2012).

Allergic transfusion reactions (anaphylactic transfusion reactions) are most often seen in patients with other allergies. They may have urticaria, itching, bronchospasm, or anaphylaxis. Onset usually occurs during or up to 24 hours after the transfusion. Patients with an allergy history can be given leukocyte-reduced or washed RBCs in which the WBCs, plasma, and immunoglobulin A have been removed, reducing the possibility of an allergic reaction.

Bacterial transfusion reactions occur from infusion of contaminated blood products, especially those contaminated with a gram-negative organism. Manifestations include tachycardia, hypotension, fever, chills, and shock. The onset of a bacterial transfusion reaction is rapid. (See Chapter 37 for care of the patient with septic shock.)

Circulatory overload can occur when a blood product is infused too quickly, especially in an older adult. This is most common with whole-blood transfusions or when the patient receives multiple packed RBC transfusions. Manifestations include:

- Hypertension
- Bounding pulse
- Distended jugular veins
- Dyspnea
- Restlessness
- Confusion

You can both manage and prevent this complication by monitoring intake and output, infusing blood products more slowly, and giving diuretics. (See Chapter 11 for management of patients with fluid overload.)

Transfusion-associated graft-versus-host disease (TA-GVHD) is a rare but life-threatening problem that occurs more often in an immunosuppressed patient. Its cause in immunosuppressed patients is similar to that of GVHD that occurs with allogeneic stem cell transplantation, discussed on p. 811, in which donor T-cell lymphocytes attack host tissues.

Manifestations usually occur within 1 to 2 weeks and include thrombocytopenia, anorexia, nausea, vomiting, chronic hepatitis, weight loss, and recurrent infection.

TA-GVHD has an 80% to 90% mortality rate but can be prevented by using irradiated blood products. Irradiation destroys T-cells and their cytokine products.

Transfusion-related acute lung injury (TRALI) is a life-threatening event that occurs most often when donor blood contains antibodies against the recipient's neutrophil antigens, HLA, or both (Kessler et al., 2012). Common manifestations are a rapid onset of dyspnea and hypoxia within 6 hours of the transfusion.

Acute pain transfusion reaction or APTR is a recently identified but rare event that can occur during or shortly after transfusion of any blood product. Its actual pathophysiology has not yet been elucidated. The manifestations are severe chest pain, back pain, joint pain, hypertension, and redness of the head and neck (Hardwick et al., 2013). Most patients also have anxiety. The reaction does not appear to be life threatening, and most patients respond well with drugs for pain and rigors. Although the manifestations are general, diagnosis can be supported with a positive direct antibody test (DAT), indicating that some degree of hemolysis has occurred but is not widespread. APTR management focuses on patient

support and drugs to control or reduce manifestations.

Interventions for transfusion reactions occurring during transfusion (hemolytic reactions, allergic reactions, and bacterial reactions) begin with stopping the transfusion and removing the blood tubing. (For hemolytic and suspected bacterial reactions, return the component bag, labels, and all tubing to the blood bank or laboratory.) Notify the Rapid Response Team. If the patient has no other IV access, keep the access and flush with normal saline. *Do not flush the contents of the blood transfusion tubing, which would allow more of the reaction-causing blood to enter the patient.* Usually oxygen is applied and diphenhydramine (Benadryl) is administered by IV push. If manifestations of shock are present, fluid resuscitation and hemodynamic monitoring are needed. Blood pressure support with vasopressors may be needed (see Chapter 37). Other drug therapy is supportive, such as antipyretics for fever, antibiotics for suspected bacterial contamination, and meperidine for rigors.

Autologous Blood Transfusions

Autologous blood transfusions involve collection and infusion of the patient's own blood. This type of transfusion eliminates compatibility problems and reduces the risk for transmitting bloodborne diseases. The four types of autologous blood transfusions are preoperative autologous blood donation, acute normovolemic hemodilution, intraoperative autologous transfusion, and postoperative blood salvage.

Autologous blood donation before surgery is the most common type of autologous blood transfusion. It involves collecting whole blood from the patient (who must meet certain criteria), dividing it into components, and storing it for later use. As long as hematocrit and hemoglobin levels are within a safe range, the patient can donate blood on a weekly basis until the prescribed amount of blood is obtained. Fresh packed RBCs may be stored for 40 days. For patients with rare blood types, blood may be frozen for up to 10 years.

Acute normovolemic hemodilution involves withdrawal of a patient's RBCs and volume replacement just before a surgical procedure. The goal is to decrease RBC loss during surgery. The blood is stored at room temperature for up to 6 hours and reinfused after surgery. This type of autologous transfusion is not used with anemic patients or those with poor kidney function.

Intraoperative autologous transfusion and blood salvage after surgery are the recovery and reinfusion of a patient's own blood from an operative field or from a bleeding wound. Special devices collect, filter, and drain the blood into a transfusion bag. This blood is used for trauma

or surgical patients with severe blood loss. The salvaged blood must be reinfused within 6 hours.

Transfuse autologous blood products using the guidelines previously described. Although the patient receiving autologous blood is not at risk for some types of transfusion reactions, circulatory overload or bacterial transfusion reactions can still occur and are managed in the same way they are managed in transfusions derived from donors.

NCLEX Examination Challenge

Safe and Effective Care Environment

The nurse who just came on duty observes that the client, whose blood type is AB negative, is receiving a transfusion with type O negative packed red blood cells. What is the nurse's best first action?
A Call the blood bank.
B Take and record the client's vital signs.
C Stop the transfusion and keep the IV open.
D Document the observation as the only action.

Nursing Concepts and Clinical Judgment Review

What might you NOTICE if the patient is experiencing inadequate gas exchange and perfusion as a result of hematologic problems?

- Skin cyanosis or pallor (in patients with light skin)
- Cyanosis or pallor of the lips and oral mucous membranes
- Tachycardia
- Tachypnea and dyspnea
- Slow capillary refill
- Cool to cold extremities
- Change in cognition, acute confusion
- Decreased oxygen saturation
- Decreased urine output
- Presence of bruises or petechiae
- Bleeding of gums, at IV sites, at injection sites

What should you INTERPRET and how should you RESPOND to this patient experiencing inadequate gas exchange and perfusion as a result of a hematologic problem?

Perform and interpret physical assessment, including:

- Taking vital signs

- Monitoring oxygen saturation by pulse oximetry
- Checking for blood in stool, urine, emesis
- Checking for bleeding in the mouth, around IV sites, drains, urinary catheters
- Checking most recent laboratory values for hematocrit and hemoglobin levels and platelet and RBC counts
- Assessing cognition

Respond by:

- Applying oxygen
- Keeping the patient's head elevated to about 30 degrees
- Handling the patient gently
- Keeping the patient warm (blankets)
- Applying firm pressure to areas actively bleeding
- Notifying physician or Rapid Response Team
- Instituting Bleeding Precautions
- Maintaining or initiating IV therapy
- Preparing to administer blood or blood products
- Prioritizing and pacing activities to prevent fatigue

On what should you REFLECT?

- Observe patient for evidence of restored tissue perfusion (see Chapter 39)
- Think about what may have precipitated this episode and what steps could be taken to identify it earlier.

Get Ready for the NCLEX® Examination!

Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Use aseptic technique during all central line dressing changes or any invasive procedure. **Safety** QSEN
- Use good handwashing techniques before providing any care to a patient who is either immunocompromised or immune deficient. **Safety** QSEN
- Modify the environment to protect patients who have thrombocytopenia. **Safety** QSEN
- Use Bleeding Precautions for any patient with thrombocytopenia or pancytopenia (see Chart 40-7). **Safety** QSEN
- Ensure informed consent is obtained before any invasive procedure or transfusion. **Safety** QSEN
- Verify with another registered nurse prescriptions for transfusion of blood products. **Safety** QSEN
- Use at least two forms of identification for the patient who is to receive a blood product transfusion (e.g., name, birthdate, identification number). **Safety** QSEN

Health Promotion and Maintenance

- Teach patients with sickle cell disease to avoid conditions that are known to trigger crises. **Patient-Centered Care** QSEN
- Teach people to avoid unnecessary contact with environmental chemicals or toxins. If contact cannot be avoided, teach people to use safety precautions.
- Identify patients at high risk for infection because of disease or therapy. **Patient-Centered Care** QSEN
- Teach the patient and family about the manifestations of infection and when to seek medical advice. **Patient-Centered Care** QSEN
- Instruct patients who have anemia as a result of dietary deficiency which foods are good sources of iron, folic acid, and vitamin B_{12}. **Patient-Centered Care** QSEN
- Teach precautions to take to avoid injury (see Chart 40-11) to patients at risk for poor clotting and increased bleeding. **Patient-Centered Care** QSEN

Psychosocial Integrity

- Allow the patient the opportunity to express his or her feelings regarding the diagnosis of leukemia or lymphoma or the treatment regimen. **Patient-Centered Care** QSEN
- Explain all procedures, restrictions, drugs, and follow-up care to the patient and family. **Patient-Centered Care** QSEN
- Offer alternative therapies for relaxation, pain reduction, and distraction, such as massage, music therapy, and guided imagery. **Patient-Centered Care** QSEN
- Reassure patients having pain that using opioid analgesics for needed pain relief is not drug abuse. **Patient-Centered Care** QSEN

Physiological Integrity

- Pace nonurgent health care activities to reduce the risk for fatigue among patients with anemia or pancytopenia. **Patient-Centered Care** QSEN
- Assess patients in the induction phase of chemotherapy, those after HSCT, and anyone with neutropenia every 8 hours for manifestations of infection. **Evidence-Based Practice** QSEN
- Assess the skin integrity of the perianal region of a patient with leukemia or profound neutropenia after every bowel movement. **Patient-Centered Care** QSEN
- Administer analgesics on a schedule rather than PRN. **Evidence-Based Practice** QSEN
- Use normal saline as the solution infusing with blood products.
- Transfuse blood products more slowly to older patients or those who have a cardiac problem. **Patient-Centered Care** QSEN
- Remain with the patient during the first 15 minutes of infusion of any blood product. **Safety** QSEN
- Do not administer any drugs with infusing blood products. **Evidence-Based Practice** QSEN
- Make referrals to support groups sponsored by organizations such as the Sickle Cell Foundation Support Group, American Cancer Society, Leukemia and Lymphoma Society of America, and the National Hemophilia Foundation. **Teamwork and Collaboration** QSEN

UNIT X

Problems of Mobility, Sensory Perception, and Cognition: Management of Patients with Problems of the Nervous System

OUTLINE

Concept Overview: Mobility, Sensory Perception, and Cognition

The term *mobility* means movement. When referring to physical mobility, it means the ability of the body to purposely move (Giddens, 2013). Mobility is needed for ADL performance and many body functions, including digestion, elimination, circulation, and muscle integrity. In some cases, it helps keep a person *safe* by being able to move to prevent injury.

Mobility is accomplished primarily through the integration of the neurologic and musculoskeletal body systems. Risk factors for decreased mobility are typically acute and chronic health problems that cause pain or injury (Giddens, 2013).

Sensory perception refers to receiving sensory input from the cells of the skin (feeling), eyes (seeing), and ears (hearing) and accurately interpreting this input in the neurons of the central nervous system (CNS). Therefore sensory perception is also needed to keep the body *safe*. For example, if a person cannot feel water temperature, a burn may result. If vision is impaired, a fall may occur.

Cognition refers to mental processes and intellectual function and is controlled by certain neurons in the gray matter of the brain. These cells are very sensitive to serum glucose and oxygen levels. If either of these substances falls below the amounts needed, the cells cannot function properly, resulting in diminished cognitive ability and a decreased level of consciousness.

One or all of these three concepts may be impaired as a result of disease, injury, surgery, or drugs. Problems of the neurologic, sensory, and musculoskeletal systems most commonly affect the need for mobility, sensory perception, and cognition. The interrelationship of these concepts can be compared to a computer and its parts.

As seen in Fig. 1, the computer's central processing unit (CPU), or processor, is the brain of the machine (the *cognitive* center). Much like the spinal cord, it works with the motherboard to send and receive messages (input and output). The connected pins and wires function like the spinal nerves. Peripherals such as the mouse and keyboard are similar in function to the peripheral nervous system (PNS) (sensory perception) and musculoskeletal system (mobility). When all of these parts are working properly, the computer functions without any problems.

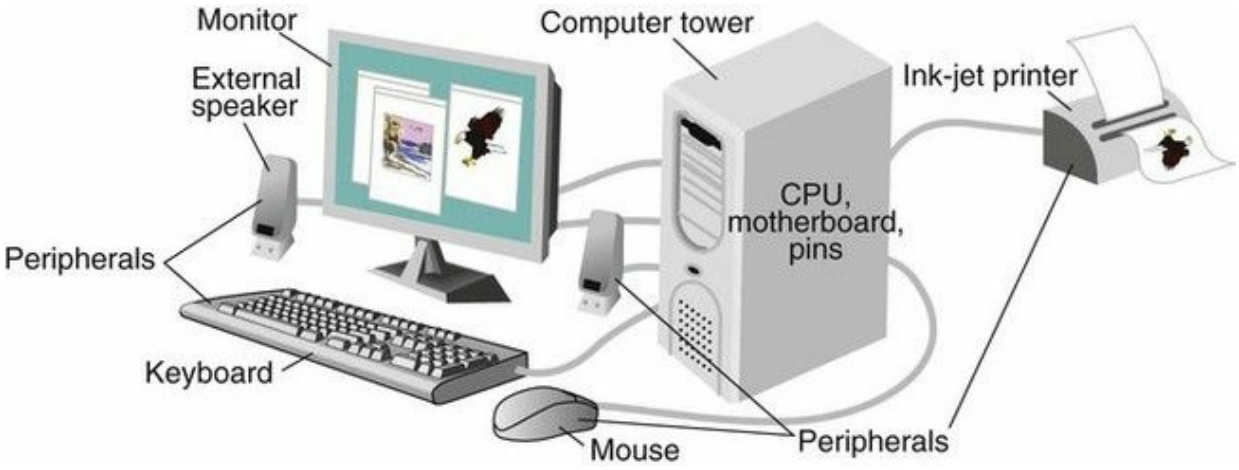

FIG. 1

However, when the CPU (brain) does not work properly (decreased cognition), the motherboard (spinal cord) and/or peripherals (PNS and muscles) may not function as they should (decreased mobility and sensory perception). If the motherboard (spinal cord) is broken, no information is sent to or from any of the other parts of the computer. In both cases, there is no display on the monitor (Fig. 2).

CHAPTER 41

Assessment of the Nervous System

Rachel L. Gallagher

PRIORITY CONCEPTS

- Cognition
- Mobility
- Sensory Perception

Learning Outcomes

Safe and Effective Care Environment

1. Collaborate with health care team members to establish priorities in neurologic assessment.

Health Promotion and Maintenance

2. Identify factors such as risky behaviors or lifestyle choices that place patients at risk for neurologic health problems.
3. Detect neurologic health problems early with health screening and physical assessment strategies.

Psychosocial Integrity

4. Explain psychological responses to neurologic health problems.

Physiological Integrity

5. Document findings from the neurologic history and physical examination to identify new and chronic changes in cognition, mobility, and sensory perception.
6. Perform a comprehensive and a rapid focused neurologic examination to manage conditions and promote patient safety related to impaired

neurologic function.

7. Use interventions to provide assistance in the performance of activities of daily living when neurologic conditions interfere with self-care.
8. Reduce complications from diagnostic testing by determining risk factors for adverse reaction to contrast media.
9. Review neurologic anatomy and physiology to identify changes that result in health alterations.
10. Describe common physiologic changes associated with aging that affect the nervous system.

 http://evolve.elsevier.com/Iggy/

The major divisions of the nervous system are the central nervous system (CNS) and peripheral nervous system (PNS). The PNS is further divided into the somatic and autonomic systems. These systems work together to control cognition, mobility, and sensory perception. The nervous system interacts with the endocrine system to balance fluid and electrolytes. In addition, through the autonomic nervous system (ANS), it innervates many other body systems including the reproductive and digestive organs to promote their function. For example, the sacral spinal nerves (part of the ANS) stimulate the detrusor muscle to contract when the urinary bladder is full, contributing to elimination.

Health problems involving trauma and diseases of the nervous system can impair fluid and electrolyte balance, thermoregulation, elimination, and many other functions. One of the earliest and most sensitive functions that signal new-onset brain disorders is cognition, a term used to refer to all the processes in human thought. The primary role of the nurse is to help restore these human needs or assist the patient adapt to their deficits and avoid complications from dysfunction.

Anatomy and Physiology Review

The CNS is composed of the brain and the spinal cord. The brain is contained within the cranium; the brain's role is to direct the regulation and function of the nervous system and other systems of the body. The spinal cord is lodged in the vertebral canal. From the brain, the spinal cord descends down the middle of the back and is surrounded and protected by the bony vertebral column. The spinal cord is surrounded by a clear fluid called *cerebrospinal fluid (CSF)* that protects the delicate nerve tissues against damage from banging against the inside of the vertebrae.

The PNS is composed of 12 pairs of cranial nerves, 31 pairs of spinal nerves, and the autonomic nervous system. The autonomic nervous system is further subdivided into sympathetic and parasympathetic fibers.

The nervous system contains two types of cells: neurons, which transmit or conduct nerve impulses; and neuroglia cells, which have an interdependent role with the neuron.

Nervous System Cells: Structure and Function

Two types of cells make up the nervous system: neurons and neuroglia cells. The basic unit of the nervous system, the **neuron**, transmits impulses, or "messages." Some neurons are **motor** (causing purposeful physical movement or mobility), and some are **sensory** (resulting in the ability to perceive stimulation through one's sensory organs or sensory perception). Some process information and some retain information. When a neuron receives an impulse from another neuron, the effect may be excitation or inhibition. Each neuron has a *cell body,* or *soma;* short, branching processes called *dendrites;* and a single *axon* (Fig. 41-1).

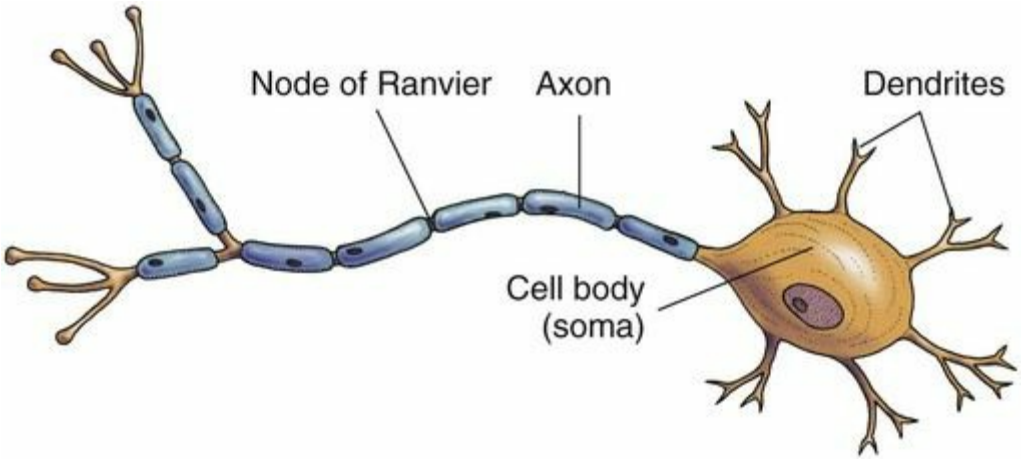

FIG. 41-1 The structure of a typical neuron.

Afferent neurons, also known as *sensory neurons,* are specialized to send impulses toward the CNS, away from the PNS. *Efferent* neurons are motor nerve cells that carry signals from the CNS to the cells in the PNS. Each dendrite synapses with another cell body, axon, or dendrite and sends impulses along the efferent and afferent neuron pathways.

Many axons are covered by a **myelin sheath**—a white, lipid covering. Myelinated axons appear whitish and therefore are also called **white matter.** Nonmyelinated axons have a grayish cast and are called **gray matter.** Myelinated axons have gaps in the myelin called *nodes of Ranvier.* The nodes of Ranvier play a major role in impulse conduction (see Fig. 41-1). When the myelin is impaired, the impulses cannot travel from the brain to the rest of the body, such as in patients with multiple sclerosis.

The enlarged distal end of each axon is called the *synaptic* or *terminal knob.* Within the synaptic knobs are the mechanisms for manufacturing, storing, and releasing a transmitter substance. Each neuron produces a specific **neurotransmitter** chemical (e.g., acetylcholine or serotonin) that can either enhance or inhibit the impulse but cannot do both. Other substances, although not specifically identified as neurotransmitters, are considered probable transmitters or neuromodulators.

Impulses are transmitted to their eventual destination through synapses, or spaces between neurons. There are two distinct types of synapses: *neuron to neuron* and *neuron to muscle* (or gland). Between the terminal knob and the next cell is a small space called the *synaptic cleft.* The knob, the cleft, and the portion of the cell to which the impulse is being transmitted make up the **synapse.**

Neuroglia cells, which vary in size and shape, provide protection, structure, and nutrition for the neurons. They are classified into four types: astroglial cells, ependymal cells, oligodendrocytes, and microglial cells. These cells are also part of the blood-brain barrier and help

regulate cerebrospinal fluid (CSF).

Central Nervous System: Structure and Function

The central nervous system (CNS) is composed of the *brain,* which directs the regulation and function of the nervous system and all other systems of the body, and the *spinal cord,* which starts reflex activity and transmits impulses to and from the brain.

Brain

The **meninges** form the protective covering of the brain and the spinal cord. The outside layer is the *dura mater.* The **subdural space** is located between the dura mater and the middle layer, the *arachnoid.* The *pia mater* is the most inner layer. Situated between the arachnoid and pia mater is the **subarachnoid space,** where CSF circulates. A potential space, referred to as the *epidural space,* is located between the skull and the outer layer of the dura mater. This area also extends down the spinal cord and is used for the delivery of epidural analgesia and anesthesia.

The dura mater also lies between the cerebral hemispheres and the cerebellum and is called the *tentorium.* It helps decrease or prevents the transmission of force from one hemisphere to another and protects the lower brainstem when head trauma occurs. Clinical references may be made to a lesion (e.g., a tumor) as being **supratentorial** (above the tentorium) or **infratentorial** (below the tentorium).

Major Parts of the Brain.

The brain consists of three main areas—the brainstem, the cerebellum, and the forebrain. The *brainstem* connects the rest of the brain with the CNS. It is concerned primarily with life support and basic functions such as movement.

The *cerebellum* is concerned with coordination of movement and works together with the brainstem to focus on the functionality of the muscles. This structure is found below the occipital lobe and adjacent to the brainstem.

The *forebrain* lies above the brainstem and cerebellum and is the most advanced in evolution. This area of the brain is further divided into three areas—the diencephalon, the cerebrum, and the cerebral cortex.

The *diencephalon,* which lies below the cerebrum, includes the thalamus, hypothalamus, and epithalamus (Fig. 41-2). The **thalamus** is the major "relay station," or "central switchboard," for the CNS. The **hypothalamus** plays a major role in autonomic nervous system control

(controlling temperature and other functions) and cognition. The epithalamus contains the roof of the third ventricle and the pineal gland. The epithalamus connects the pathways to regulate emotion. Pathways through the epithalamus also contribute to smooth voluntary motor function.

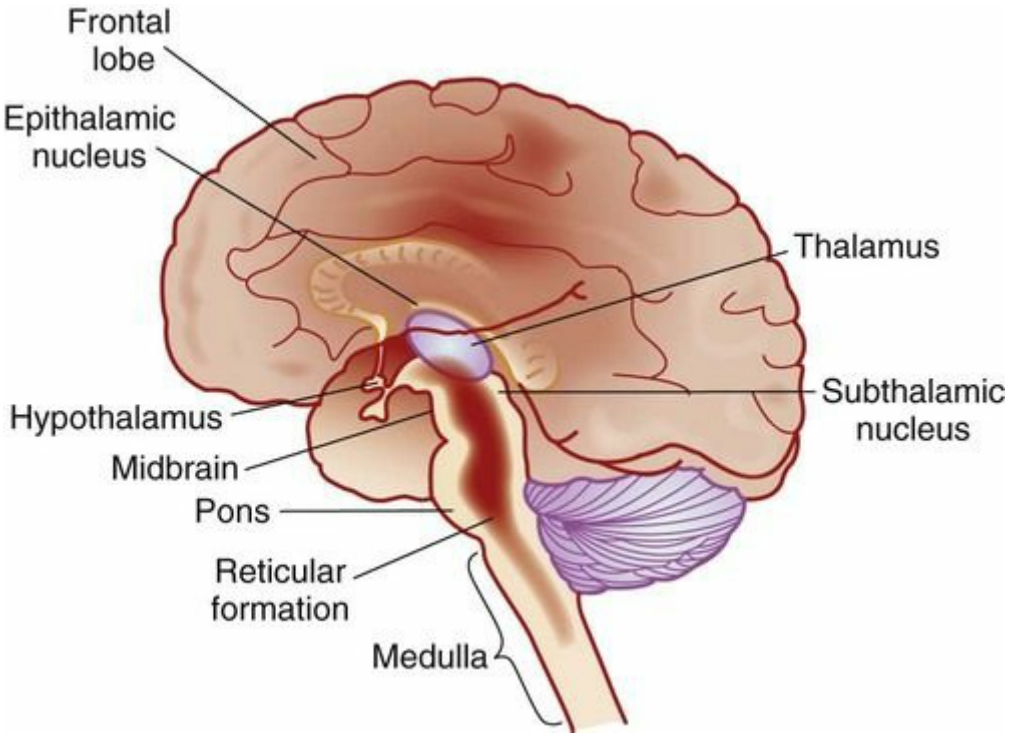

FIG. 41-2 The structures of the brainstem and diencephalon.

The *cerebrum* is the largest part of the brain and controls intelligence, creativity, and memory. The "gray matter" of the cerebrum is the central cortex—the center that receives information from the thalamus and all the lower areas of the brain. The cerebrum consists of two halves, referred to as the *right hemisphere* and the *left hemisphere,* which are joined by the corpus callosum. The *left* hemisphere is the dominant hemisphere in most people (even in many left-handed people). Within the deeper structures of the cerebrum are the right and left lateral ventricles. At the base of the cerebrum near the ventricles is a group of neurons called the *basal ganglia,* which help regulate motor function.

The *cerebral cortex* is part of the cerebrum and is involved with almost all of the higher functions of the brain. This part of the brain processes and communicates all information coming from the peripheral nervous system (PNS). It also translates the impulses into understandable feelings and thoughts. The cerebral cortex is so complex that it is further divided into four lobes—the frontal lobe, parietal lobe, temporal lobe, and occipital lobe.

The frontal lobe is found at the front of the head near the temples and forehead. It processes voluntary muscle movements and higher functioning actions such as thought and speech. It also helps control mood, planning for the future, setting goals, and making judgments. The parietal lobe is found behind the frontal lobe. It processes spatial awareness and receives and processes information about temperature, taste, touch, and movement coming from the rest of the body. Reading and arithmetic are also processed in this lobe. The temporal lobes are located in the area of the brain parallel to the ears. They process hearing, memory, and language functions. The occipital lobe is located in the posterior of the brain and assists in the processing of visual information.

Located in the frontal lobe, the **motor cortex** controls voluntary movement. Corticospinal tracts, also called *pyramidal tracts,* begin in the motor cortex and travel through the brain before crossing in the medulla. This crossing explains how right motor cortex damage affects the movement in the left side of the body and vice versa, such as in many patients who have cerebral strokes. The cerebrum is divided into lobes by sulci (fissures). These lobes work together and are connected by nerve fibers. The name and main functions of cerebral lobes are listed in Table 41-1.

TABLE 41-1

Cerebral Lobe Main Functions

Frontal Lobe
• The primary motor area (also known as the *motor "strip"* or *cortex*) • Broca's speech center on the dominant side • Voluntary eye movement • Access to current sensory data • Access to past information or experience • Affective response to a situation • Regulates behavior based on judgment and foresight • Judgment • Ability to develop long-term goals • Reasoning, concentration, abstraction
Parietal Lobe
• Understand sensory input such as texture, size, shape, and spatial relationships • Three-dimensional (spatial) perception • Important for singing, playing musical instruments, and processing nonverbal visual experiences • Perception of body parts and body position awareness • Taste impulses for interpretation
Temporal Lobe
• Auditory center for sound interpretation • Complicated memory patterns • Wernicke's area for speech
Occipital Lobe
• Primary visual center
Limbic Lobe
• Emotional and visceral patterns connected with survival • Learning and memory

Two important speech areas of the cerebrum are Broca's area and Wernicke's area. **Broca's area** (speech area), also located in the frontal lobe, is responsible for the formation of words, or speech. **Wernicke's area** (language area) is located in the temporal lobe and allows processing of words into coherent thought and understanding of written or spoken words.

The *hypophysis (pituitary gland)* has two lobes, each releasing specific hormones into the circulation under the regulation of the hypothalamus. The pituitary is often referred to as the "master gland" because of its control of numerous hormonal functions. However, the hypothalamus actually controls its functions.

The *cerebellum* receives immediate and continuous information about the condition of the muscles, joints, and tendons. Cerebellar function enables a person to:

- Keep an extremity from overshooting an intended target
- Move from one skilled movement to another in an orderly sequence
- Predict distance or gauge the speed with which one is approaching an object
- Control voluntary movement

• Maintain equilibrium

Unlike the motor cortex, cerebellar control of the body is **ipsilateral** (situated on the same side). The right side of the cerebellum controls the right side of the body, and the left cerebellum controls the left side of the body.

The brainstem includes the midbrain, pons, and medulla. The functions of these structures are presented in Table 41-2. Throughout the brainstem are special cells that constitute the **reticular activating system (RAS),** which controls awareness and alertness. For example, this tissue awakens a person from sleep when presented with a stimulus such as loud noise or pain or when it is time to awaken. The reticular formation area has many connections with the cerebrum, the rest of the brainstem, and the cerebellum.

TABLE 41-2

Brainstem Functions

Medulla
• Cardiac-slowing center • Respiratory center • Cranial nerves IX (glossopharyngeal), X (vagus), XI (accessory), and XII (hypoglossal) emerge from the medulla, as do portions of cranial nerves VII (facial) and VIII (vestibulocochlear)
Pons
• Cardiac acceleration and vasoconstriction centers • Pneumotaxic center helps control respiratory pattern and rate • Four cranial nerves originate from the pons: V (trigeminal), VI (abducens), VII (facial), and VIII (vestibulocochlear)
Midbrain
• Contains the cerebral aqueduct or aqueduct of Sylvius • Location of periaqueductal gray, which may abolish pain when stimulated • Cranial nerve nuclei III (oculomotor) and IV (trochlear) located here

Circulation in the Brain.

Circulation in the brain originates from the carotid and vertebral arteries (Fig. 41-3). The internal carotid arteries branch into the anterior cerebral artery (ACA) and middle cerebral artery (MCA), the largest ones. The two posterior vertebral arteries become the basilar artery, which then divides into two posterior cerebral arteries. The anterior, middle, and posterior cerebral arteries are joined together by small communicating arteries to form a ring at the base of the brain known as the **circle of Willis.**

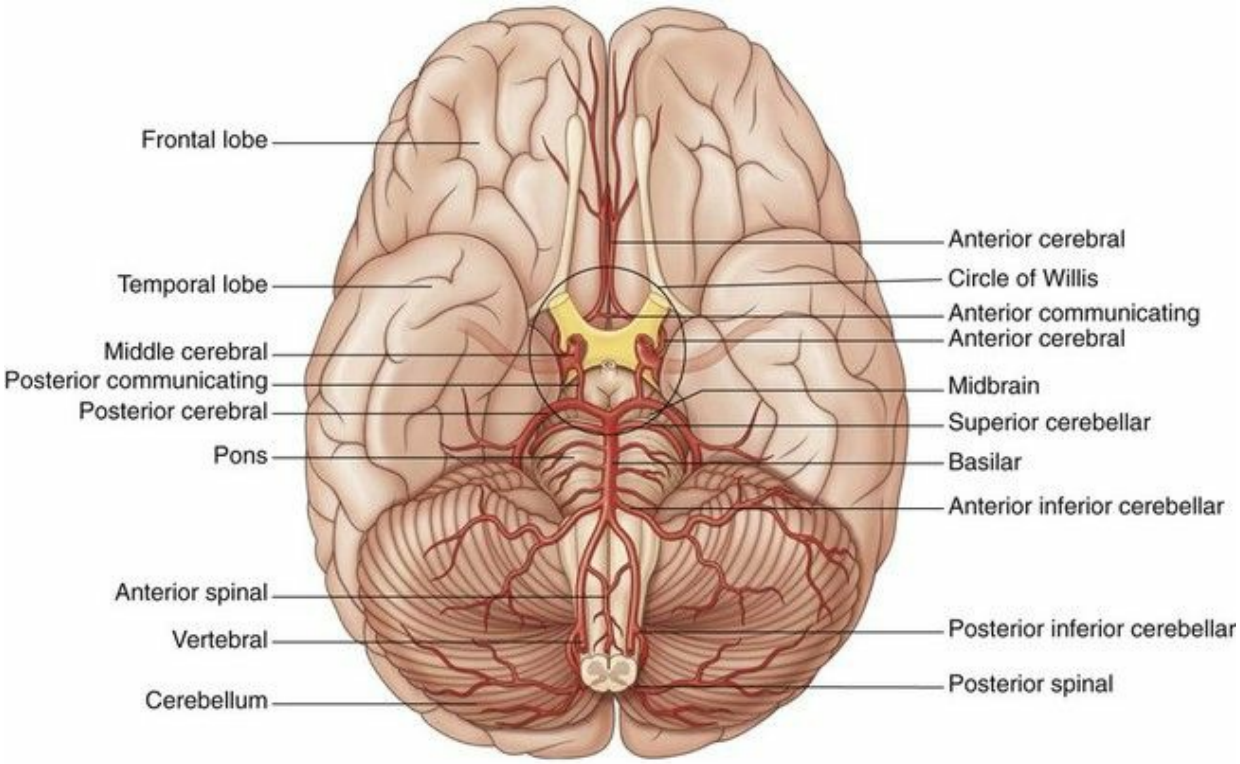

FIG. 41-3 Cerebral circulation and the circle of Willis at the base of the brain.

The *middle* cerebral artery supplies the lateral surface of the cerebrum from about the mid-temporal lobe upward (i.e., the area for hearing and upper body motor and sensory neurons). The *anterior* cerebral artery supplies the midline, or medial, aspect of the same area (i.e., the lower body motor and sensory neurons). The *posterior* cerebral arteries supply the area from the mid-temporal region down and back (occipital lobe), as well as much of the brainstem. When blood flow is interrupted in any of these arteries (e.g., by a clot), the area of the brain being supplied is affected and may not function as it should.

The *blood-brain barrier (BBB)* seems to exist because the endothelial cells of the cerebral capillaries are joined tightly together. This barrier keeps some substances in the bloodstream out of the cerebrospinal circulation and out of brain tissue. Substances that can pass through the BBB include oxygen, glucose, carbon dioxide, alcohol, anesthetics, and water. Large molecules such as albumin, any substance bound to albumin, and many antibiotics are prevented from crossing the barrier.

Cerebrospinal fluid (CSF) also circulates, surrounds, and cushions the brain and spinal cord. While moving through the subarachnoid space, the fluid is continuously produced by the choroid plexus, reabsorbed by the arachnoid villi, and then channeled into the superior sagittal sinus. Expanded areas of subarachnoid space, where there are large amounts of CSF, are called *cisterns*. The largest one is the lumbar cistern, the site of

lumbar puncture, from the level of the second lumbar vertebra to the second sacral vertebra (L2-S2).

Spinal Cord

The spinal cord controls body movement (mobility); regulates organ function; processes sensory information from the extremities, trunk, and many internal organs; and transmits information to and from the brain. It contains H-shaped **gray matter** (neuron cell bodies) that is surrounded by **white matter** (myelinated axons). The white matter is divided into posterior, lateral, and anterior columns. Groups of cells in the white matter (ascending and descending tracts) have been fairly well identified (Fig. 41-4).

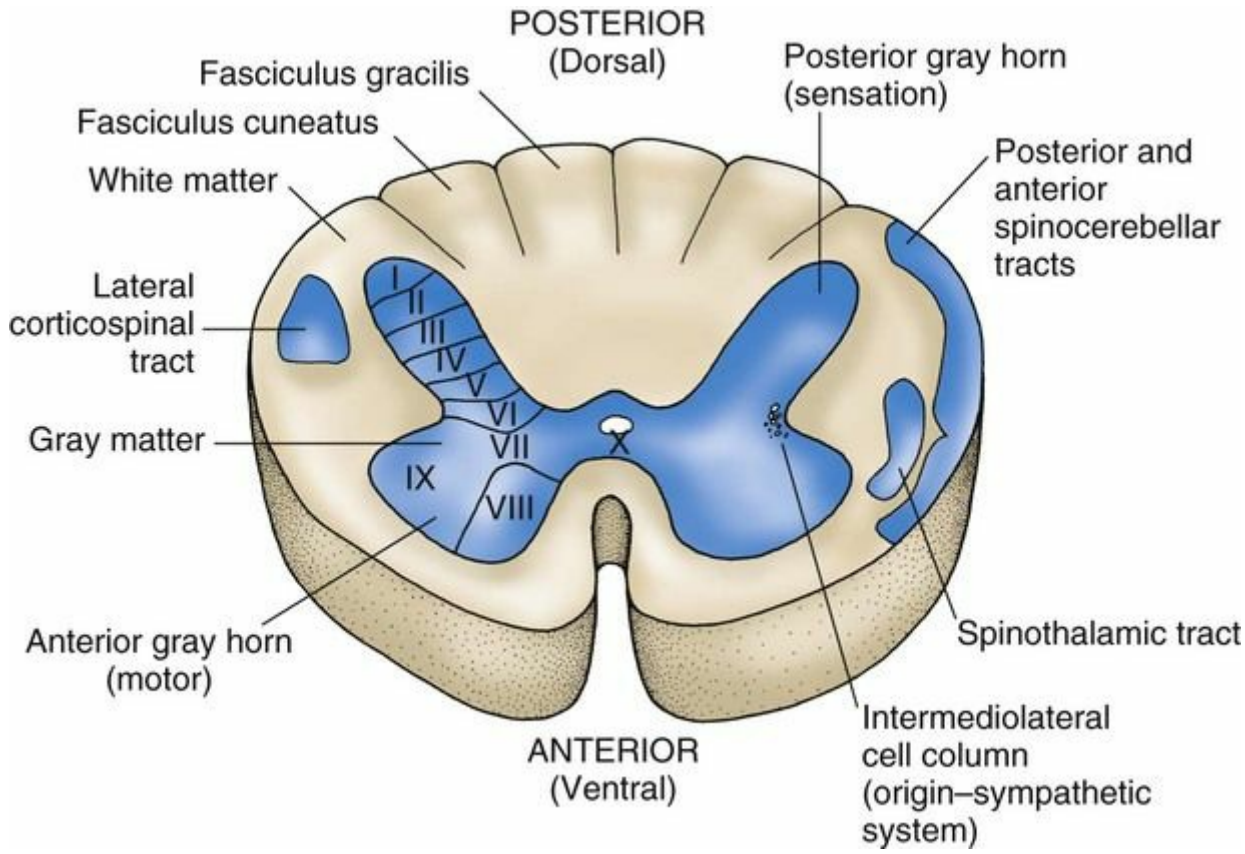

FIG. 41-4 A cross section of the spinal cord showing the common tracts.

Ascending Tracts.

Ascending tracts originate in the spinal cord and end in the brain. Three groups of ascending tracts are important for understanding the patient with neurologic problems: spinothalamic tracts, spinocerebellar tracts, and fasciculi gracilis and cuneatus (posterior white columns).

As the name indicates, *spinothalamic* tracts begin in the spinal cord with most ending in the thalamus. These tracts carry sensory perception of pain, temperature, light touch, and pressure. The axon fibers from the cells cross to the opposite side and then continue up to the thalamus. Some branches end in the medulla and pons.

Spinocerebellar tracts begin in the spinal cord and end in the cerebellum. The *posterior* spinocerebellar tract transmits impulses of **proprioception** (awareness of position and movements of body parts) or movement, mostly from the lower extremities. The impulses enter the posterior gray horn and synapse with tracts contained in the spinal cord. Spinocerebellar axons then connect on the *same,* or ipsilateral, side. These axons begin at the second lumbar level and ascend to the medulla and then, with additional synapses to neurons, to the cerebellum.

The *anterior* spinocerebellar tract begins lower in the lumbar spine than does the posterior tract. These fibers cross immediately and ascend as an opposite-side tract, transmitting proprioceptive impulses from the lower extremities. The fibers cross again in the midbrain on their way to the cerebellum. Because these fibers have crossed the midline twice, the sensations end on the side on which they started.

The *posterior white columns* transmit this information to the thalamus:

- The sensory perception of the position, location, and proprioception or orientation and movement of the body and its parts including muscles, joints, and tendons
- Vibratory sense
- Light touch from the skin
- Localization

Most of the fibers ascend on the *same* side as their origin to the medulla, where they cross and then synapse in the thalamus, with termination in the parietal lobe. This tract allows a person to feel an exact point of pressure on the skin. Recognition of pressure includes the shape of an object (with eyes closed), movement across the skin (a number being written), and awareness of two points of touch close together (two-point discrimination).

Descending Tracts.

Descending tracts *begin* in the brain and *end* in the spinal cord. The major descending tract of importance for understanding neurologic problems is the lateral *corticospinal,* or *pyramidal,* tract. The corticospinal tract originates in the motor cortex of the frontal lobe and portions of the parietal lobe. The lateral tract fibers cross to the opposite side at the level of the medulla. After crossing, the fibers descend and synapse with

interneurons of the gray matter in the spinal cord. These few fibers connect directly with lower motor neurons (LMNs). The cervical spine has a high concentration of fibers synapsing with interneurons, which possibly reflects the complexity of hand and finger movements.

The motor neurons of the other descending tracts and the basal ganglia used to be referred to as an *extrapyramidal system*. It was thought that pyramidal neurons caused voluntary muscle activity and that extrapyramidal neurons caused automatic or involuntary muscle action. However, all of the descending tracts and the basal ganglia are necessary for mobility. The term *extrapyramidal* is still often used clinically, meaning *abnormal spontaneous movement.*

Peripheral Nervous System: Structure and Function

The peripheral nervous system (PNS) is composed of the spinal nerves, cranial nerves, and autonomic nervous system.

There are 31 pairs of spinal nerves (8 cervical, 12 thoracic, 5 lumbar, 5 sacral, and 1 coccygeal) exiting from the spinal cord. Each of the nerves has a posterior and an anterior branch. The posterior branch carries sensory information (sensory perception) to the cord *(afferent pathway).* The anterior branch transmits motor impulses (mobility) to the muscles of the body *(efferent pathway).*

Each spinal nerve is responsible for the muscle innervation and sensory reception of a given area of the body. The cervical and thoracic spinal nerves are relatively close to their areas of responsibility, whereas the lumbar and sacral spinal nerves are some distance from theirs. Because the spinal cord ends between L1 and L2, the axons of the lumbar and sacral cord extend downward before exiting at the appropriate intervertebral foramen. The area controlled by each spinal nerve is roughly reflected in the dermatomes. **Dermatomes** represent sensory input from spinal nerves to specific areas of the skin (Fig. 41-5). For example, the patient with an injury to cervical spinal nerves C6 and C7 has sensory changes in the thumb, index finger, middle finger, middle of the palm, and back of the hand.

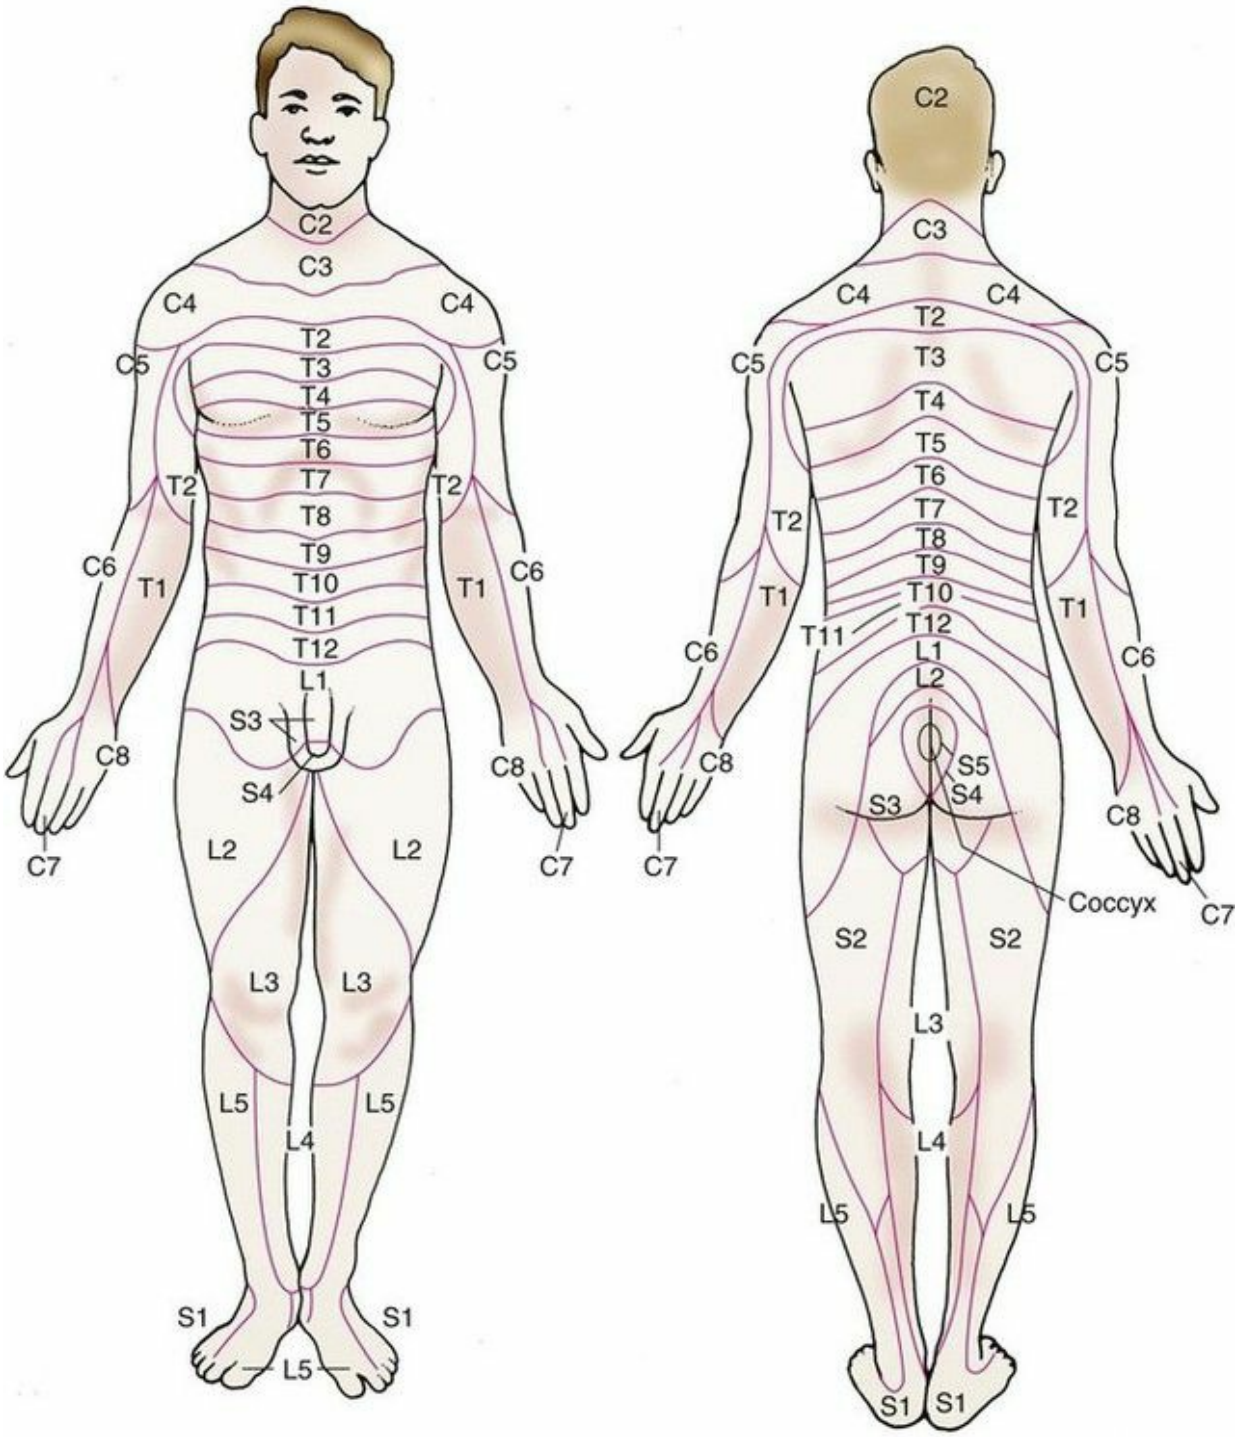

FIG. 41-5 Dermatomes (cutaneous innervation of spinal nerves). *C,* Cervical; *L,* lumbar; *S,* sacral; *T,* thoracic.

Sensory receptors throughout the body monitor and transmit impulses of pain, temperature, touch, vibration, pressure, visceral sensation, and proprioception. Sensory receptors also monitor and transmit the sensory perceptions of the special senses—vision, taste, smell, and hearing.

The cell bodies of the anterior spinal nerves are located in the anterior gray matter (anterior horn) of each level in the spinal cord. The anterior motor neurons are also referred to as *lower motor neurons.* As each nerve axon leaves the spinal cord, it joins other spinal nerves to form **plexuses**

(clusters of nerves). Plexuses continue as trunks, divisions, and cords and finally branch into individual peripheral nerves.

The **reflex arc** is a closed circuit of spinal and peripheral nerves and therefore requires no control by the brain (Fig. 41-6).

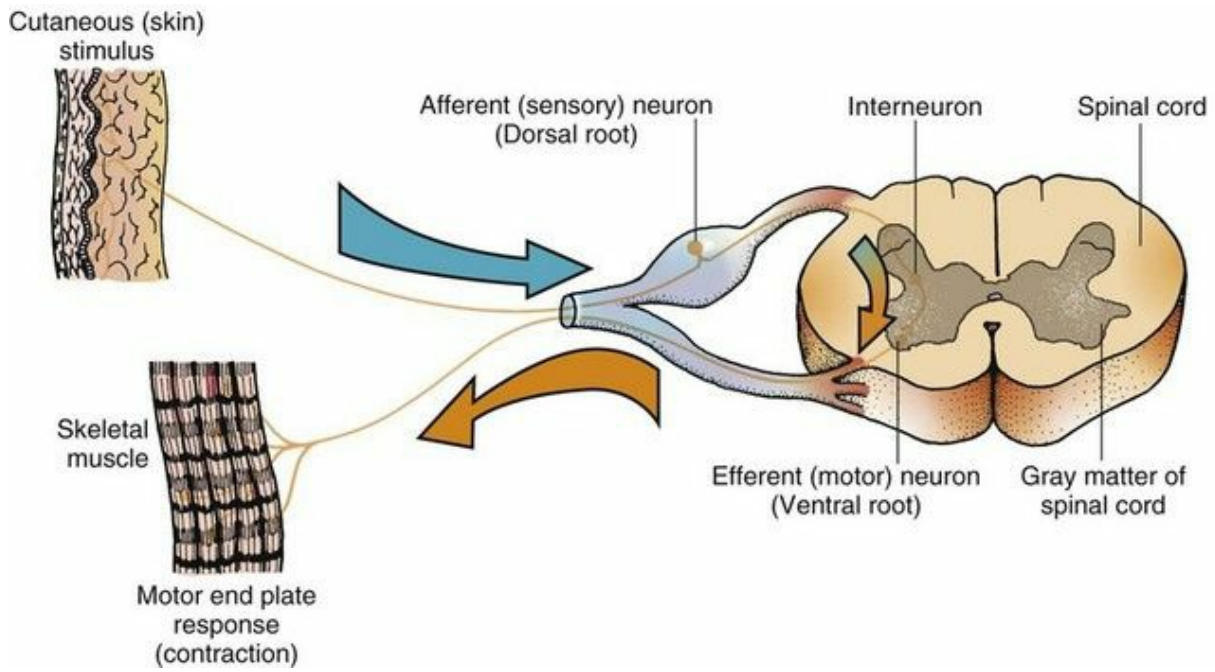

FIG. 41-6 An example of reflex activity. Stimulation of skin results in involuntary muscle contraction (reflex arc).

Reflexes consist of sensory input from:

- Skeletal muscles, tendons, skin, organs, and special senses
- Small cells in the spinal cord lying between the posterior and anterior gray matter (interneurons)
- Anterior motor neurons, along with the muscles they innervate

There are 12 *cranial nerves.* Their number, name, origin, type, and function are summarized in Table 41-3. Cranial nerve function is an important part of the nursing assessment of the patient with a neurologic problem. For example, cranial nerves II, III, IV, and VI are important for assessment of the patient with a stroke or traumatic brain injury.

TABLE 41-3

Origins, Types, and Functions of the Cranial Nerves

CRANIAL NERVE	ORIGIN	TYPE	FUNCTION
I: Olfactory	Olfactory bulb	Sensory	Smell
II: Optic	Midbrain	Sensory	Central and peripheral vision
III: Oculomotor	Midbrain	Motor to eye muscles	Eye movement via medial and lateral rectus and inferior oblique and superior rectus muscles; lid elevation via the levator muscle
		Parasympathetic-motor	Pupil constriction; ciliary muscles
IV: Trochlear	Lower midbrain	Motor	Eye movement via superior oblique muscles
V: Trigeminal	Pons	Sensory	Sensory perception from skin of face and scalp and mucous membranes of mouth and nose
		Motor	Muscles of mastication (chewing)
VI: Abducens	Inferior pons	Motor	Eye movement via lateral rectus muscles
VII: Facial	Inferior pons	Sensory	Pain and temperature from ear area; deep sensations from the face; taste from anterior two thirds of the tongue
		Motor	Muscles of the face and scalp
		Parasympathetic-motor	Lacrimal, submandibular, and sublingual salivary glands
VIII: Vestibulocochlear	Pons-medulla junction	Sensory	Hearing Equilibrium
IX: Glossopharyngeal	Medulla	Sensory	Pain and temperature from ear; taste and sensations from posterior one third of tongue and pharynx
		Motor	Skeletal muscles of the throat
		Parasympathetic-motor	Parotid glands
X: Vagus	Medulla	Sensory	Pain and temperature from ear; sensations from pharynx, larynx, thoracic and abdominal viscera
		Motor	Muscles of the soft palate, larynx, and pharynx
		Parasympathetic-motor	Thoracic and abdominal viscera; cells of secretory glands; cardiac and smooth muscle innervation to the level of the splenic flexure
XI: Accessory	Medulla (anterior gray horn of the cervical spine)	Motor	Skeletal muscles of the pharynx and larynx and sternocleidomastoid and trapezius muscles
XII: Hypoglossal	Medulla	Motor	Skeletal muscles of the tongue

Autonomic Nervous System: Structure and Function

The **autonomic nervous system (ANS)** is composed of two parts: the sympathetic nervous system (SNS) and the parasympathetic nervous system. ANS functions are not usually under conscious control but may be altered in some people by using biofeedback and other methods.

The SNS cells originate in the gray matter of the spinal cord from T1 through L2 or L3. This part of the ANS is considered *thoracolumbar* because of its anatomic location. The SNS stimulates the functions of the body needed for "fight or flight" (e.g., heart and respiratory rate). It also inhibits certain functions not needed in urgent and stressful situations.

The parasympathetic cells originate in the gray matter of the sacral area of the spinal cord (from S2 through S4) plus portions of cranial nerves III, VII, IX, and X *(craniosacral)*. The parasympathetic nervous system can slow body functions when needed and contribute to digestion and reproduction ("feed and breed").

Parasympathetic fibers to the organs have some sensory ability in addition to motor function. Sensory perceptions of irritation, stretching of an organ, or a decrease in tissue oxygen are transmitted to the thalamus through pathways not yet fully understood. Because pain from internal organs is often felt below the body wall innervated by the spinal nerve, it is presumed that there are connections between the viscera and body structure that relay pain sensation.

Neurologic Changes Associated with Aging

Neurologic changes associated with aging often affect mobility and sensory perception. *Motor changes* in late adulthood can cause slower movement and response time and decreased sensory perception (Chart 41-1). Any problems that affect the nerves, bones, muscles, or joints also affect motor and therefore ADL ability. Determining functional status—a combination of cognition, mobility, and sensory perception—is a recommended core measure for patients with complex chronic conditions (www.cms.gov).

Chart 41-1 Nursing Focus on the Older Adult

Changes in the Nervous System Related to Aging

PHYSIOLOGIC CHANGES	NURSING IMPLICATIONS	RATIONALES
Slower processing time	Provide sufficient time for the affected older adult to respond to questions and/or direction.	Allowing adequate time for processing helps differentiate normal findings from neurologic deterioration.
Recent memory loss	Reinforce teaching by repetition, using written teaching, and employing memory aids like electronic alarms or applications for electronic devices that provide recurrent alerts.	Greatest loss of brain weight is in the white matter of the frontal lobe. Intellect is not impaired, but the learning process is slowed. Repetition helps the patient learn new information and recall it when needed.
Decreased sensory perception of touch	Remind the patient to look where his or her feet are placed when walking. Instruct the patient to wear shoes that provide good support when walking. If the patient is unable, change his or her position frequently (every hour) while he or she is in bed or the chair.	Decreased sensory perception may cause the patient to fall.
Change in perception of	Ask the patient to describe the nature and specific characteristics of	Accurate and complete nursing assessment ensures that the interventions

pain	pain. Monitor additional assessment variables to detect possible health problems.	will be appropriate for the older adult (see Chapter 2).
Change in sleep patterns	Ascertain sleep patterns and preferences. Ask if sleep pattern interferes with ADLs. Adjust the patient's daily schedule to his or her sleep pattern and preference as much as possible (e.g., evening versus morning bath).	Older adults require as much as younger adults. It is more common for older adults to fall asleep early and arise early.
Altered balance and/or decreased coordination	Instruct the patient to move slowly when changing positions. If needed, advise the patient to hold on to handrails when ambulating. Assess the need for an ambulatory aid, such as a cane.	The patient may fall if moving too quickly. Assistive and adaptive aids provide support and prevent falls.
Increased risk for infection	Monitor carefully for infection.	Older adults often have structural deterioration of microglia, the cells responsible for cell-mediated immune response in the central nervous system (CNS).
Changes in sleep patterns	Assess sleep habits. Provide usual bedtime routines. Decrease noise and light at night.	Age-related changes include more time in bed spent awake before falling asleep, reduced sleep time, daytime napping, and changes in circadian rhythm leading to "early to bed and early to rise."

Sensory changes in older adults can also affect their daily activities. Pupils decrease in size, which restricts the amount of light entering the eye, and adapt more slowly. Older adults need increased lighting to see. Chapter 48 describes collaborative care for persons with hearing loss. Touch sensation decreases, which may lead to falls because the older person may not feel small objects or a step underfoot. Vibration sense may be lost in the ankles and feet. These changes can contribute to falls. (See the discussion on fall prevention in Chapter 2.)

Cognitive functions of perceiving, registering, storing, and using information often change as a normal part of aging. Therefore it is important to differentiate between these expected findings and those of dementia, depression, and delirium. Failure to correctly diagnosis pathologic cognitive problems may lead to a poor patient outcome. For example, unsafe driving can be both a cause and a result of cognitive changes. The cognitive changes may be reversible, allowing the person to continue to drive once the condition is resolved, or irreversible,

indicating the health care provider may need to assist with advice or efforts to stop the person from continuing to drive (Iverson et al., 2010).

Intellect does not decline as a result of aging. However, a person with certain health problems may have a decrease in cognitive level. *Cognitive decline is frequently caused by drug interactions or toxicity or by an inadequate oxygen supply to the brain.* Some older adults may need more time than a younger person to process questions, learn and process new information, solve problems, or complete analogies.

Subtle memory changes can occur for many older people. Long-term memory seems better than recall (recent) or immediate (registration) memory. Older adults may need more time to retrieve information. These changes may be partly due to the loss of cerebral neurons, which is associated with the aging process.

Biorhythms vary among people. Circadian responses are reduced in older adults, and the sleep-wake cycle may become less responsive to stimuli that signal patterns of sleep. Older adults may experience changes in sleep architecture and sleeping patterns (Touhy & Jett, 2014). For example, older adults are more likely to go bed earlier and experience an earlier awakening compared with younger adults. They are also more likely to experience more periods of wakefulness lasting 30 or more minutes during the night. On average, an older person needs as much sleep as a younger person but is more likely to nap in the afternoon.

Sleep deprivation at any age can lead to significant changes in cognition. Sleep deprivation, common in many inpatient settings, is related to both the earlier onset and greater severity of delirium. Lack of sleep can worsen symptoms of mild dementia. Sleep deprivation can also interfere with normal immune function and wound healing. Interrupted sleep and sleep deprivation can also impair physical function and self-management. Sleep and rest are both necessary for health. Nurses can review sleep habits and promote a good sleep environment, including periods of rest and do-not-disturb during patient care (see the Quality Improvement box).

Quality Improvement QSEN

Unit-based Quality Improvement Project Promotes Patient Sleep

Faraklas, I., Holt, B., Tran, S., Lin, H., Saffle, J., & Cochran, A. (2013). Impact of a nursing-driven sleep hygiene protocol on sleep quality. *Journal of Burn Care and Research, 34*(2), 249-254.

Sleep is important to cognition. In this report, a nurse-driven protocol and the use of a sound meter to monitor noise was used to evaluate patient perceptions of sleep in acutely ill and burned adults. Noise reduction, reduced lighting, and prioritizing and clustering care activities to minimize sleep interruptions between midnight and 5 am were phased in over several months in a single unit. When the protocol was fully implemented, patient self-reports indicated an improvement in falling asleep and going back to sleep compared with self-reports before the protocol was implemented. Because it is a nurse-driven protocol, it can be implemented and adapted in quick cycles to meet quality improvement goals. For example, other studies confirm that the use of a sound meter can contribute to noise reduction. The cost of sound meters is small (less than $25), and they can be placed in high impact areas, including alarm stations or where staff commonly converse. The sound meter detects decibels providing immediate feedback to staff about high noise levels that can disrupt patient sleep.

Commentary: Implications for Practice and Research

Steps to improve patient sleep can be implemented without increasing the workload of nurses or increasing the cost of care. Both light reduction and clustering care activities require thoughtful planning and collaboration with health care team members so that the period of planned uninterrupted rest for a patient is recognized. The immediate feedback from a device to monitor decibels is helpful to noise reduction. Although this is a single unit report, the protocol can be used in a variety of inpatient settings. Phasing in interventions of light reduction, noise monitoring, and clustering activities contributes to successful changes in practice.

Mental status may be impaired as a result of infection, hypoxia, and hypoglycemia or hyperglycemia. These conditions are usually easily assessed and managed. During an acute change in mental status, assess the adult for peripheral oxygenation (Spo_2), serum glucose (fingerstick), and potential infection (e.g., fever, urine with sediment or odor, sputum production, red or draining wound). *Often a decrease in mental status is a key early sign of an infectious process in the older patient, and a urinary tract infection is a common site.*

Assessment Methods

Patient History

Obtain information from the patient about health problems and function as outlined in Chart 41-2. During your introduction, note the patient's appearance and assess his or her speech, affect, and movement. If he or she seems to have cognitive deficits or has trouble speaking or hearing, ask a family member or significant other to stay during the interview to help obtain an accurate history. Be sure that glasses, contact lenses, and hearing aids are available if the patient wears any of these aids.

Chart 41-2 Best Practice for Patient Safety & Quality Care QSEN

Establishing a Nursing Database: History

Demographic Data

- Age
- Gender

Past Medical History

- Patient's medical history
- Family's medical history
- Previous injuries or congenital problems
- Sleep disorders (e.g., insomnia, sleep apnea)
- Chronic diseases:
  - Hypertension and cardiovascular disease
  - Diabetes mellitus and thyroid disorders
  - Lung disease and conditions that cause hypoxemia
- Previous neurologic problems:
  - Headaches
  - Seizures
  - Head or spine trauma
  - Eye problems
  - Brain injury from stroke or trauma

Current History

- Current symptoms:
  - Blurred vision
  - Headache

- Speech or swallowing difficulty
- Numbness, tingling
- Weakness, clumsiness
- Bowel or bladder difficulties
- Nausea or vomiting
- Personality changes
- Seizures
- Disorientation or other change in mental status

• Allergies:
- Food
- Medications
- Environment

• Pain tolerance:
- Medications taken for pain
- Behaviors to reduce pain

• Medications:
- Prescribed
- Illicit
- Over-the-counter

• ADLs

Social History

• Usual recreational activities
• Level of physical activity each day
• Hobbies
• Alcohol consumption and use of recreational drugs
• Smoking, use of any tobacco products
• Sleep habits:
- Changes in pattern, duration, or intensity

• Work history:
- Exposure to toxic agents

• Ethnic and cultural background
• Handedness (right or left)
• Educational background

Ask the patient about his or her medical history to determine its association with the current health problem. Inquire about the ability to perform ADLs. Knowing the level of daily activity helps establish a baseline for later comparison as the patient improves or worsens. Ask whether the patient is right-handed or left-handed. This information is important for several reasons:

- The patient may be somewhat stronger on the dominant side, which is expected.
- The effects of cerebral injury or disease are more pronounced if the dominant hemisphere is involved.

Ask about family medical history such as stroke or myocardial infarction (MI) (heart attack). Some diseases occur more often in certain groups of people and may be caused by a genetic influence or other reason. For example, it has been long established that Huntington disease is inherited. A number of other neurologic diseases have a genetic basis, such as neuromuscular disorders, migraine headaches, and epilepsy. These genetic risks are described with specific neurologic diseases found later in this unit.

Physical Assessment

Compare each assessment with the patient's baseline, as well as between right and left sides and between upper and lower extremities. *Two types of neurologic assessments may be performed—a complete assessment and a focused assessment*. Some focused assessments are specifically designed to be rapid to ease repetition when recurrent neurologic assessments are needed to monitor the patient's condition over time. The type chosen depends on the information needed, the time available with the patient, and your clinical skill level. Advanced practice registered nurses (APRNs) and other health care providers usually perform the complete assessment, with selected parts done by the nurse. It is important that you understand each component of the assessment and what the results might indicate.

Complete Neurologic Assessment

A complete neurologic assessment includes a history (see Chart 41-2) and evaluation of mental status (consciousness and cognition), cranial nerves (see Table 41-3), mobility and motor system function (e.g., range, strength, posture, abnormal movements), deep tendon reflexes, sensation (e.g., pain, touch, temperature, vibration, and position), and cerebellar function (gait, balance, and coordination). Although not all components of a complete assessment are completed by the nurse, noting abnormalities at baseline or with disease progression is important. During any neurologic assessment, look for asymmetry, such as subtle unequal movement in the facial muscles.

The complete neurologic assessment is used by the health care provider to consider whether a single lesion or more than one site in the

nervous system may be contributing to abnormal physical assessment findings. A complete neurologic assessment will also help establish if a lesion or injury is in the CNS, PNS, or both. If the lesion or injury is in the CNS, a complete neurologic assessment can further help the health care provider determine if abnormalities are in the cortex, below the cortex, or multifocal. These findings, along with patient history, help determine the urgency of treatment. For example, a sudden unilateral loss in motor function and sensation is an emergency requiring a stroke center and staff with expertise to diagnose and intervene during a "**brain attack.**" A gradual unilateral loss or a variable loss (with waxing and waning symptoms) may be less urgent and not require stroke center expertise. Generally, the nurse completes a focused or rapid assessment to detect concerning changes.

Assessment of Mental Status.

Mental status assessment is generally divided into assessment of *consciousness* and *cognition*. Consciousness is the ability to be aware of the environment, an object, and oneself; consciousness is often documented as level of consciousness (LOC). Consciousness usually refers to the degree of alertness or the amount of stimulation needed to engage a patient's attention and can range from *alert* to *coma*. When alert, the patient is awake and easily engaged. A patient in coma appears to be asleep and does not rouse or react despite vigorous or noxious simulation.

Nursing Safety Priority QSEN

Action Alert

Be aware that a change in level of consciousness and orientation is an early and reliable indication that central neurologic function has declined! The patient who is described as ***alert*** is awake and responsive. A patient may be alert but not oriented to person, place, or time. Patients who are less than alert are labeled *lethargic, stuporous,* or *comatose.* A ***lethargic*** patient is drowsy but is easily awakened. One who is arousable only with vigorous or painful stimulation is ***stuporous***. The ***comatose*** patient is unconscious and cannot be aroused.

After determining alertness, the next step is to evaluate orientation. Once the patient's attention is engaged, ask him or her questions to determine orientation. Varying the sequence of questioning on repeated

assessments prevents the patient from memorizing the answers. Responses that indicate orientation include ability to answer questions about person, place, and time such as:

- The patient's ability to relate the onset of symptoms
- The name of his or her physician/nurse practitioner/nurse
- The year and month
- His or her address
- The name of the referring physician or health care agency

Time of day, drug therapy, and the need for sleep, glucose, or oxygen may affect these responses, so be sure to link any changes in orientation with respiratory status, changes in drug regimens or use of intermittent drugs, time of day/sleep deprivation, or current serum glucose values. Education, occupation, interest, culture, anxiety, and depression affect performance during assessment of mental status. What is considered "normal" may not be so for a particular patient, so adaptation of questions suggested for mental status assessment may be necessary. Be alert to both *sudden* and *subtle* changes, particularly when changes are noted by family members or others who know the patient.

NCLEX Examination Challenge

Physiological Integrity

During a client's neurologic assessment, the nurse finds that he is arousable after light touch combined with a loud voice. How does the nurse document this client's level of consciousness?

A Stuporous
B Lethargic
C Comatose
D Drowsy

Cognition is intellectual function. It is processes of thought that embody perception, attention, visuospatial recognition, language, learning, memory and executive functions of comprehension, insight, problem solving, reasoning, decision making, creativity, and metacognition (Giddens, 2013). Cognition typically is evaluated in a rapid or focused manner using tests of memory and attention that require verbal or written ability (Chart 41-3). *Loss of memory, especially recent memory, tends to be an early sign of neurologic problems.* Three types of memory can be tested: long-term (remote) memory, recall (recent) memory, and immediate memory.

Chart 41-3 Best Practice for Patient Safety & Quality Care QSEN

Assessment of Cognition

Perform assessment at the following care interactions:

- On admission to and discharge from an institutional care setting
- Upon transfer from one care setting to another
- Every 8 to 12 hours throughout hospitalization
- Following major changes in pharmacotherapy
- With behavior that is unusual for the person and/or inappropriate to the situation

Assess and document (noting "sometimes," "frequently," or "always" as observed):

- Does the patient respond to voice; require being shaken awake to communicate; doze off during a conversation or when no activities occur; or not respond to voice or touch?
- Is speech clear and understandable; disoriented to person, place, or time; inappropriate; or incomprehensible/garbled?
- Can the patient name the place, reason for admission or visit, month, and age?
- Can the patient follow one-step commands: open/close eyes; make fist/let go?
- Can the patient switch to a different topic or activity versus loses the thread of the conversation or is easily distracted (inattention)?
- Can the patient recognize a familiar object and its purpose or a familiar person and name relationship?
- Can the patient respond relevantly and quickly?
- Does the patient have unrealistic thoughts or act distrustful of others (e.g., does not dare to take his/her medicine; says that people are "listening," etc.)?
- Is the patient cooperative, euphoric, hostile, anxious, withdrawn, or guarded?
- Is the patient's appearance, behavior, or facial expression appropriate for the situation?

Remote, or long-term, **memory** can be tested by asking patients about their birth date, schools attended, the city of birth, or anything from the past that can be verified. Nurses often ask the name of the patient's contact person listed on the admission form.

Recall (recent) **memory** can be tested during the history and checked

on the medical record:
• The accuracy of the medical history
• Dates of clinic or physician appointments
• The time of admission
• Health care providers seen within the past few days
• Mode of transportation to the hospital or clinic

Immediate (new) **memory** is tested by giving the patient three unrelated words, such as "apple," "street," and "chair," and asking him or her to repeat the words to make sure they were heard. After about 5 minutes, while continuing with the examination, ask the patient to repeat the words. An alternative to this method is to give a three-step command and observe whether it is carried out correctly. For example, "Pick up the paper, fold it in half, and draw a square on it."

To assess *attention,* ask the patient to repeat a series of three numbers, such as 4, 7, and 3. The series is increased by one number with each successful repetition until seven or eight digits are achieved. If the patient has difficulty at any level (cannot repeat the series), repeat the numbers. If the patient cannot repeat, stop the procedure. Next, ask the patient to repeat the numbers backward, starting again with three digits and increasing by one each time. Normally, a person should be able to repeat five to eight digits forward and four to six backward. The serial-seven test to determine attention may also be used. The patient is asked to count backward from 100 by 7 (the examiner stops when the patient reaches 65 successfully). An alternative approach is to ask the person to subtract by three or to add forward by five. Clinical judgment and assessment skills are used when deciding which of these tests to use.

Other assessments of cognition include examining language and executive function. Many *language* skills can be assessed during the initial interview. Language skills include understanding the spoken or written word and being able to speak or write. The patient demonstrates understanding by following directions on admission (e.g., getting undressed). If he or she hesitates, it may be the patient does not understand the vocabulary or word. When speech hesitation or performance hesitation occurs, point to objects and ask the patient to name them, such as the door or bed. Speech is assessed as being normal, slow, garbled, difficult to find words, or other impairments. If the change in speech is new and represents a deterioration from a previous ability to communicate, this change must be urgently reported to the health care provider because it may indicate a stroke, new onset of confusion, or other serious neurologic condition (Rattray et al., 2011).

The health care provider or speech-language pathologist (SLP)

completes additional language tests such as reading comprehension. This is done by writing a simple command and giving it to the patient (e.g., "close your eyes"). Written language can be tested by asking the patient to write a sentence. The clinician must remember that some patients cannot read or write or may speak a language different from that of the clinician. In this case, modify the examination accordingly such as having the patient copy something that has been drawn (e.g., a cross, circle, diamond, or square).

Executive function allows for flexibility, adaptability, and goal directedness; it determines the contents of consciousness, supervises voluntary action, and is future oriented. Several approaches are used to assess executive function. Although most tests of executive function are not done by the nurse, it is important to identify and document altered executive function because this type of impairment can place the patient at risk for harm. To identify whether such a risk exists and to ensure that the need for further specialized evaluation is recognized, begin to assess the patient's judgment during the interview. Did he or she make rational decisions in dealing with his or her symptoms? Ask questions such as "What would you do if stopped for speeding?" and "What would you do if there was a fire in the wastepaper basket?" Asking the meaning of proverbs (e.g., "A stitch in time saves nine" or "A rolling stone gathers no moss") provides information about insight and abstraction. These questions might also elicit important information about a new onset of a confusional state. People from countries other than the United States or young adults may be unfamiliar with abstract proverbs. Finally, ask the patient to follow a two-step motor process such as "Show me two fingers with your right hand" (you can illustrate with your right hand) and then ask him or her to do the same thing with the other hand (removing the visual cue of your hand before asking for step two). Consult a professional interpreter to assist with language and culturally appropriate phrasing before making an evaluation of executive function to ensure that both sudden and subtle changes are identified accurately.

There are several rapid tests of cognition useful in clinical settings. One example is the Brief Interview for Mental Status (BIMS), commonly used in long-term care settings (Saliba et al., 2012). The BIMS consists of three categories. The first category is "repetition of three words." The nurse tells the patient that he or she will hear three words and then be asked to repeat them. Allow five seconds to pass between stating the words and asking for repetition. Then the three words are verbally repeated and placed into a category (e.g., blue, a color) by the assessor but not yet retested. Next, "temporal orientation" is evaluated by asking the patient

to identify the year, month, and day of week. The third category of assessment is "recall." The patient is asked to name the same three words used earlier and the assessor determines if the words are recalled independently, after coaching by naming the category, or not recalled at all. Patients can achieve scores of 0 to 15 by adding across the three categories. Scores below 8 indicate severe cognitive impairment (Saliba et al., 2012). Cognitive impairment can be permanent or temporary.

An example of permanent cognitive impairment is **dementia**, an irreversible and degenerative condition described in Chapter 42. Two screening tools useful for identifying dementia that can be completed quickly are the clock drawing test and the Mini-Cog, and each require less than 3 minutes to complete. An example of a longer test is the Mini-Mental State Examination (3MS; average time to administer, 17 minutes) (Holsinger et al., 2012).

Another consideration in assessing cognition is delirium. **Delirium**, an acute confusional state, is characterized by a new and sudden cognitive impairment (Touhy & Jett, 2014). Symptoms tend to fluctuate over the course of a day and include disturbances in consciousness, attention, memory deficits, and perceptual disturbances. Delirium can also be manifested by delusional (paranoid) thoughts and behavior. Delirium is a medical emergency and specifically places geriatric patients at risk for harm and prolonged cognitive impairment. Once a patient is identified as having delirium, reassessment should be done every shift.

Early identification and targeted interventions for delirium can decrease the occurrence and severity of delirium. Delirium is associated with significant consequences such as distress (including post-traumatic distress syndrome), prolonged hospital stay, increased morbidity and mortality, and institutionalization (Touhy & Jett, 2014). Two tests to detect new onset of delirium are the Confusion Assessment Method (CAM) and the NEECHAM Confusional Scale (Adamis et al., 2010). The CAM-ICU is used for nonverbal patients (Barr et al., 2013).

Assessment of Cranial Nerves.

Cranial nerves are typically tested to establish a baseline from which to compare progress or deterioration. However, they are not routinely tested unless the patient has a suspected problem affecting one or more of the cranial nerves (see Table 41-3). Adding the specific cranial nerves to be tested to the documentation record of a patient with a problem affecting the cranial nerves helps ensure continued comparison and assessment.

Testing pupils is a common cranial nerve test performed by nurses.

Pupil constriction is a function of cranial nerve III, the oculomotor nerve. **P**upils should be **e**qual in size, **r**ound and **r**egular in shape, and react to **l**ight and **a**ccommodation **(PERRLA)**. Estimate the size of both pupils using a millimeter ruler or a pupillometer. Patients who have had eye surgery for cataracts or glaucoma often have irregularly shaped pupils. Those using eye drops for either cataracts or glaucoma may have unequal pupils if only one eye is being treated, and the pupillary response may be altered.

To test for pupil constriction, ask the patient to close his or her eyes and dim the room lights. Bring a penlight in from the side of the patient's head, and shine the light in the eye being tested as soon as the patient opens his or her eyes. The pupil being tested should constrict **(direct response).** The other pupil should also constrict slightly **(consensual response).** To test accommodation, relight the room and ask the patient to focus on a distant object and then immediately look at an object 4 to 5 inches from the nose. The eyes should converge, and the pupils should constrict. Pinpoint, dilated, and nonreactive pupils are late signs of neurologic deterioration (Jarvis, 2016).

Assessment of Motor Function.

Throughout the physical assessment, observe the patient for involuntary tremors or movements. Describe these movements as accurately as possible, such as "pill-rolling with the thumbs and fingers at rest" or "intention tremors of both hands" (tremors that occur when the patient tries to do something). These abnormalities can indicate certain diseases, such as multiple sclerosis, or the effects of selected psychotropic drugs. In addition, assess the patient for motor movements that indicate irritability, hyperactivity, or slowed movements. Measure the patient's hand *strength* by asking him or her to grasp and squeeze two fingers of each of your hands. Then compare the grasps for equality of strength. As another means of evaluating strength, try to withdraw the fingers from the patient's grasp and compare the ease or difficulty. He or she should release the grasps on command—another assessment of consciousness and the ability to follow commands.

Collaborate with the physical therapist to test the patient's strength. To test strength against resistance, ask the patient to resist the examiner's bending or straightening of the arm, hand, leg, or foot being tested (Fig. 41-7). A five-point rating scale is commonly used (see Chapter 49, Table 49-2). Always evaluate and compare strength on each side. Compare previous results with current findings, and report all decreases to the health care providers.

FIG. 41-7 Testing for strength against resistance.

Cerebral motor or *brainstem* integrity may also be assessed. Ask the patient to close his or her eyes and hold the arms perpendicular to the body with the palms up for 15 to 30 seconds. If there is a cerebral or brainstem reason for muscle weakness, the arm on the weak side will start to fall, or "drift," with the palm pronating (turning inward). This is called a **pronator drift.** The same can be done for the lower extremities, with the patient lying on his or her stomach with the legs bent upward at the knees. However, it is easier for most patients to sit on the side of the bed and extend the legs outward.

Decortication is abnormal motor movement seen in the patient with lesions that interrupt the corticospinal pathways (Fig. 41-8, *A*). The patient's arms, wrists, and fingers are flexed with internal rotation and plantar flexion of the legs. **Decerebration** is abnormal movement with rigidity characterized by extension of the arms and legs, pronation of the arms, plantar flexion, and opisthotonos (body spasm in which the body is bowed forward) (Fig. 41-8, *B*). Decerebration is usually associated with dysfunction in the brainstem area.

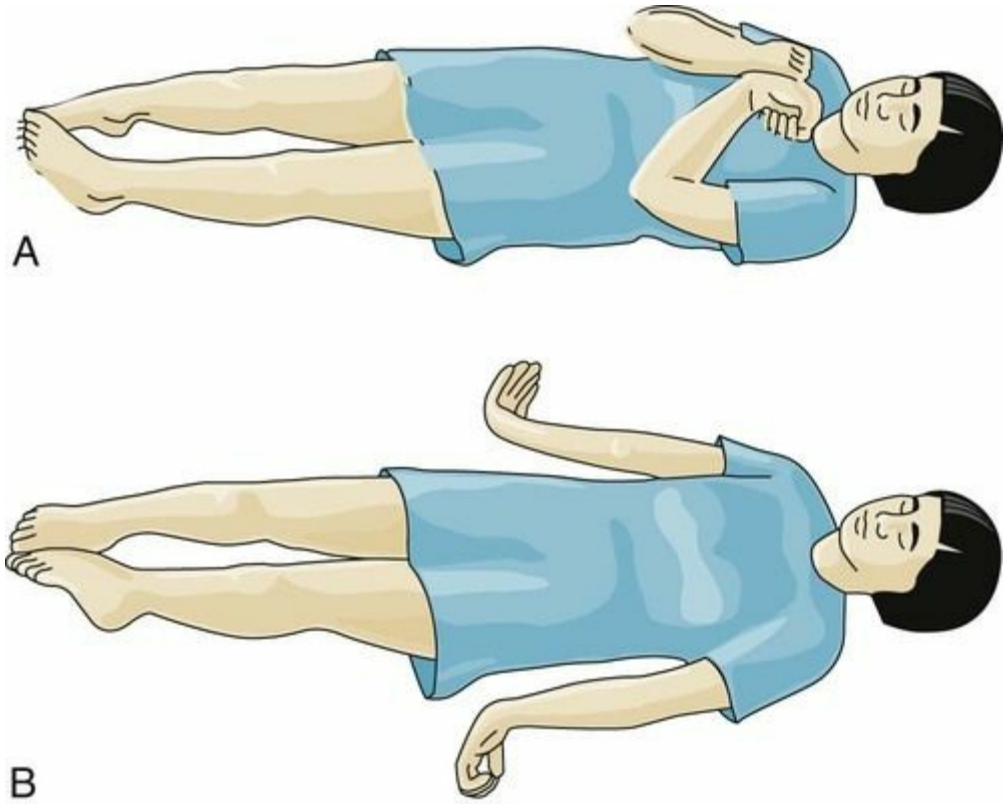

FIG. 41-8 Posturing. **A,** Decorticate posturing. **B,** Decerebrate posturing.

Assessment of Reflex Activity.

The health care provider, including the APRN, may assess deep tendon reflexes (DTRs) and superficial (cutaneous) reflexes. The **deep tendon reflexes** of the biceps, triceps, brachioradialis, and quadriceps muscles and of the Achilles tendon can be tested as part of the complete neurologic assessment (Jarvis, 2016). Striking the tendon with the reflex hammer should cause contraction of the muscle. The appropriate muscle contraction indicates an intact reflex arc. The tendon is tapped quickly but not with too much force. If the patient is tensing the muscle, the reflexes will not respond. Having the patient interlock his or her hands and pull outward will help decrease muscle tensing so the reflex can be tested.

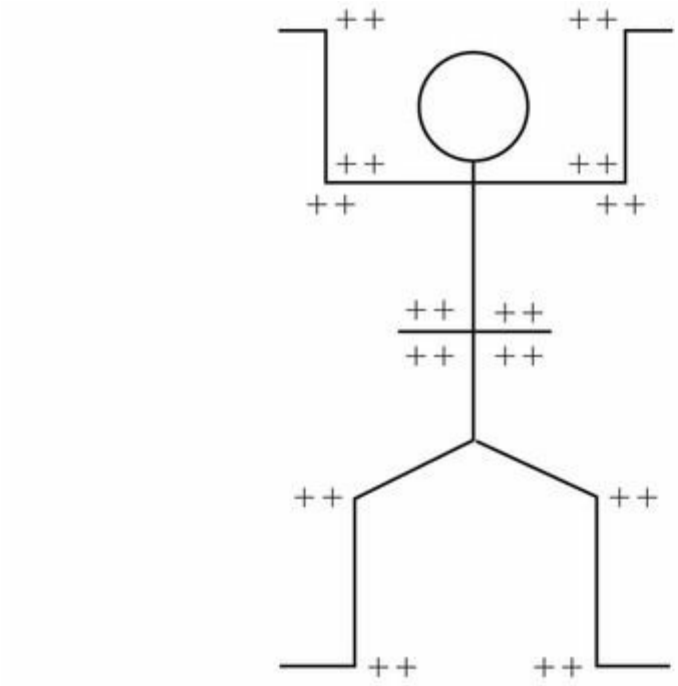
The **cutaneous (superficial) reflexes** usually tested are the plantar reflexes and sometimes the abdominal reflexes. The plantar reflex is tested with a pointed (but not sharp) object, such as the handle end of the reflex hammer or the rounded end of bandage scissors. The normal response is plantar flexion of all toes. **Babinski's sign**, a dorsiflexion of the great toe and fanning of the other toes, is abnormal in anyone older than 2 years and represents the presence of central nervous system (CNS) disease. The term "positive Babinski's sign" (abnormal response)

and “negative Babinski's sign” (normal response) are clinically used terms but are not correct. Health care providers may also use the terms “upgoing” or “downgoing” to refer to the toes of the stimulated foot. “Upgoing” toes are an abnormal response that indicates the presence of pathology in the CNS. Babinski's sign can occur with drug and alcohol intoxication, after a seizure, or in patients with multiple sclerosis or liver disease.

To test the abdominal reflex, stroke the patient's abdomen in all four quadrants diagonally toward the umbilicus. The umbilicus should deviate toward the stimulus, but obesity may mask the reflex. The abdominal reflex can be absent in both upper and lower motor neuron disease.

Hyperactive reflexes indicate possible upper motor neuron disease, tetanus, or hypocalcemia. *Hypoactive* reflexes may result from lower motor neuron disease (damage to the spinal cord), disease of the neuromuscular junction, muscle disease, or health problems such as diabetes mellitus, hypothyroidism, or hypokalemia.

Asymmetry of reflexes is an important finding because it probably indicates a disease process. The results of reflex testing are recorded by the use of a stick figure and a scale of 0 to 4 (Fig. 41-9). A score of 2 is considered normal, although scores of 1 (hypoactive) or 3 (stronger than normal) may be normal for a particular patient. **Clonus** (also called *myoclonus*) is the sudden, brief, jerking contraction of a muscle or muscle group often seen in seizures.



0	Absent, no response
1 (+)	Weaker than normal, hypoactive
2 (++)	Normal
3 (+++)	Stronger or more brisk than normal
4 (++++)	Hyperactive
	(Note: 1 and 3 may be normal for some individuals)

FIG. 41-9 A stick figure and scale for recording reflex activity.

Assessment of Sensory Function.

The assessment of sensory function is done for patients with problems affecting the spinal cord or spinal nerves, such as trauma, intervertebral disk disease, Guillain-Barré syndrome (GBS), tumor, infection, stenosis, or transverse myelitis. The sensory assessment includes pain, superficial and deep sensation, light touch, and proprioception. *Pain and light touch are the most commonly assessed.*

The acuity level of the patient determines how often the sensory assessment is done. For example, patients with acute spinal cord trauma or ascending GBS are assessed every hour until stable and then every 4 hours. As the condition improves, sensory assessment may be needed only once each shift. Findings are documented according to agency protocol. A special spinal cord assessment flow sheet may be used to document sensory and/or motor findings for the patient with a spinal cord injury.

Pain and temperature sensation are transmitted by the same nerve endings. Therefore if one sensation is tested and found to be intact, it can safely be assumed that the other is intact. Testing temperature sensation can usually be accomplished using a cold reflex hammer and the warm

touch of the hand for patients with known or suspected spinal problems.

Assess for *pain perception* with any sharp or dull object, such as the tips of a cotton-tipped applicator. While the patient's eyes are open, demonstrate what will be done. Then ask him or her to keep eyes closed and to indicate whether the touch is sharp or dull. The sharp and dull ends should be changed at random so he or she does not anticipate the next type of stimulus for sensory perception. Not all areas need to be tested unless a spinal cord injury has occurred. If testing begins on the hands and feet, there is no need to test the other parts of the extremities because the tracts transmitting pain and temperature sensations are intact. Compare reactions on each side. A sensation reported as dull when the stimulus was actually sharp requires further testing. A patient with sensory loss as a result of diabetes mellitus or peripheral vascular disease may or may not be aware of the loss until tested. Some patients with chronic illness may report that they have had sensory losses for a long time. Prior to testing for pain, the nurse must check to determine whether the patient is on anticoagulant therapy. If the patient is on anticoagulant therapy, then any testing with a sharp object must be avoided—this can cause bleeding.

Light *touch discrimination* is likely to be normal if pain and temperature sensory tracts are intact. Touch discrimination and two-point discrimination may be assessed as part of a complete neurologic examination by the physician or APRN.

For testing **touch discrimination,** the patient closes his or her eyes. The practitioner touches the patient with a finger and asks that he or she point to the area touched. This procedure is repeated on each extremity at random rather than at sequential points. Next, the practitioner touches the patient on each side of the body on corresponding sites at the same time. The patient should be able to point to both sites.

The clinician then touches the patient in two places on the same extremity with two objects, such as cotton-tipped applicators. A person can normally identify two points fairly close together depending on the location of the stimuli. When an area is heavily innervated, the *two-point discrimination will feel closer.*

Abnormal sensory findings may have a CNS or a peripheral nervous system (PNS) cause. The neuropathies of diabetes, malnutrition, and vascular problems have a PNS cause. Damage to a specific spinal nerve may not result in significant sensory loss because the spinal nerves overlap. Injury to several nearby spinal nerves is manifested as decreased or absent sensory perception in the dermatomes of those nerves.

CNS problems can occur within the spinal cord, the brainstem, the

cerebellum, and the cerebral cortex. Sensory deficits from spinal cord damage vary with the location of the damage. Involvement of only the posterior column leads to lost proprioception (position sense) below the level of the damage on the same side or on both sides (if both the right and left posterior columns are involved). A lesion involving only the right spinothalamic tract results in a loss of pain and temperature sensations below the lesion on the *left* side. Problems in the brainstem, thalamus, and cortex generally result in loss of sensation on the **contralateral** (opposite) side of the body. Cerebellar lesions result in sensory deficits on the *same* side of the body.

Assessment of Cerebellar Function.

Most of the assessment of cerebellar function can be performed with the patient sitting on the side of the bed or examining table. Fine *coordination* of muscle activity is tested. If cerebellar problems are suspected or diagnosed, ask the patient to perform these tasks with his or her eyes closed:

- Run the heel of one foot down the shin of the other leg and repeat with the other leg (the patient should be able to do this smoothly and keep the heel on the shin).
- Place the hands palm-up and then palm-down on each thigh, repeating as fast as possible (this can normally be done rapidly).
- With arms out at the side, touch the finger to the nose 2 or 3 times, with eyes open and then with eyes closed (this can be done with alternating arms or with each arm individually).

For the last part of the cerebellar assessment, the *ambulatory* patient stands for testing of *gait and equilibrium*. Gait and equilibrium are usually tested at the end or beginning of the entire neurologic assessment. Ask the patient to walk across the room, turn, and return. Observe for uneven steps, difficulty walking, and so forth. To evaluate balance, ask him or her to stand on one foot and then on the other. Tiptoe walking and heel-to-toe walking can also demonstrate gait problems. For patients with sciatic nerve involvement, pain may worsen when they walk on their toes or heels.

To test equilibrium, ask the patient to stand with arms at the sides, feet and knees close together, and eyes open. Check for swaying, and then ask him or her to close his or her eyes and maintain position. The examiner should be close enough to prevent falling if the patient cannot stay erect. If he or she sways with the eyes closed but not when the eyes are open (the **Romberg sign**), the problem is probably **proprioceptive** (awareness of body position). If the patient sways with the eyes both open and

closed, the neurologic disturbance is probably *cerebellar* in origin.

If the patient cannot perform any of these activities smoothly, the problem is manifested on the same side as the cerebellar lesion. If both lobes of the cerebellum are involved, the incoordination affects both sides of the body (bilateral).

Rapid Neurologic Assessment

A rapid neurologic assessment, or "neuro check," is completed when the patient is admitted to a health care facility on an emergent basis. It is also part of ongoing patient assessment and performed in the event of a sudden change in neurologic status. The typical record contains data related to alertness, orientation, movement of arms and legs, and pupil size and reaction to light. *Be sure to document all aspects of the rapid neurologic assessment.* One example of a rapid neurologic assessment is the National Institutes of Health Stroke Scale, described in Chapter 45 (Table 45-2). (See the Quality Improvement box.)

Quality Improvement QSEN

System-Wide Project Standardizes Assessments and Communication for Neuroscience Patients

Iacono L.A., Wells C., & Mann-Finnerty, K. (2014). Standardizing neurological assessments. *The Journal of Neuroscience Nursing, 46*(2), 125-132.

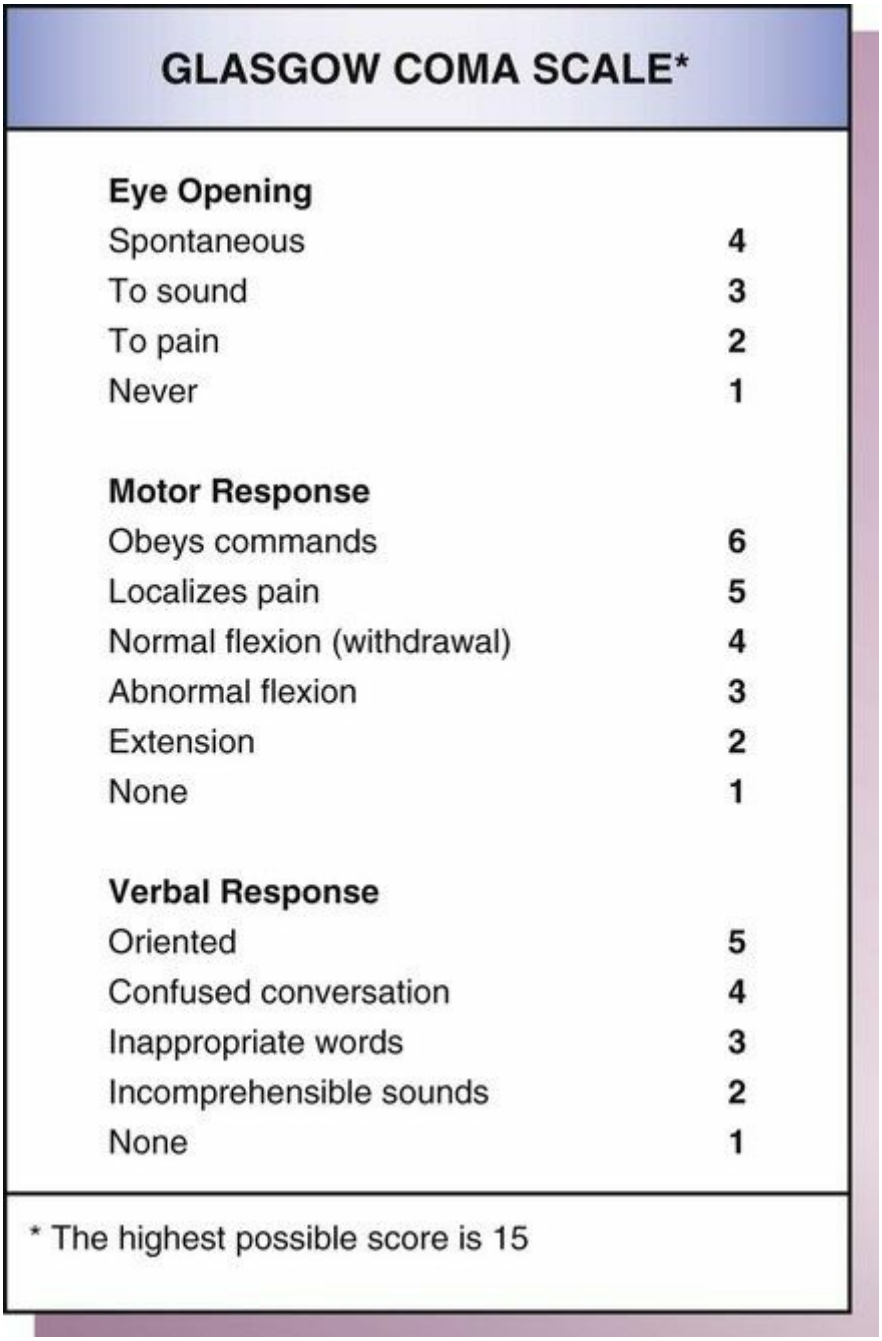
The nursing and physician leadership team at a large urban hospital identified an opportunity to improve neurologic assessment by adopting standard assessment tools. Problems during transitions in care, particularly when reporting neurologic deterioration to health care team members, alerted staff to the need to address issues in quality and safety. Assessment tools were identified and evaluated. Modifications were made to three tools to capture team-generated key components to a neurologic assessment and to improve the process for describing neurologic deterioration. The Basic Neurological Check (addressing alertness, orientation, facial palsy, and four-limb strength), the National Institutes of Health Stroke Scale (NIHSS) Neurological Check (specific for patients with stroke or suspected stroke), and the Coma Neurological Check (based on the Glasgow Coma Scale) were then incorporated into electronic documentation. An algorithm to help health care providers and nurses determine which neurologic tool to use was made available and folded into training. Mandatory training about the use of the tools

was implemented. Ongoing education during orientation for new nurses as well as in-depth training of nurse educators and assistant managers to provide reinforcement and feedback also took place. Three short videos, one for each of the selected neurologic tools, were developed for staff viewing. Following implementation, nurses and physicians report that observations were more consistent and changes were more measurable. Use of the standardized neurologic assessment tools in the neuroscience patient population has helped in early identification of neurologic symptoms. Nurses verbalized more confidence in their ability to identify clinical important symptoms so that early intervention can occur. The authors emphasized the role of nurse educators in training and reinforcement of learning and outcome measures.

Commentary: Implications for Practice and Research

This quality improvement project began in a stroke unit and then was expanded to all units where patients with neurologic conditions received care. This is an example of a team working together to solve a system-wide problem. Both practice and communication issues were identified as contributing to delayed recognition of clinical deterioration in neuroscience patients and in confusion or error during hand-offs. The use of nurse educators as champions was an effective strategy of adoption and ongoing achievement of goals for care.

A second example of standard rapid neurologic assessment is the **Glasgow Coma Scale (GCS)** (Fig. 41-10). The GCS is used in many acute care settings to establish baseline data in each of these areas: eye opening, motor response, and verbal response. The patient is assigned a numeric score for each of these areas. The lower the score, the lower the patient's neurologic function. For patients who are intubated and cannot talk, record their score with a “t” after the number for verbal response.



GLASGOW COMA SCALE*

Eye Opening	
Spontaneous	4
To sound	3
To pain	2
Never	1
Motor Response	
Obeys commands	6
Localizes pain	5
Normal flexion (withdrawal)	4
Abnormal flexion	3
Extension	2
None	1
Verbal Response	
Oriented	5
Confused conversation	4
Inappropriate words	3
Incomprehensible sounds	2
None	1

* The highest possible score is 15

FIG. 41-10 The Glasgow Coma Scale.

The GCS is easy to teach and has demonstrated a consistent score among trained assessors. The reliability of the GCS is based on recording the patient's "best" response. If the patient does not follow commands or is unresponsive to voice, then the nurse proceeds to increasingly noxious (painful) stimuli to elicit an eye and motor response. Typically, the patient's response to central pain (brain response) is assessed first. On the basis of this response, peripheral pain may then be assessed. Failure to apply painful stimuli appropriately may lead to an incorrect conclusion about the patient's neurologic status. If the patient responds fully to voice or light touch, there is no need to progress to more vigorous or painful stimuli.

Start with the least noxious irritation or pressure and proceed to more painful stimulation if the patient does not respond. Begin each phase of the assessment by speaking in a normal voice. If no response is obtained, use a loud voice. If the patient does not respond, gently shake him or her. The shaking should be similar to that used in attempting to wake up a child. If that is unsuccessful, apply painful stimuli using one of these methods:

- Supraorbital (above eyes) pressure by placing a thumb under the orbital rim in the middle of the eyebrow and pushing upward. Do not use this technique if the patient has orbital or facial fractures.
- Trapezius muscle squeeze by pinching or squeezing the trapezius muscle located at the angle of the shoulder and neck muscle.
- Mandibular (jaw) pressure to the jaw by using your index and middle fingers to pinch the lower jaw.
- Sternal (breastbone) rub by making a fist and rubbing/twisting your knuckles against the sternum.

The tissue in these areas is tender, and bruising is not unusual. Therefore do not use this technique for older adults or for patients who may experience severe bruising (e.g., recipients of anticoagulant therapy). Peripheral pain is assessed with pressure at the base of the nail on one finger and one toe and both on the right and left.

The patient may respond to painful stimuli in several ways. Although the initial response to pain may be abnormal flexion or extension, continued application of pain for no more than 20 to 30 seconds may demonstrate that he or she can localize or withdraw. If the patient does not respond after 20 to 30 seconds, stop applying the painful stimulus.

Nursing Safety Priority QSEN

Critical Rescue

A decrease of 2 or more points in the Glasgow Coma Scale total is clinically significant and should be communicated to the health care provider immediately. Other findings requiring urgent communication with the health care provider include a new finding of abnormal flexion or extension, particularly of the upper extremities (decerebrate or decorticate posturing); pinpoint, dilated, and nonreactive pupils; and sudden or subtle changes in mental status. Remember, changes in cognition are the earliest signs of changes in neurologic status. Early recognition of neurologic changes and communicating changes to the health care provider provide the best opportunity to prevent

complications and preserve function.

Psychosocial Assessment

Depression can result in cognitive and behavioral changes that are similar to delirium or dementia. Depression is a common mental health disorder that is often missed in a variety of health care settings, especially in settings that care for older adults (Touhy & Jett, 2014). Consider using a depression screening tool like the Center for Epidemiological Studies Depression-Revised (CESD-R) or the Geriatric Depression Scale (short form) to identify patients with depressive symptoms, and consider referring them to the appropriate provider (both primary care and mental health care) if the screening is positive.

Patients vary in their responses to a suspected or actual health problem, often depending on whether it is acute or chronic. Response is also influenced by mobility, sensory perception, and/or cognition; these abilities can be temporarily or permanently altered as a result of neurologic disease or injury. For example, patients who have a mild stroke and no lasting neurologic deficits are less likely to be severely depressed than patients who experience a loss of independent movement or impaired communication as a result of a stroke.

Age may also be a factor in how a patient accepts the illness. For instance, a young adult who has a motorcycle crash causing a traumatic brain injury (TBI) may react differently from an older adult who has a spinal injury. In some cases, the patient's emotional responses result from the health problem itself, especially for TBI patients.

Men may feel differently about their illness than women. Male patients who have had strokes are depressed more often than women who have had strokes. Discussions of these response differences can be found in the following chapters on specific neurologic health problems.

Regardless of what the health problem is, do not assume that everyone reacts the same way to his or her illness or injury. Consider the cultural background of the patient because this will influence his or her reaction to pain or injury. Patients experience the grieving process and may fluctuate between denial, anger, and depression. Encourage patients to express their feelings. Refer them to the appropriate support services if needed. Assess support systems, including family members and friends, if available. Document your assessment and interventions.

Diagnostic Assessment

Laboratory Assessment

Fluid, electrolyte, and glucose abnormalities can cause neurologic impairment. The basic metabolic panel and serum calcium, phosphorus, and magnesium are evaluated. Both anemia and malnutrition can contribute to neurologic disorders so a complete blood count and serum levels of albumin and minerals/vitamins (particularly B vitamins) are collected. Collection of arterial blood to evaluate pH, oxygen, and carbon dioxide levels may be done because these three results, when either too high or too low, will alter neurologic status. Serum evaluation may be required to determine the presence of a **toxidrome** from prescribed or illicit drugs. For patients with a neurologic problem resulting from an infection, cultures are necessary to identify the pathogen. Although the cause of infection must be determined for any patient, this is especially true for those with existing CNS disease. The blood-brain barrier is often not intact in neurologic disease, and the patient is more likely to get an infection of the nervous system, such as meningitis or encephalitis.

Imaging Assessment

Plain X-Rays.

Plain *x-rays* of the skull and spine are used to determine bony fractures, curvatures, bone erosion, bone dislocation, and possible calcification of soft tissue, which can damage the nervous system. Several views are taken—anteroposterior, lateral, oblique, and, when necessary, special views of the facial bones. *In head trauma and multiple injuries, one of the first priorities is to rule out cervical spine fracture.*

Explain that the x-ray procedure for the skull and spine is similar to that for a chest x-ray. The patient must remain still during the procedure. Remind him or her that the exposure to radiation is minimal. If the patient is in traction and a portable x-ray unit is not available, the nurse may need to accompany him or her to assist with positioning. Any patient who cannot walk from a wheelchair to the x-ray table should be transferred to the radiology department on a stretcher. Hospitals may have specific procedures for transferring patients in wheelchairs or on stretchers to the radiology department. Check with your hospital on this procedure. For example, with a patient who is confused or disoriented, the hospital radiology department staff may require two or more hospital personnel to assist with the transfer. The patient is positioned for each of the desired views and is asked to not move just before each x-ray. Follow-up care is not required.

In general, for any image that involves being placed in a scanner, the nurse needs to be aware of special circumstances that can either prevent the procedure from taking place or can interfere with the procedure. If the patient is alert and claustrophobic, two options are available: one is a mild sedative such as diazepam (Valium) to calm the patient; the other option is an open scanner. The nurse must determine whether the patient has any metal prosthetics, such as heart valves or shrapnel in the part of the body to be scanned. If the patient does have any type of metal object in the body part to be examined, the nurse must notify radiology immediately because the procedure may need to be cancelled. If the patient does have a metal prosthetic or device, the nurse should ask the patient or significant other if the patient carries a medical alert card from the manufacturer. Medical device manufacturers issue cards to physicians for their patients to carry with the device number and instructions if radiologic diagnostic testing is needed.

Cerebral Angiography.

Cerebral angiography (arteriography) is done to visualize the cerebral circulation to detect blockages in the arteries or veins in the brain, head, or neck. It remains the gold standard for the diagnosis of intracranial vascular disease and is required for any transcatheter therapy or for surgical intervention. Angiography may be used to identify aneurysms, traumatic injuries, strictures/occlusions, tumors, blood vessel displacement from edema, and arteriovenous (AV) malformations. Chart 41-4 lists the precautions that must be taken for patients having any test using an iodine-based contrast agent. Risk factors for adverse events must be determined before scheduling the test. Patients sensitive to iodine may be sensitive to iodinated contrast agents; as well, patients with a history of hypersensitivity in general (e.g., multiple food allergies or asthma) are more likely to have an adverse reaction compared with the general population. Seafood allergies are no longer considered an indicator of iodinated contrast allergy. Table 41-4 describes patient preparation and follow-up nursing care for cerebral angiography and other imaging tests.

Chart 41-4 Best Practice for Patient Safety & Quality Care QSEN

Precautions for the Use of Iodine-Based or Gadolinium Contrast for Diagnostic Testing

Special precautions are taken for patients who will receive an iodinated or high osmolar contrast agent as part of their diagnostic test. These measures include:

- Following agency guidelines regarding informed consent.
- Screening patients at risk for developing contrast-induced kidney damage:
  - Ask the patient about all allergies (food, drug, environmental antigens), asthma, and prior reaction to contrast agents.
  - Review for the presence of these conditions:
    - Pre-existing renal disease such as a diagnosis of chronic kidney disease
    - Diabetic nephropathy
    - Heart failure
    - Dehydration
    - Older age
    - Drugs that interfere with renal perfusion such as metformin or NSAIDs
    - Administration of contrast media in the previous 72 hours
- Evaluating current kidney function. Patients with a serum creatinine greater than or equal to 1.5 mg/dL OR a calculated glomerular filtration rate (GFR) of less than 60 mL/min are at highest risk for kidney damage from contrast.
- Communicating with the health care provider before diagnostic testing when risk factors and allergic reaction to iodinated contrast are present.
  - Consider including a discussion of the patient's serum creatinine as a component of the "time-out" process prior to a diagnostic procedure.
  - Document the date, time, and name of the health care provider with whom communication of risk occurred and what actions were prescribed, if any.
  - Some diagnostic tests can be completed with a lower volume of contrast or an alternate agent.
  - Medications that are associated with kidney damage may be held for 24-48 hours before AND after the test.
- Providing adequate hydration before and after contrast administration:
  - Collaborate with the health care provider to determine whether hydration before the diagnostic test, typically with intravenous normal saline, is used. Bicarbonate with normal saline or an intravenous dose of *N*-acetylcysteine may be used in a high-risk patient.

- Determine the optimal post-diagnostic intake and output. Provide sufficient hydration to flush out the contrast with oral or IV fluids over the 4-5 hours following the test.

- Re-evaluating serum creatinine and glomerular filtration rate (GFR) 24-48 hours after the diagnostic test. Communicate an increase of serum creatinine 0.5 mg/dL above baseline and a decrease in GFR >25% to the health care provider. Document communication and follow-up interventions, if any. Generally, the peak creatinine rise is at 48-72 hours after the administration of contrast.

TABLE 41-4

Preparation and Follow-Up for Selected Diagnostic Procedures

TEST	PATIENT CARE PREPARATION	PATIENT CARE FOLLOW-UP
Sonography or Ultrasonography	No preparation is needed. This diagnostic imaging approach is noninvasive and not painful. A light and moderate touch with a probe occurs along the neck/carotid vessels.	The gel used to enhance probe images can be immediately wiped off or removed with water.
Cerebral angiography	Determine whether the patient is allergic to iodinated contrast agents, and follow the guideline in Chart 41-4. To minimize risk for aspiration, assess for the presence of nausea or recent vomiting and medicate as needed. Ensure that the patient is NPO 4 to 6 hours before the test. Reinforce these important points: • Your head is immobilized during the procedure. • Do not move during the procedure. • Contrast dye is injected through a catheter placed in the femoral artery. You will feel a warm or hot sensation when the dye is injected—this is normal. • You will be able to talk to the physician—let him or her know if you are in pain or have any concerns. Assess and document neurologic signs, vital signs, and neurovascular checks.	Follow agency policy regarding care of the injection site, which may include: • Check dressing for bleeding and swelling around site. • Apply ice pack to site. • Keep the extremity straight and immobilized. • Maintain pressure dressing for 2 hours. Check the extremity for adequate circulation to include skin color and temperature, pulses distal to the injection site, and capillary refill. If bleeding is present, maintain manual pressure on the site and notify the physician immediately. Assess vital signs with neurologic examination. Increase oral or IV fluid intake unless contraindicated. Document assessments and interventions.
Computed tomography (CT) with and without contrast CT angiography (CTA) CT myelogram	Follow the guidelines listed in Chart 41-4 if a contrast agent is to be given. Determine whether the patient is claustrophobic and whether a closed CT scan is used. Inform the radiology staff or physician to determine if pre-procedure sedation is necessary. Instruct the patient to remove hairpins, hairpieces, or wigs. Inform the patient that the scanner may make noise or knocking sounds. Reassure the patient that he or she will be able to communicate with the technician throughout the procedure. If contrast is used, the patient may feel a warm or cool sensation after the dye is injected. Occasionally the patient may report a slight metallic taste. A lumbar puncture is performed before an intrathecal contrast-enhanced CT.	Monitor the patient for a delayed allergic response if contrast medium was used.
Positron emission tomography (PET)	Follow preparation as listed for CT. Instruct the patient to withhold caffeine, alcohol, and tobacco for 24 hours before the test. Ensure that the patient has been NPO status for 4 to 12 hours before the procedure (if the patient is diabetic, no insulin is given before the test). Do not give any glucose solutions and any other drugs that alter glucose metabolism. Insert two IV lines.	The radioisotope is eliminated in the urine; no special precautions required. Encourage the patient to increase fluid intake unless contraindicated.
Single-photon emission computed tomography (SPECT)	Patient preparation is similar to that for PET/CT. Determine whether the patient has recently had other nuclear medicine screenings, which may leave traces of the radiopharmaceutical agent. Follow the guidelines listed in Chart 41-4 regarding use of a contrast agent.	The patient can return to his or her previous activity level.
Magnetic resonance imaging (MRI) Magnetic resonance angiography (MRA) Magnetic resonance spectroscopy (MRS)	Follow the information for CT scan. No metal objects may enter the MRI room. Ask the patient about any metal implants including any type of pacemaker device, implantable pumps, or stimulating devices. Instruct the patient to remove all metal objects (jewelry, earrings, body piercings, hairpins, watches, rings, pens). Check with the radiologist regarding tattoos. Do not enter the MRI room unless you have checked with the radiology technician and are sure that neither you nor the patient has any metal device. Ensure all equipment and supplies are free of metal. Gadolinium contrast is to be avoided in patients with low renal function (i.e., glomerular filtration rate <30 mL/min/1.73 m^2.)	No special post-procedure or follow-up care is required. Avoid risk for nephrogenic systemic fibrosis following gadolinium for contrast by restricting its use to patients with normal renal function or using an alternate medium during MRI with contrast diagnostic imaging.
Lumbar puncture	Explain the procedure, noting that some discomfort may be felt when the local anesthetic is injected or that pain may occur in the leg(s) when the spinal needle is inserted. Place the patient in the fetal position, and remind him or her to remain still. If needed, keep the patient from moving.	Obtain vital signs and complete neurologic checks. Follow agency policy regarding bedrest and remaining flat. Encourage the patient to increase fluid intake unless contraindicated. Monitor for complications, especially increased intracranial pressure (severe headache, nausea, vomiting, photophobia, and change in level of consciousness). Observe the needle insertion site for leakage. Notify the physician if it occurs. Provide drug for headache. Notify the physician if drug does not relieve pain.

TEST	PATIENT CARE PREPARATION	PATIENT CARE FOLLOW-UP
Electroencephalogram (EEG)	Ensure that hair is clean and without conditioners, hair creams, lotions, sprays, or styling gels. Avoid the use of sedatives or stimulants in the 12-24 hours preceding the EEG. Instruct the patient not to fast before the test because hypoglycemia can affect the recording. Ensure a quiet room with signage to inform visitors of EEG recording in progress. Instruct the patient or family members about the reasons for periodic or continuous monitoring. The reasons for EEG monitoring include: • Determining the general activity of the cerebral hemispheres. • Determining the origin of seizure activity (epilepsy). • Determining cerebral function in epilepsy and other pathologic conditions such as tumors, abscesses, cerebrovascular disease, hematomas, injury, metabolic diseases, degenerative brain disease, and drug intoxication. • Differentiating between organic and hysterical or feigned blindness or deafness. • Monitoring cerebral activity during surgical anesthesia or sedation in the intensive care unit. • Diagnosing sleep disorders. If the EEG is related to a sleep disorder diagnosis, the patient may be asked to sleep less the night before the EEG. • Assisting in the determination of brain death.	The gel and glue used for placing electrodes can be washed out immediately after the test ends. Acetone or witch hazel will dissolve the paste. Advise the patient who has had a sleep-deprived EEG not to drive home.

The patient is placed on an examining table and made as comfortable as possible. At this time, dentures and hearing aids must be removed. He or she is then connected to cardiac monitoring throughout the procedure. Deep or moderate sedation is usually not used, although the patient may be given medication for relaxation.

The interventional radiologist or other specially trained physician numbs the area at the groin and inserts a catheter into the femoral artery. Under fluoroscopic guidance, the catheter is advanced into a carotid or vertebral artery. Then the physician injects iodinated contrast material into each vessel while recording images from different angles over the head and neck. After all the vessels have been imaged, the radiologist reviews all the images and consults with the referring physician to decide whether the patient could benefit from a therapeutic radiologic procedure or surgery to treat the problem. An arterial closure device is typically used to seal the artery and prevent bleeding.

The x-ray images are stored on a computer. With older equipment, a two-dimensional picture of the vessels is produced. Most radiographic systems now come with software to create three-dimensional images of the blood vessels in the head and/or neck. These systems can also display a "subtracted image" made from two images—one just before the contrast was injected and one with the contrast in the artery. The risks of the procedure are contrast reaction (including hives and flushing), thrombosis (clotting), and bleeding from the entry site. Patients with known contrast sensitivity are pre-treated with steroids.

Computed Tomography.

Computed tomography (CT) scanning is an accurate, quick, easy, noninvasive, painless, and least-expensive method of diagnosing

neurologic problems (see Table 41-4). Using x-rays (i.e., ionizing radiation), pictures are taken at many horizontal levels, or slices, of the brain or spinal cord (Schmidt, 2012). A computer then generates three-dimensional detailed anatomic pictures of tissues, typically the brain, spinal cord, or peripheral neuromuscular system in neurologic testing. A contrast medium may be used to enhance the image. CT scans distinguish bone, soft tissue (e.g., the brain, vascular system, and ventricular system), and fluids such as cerebrospinal fluid (CSF) or blood. Tumors, infarctions, hemorrhage, hydrocephalus, and bone malformations can also be identified.

The patient is placed on a movable table in a head-holding device. He or she must remain completely still during the test, which may be difficult. The table is positioned in the machine—a large, donut-shaped structure. Depending on the scan, the patient may be completely enclosed or in a more open situation. A noncontrast series of pictures are taken first. Then, if needed, the patient is withdrawn from the scanner and given an injection of the iodinated contrast medium. The scan is then repeated. Each set of head scans takes less than 5 minutes in newer scanners. Spinal studies take about 10 minutes per body section (cervical, thoracic, lumbar) and are less likely to require contrast injection.

Most patients with new neurologic symptoms have both a pre-contrast and post-contrast study of the head. Contrast-enhanced CT is especially useful in locating and identifying tumor types and abscesses. For situations in which bleeding is the only concern (e.g., in trauma patients), contrast scans are not usually required.

After a standard CT scan, imaging software digitally removes images of soft tissue so that only images of bone remain. Through the use of this technology, bone deformities, trauma, and birth defects are more easily identified.

CT angiography involves administering contrast dye IV before the CT scan. It is used to identify blockages or narrowing of blood vessels, aneurysms, and other blood vessel abnormalities.

An intrathecal contrast-enhanced CT scan is performed to diagnose disorders of the spine and spinal nerve roots. A lumbar puncture is performed so that a small amount of spinal fluid can be removed and mixed with contrast dye and injected. The patient is positioned to allow for the contrast medium to move around the spinal cord and nerve roots as needed. The patient may have a headache after the procedure. Follow facility policy regarding patient positioning after the procedure.

Magnetic Resonance Imaging.

Magnetic resonance imaging (MRI or MR) has advantages over CT in the diagnostic imaging of the brain, spinal cord, and nerve roots. It does not use ionizing radiation but, instead, relies on magnetic fields. Multiple sets of images are taken that are used to determine normal and abnormal anatomy. Images may be enhanced with the use of gadolinium, a non–iodine-based contrast medium. MRIs of the spine have largely replaced CT scans and myelography for evaluation. Bony structures cannot be viewed with MR; CT scans are the best way to see bones. Some facilities have a *functional MRI (fMRI)* machine that can assess blood flow to the brain rather than merely show its anatomic structure.

In addition to the traditional MRI, a *magnetic resonance angiography (MRA), magnetic resonance spectroscopy (MRS),* or *diffusion imaging (DI)* may be requested. MRA is used to evaluate blood flow and blood vessel abnormalities such as an arterial blockage, intracranial aneurysms, and AV malformations. MRS is used to detect abnormalities in the brain's biochemical processes, such as that which occurs in epilepsy, Alzheimer's disease, and brain attack (stroke). DI uses MRI techniques to evaluate ischemia in the brain to determine the location and severity of a stroke.

Newer, open-sided units ("open MRI") now produce adequate images for those patients who do not want standard MRI scanners. MRI has been contraindicated for patients with cardiac pacemakers, other implanted pumps or devices, and ion-containing metal aneurysm clips. However, extensive trials are testing ways to safely scan some patients with pacemakers. Other implanted devices, such as vascular stents, intravascular catheter (IVC) filters, and metal antiembolic devices, may be scanned immediately or after a certain period of time, depending on manufacturers' recommendations. MRI may also be contraindicated in patients who are confused or agitated, have unstable vital signs, are on continuous life support, or have older tattoos (which contain lead). New physiologic monitoring systems made specifically for the scanner allow some patients who are unstable to be scanned. A comprehensive online list of medical devices tested for MRI safety and compatibility can be found at *www.mrisafety.com*. Medical personnel must remove any medical devices they are carrying or wearing and ensure that only approved devices are allowed in the MRI room (see Table 41-4).

Positron Emission Tomography.

Positron emission tomography (PET) is a diagnostic tool that is not available in all medical centers (see Table 41-4). Its benefit over a CT scan or MRI is that it provides information about the *function* of the brain, specifically glucose and oxygen metabolism and cerebral blood flow.

Current CT scanners provide information about the *structure* of the central nervous system (CNS). The newest PET machines are combination CT-PET scanners that fuse images together to produce better information about the type and location of brain dysfunction.

The physician or nuclear medicine technologist injects the patient with IV deoxyglucose, which is tagged to an isotope. The isotope emits activity in the form of positrons, which are scanned and converted into a color image by computer. The more active a given part of the brain, the greater the glucose uptake. This test is used to evaluate drug metabolism and detect areas of metabolic alteration that occur in dementia, epilepsy, psychiatric and degenerative disorders, neoplasms, and Alzheimer's disease. The level of radiation is equivalent to that of five or six x-rays but much less than exposure during CT.

Teach the patient that he or she will be NPO the night before morning testing and 4 hours before afternoon testing. Patients with diabetes have their test in the morning before taking their antidiabetic drugs. During this 2- to 3-hour procedure, the patient may be blindfolded and have earplugs inserted for all or part of the test. He or she is asked to perform certain mental functions to activate different areas of the brain. Older adults and patients with mental health/behavioral health problems may be too anxious to have a PET scan.

Single-Photon Emission Computed Tomography.

The limitation of PET may be overcome through the use of **single-photon emission computed tomography (SPECT)**. This test uses a radiopharmaceutical agent that enables radioisotopes to cross the blood-brain barrier. The agent is administered by IV injection. Gamma-emitting radionuclides have longer half-lives, therefore eliminating the need for a cyclotron near the scanner. Although SPECT is less expensive than PET, the resolution of the images is limited. SPECT is particularly useful in studying cerebral blood flow, amnesia, neoplasms, head trauma, or persistent vegetative state. The test is contraindicated in women who are breast-feeding.

The patient is injected with the material about 1 hour before the actual scan by the radiologist, certified nuclear medicine technologist, or specially trained RN. The patient is positioned on an x-ray table in a quiet dark room for the actual scans. Several gamma cameras scan his or her head. When completed, the images are downloaded to a computer.

Magnetoencephalography.

Magnetoencephalography (MEG) is a noninvasive imaging technique

used to measure the magnetic fields produced by electrical activity in the brain via extremely sensitive devices such as superconducting quantum interference devices (SQUIDs). MEG is somewhat similar to electroencephalography (EEG). The advantage is greater accuracy because of the minimal distortion of the signal. This allows for more usable and reliable localization of brain function. The brain can be observed "in action" rather than just viewing a still MRI image. These machines are not widely available because of their extremely high cost.

NCLEX Examination Challenge

Physiological Integrity

A client with possible Parkinson disease is scheduled to have magnetic resonance imaging (MRI). The daughter asks the nurse how this test is different from a computed tomography (CT) scan. What is the nurse's best response?

A "The MRI scan provides better contrast between normal tissue and pathologic tissue."
B "They are not different; both use ionizing radiation."
C "The MRI will not require contrast material and has no special precautions."
D "The CT scan does not provide a view of deep brain structures like the region where Parkinson originates.

Other Diagnostic Assessment

Electromyography.

Electromyography (EMG) is used to identify nerve and muscle disorders as well as spinal cord disease. (See Chapter 44 for a description of patient preparation, procedure, and follow-up care.) Electromyography and electroneurography or nerve conduction velocity studies (NCVSs) are usually used together and are referred to as *electromyoneurography.*

Electroencephalography.

Electroencephalography (EEG) records the electrical activity of the cerebral hemispheres. Each graphic recording represents electrical impulses within the brain. The frequency, amplitude, and characteristics of the brain waves are recorded. For example, a cerebral tumor or infarct may have abnormally slow waveforms. EEGs are used both as a diagnostic test and to provide sustained monitoring, and the indications

for testing and monitoring are listed in Table 41-4.

Abnormal results on an EEG test may be due to:

- An abnormal structure in the brain, such as a brain tumor
- Attention problems
- Tissue death due to a blockage in blood flow (cerebral infarction)
- Drug or alcohol intoxication
- Inflammation of the brain (encephalitis)
- Ischemia to brain tissue from low blood flow to the brain during a migraine or a surgical procedure like a carotid endarterectomy
- Seizure disorder
- Sleep disorder or sleep deprivation

Fasting is avoided before EEG testing because hypoglycemia can alter the test results. The patient is placed on a reclining chair or bed. According to an internationally accepted procedure, 16 or more electrodes are applied to the scalp with a jelly-like substance and connected to the machine. The physician or EEG technician places glue over the electrodes to prevent slippage. The patient must lie still with his or her eyes closed during the initial recording. The rest of the test engages the patient in certain activities: hyperventilation, photic stimulation, and sleep. A portable EEG may be performed at the bedside if necessary, but the preference is for the EEG to be done in a very quiet room.

Hyperventilation produces cerebral vasoconstriction and alkalosis, which increases the likelihood of seizure activity. The patient is asked to breathe deeply 20 times per minute for 3 minutes. In *photic stimulation,* a flashing bright light is placed in front of the patient. Frequencies of 1 to 20 flashes per second are used with the patient's eyes open and then closed. If the patient's seizures are photosensitive in origin, seizure activity may be seen on the EEG. A *sleep* EEG may be performed to aid in the detection of abnormal brain waves that are seen only when the patient is sleeping, such as with frontal lobe epilepsy (Pagana & Pagana, 2014).

During an EEG test, which takes 45 to 120 minutes, the recording can be stopped about every 5 minutes to allow the patient to move. If the patient moves during the recording, movement creates a change in the brain waves and the technician will note movements on the graph. Examples of unintentional movement that can affect the recordings are tongue movement, eye blinking, and muscle tensing. The technician may induce or request certain movements or sensory stimulation and record these events on the EEG record to link changes in brain waves with motor activity or sensory stimulation; these intentional movements are also

documented on the EEG recording.

Evoked Potentials.

Evoked potentials (also called *evoked response*) measure the electrical signals to the brain generated by sound, touch, or light. These tests are used to assess sensory nerve problems and confirm neurologic conditions including multiple sclerosis, brain tumor, acoustic neuroma (small tumors of the inner ear), and spinal cord injury. Evoked potentials are also used to test sight and hearing (especially in infants and young children), monitor brain activity in comatose patients, and confirm brain death (Wijdicks et al., 2010). During evoked potentials, a second set of electrodes is attached to the part of the body that will experience sensation. A stimulus is applied, and the amount of time it takes for the impulse generated by the stimulus to reach the brain is recorded. Under normal circumstances, the process of signal transmission is instantaneous.

Auditory evoked potentials (also called *brainstem auditory evoked response*) are used to assess high-frequency hearing loss, diagnose any damage to the acoustic nerve and auditory pathways in the brainstem, and detect acoustic neuromas. The patient sits in a soundproof room and wears headphones. Clicking sounds are delivered one at a time to one ear while a masking sound is sent to the other ear.

Visual evoked potentials detect loss of vision from optic nerve damage (in particular, damage caused by multiple sclerosis). The patient sits close to a screen and is asked to focus on the center of a shifting checkerboard pattern. Only one eye is tested at a time. The other eye is either kept closed or covered with a patch.

Somatosensory evoked potentials measure response from stimuli to the peripheral nerves and can detect nerve or spinal cord damage or nerve degeneration from multiple sclerosis and other degenerating diseases. Tiny electrical shocks are delivered by electrode to a nerve in an arm or leg.

Cerebral Blood Flow Evaluation.

Cerebral blood flow (CBF) can be measured in many areas of the brain with the use of radioactive substances. It is particularly useful in evaluating cerebral vasospasm. Explain the test, and ask the physician if central nervous system (CNS) depressants and stimulants should be withheld for 24 hours before the test.

Lumbar Puncture.

Lumbar puncture (spinal tap) is the insertion of a spinal needle into the subarachnoid space between the third and fourth (sometimes the fourth and fifth) lumbar vertebrae (see Table 41-4).

A lumbar puncture (LP) is used to:

- Obtain cerebrospinal fluid (CSF) pressure readings with a manometer
- Obtain CSF for analysis
- Check for spinal blockage caused by a spinal cord lesion
- Inject contrast medium or air for diagnostic study
- Inject spinal anesthetics
- Inject selected drugs

Because of the danger of sudden release of CSF pressure, a lumbar puncture is not done for patients with symptoms indicating severely increased ICP. The procedure is also not performed in patients with skin infections at or near the puncture site because of the danger of introducing infective organisms into the CSF.

Before an LP is performed, position the patient in a fetal side-lying position to separate the vertebrae and move the spinal nerve roots away from the area to be accessed. The health care provider then cleans the skin site thoroughly. The injection site is determined, and a local anesthetic is injected. In a few minutes, a spinal needle is inserted between the third and fourth lumbar vertebrae. Instruct the patient to inform the provider if there is shooting pain or a tingling sensation. After determining proper placement in the subarachnoid space by removing the stylet and seeing CSF, the patient is asked to relax as much as possible so the pressure reading will be accurate. Opening and closing pressure readings are taken and recorded. Three to five test tubes of CSF are usually collected and numbered sequentially. After specimen collection, the needle is withdrawn, slight pressure is applied, and an adhesive bandage strip is placed over the insertion site.

Nursing Safety Priority QSEN

Action Alert

Be sure that the patient does not move during a lumbar puncture. If the patient is restless or cannot cooperate, two people may need to assist instead of one. The patient may need a sedative to reduce movement. Consider patient needs for additional assistance or sedation before beginning the procedure.

Examination of CSF has been a useful diagnostic tool for some time.

Recent technical advances are increasing the number of analyses that can be done on CSF. The normal characteristics of CSF and some of the more common abnormalities are given in Table 41-5. Gram-stain smears can test for particular types of meningitis, such as tubercular meningitis. CSF can be cultured, and sensitivity studies determine the best choice of antibiotic if an infection is diagnosed. A specific test for neurosyphilis is the fluorescent treponemal antibody absorption (FTA-ABS) test. Cytologic studies of CSF can identify tumor cells.

TABLE 41-5

Significance of Cerebrospinal Fluid Findings

FINDINGS	SIGNIFICANCE
Pressure	
More than 20 cm H_2O	Indicates increased spinal pressure, most often from bleeding, tumors, or infection within the central nervous system (CNS)
Color/Appearance	
Clear, colorless	Normal
Pink-red to orange	Red blood cells present
Yellow	Bilirubin present owing to hemolysis of red blood cells; possible causes include subarachnoid hemorrhage, jaundice, increased cerebrospinal fluid (CSF) protein, hypercarotenemia, or hemoglobinemia
Brown	Methemoglobin present, indicating previous meningeal hemorrhage
Unclear or hazy	Cell count is elevated
Cells	
0-5 small lymphocytes/mm^3	Normal
More than 5 lymphocytes/mm^3	Reaction to infection, tumor, chemical substance, or blood
Proteins	
Total	
15-45 mg/dL *(up to 70 mg/dL in older adults)*	Normal
45-100 mg/dL	Paraventricular tumor
50-200 mg/dL	Viral infection
More than 500 mg/dL	Bacterial infection, Guillain-Barré syndrome
Less than 15 mg/dL	Meningismus, pseudotumor cerebri, hyperthyroidism, normal finding after lumbar puncture
Immune Gamma Globulin (IgG, the most important protein)	
3%-12% of total protein	Normal
More than 12% of total protein	Multiple sclerosis, neurosyphilis, or viral infection
Albumin/Globulin Ratio	
8 : 1	Normal
Glucose	
50-75 mg/dL or 60%-70% of blood glucose level	Normal
Less than 50 mg/dL (usually accompanied by the presence of pathologic organisms)	May occur with bacterial, fungal, or viral meningitis; CNS leukemia; or cancer
Other Characteristics	
Lactic Acid	
10-25 mg/dL	Normal
More than 25 mg/dL	Systemic acidosis or increased CSF glucose metabolism
Glutamine	
6-15 mg/dL	Normal
More than 15 mg/dL	Hepatic coma or cirrhosis of liver
Lactate Dehydrogenase	
10% of serum level or 2.0-7.2 units/mL	Normal
More than 10% of serum level	Bacterial meningitis, inflammatory diseases of CNS

Complications of lumbar puncture, although not common, include brainstem herniation (discussed in Chapter 45), infection, CSF leakage, and hematoma formation.

Transcranial Doppler Ultrasonography.

Intracranial hemodynamics can be evaluated through the use of the transcranial Doppler (TCD). It uses sound waves to measure blood flow through the arteries. The test is particularly valuable in evaluating cerebral vasospasm or narrowing of arteries. TCD is safe, can be used repeatedly for the same patient, and is an inexpensive alternative to angiography.

Muscle and Nerve Biopsies.

Muscle or *nerve biopsies* are used to diagnose neuromuscular disorders. They may also reveal if a person is a carrier of a defective gene that could be passed on to children. Under local anesthesia, an incision is made into the skin or a hollow needle is inserted through the skin to remove a small sample of muscle or nerve. A CT scan or MRI is performed before a *brain biopsy.* This procedure involves injection of a local anesthetic into the scalp, drilling a small hole through the skull, and inserting a hollow needle into the site of the lesion. Muscle, nerve, and brain biopsy samples are analyzed under a microscope to identify abnormalities.

Nursing Concepts and Clinical Judgment Review

What might you NOTICE in a patient with adequate cognition, mobility, and sensory perception?

Physical assessment:

- Alert and oriented, intact short-term and long-term memory, appropriate judgment, and adequate attention span
- Communicates clearly
- Moves all four extremities without assistance and normal strength
- Performs ADLs independently
- Walks, with or without assistive devices, using normal gait
- No deficits in or unusual sensory perception
- Pupils equal in size, round and regular in shape, and reactive to light and accommodation (PERRLA)

Diagnostic assessment:

- Normal ECG
- Normal CSF
- Normal EEG
- Normal CT scan of brain
- Normal MRI scan of spinal cord

Get Ready for the NCLEX® Examination!

Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Perform a neurologic examination that may be either comprehensive or focused as determined by patient needs. **Patient-Centered Care** QSEN
- Identify key changes in the examination that need to be communicated urgently to the health care provider or other team members. **Teamwork and Collaboration** QSEN
- Collaborate with the health care provider, physical therapist, and speech-language pathologist to establish priorities in neurologic assessment. **Teamwork and Collaboration** QSEN

Health Promotion and Maintenance

- Evaluate the presence of risk factors that place patients at risk for neurologic health problems such as behaviors that result in serious harm (e.g., driving recklessly) and lifestyle choices. **Evidence-Based Practice** QSEN
- Detect neurologic changes early with health screening and physical assessment strategies that reflect the prioritized assessment. Recall that a deterioration in level of consciousness (e.g., from alert to lethargic) is the most sensitive and reliable indicator of an adverse neurologic change. Include a daily evaluation for acute confusion or delirium in hospital settings. **Evidence-Based Practice** QSEN
- Consider loss of short-term memory as a potential early sign of neurologic problems. Use findings from diagnostic imaging tests to help evaluate potential neurologic impairment (Tables 41-4 and 41-5).

Psychosocial Integrity

- Assess the reaction of the person to neurologic disease. The psychological responses to neurologic health problems can vary by age, gender, and cultural background. **Patient-Centered Care** QSEN
- Encourage patients to express their feelings, and refer them to appropriate support services as needed.

Physiological Integrity

- Take a patient history, including information listed in Chart 41-2.

Patient-Centered Care QSEN

- Evaluate the patient's cognitive abilities on admission and regularly thereafter, using a systematic approach (Chart 41-3). **Evidence-Based Practice** QSEN
- Use the Glasgow Coma Scale for patients with new traumatic brain injury.
- Use the BIMS, CAM, CAM-ICU, or other validated tool to detect delirium, an acute confusional state.
- Assess motor and sensory function to reduce harm from acute deterioration or chronic deficits. This type of assessment is also needed for discharge planning.
- Include assessment of gait, balance, and coordination to determine risk for falls. **Safety** QSEN
- Check cranial nerve III by examining pupils for size, shape, and reaction to light. Pupils should be equal in size, round and regular in shape, and become smaller in bright light. Changes in eye signs can indicate new neurologic deterioration in nonverbal patients. **Evidence-Based Practice** QSEN
- Accommodation occurs when the eyes converge and pupils constrict as an object is moved from several feet away to within 4 to 5 inches of the nose.
- Promote independence in consultation with physical and occupational therapists and the use of assistive devices like a walker or brace. **Teamwork and Collaboration** QSEN
- Assist with the performance of daily living activities when the neurologic condition interferes with self-care. **Patient-Centered Care** QSEN
- Reduce complications for patients having neurologic diagnostic testing by providing adequate teaching and preparation as outlined in Table 41-4. **Evidence-Based Practice** QSEN
- Use serum creatinine or estimated glomerular filtration rate to identify patients with reduced kidney function. Older adults and patients with chronic kidney disease, diabetes, or heart failure are at high risk for kidney damage from iodinated and gadolinium contrast media. Provide adequate fluid intake before and after diagnostic testing to flush contrast after a diagnostic test (see Chart 41-4).
- Teach patients having an EEG to follow the precautions listed in Table 41-4.
- Check for bleeding after patients have an angiography. If bleeding is observed, call the radiologist immediately.
- Before MRI, check for implanted devices such as pacemakers, vascular

stents, pumps, and aneurysm clips.

- Link abnormal neurologic function with anatomy and physiology to anticipate impaired function, prognosis, and safe, effective interventions. **Evidence-Based Practice** QSEN
- Cerebrospinal fluid (CSF) is clear and colorless with few cells. Significant changes include the presence of cells, color, and turbidity (Table 41-5).
- Use findings from diagnostic imaging tests and anatomic location of injury to locate potential neurologic impairment for a focused examination (Tables 41-1, 41-2, and 41-3).
- Decerebrate or decorticate posturing and pinpoint or dilated nonreactive pupils are late signs of neurologic deterioration.
- Recognize that older adults do not normally experience deterioration in cognition and memory but do experience physical and physiological changes that affect mobility and sensory perception (Chart 41-1). **Patient-Centered Care** QSEN
- Provide a safe environment when memory loss is part of the older adult's health status by using memory aids and assistive technology to meet teaching or self-care goals. **Safety** QSEN
- Provide safe opportunities for mobility, including physical activity like walking, when caring for older adults. Mobility and physical activity promote cognition.

CHAPTER 42

Care of Patients with Problems of the Central Nervous System

The Brain

Rachel L. Gallagher

PRIORITY CONCEPTS

- Cognition
- Pain
- Mobility
- Infection

Learning Outcomes

Safe and Effective Care Environment

1. Plan with the interdisciplinary team for transitions in care including discharge to home or other setting for patients with chronic problems of the brain.
2. Implement interventions to protect patients with chronic brain conditions from injury and infection, including pain management.
3. Provide written instructions about drug therapy for chronic health problems to patients and caregivers when transitioning to a new care setting.

Health Promotion and Maintenance

4. Teach patients with chronic headaches about preventive and management approaches to therapy.
5. Develop a teaching plan about drug therapy for patients with epilepsy.

6. Teach patients about vaccination to prevent meningitis.

Psychosocial Integrity

7. Include family members, patient preferences, and values in planning care, including strategies to reduce the psychosocial impact of chronic brain conditions on patients and family members.
8. Identify community resources to support caregivers or patients with chronic neurodegenerative diseases to promote cognition and mobility.

Physiological Integrity

9. Compare and contrast assessment and management for migraine and cluster headaches.
10. Differentiate the common types of seizures, including presenting clinical manifestations.
11. Prioritize evidence-based care for patients with a seizure disorder, including appropriate seizure precaution interventions.
12. Identify nursing priorities for patients with bacterial meningitis and encephalitis.
13. Identify the genetic and environmental influences on development of Parkinson disease (PD), dementia (Alzheimer's disease [AD]), and Huntington disease (HD).
14. Document a collaborative plan of care for patients with chronic brain conditions like PD, dementia, and HD based on patient values and preferences.
15. Prevent or reduce common risk factors that contribute to functional decline and decreased quality of life in adults and older adults with chronic brain disorders.

 http://evolve.elsevier.com/Iggy/

This chapter discusses five chronic and two acute neurologic conditions. All of these neurologic disorders interfere with self-management and independence; many of them contribute to chronic pain and reduced mobility. Care of patients with chronic neurologic disorders requires coordination by nurses and significant collaboration with other members of the interdisciplinary health care team. The patient and family are the center of the collaborative team in making decisions about

the plan of care (Quality and Safety Education for Nurses [QSEN], 2014).

Headaches

Almost everyone has had a headache at some time in his or her life. Some headaches are related to sinus congestion, allergies, or stress and are temporary. Others can be very serious and potentially life threatening. For example, an abnormal neurologic assessment together with symptoms of a cluster headache may indicate a serious neurologic problem. Patients with these symptoms are referred immediately to their health care provider or the emergency department.

Although there are many types and causes of headaches, the focus of this section is on two common types that cause people to seek medical attention: migraine headaches and cluster headaches. Patients are usually managed in the ambulatory care setting by the primary health care provider. However, it is not unusual for the person in severe pain to seek treatment in the emergency department. Refer to Chart 42-1 for questions to determine the pattern of headaches when assessing a patient.

Chart 42-1 Determining a Pattern of Headaches

Ask the patient:

- When do the headaches occur?
- How do they start?
- How often?
- How long do they last?
- Do you have the same type of headache all the time?
- Where do you feel the headache pain?
- Does the headache pain spread to other areas of the head?
- How does the headache pain feel: throbbing, stabbing, pounding, squeezing, or something else?
- Do you ever have accompanying symptoms with your headache, such as nausea, vomiting, diarrhea, dizziness, changes in vision, weakness?
- Do certain foods, alcohol, or other things trigger the headaches?
- Have there been any recent changes in your headaches?
- How do you treat the headaches? Does this treatment work?
- How often and what drug or herbal remedy do you take?
- Has a headache ever been severe enough to go to the emergency room for treatment?
- Have you ever been hospitalized for headache treatment?
- Have you ever seen a specialist (neurologist) for your headache?
- What do think might be causing your headaches?

- Is there a family history of headaches?
- Do you have to stop what you are doing or miss work when you get a headache?

Nursing Safety Priority QSEN

Action Alert

Encourage patients to keep a headache diary to help identify the type of headache they are experiencing and the response to medication or other intervention. Teach them to notify their health care provider if the quality, intensity, or nature of the headache increases or changes. Encourage them to report whether the headache is associated with new or unusual visual changes and whether the prescribed drug is no longer effective.

Migraine Headache

Pathophysiology

A **migraine headache** is a common clinical syndrome characterized by recurrent episodic attacks of head pain that serve no protective purpose. Migraine headache pain is usually described as throbbing and unilateral. Migraine can be accompanied by associated symptoms such as nausea or sensitivity to light, sound, or head movement. Migraine disorders are further characterized by multiple subtypes (McCance et al., 2014). Migraine pain and associated symptoms can last 4 to 72 hours. Migraines tend to be familial, and women are affected more commonly than men. Women diagnosed with migraines are more likely to have major depressive disorder (Modgill et al., 2012). Migraine sufferers are also at risk for stroke and epilepsy (McCance et al., 2014).

The cause of migraine headaches is not clear but includes a combination of neuronal hyperexcitability and vascular, genetic, hormonal, and environmental factors. In general, experts suggest that migraines are a neurogenic process with secondary cerebral vasodilation followed by a sterile brain tissue inflammation. Patients may inherit a condition of neuronal hyperexcitability from ion channel variations, particularly calcium and sodium-potassium pump channels, as well as from genetic variations in serotonin and dopamine receptors. Following stimulation of these hyper-excitable neuronal pathways, vascular changes occur. Pain-sensing cells in the blood vessels of the brain initiate the attack. Activation of the trigeminal nerve pathways contributes to the

cascade of events that activate **nociceptors**. Substances that increase sensitivity to pain such as glutamate are synthesized through the trigeminal pathway (McCance et al., 2014). As cerebral arteries dilate, **prostaglandins** are released (chemicals that cause inflammation and swelling). Vasodilation, in turn, allows prostaglandins and other intravascular molecules to leak (**extravasate**), contributing to widespread tissue swelling and the sensation of throbbing pain.

Many patients find that certain factors, or *triggers*, such as caffeine, red wine, and monosodium glutamate (MSG), tend to cause migraine headache attacks. Each patient is different regarding which environmental factors trigger headaches. For some patients, stress or a change in weather can lead to an attack. These stimuli are thought to initiate the cascade of events that cause migraines by activating hyper-excitable neurons. Neurons involved in the initiation and propagation of migraines may have an early sensitization to neurotransmitters such that patients become increasingly susceptible to triggers and to the cascade of events that culminate in migraine pain. Thus care includes not only managing pain but also disrupting the migraine cascade to decrease sensitization and recurrent attacks.

Patient-Centered Collaborative Care

Assessment

Migraines fall into three categories: migraines with aura, migraines without aura, and atypical migraines. An **aura** is a sensation such as visual changes that signals the onset of a headache or seizure. In a migraine, the aura occurs immediately before the migraine episode. *Most headaches are migraines without aura*. The key features of migraines are listed in Chart 42-2. **Atypical migraines** are less common and include menstrual and cluster migraines. The stages of migraine may include:

Chart 42-2 Key Features

Migraine Headaches

Phases of Migraine with Aura (Classic Migraine)

First, or Prodrome, Phase

- Aura develops over a period of several minutes and lasts no longer than 1 hour.
- Well-defined transient focal neurologic dysfunction exists.

- Pain may be preceded by:
  - Visual disturbances
    - Flashing lights
    - Lines or spots
    - Shimmering or zigzag lights
- A variety of neurologic changes, including:
    - Numbness, tingling of the lips or tongue
    - Acute confusional state
    - Aphasia
    - Vertigo
    - Unilateral weakness
    - Drowsiness

Second Phase

- Headache is accompanied by nausea and vomiting.
- Pain usually begins in the temple. It increases in intensity and becomes throbbing within 1 hour.

Third Phase

- Pain changes from throbbing to dull.
- Headache, nausea, and vomiting usually last from 4 to 72 hours. (Older patients may have aura without pain, known as a *visual migraine.*)

Migraine Without Aura (Common Migraine)

- Migraine begins without an aura before the onset of the headache.
- Pain is aggravated by performing routine physical activities.
- Pain is unilateral and pulsating.
- One of these symptoms is present:
  - Nausea and/or vomiting
  - **Photophobia** (light sensitivity)
  - **Phonophobia** (sound sensitivity)
- Headache lasts for 4 to 72 hours.
- Migraine often occurs in the early morning, during periods of stress, or in those with premenstrual tension or fluid retention.

Atypical Migraine

- Status migrainous:
  - Headache lasts longer than 72 hours.
- Migrainous infarction:
  - Neurologic symptoms are not completely reversible within 7 days.
  - Ischemic infarct is noted on neuroimaging.
- Unclassified:

■ Headache does not fulfill all of the criteria to be classified a migraine.

- Prodromal (or prodrome) phase, in which the patient has specific symptoms such as food cravings or mood changes
- Aura phase (if present), which generally involves visual changes, flashing lights, or **diplopia** (double vision)
- Headache phase, which may last a few hours to a few days
- Termination phase, in which the intensity of the headache decreases
- Postprodrome phase, in which the patient is often fatigued, may be irritable, and has muscle pain

The diagnosis of migraine headache is based on the patient's history and on physical, neurologic, and psychological assessment. The typical migraine is described as a unilateral, fronto-temporal, *throbbing* pain in the head that is often worse behind one eye or ear. It is often accompanied by a sensitive scalp, anorexia, **photophobia** (sensitivity to light), **phonophobia** (sensitivity to noise), and nausea with or without vomiting. Patients tend to have the same clinical manifestations each time they have a migraine headache. Some may have to refrain from regular activities for several days if they cannot control or relieve the pain in its early stage.

Some physicians recommend screening patients with migraines using the Minnesota Multiphasic Personality Inventory–2 to identify personality traits and possible mental health/behavioral health problems like depression that may contribute to the headache experience (Rausa et al., 2013). Neuroimaging such as magnetic resonance imaging (MRI) may be indicated if the patient has other neurologic findings, a history of seizures, findings not consistent with a migraine, or a change in the severity of the symptoms or frequency of the attacks.

Neuroimaging is also recommended in patients older than 50 years with a new onset of headaches, especially women. Women with a history of migraines with visual symptoms may have an increased risk for stroke, particularly if a migraine with visual symptoms occurred in the past year. Teach women older than 50 years who have migraines about the risk factors for cardiovascular disease. Encourage them to notify their health care provider if they experience symptoms such as facial drooping, arm weakness, or difficulties with speech.

Interventions

The priority for care of the patient having migraines is pain management. This outcome may be achieved by abortive and preventive therapy. Drug therapy, trigger management, and complementary and alternative

therapies are the major approaches to care. Provide detailed patient and family education regarding the collaborative plan of care. Effective physician/patient communication is increasingly important in managing the symptoms of migraines. Tools to help patients communicate with their health care provider and partner with their provider to manage pain are best practices in migraine diagnosis and treatment (Marcus, 2014).

Abortive Therapy.

Abortive therapy is aimed at alleviating pain during the aura phase (if present) or soon after the headache has started. *Drug therapy* is prescribed to manage migraine headaches. Some of the drugs being used have major side effects, contraindications, and nursing implications. The health care provider must consider any other medical conditions that the patient has when prescribing drug therapy. In general, the patient is started on a low dose that is increased until the desired clinical effect is obtained. Table 42-1 lists commonly used drugs for migraine headaches. Many new drugs are being investigated for this painful and often debilitating health problem.

TABLE 42-1

Commonly Used Drugs for Migraine Headache

Nonspecific Analgesics
• Acetaminophen • Isometheptene • Butalbital
Nonsteroidal Anti-Inflammatory Drugs (NSAIDs)
• Ibuprofen • Naproxen
Ergotamine Preparations
• Ergotamine with caffeine (oral or suppository) (Cafergot, Migergot) • Ergotamine sublingual (SL) (Ergomar SL) • Medihaler ergotamine (oral inhalation aerosol) • Dihydroergotamine (DHE) nasal spray (Migranal)
Beta Blockers
• Propranolol • Timolol
Calcium Channel Blockers
• Verapamil (Calan)
Triptan Preparations
• Almotriptan (Axert) • Eletriptan (Relpax) • Rizatriptan (Maxalt) • Zolmitriptan (Zomig) • Sumatriptan (Imitrex) • Frovatriptan (Frova)
Isometheptene Combination
• Midrin
Antiepileptic Drugs (AEDs)
• Divalproex (Depakote) • Topiramate (Topamax)

Mild migraines may be relieved by acetaminophen (APAP) (Tylenol, Abenol). NSAIDs such as ibuprofen (Motrin) and naproxen (Naprosyn) may also be prescribed. In the United States, the Food and Drug Administration (FDA) has approved several over-the-counter (OTC) anti-inflammatory drugs for migraines, including Advil Migraine Capsules, Motrin Migraine Pain Caplets, and Excedrin Migraine Tablets or Caplets (contain APAP, aspirin, and caffeine). Caffeine narrows blood vessels by blocking adenosine, which dilates vessels and increases inflammation. Antiemetics may be prescribed to relieve nausea and vomiting. Metoclopramide (Reglan, Clopra) may be administered with NSAIDs to promote gastric emptying and decrease vomiting.

For more *severe* migraines, drugs such as triptan preparations, ergotamine derivatives, and isometheptene combinations are needed. A potential side effect of these drugs is **rebound headache,** also known as **medication overuse headache,** in which another headache occurs after

the drug relieves the initial migraine.

Triptan preparations relieve the headache and associated symptoms by activating the 5-HT (serotonin) receptors on the cranial arteries, the basilar artery, and the blood vessels of the dura mater to produce a vasoconstrictive effect. Examples are listed in Table 42-1. For many patients, these drugs are highly effective for pain, nausea, vomiting, and light and sound sensitivity with few side effects. Most are contraindicated in patients with actual or suspected ischemic heart disease, cerebrovascular ischemia, hypertension, and peripheral vascular disease and in those with Prinzmetal's angina because of the potential for coronary vasospasm. Patients respond differently to drugs, and several types or combinations may be tried before the headache is relieved.

Nursing Safety Priority QSEN

Drug Alert

Teach patients taking triptan drugs to take them as soon as migraine symptoms develop. Instruct patients to report angina (chest pain) or chest discomfort to their health care providers immediately to prevent cardiac damage from myocardial ischemia. Remind them to use contraception (birth control) while taking the drugs because the drugs may not be safe for women who are pregnant. Teach them to expect common side effects that include flushing, tingling, and a hot sensation. These annoying sensations tend to subside after the patient's body gets used to the drug. Triptan drugs should not be taken with selective serotonin reuptake inhibitor (SSRI) antidepressants or St. John's wort, an herb used commonly for depression (Lilley et al., 2014).

Ergotamine preparations such as Cafergot are taken at the start of the headache. The patient may take up to six tablets in 24 hours or use a rectal suppository. Dihydroergotamine (DHE) may be given IV, IM, or as a nasal spray (Migranal) with an antiemetic if pain control and relief of nausea are not achieved with other drugs. DHE should not be given within 24 hours of a triptan drug.

Midrin is a combination drug containing APAP, isometheptene, and dichloralphenazone. It is the most common *isometheptene combination* given for treating migraines and is an excellent option when ergotamine preparations are not tolerated or do not work.

Other drugs that have been prescribed to relieve migraine pain include

opioids and barbiturates. *These drugs should be avoided if at all possible because they are addictive. Some opioids actually cause a migraine.*

Preventive Therapy.

Prevention drugs and other strategies are used when a migraine occurs more than twice per week, interferes with ADLs, or is not relieved with acute treatment. Unless otherwise contraindicated, the health care provider may initially prescribe an NSAID, a beta-adrenergic blocker, a calcium channel blocker, or an antiepileptic drug (AED). Propranolol (Inderal, Apo-Propranolol, Novopranol) and timolol (Blocadren, Apo-Timol) are the only *beta blockers* approved for migraine prevention. Verapamil (Calan, Apo-Verap), a *calcium channel blocking agent*, may also be used for some patients. The calcium channel and beta blockers are thought to reduce the activity of hyper-excitable neurons and act on the neurogenic causes of migraine. Both calcium channel blockers and beta blockers interfere with vasodilation, a contributing cause of migraine pain. Both beta-adrenergic blockers and calcium channel blocking drugs can lower blood pressure and decrease pulse rate.

Nursing Safety Priority QSEN

Drug Alert

Teach patients who take beta-adrenergic blockers or calcium channel blockers how to take their pulse. Encourage them to report bradycardia or adverse reactions such as fatigue and shortness of breath to their health care provider as soon as possible.

Topiramate (Topamax) is one of the most common *antiepileptic drugs (AEDs)* used for migraines, but it should be used in low doses of 25 to 100 mg daily. The mechanism of action is not clear, but this drug may inhibit the sodium channels, channels that may be hyper-excitable in patients with migraine. Reports of suicides have been associated with this drug when it is used in larger doses of 400 mg daily, most often with patients who have bipolar disorder.

For chronic migraine, onabotulinumtoxinA (Botox) is the only therapy approved for adults. Doses of 75 to 260 units are administered in seven specific areas of the head and neck by the health care provider. Monthly treatments for up to five treatment cycles are considered safe and effective (Diener et al., 2014; Carod-Artel, 2014).

In addition to drug therapy, *trigger avoidance and management* are important interventions for preventing migraine episodes. For example, some patients find that avoiding tyramine-containing products, such as pickled products, caffeine, beer, wine, preservatives, and artificial sweeteners, reduces their headaches. Others have identified specific factors that trigger an attack for them. Help patients identify triggers that could cause migraine episodes, and teach them to avoid them once identified (Chart 42-3). For example, at the beginning of a migraine attack, the patient may be able to reduce pain by lying down and darkening the room. He or she may want both eyes covered and a cool cloth on the forehead. If the patient falls asleep, he or she should remain undisturbed until awakening.

Chart 42-3 Patient and Family Education: Preparing for Self-Management

Factors That May Trigger a Migraine Attack

Teach patients to avoid factors that may trigger a migraine attack.

Foods Commonly Associated with Migraines

- Alcoholic drinks: beer, wine, and hard liquor
- Aged cheese or other foods with tyramine
- Caffeine found in beverages such as coffee, tea, cola OR caffeine withdrawal
- Chocolate
- Foods with yeast such as pastry and fresh breads
- Monosodium glutamate (MSG)
- Nitrates (meats), pickled or fermented foods
- Nuts
- Artificial sweeteners
- Smoked fish

Drugs Associated with Migraines

- Cimetidine (Tagamet)
- Estrogens
- Nitroglycerin
- Nifedipine (Procardia, Nifed)

Other Factors That Can Trigger a Migraine Attack

- Anger, conflict
- Fatigue

- Hormonal fluctuations, such as menstruation, pregnancy, and menopause
- Light glare
- Missed meals, hypoglycemia
- Psychological stress
- Sleep problems
- Smells, such as tobacco smoke
- Travel to different altitudes

Complementary and Alternative Therapies.

Many patients use complementary and alternative therapies as adjuncts to drug therapy. Yoga, meditation, massage, exercise, and biofeedback are helpful in preventing or treating migraines for some patients. Vitamin B_{12} (riboflavin), coenzyme *Q10*, and magnesium supplement to maintain normal serum values have a role in migraine prevention (Mauskop, 2012).

Acupuncture and acupressure may be effective in relieving pain for some patients. Some plastic surgeons have resected the trigeminal nerve to relieve chronic migraine pain. A number of herbs are also used for headaches, both for prevention and pain management. Teach patients that all herbs and nutritional remedies should be approved by their health care provider before use because they could interact with prescribed medication. At this time, there is insufficient evidence to support any herb or natural remedy, but some patients have had positive results.

NCLEX Examination Challenge

Health Promotion and Maintenance

The nurse is preparing a teaching plan for a client with migraine headaches. Which of these foods or food additives may trigger a migraine headache?

A Salt
B Sugar
C Tyramine
D Glutamine

Cluster Headache

Pathophysiology

Cluster headaches are manifested by brief (30 minutes to 2 hours),

intense unilateral pain that generally occurs in the spring and fall without warning. It is classified as the *most common chronic short-duration headache* with pain lasting less than 4 hours. Also referred to as *trigeminal autonomic cephalalgia,* it is far less common than migraines. Cluster headaches typically develop in men between 20 and 50 years of age. The cause and mechanism of cluster headaches are not known but have been attributed to vasoreactivity and neurogenic inflammation (McCance et al., 2014). Neuroimaging studies suggest that cluster headaches are related to an overactive and enlarged hypothalamus.

Patient-Centered Collaborative Care

Assessment

Question the patient about prescribed drugs for both the prevention and relief of the headache, as well as OTC drugs and herbal preparations he or she may be taking. Interventions used by the patient may include relaxation techniques, meditation, acupuncture, massage therapies, and avoidance of the known headache trigger. Ask the patient to recall a typical week's activities and any recent changes in lifestyle. Explore the relationship of cluster headache onset with emotional and behavioral precipitating factors such as bursts of anger, prolonged anticipation, excessive physical activity, and excitement. Ask him or her to identify bedtimes and waking times to help assess changes in activity or lack of continuity in the sleep-wake cycle.

The pain of these unilateral (one-sided) oculotemporal or oculofrontal headaches is often described as excruciating, boring, and *nonthrobbing*. The intense pain is felt deep in and around the eye. The headaches occur at about the same time of day for about 4 to 12 weeks (hence the term *cluster*), followed by a period of remission for 9 months to a year. This episodic form is the most common, although there is a chronic, intractable form in which there may not be a remission for more than a year.

The pain may radiate to the forehead, temple, or cheek. It may also radiate, but to a lesser extent, to the ear and neck. The temporal artery may be prominent and tender. The patient often paces, walks, or sits and rocks during an attack. A cluster is the only headache type in which this behavior occurs. During periods of remission, alcohol does not cause a headache (as it does during the headache period). The onset of the pain is associated with relaxation, napping, or rapid eye movement (REM) sleep.

The headache usually occurs with:

- **Ipsilateral** (same side) tearing of the eye
- **Rhinorrhea** ("runny nose") or congestion
- **Ptosis** (drooping eyelid)
- Eyelid edema
- Facial sweating
- **Miosis** (constriction of pupils)

The ptosis may become permanent. Assess for possible bradycardia, flushing or pallor of the face, increased intraocular pressure, and increased skin temperature. Nausea and vomiting may also occur. The patient may become restless and agitated from the intense pain of the headache.

Interventions

Explain the need for and importance of a consistent sleep-wake cycle. The health care provider typically prescribes some of the same types of drugs used for migraines, such as triptans, ergotamine preparations, calcium channel blockers, and antiepileptic drugs (see discussion of drug therapy in the Migraine Headache section). Additional drugs include lithium and corticosteroids. OTC civamide (a capsaicin isomer), available as a nasal spray, oral melatonin, and oral glucosamine are also used by some patients. Provide health teaching about drug therapy (Lilley et al., 2014).

During the periods of attack, teach the patient to wear sunglasses and to sit facing away from the window to help decrease exposure to light and glare. For a cluster migraine, the health care provider may prescribe oxygen via high-flow mask at 12 L/min. High-flow oxygen to manage a cluster migraine is typically administered with the patient in a sitting position. Administer the oxygen for 15 to 20 minutes; most patients report relief within 15 minutes. High-flow oxygen is thought to inhibit activity of the carotid bodies and reduce the vasoreactivity of cerebral blood vessels to neurogenic stimuli. Patients may use oxygen at home. Teach them about the precautions that must be taken when oxygen is used (see Chapter 28).

Surgical intervention may be recommended for patients with *chronic* drug-resistant cluster headaches. Invasive ambulatory care procedures, such as *percutaneous stereotactic rhizotomy (PSR),* are performed with varying success rates. Information about this procedure is found in Chapter 44 in the Trigeminal Neuralgia section. Long-term high-frequency electrical stimulation of the posterior hypothalamus, also known as *deep brain stimulation,* may reduce or eliminate pain (see procedure discussion on p. 871 in the Parkinson Disease section). It has not been approved by the FDA but is being investigated. Both of these

procedures have major complications that can cause permanent brain or nerve damage. Therefore they are done as a last resort.

Seizures and Epilepsy

Pathophysiology

A **seizure** is an abnormal, sudden, excessive, uncontrolled electrical discharge of neurons within the brain that may result in a change in level of consciousness (LOC), motor or sensory ability, and/or behavior. A single seizure may occur for no known reason. Some seizures are caused by a pathologic condition of the brain, such as a tumor. In this case, once the underlying problem is treated, the patient is often asymptomatic.

Epilepsy is defined by the National Institute of Neurological Disorders and Stroke as two or more seizures experienced by a person. It is a chronic disorder in which repeated unprovoked seizure activity occurs. It may be caused by an abnormality in electrical neuronal activity; an imbalance of neurotransmitters, especially gamma aminobutyric acid (GABA); or a combination of both (McCance et al., 2014).

Types of Seizures

The International Classification of Epileptic Seizures recognizes three broad categories of seizure disorders: generalized seizures, partial seizures, and unclassified seizures.

Five types of **generalized seizures** may occur in adults and involve *both* cerebral hemispheres. The *tonic-clonic seizure* lasting 2 to 5 minutes begins with a **tonic phase** that causes stiffening or rigidity of the muscles, particularly of the arms and legs, and immediate loss of consciousness. **Clonic** or **rhythmic** jerking of all extremities follows. The patient may bite his or her tongue and may become incontinent of urine or feces. Fatigue, acute confusion, and lethargy may last up to an hour after the seizure.

Occasionally, only tonic or clonic movement may occur. A *tonic seizure* is an abrupt increase in muscle tone, loss of consciousness, and autonomic changes lasting from 30 seconds to several minutes. The *clonic seizure* lasts several minutes and causes muscle contraction and relaxation.

The *myoclonic seizure* causes a brief jerking or stiffening of the extremities that may occur singly or in groups. Lasting for just a few seconds, the contractions may be symmetric (both sides) or asymmetric (one side).

In an *atonic (akinetic) seizure*, the patient has a sudden loss of muscle tone, lasting for seconds, followed by **postictal** (after the seizure) confusion. In most cases, these seizures cause the patient to fall, which may result in injury. This type of seizure tends to be most resistant to drug therapy.

Partial seizures, also called *focal* or *local* seizures, begin in a part of *one* cerebral hemisphere. They are further subdivided into two main classes: complex partial seizures and simple partial seizures. In addition, some partial seizures can become generalized tonic-clonic, tonic, or clonic seizures. Partial seizures are most often seen in adults and generally are less responsive to medical treatment when compared with other types.

Complex partial seizures may cause loss of consciousness **(syncope),** or "black out," for 1 to 3 minutes. Characteristic automatisms may occur as in absence seizures. The patient is unaware of the environment and may wander at the start of the seizure. In the period after the seizure, he or she may have **amnesia** (loss of memory). Because the area of the brain most often involved in this type of epilepsy is the temporal lobe, complex partial seizures are often called *psychomotor* seizures or *temporal lobe* seizures.

Considerations for Older Adults

Patient-Centered Care QSEN

Complex partial seizures are most common among older adults. These seizures are difficult to diagnose because symptoms appear similar to dementia, psychosis, or other neurobehavioral disorders, especially in the **postictal stage** (after the seizure). New-onset seizures in older adults are typically associated with conditions such as hypertension, cardiac disease, diabetes mellitus, stroke, dementia, and recent brain injury (Lin et al., 2012).

The patient with a *simple partial seizure* remains conscious throughout the episode. He or she often reports an **aura** (unusual sensation) before the seizure takes place. This may consist of a "déjà vu" (already seen) phenomenon, perception of an offensive smell, or sudden onset of pain. During the seizure, the patient may have one-sided movement of an extremity, experience unusual sensations, or have autonomic symptoms. Autonomic changes include a change in heart rate, skin flushing, and epigastric discomfort.

Unclassified, or **idiopathic, seizures** account for about half of all seizure activity. They occur for no known reason and do not fit into the generalized or partial classifications.

Etiology and Genetic Risk

Primary or *idiopathic epilepsy* is not associated with any identifiable brain lesion or other specific cause; however, genetic factors most likely play a

role in its development. *Secondary seizures* result from an underlying brain lesion, most commonly a tumor or trauma. They may also be caused by:

- Metabolic disorders
- Acute alcohol withdrawal
- Electrolyte disturbances (e.g., hyperkalemia, water intoxication, hypoglycemia)
- High fever
- Stroke
- Head injury
- Substance abuse
- Heart disease

Seizures resulting from these problems are not considered epilepsy. Various risk factors can trigger a seizure, such as increased physical activity, emotional stress, excessive fatigue, alcohol or caffeine consumption, or certain foods or chemicals.

Patient-Centered Collaborative Care

Assessment

Question the patient or family about how many seizures the patient has had, how long they last, and any pattern of occurrence. Ask the patient or family to describe the seizures that the patient has had. Clinical manifestations vary depending on the type of seizure experienced, as described earlier. Ask about the presence of an aura before seizures begin **(preictal phase).** Question whether the patient is taking any prescribed drugs or herbs or has had head trauma or high fever. Assess any alcohol and/or illicit drug history. Ask about any other medical condition such as a previous stroke or hypertension.

If the seizure is a new symptom, ask the patient or family if any loss of consciousness or brain injury has occurred, both in the recent and distant past. Oftentimes, patients may have had a head or brain injury sufficient to cause a loss of consciousness but may not remember this at the time of the seizure, especially if it was during their childhood.

Diagnosis is based on the history and physical examination. A variety of diagnostic tests are performed to rule out other causes of seizure activity and to confirm the diagnosis of epilepsy. Typical diagnostic tests include an electroencephalogram (EEG), computed tomography (CT) scan, MRI, or positron emission tomography (PET) scan. These tests are described in Chapter 41. Laboratory studies are performed to identify metabolic or other disorders that may cause or contribute to seizure

activity.

Interventions

Removing or treating the underlying condition or cause of the seizure manages *secondary* epilepsy and seizures that are not considered epileptic. *In most cases, primary epilepsy is successfully managed through drug therapy.*

Nonsurgical Management.

Most seizures can be completely or almost completely controlled through the administration of **antiepileptic drugs (AEDs),** sometimes referred to as *anticonvulsants,* for specific types of seizures.

Drug Therapy.

Drug therapy is the major component of management (Chart 42-4). The health care provider introduces one antiepileptic drug (AED) at a time to achieve seizure control. If the chosen drug is not effective, the dosage may be increased or another drug introduced. At times, seizure control is achieved only through a combination of drugs. The dosages are adjusted to achieve therapeutic blood levels without causing major side effects.

Chart 42-4 Common Examples of Drug Therapy

Epilepsy

DRUG	INDICATION FOR USE	NURSING INTERVENTIONS
Carbamazepine (Tegretol, Tegretol-XR, Carbatrol)	Partial, generalized tonic-clonic seizures	Monitor for headache, dizziness, diplopia or blurred vision, N/V, and leukopenia. Monitor CBC. Do not crush or chew sustained-release capsules.
Clonazepam (Klonopin)	Absence, myoclonic, and akinetic seizures	Monitor results of liver function tests.
Clorazepate dipotassium	Adjunctive management of partial seizures	Give with food. Monitor blood pressure.
Diazepam (Valium, Apo-Diazepam), lorazepam (Ativan), Diastat (diazepam rectal gel delivery system)	Status epilepticus	Monitor airway, breathing, circulation (ABCs).
Divalproex (Depakote), valproic acid (Depakene)	All types of seizures	Monitor for hair loss, tremor, increased liver enzymes, bruising, and N/V. Monitor CBC, PT, PTT, and AST.
Ethosuximide (Zarontin)	Absence seizures	Watch for N/V, skin rash, lethargy, and anorexia. Monitor CBC and liver function tests. (Drug used infrequently.)
Felbamate (Felbatol)	Adjunctive therapy for intractable complex partial seizures	Note that aplastic anemia and liver failure are major sequelae of treatment. Patient must sign consent for use, acknowledging risk for aplastic anemia and liver failure. Monitor CBC. Monitor liver function tests. Watch for anorexia and weight loss.
Gabapentin (Neurontin)	Partial seizures	Watch for increased appetite and weight gain. Monitor for ataxia, irritability, dizziness, and fatigue.
Lamotrigine (Lamictal)	Partial seizures	Watch for diplopia, headaches, dizziness, drowsiness, ataxia, N/V, and life-threatening rash when given with valproic acid.
Levetiracetam (Keppra)	Adjunct management of partial seizures	Monitor renal function carefully. Notify health care provider for gait or coordination problems.
Oxcarbazepine (Trileptal)	Partial seizures	Monitor for hyponatremia.
Phenobarbital (Barbita, Luminal)	Generalized tonic-clonic seizures, partial seizures	Note that this is less desirable than other antiepileptic drugs (AEDs) because of sedation. Be aware that overdose can be fatal. Monitor for drowsiness, sleep disturbances, impaired cognition, and depression.
Phenytoin (Dilantin), fosphenytoin (Cerebyx)	All types, except absence, myoclonic, and atonic seizures; for status epilepticus	Monitor for gastric distress, gingival hyperplasia, anemia, ataxia, and nystagmus. Check CBC and calcium levels; monitor for therapeutic drug levels (10-20 mcg/mL) and toxic levels (>30 mcg/mL). For IV phenytoin, flush catheter with saline before and after administration. For fosphenytoin, use phenytoin equivalent for dosing.
Primidone (Mysoline, Sertan)	Partial seizures, generalized tonic-clonic seizures	Monitor for vertigo and lethargy. Watch for drug interactions with phenobarbital and isoniazid.
Tiagabine (Gabitril)	Partial seizures	Monitor for dizziness, weakness, nervousness, psychomotor slowing, nystagmus, and paresthesias. Administer with food.
Topiramate (Topamax)	Adjunctive therapy for intractable partial seizures	Monitor for ataxia, confusion, dizziness, and fatigue. Be aware of increased risk for renal calculi.
Valproate (Depakote), valproate sodium injection (Depacon)	Simple and complex absence seizures Adjunct therapy for partial complex and generalized tonic-clonic seizures	Monitor for hair loss, tremor, increased liver enzymes, bruising, and N/V. Monitor CBC, PT, PTT, AST.
Zonisamide (Zonegran)	Adjunctive therapy for partial seizures	Monitor CBC, platelets, and renal function. Assess mental status, especially memory.

AST, Aspartate aminotransferase; *CBC,* complete blood count; *N/V,* nausea and vomiting; *PT,* prothrombin time; *PTT,* partial thromboplastin time.

Gender Health Considerations

Patient-Centered Care QSEN

Management of women with epilepsy is challenging. Hormonal changes from menstrual cycling and the interaction of oral contraceptives with antiepileptic drugs (AEDs) require the health care provider and patient to be aware of a variety of guidelines and to more frequently monitor drug effectiveness. There are potential teratogenic risks associated with AEDs. Despite the considerable risk for

teratogenicity with AEDs use in pregnancy, more than 90% of pregnancies are uneventful (Babtain, 2012). AEDs can also contribute to osteoporosis in menopausal women. As a result, coordination between the neurologist, the woman's health care provider, and the patient is required for safe, effective care. Nurses can facilitate patient education, communication, and collaboration to promote safe, effective care.

Teach patients to take their drugs on time to maintain therapeutic blood levels and maximum effectiveness. Emphasize the importance of taking their AEDs as prescribed. Instruct patients that they can build up sensitivity to the drugs as they age. If sensitivity occurs, tell them they will need to have blood levels of this drug checked frequently to adjust the dose. In some cases, the antiseizure effects of drugs can decline and lead to an increase in seizures. Because of this potential for "drug decline and sensitivity," patients need to keep their scheduled laboratory appointments to check serum drug levels.

Be aware of drug-drug and drug-food interactions. For instance, warfarin (Coumadin, Warfilone) should not be given with phenytoin (Dilantin). Document side and adverse effects of the prescribed drugs, and report to the health care provider. Patients should be taught that some citrus fruits, such as grapefruit juice, can interfere with the metabolism of these drugs. This interference can raise the blood level of the drug and cause the patient to develop drug toxicity.

Self-Management Education.

Provide self-management education for the patient and family (Chart 42-5). Ask them what they understand about the disorder, and correct any misinformation. As new information is presented, be sure that the patient and family can understand it. Refer patients and families to the Epilepsy Foundation of America for more information and community support groups. Encourage patients and their significant others to utilize information from the Epilepsy Foundation website (www.epilepsy.com).

Chart 42-5 Patient and Family Education: Preparing for Self-Management

Health Teaching for the Patient with Epilepsy

- Drug therapy information:
  - Name, dosage, time of administration
  - Actions to take if side effects occur

- Importance of taking drug as prescribed and not missing a dose
- What to do if a dose is missed or cannot be taken
- Importance of having blood drawn for therapeutic or toxic levels as requested by the health care provider

- Do not take any medication, including over-the-counter drugs, without asking your health care provider.
- Wear a medical alert bracelet or necklace, or carry an identification card indicating epilepsy.
- Follow up with your neurologist, physician, or other health care provider as directed.
- Be sure a family member or significant other knows how to help you in the event of a seizure and knows when your health care provider or emergency medical services should be called.
- Investigate and follow state laws concerning driving and operating machinery.
- Avoid alcohol and excessive fatigue.
- Contact the Epilepsy Foundation (www.epilepsy.com) or other organized epilepsy group for additional information. Epilepsy Canada (www.epilepsy.ca) also provides resources and support.

Emphasize that AEDs must not be stopped even if the seizures have stopped. Discontinuing these drugs can lead to the recurrence of seizures or the life-threatening complication of status epilepticus (discussed below). Some patients may stop therapy because they do not have the money to purchase the drugs. Refer limited-income patients to the social services department for assistance or to a case manager to locate other resources.

A balanced diet, proper rest, and stress-reduction techniques usually minimize the risk for breakthrough seizures. Encourage the patient to keep a seizure diary to determine whether there are factors that tend to be associated with seizure activity. Patients should follow state law concerning allowances for driving a motor vehicle.

All states prohibit discrimination against people who have epilepsy. Patients who work in occupations in which a seizure might cause serious harm to themselves or others (e.g., construction workers, operators of dangerous equipment, pilots) may need other employment. They may need to decrease or modify strenuous or potentially dangerous physical activity to avoid harm, although this varies with each person. Various local, state, and federal agencies can help with finances, living arrangements, and vocational rehabilitation.

Seizure Precautions.

Precautions are taken to prevent the patient from injury if a seizure occurs. Specific seizure precautions vary depending on health care agency policy.

Nursing Safety Priority QSEN

Action Alert

Seizure precautions include ensuring that oxygen and suctioning equipment with an airway are readily available. If the patient does not have an IV access, insert a saline lock, especially if he or she is at significant risk for generalized tonic-clonic seizures. The saline lock provides ready access if IV drug therapy must be given to stop the seizure.

Siderails are rarely the source of significant injury, and the effectiveness of the use of padded siderails to maintain safety is debatable. Padded siderails may embarrass the patient and the family. Follow agency policy about the use of siderails because they may be classified as a restraint device. Other methods to protect the patient, such as placing a mattress on the floor, may be used instead of siderails.

Padded tongue blades do not belong at the bedside and should NEVER be inserted into the patient's mouth because the jaw may clench down as soon as the seizure begins! Forcing a tongue blade or airway into the mouth is more likely to chip the teeth and increase the risk for aspirating tooth fragments than prevent the patient from biting the tongue. Furthermore, improper placement of a padded tongue blade can obstruct the airway.

Seizure Management.

The actions taken during a seizure should be appropriate for the type of seizure (Chart 42-6). For example, for a simple partial seizure, observe the patient and document the time that the seizure lasted. Redirect the patient's attention away from an activity that could cause injury. Turn the patient on the side during a generalized tonic-clonic or complex partial seizure because he or she may lose consciousness. If possible, turn the patient's head to the side to prevent aspiration and allow secretions to drain. Remove any objects that might injure the patient.

Chart 42-6 Best Practice for Patient Safety & Quality Care QSEN

Care of the Patient During a Tonic-Clonic or Complete Partial Seizure

- Protect the patient from injury.
- Do not force anything into the patient's mouth.
- Turn the patient to the side to keep the airway clear.
- Loosen any restrictive clothing the patient is wearing.
- Maintain the patient's airway and suction oral secretions as needed.
- Do not restrain or try to stop the patient's movement; guide movements if necessary.
- Record the time the seizure began and ended.
- At the completion of the seizure:
  - Take the patient's vital signs.
  - Perform neurologic checks.
  - Keep the patient on his or her side.
  - Allow the patient to rest.
  - Document the seizure (see Chart 42-7).

It is not unusual for the patient to become cyanotic during a generalized tonic-clonic seizure. The cyanosis is generally self-limiting, and no treatment is needed. Some health care providers prefer to give the high-risk patient (e.g., older adult, critically ill, or debilitated patient) oxygen by nasal cannula or facemask during the postictal phase. He or she is not restrained because this may cause injury and may worsen the situation, causing more seizure activity. For any type of seizure, carefully observe the seizure and document assessment findings (Chart 42-7).

Chart 42-7 Focused Assessment

Seizures: Nursing Observations and Documentation

- How often the seizures occur:
  - Date, time, and duration of the seizure
- Description of each seizure:
  - Tonic, clonic
  - Staring spells, blinking
  - Automatism
- Whether more than one type of seizure occurs
- Sequence of seizure progression:
  - Where the seizure began
  - Body part first involved
- Observations during the seizure:

  - Changes in pupil size and any eye deviation
  - Level of consciousness
  - Presence of apnea, cyanosis, and salivation
  - Incontinence of bowel or bladder during the seizure
  - Eye fluttering
  - Movement and progression of motor activity
  - Lip smacking or other automatism
  - Tongue or lip biting
- How long the seizures last
- When the last seizure took place
- Whether the seizures are preceded by an aura:
  - Dizziness, numbness, or visual disturbances
  - Gustatory (taste) or auditory disturbances
- What the patient does after the seizure:
  - Feels drowsy or weak
  - May resume normal behavior
  - May be unaware that the seizure took place
- How long it takes for the patient to return to pre-seizure status

Emergency Care: Acute Seizure and Status Epilepticus Management.

Seizures occurring in greater intensity, number, or length than the patient's usual seizures are considered *acute.* They may also appear in clusters that are different from the patient's typical seizure pattern. Treatment with lorazepam (Ativan, Apo-Lorazepam) or diazepam (Valium, Meval, Vivol, Diastat [rectal diazepam gel]) may be given to stop the clusters to prevent the development of status epilepticus. IV phenytoin (Dilantin) or fosphenytoin (Cerebyx) may be added.

Status epilepticus is a medical emergency and is a prolonged seizure lasting longer than 5 minutes or repeated seizures over the course of 30 minutes. It is a potential complication of all types of seizures. *Seizures lasting longer than 10 minutes can cause death!* Common causes of status epilepticus include:

- Sudden withdrawal from antiepileptic drugs
- Infection
- Acute alcohol or drug withdrawal
- Head trauma
- Cerebral edema
- Metabolic disturbances

Nursing Safety Priority QSEN

Critical Rescue

Convulsive status epilepticus must be treated promptly and aggressively! Establish an airway and notify the health care provider or Rapid Response Team immediately if this problem occurs! Establishing an airway is the priority for this patient's care. Intubation by an anesthesia provider or respiratory therapist may be necessary. Administer oxygen as indicated by the patient's condition. If not already in place, establish IV access with a large-bore catheter, and start 0.9% sodium chloride. The patient is usually placed in the intensive care unit for continuous monitoring and management.

Blood is drawn to determine arterial blood gas levels and to identify metabolic, toxic, and other causes of the uncontrolled seizure. Brain damage and death may occur in the patient with tonic-clonic status epilepticus. Left untreated, metabolic changes result, leading to hypoxia, hypotension, hypoglycemia, cardiac dysrhythmias, or lactic (metabolic) acidosis. Further harm to the patient occurs when muscle breaks down and myoglobin accumulates in the kidneys, which can lead to renal failure and electrolyte imbalance. *This is especially likely in the older adult.*

The drugs of choice for treating status epilepticus are IV-push lorazepam (Ativan, Apo-Lorazepam) or diazepam (Valium). Diazepam rectal gel (Diastat) may be used instead. Lorazepam is usually given as 4 mg over a 2-minute period. This procedure may be repeated, if necessary, until a total of 8 mg is reached.

To prevent additional tonic-clonic seizures or cardiac arrest, a loading dose of IV phenytoin (Dilantin) is given and oral doses administered as a follow-up after the emergency is resolved. Initially, give phenytoin at no more than 50 mg/min using an infusion pump. An alternative to phenytoin is fosphenytoin (Cerebyx), a water-soluble phenytoin prodrug. It is compatible with most IV solutions. It also causes fewer cardiovascular complications than phenytoin and can be given in an IV dextrose solution. After administration, fosphenytoin converts to phenytoin in the body. Therefore the FDA requires the dosage to be written as a phenytoin equivalent (PE): 150 mg of fosphenytoin equals 100 mg of phenytoin. Give fosphenytoin at a rate of 100 to 150 mg/min IV piggyback (Lilley et al., 2014).

Serum drug levels are checked every 6 to 12 hours after the loading dose and then 2 weeks after oral phenytoin has started. Teach the patient about the side and adverse effects of any AED that is prescribed (see Chart 42-4).

NCLEX Examination Challenge

Safe and Effective Care Environment

A client with a history of seizures is placed on seizure precautions. What emergency equipment will the nurse provide at the bedside? **Select all that apply.**

A Oropharyngeal airway
B Oxygen
C Nasogastric tube
D Suction setup
E Padded tongue blade

Surgical Management.

Patients who cannot be managed effectively with drug therapy may be candidates for surgery, including vagal nerve stimulation (VNS) and conventional surgical procedures. VNS has been very successful for many patients with epilepsy.

Vagal Nerve Stimulation.

Vagal nerve stimulation (VNS) may be performed for control of continuous simple or complex partial seizures. Patients with generalized seizures are not candidates for surgery because VNS may result in severe neurologic deficits. The stimulating device (much like a cardiac pacemaker) is surgically implanted in the left chest wall. An electrode lead is attached to the left vagus nerve, tunneled under the skin, and connected to a generator. The procedure usually takes 2 hours with the patient under general anesthesia. The stimulator is activated by the physician either in the operating room or, more commonly, 2 weeks after surgery. Programming is adjusted gradually over a period of time. The pattern of stimulation is individualized to the patient's tolerance. The generator runs continuously, stimulating the vagus nerve according to the programmed schedule.

The patient can activate the VNS with a handheld magnet when experiencing an aura, thus aborting the seizure. Patients experience a change in voice quality, which signifies that the vagus nerve has been stimulated. They usually report a relief in intensity and duration of seizures and an improved quality of life.

Observe for complications after the procedure such as hoarseness (most common), cough, dyspnea, neck pain, or dysphagia (difficulty swallowing). Teach the patient to avoid MRIs, microwaves, shortwave

radios, and ultrasound diathermy (a physical therapy heat treatment).

Conventional Surgical Procedures.

A small percentage of patients with epilepsy cannot be fully controlled with drug therapy or VNS. When all other options are exhausted, conventional surgery may be needed to improve the patient's quality of life. The largest group of conventional surgical candidates includes those with complex partial seizures in the frontal or temporal lobe.

Before surgery, the patient is admitted to a special inpatient observation unit. While there, he or she has continuous electroencephalogram (EEG) recording, close observation, and in many hospitals, video monitoring at all times except during personal care activities. The patient is taken off all AEDs. After the seizure area is identified, electrodes may be surgically implanted into the brain tissue to identify the extent of the focal area. This step is followed by additional continuous EEG and video monitoring, as well as close observation by the nursing staff. The area is surgically removed if vital areas of brain function will not be affected.

Preoperative care is similar to that described for patients undergoing a craniotomy (see Chapter 45). Preoperative diagnostic tests include MRI and single-photon emission computed tomography (SPECT)/positron emission tomography (PET) scans as described in Chapter 41. An intracarotid amobarbital test (Wada test) and neuropsychological testing are also done. The Wada test assesses hemispheric lateralization of language and memory after injection of amobarbital, a short-acting anesthetic. This procedure establishes the safety of surgery to preserve language memory. Neuropsychological testing evaluates memory, visuospatial function, language function, and intelligence quotient (IQ) to identify deficiencies in the brain that might correspond to areas believed to be the epileptic region. It is also used to compare preoperative and postoperative cognition.

Another surgical approach, the *partial corpus callosotomy,* may be used to treat tonic-clonic or atonic seizures in patients who are not candidates for other surgical procedures. The surgeon sections the anterior two thirds of the corpus callosum, preventing neuronal discharges from passing between the two hemispheres of the brain. This surgery usually reduces the number and severity of the seizures, making them more likely to respond to more conventional drug therapy. This procedure is not as commonly done as other surgeries but is very successful for some patients.

Infections

Meningitis

Pathophysiology

Meningitis is an inflammation of the meninges, specifically the pia mater and arachnoid. Bacterial and viral organisms are most often responsible for meningitis, although fungal and protozoal meningitis also occur. Cancer and some drugs, notably NSAIDs, antibiotics, and intravenous immunoglobulins, can also cause sterile meningitis. Regardless of cause of meningitis, the symptoms are similar.

The organisms responsible for meningitis enter the central nervous system (CNS) via the bloodstream or are directly introduced into the CNS. Direct routes of entry occur as a result of penetrating trauma, surgical procedures on the brain or spine, or a ruptured brain **abscess**. A basilar skull fracture may lead to meningitis as a result of the direct communication of cerebrospinal fluid (CSF) with the ear or nasal passages, manifested by **otorrhea** (ear discharge) or **rhinorrhea** (nasal discharge, or "runny nose") that is actually CSF. The infecting organisms follow the tract created by skull damage to enter the CNS and circulate in the CSF. The patient with an infection in the head (i.e., eye, ear, nose, mouth) or neck has an increased risk for meningitis because of the proximity of anatomic structures. Infections linked to meningitis include otitis media, acute or chronic sinusitis, and tooth abscess; there are also reports of rare infection from a tongue piercing leading to meningitis. The immunocompromised patient (e.g., one without a spleen) receiving treatment for cancer, taking immunosuppressant drugs to manage autoimmune disease or solid organ transplant, and older adults) is also at increased risk for meningitis. The infecting organism may spread to both cranial and spinal nerves, causing irreversible neurologic damage. Increased intracranial pressure (ICP) may occur as a result of blockage of the flow of CSF, change in cerebral blood flow, or thrombus (blood clot) formation.

Viral meningitis, the most common type, is sometimes referred to as *aseptic meningitis* because no organisms are typically isolated from culture of the CSF. Common viral organisms causing meningitis are enterovirus, herpes simplex virus–2 (HSV-2), varicella zoster virus (VZV) (also causes chickenpox and shingles), mumps virus, and the human immune deficiency virus (HIV). The severity of symptoms can vary by the infecting viral agent. For example, the herpes simplex virus alters cellular metabolism, which quickly results in necrosis of the cells. HSV-2

meningitis may be accompanied by genital infections. Other viruses cause an alteration in the production of enzymes or neurotransmitters. While these alterations result in cell dysfunction, neurologic defects are more likely to be temporary and a full recovery occurs as the inflammation resolves. Treatment may include the administration of antiviral agents.

Cryptococcus neoformans meningitis is the most common *fungal* infection that affects the central nervous system (CNS) of patients with acquired immune deficiency syndrome (AIDS). Fulminant invasive fungal sinusitis is also a recognized cause of fungal meningitis. The clinical manifestations vary because the compromised immune system affects the inflammatory response. For example, some patients have fever and others do not. Treatment is symptomatic and includes IV antifungal agents.

The most frequently involved organisms responsible for bacterial meningococcal meningitis are *Streptococcus pneumoniae (pneumococcal disease)* and *Neisseria meningitidis. N. meningitidis* meningitis is also known as *meningococcal meningitis. Meningococcal meningitis is a medical emergency with a fairly high mortality rate, often within 24 hours*. Unlike other types, this disorder is highly contagious. Outbreaks of meningococcal meningitis are most likely to occur in areas of high population density, such as college dormitories, military barracks, and crowded living areas.

Nursing Safety Priority QSEN

Action Alert

People ages 16 through 21 years have the highest rates of infection from life-threatening *N. meningitidis* meningococcal infection. The Centers for Disease Control and Prevention (CDC) recommends an initial meningococcal vaccine between ages 11 and 12 years with a booster at age 16 years (www.cdc.gov). Adults are advised to get an initial or booster vaccine if living in a shared residence (residence hall, military barracks, group home), traveling or residing in countries in which the disease is common, or are immunocompromised due to a damaged or surgically removed spleen or a serum complement deficiency. If the patient's baseline vaccination status is unclear and the immediate risk for exposure to *N. meningitidis* infection is high, the CDC recommends vaccination. It is safe to receive a booster as early as 8 weeks after the initial vaccine.

Patient-Centered Collaborative Care

Assessment

Perform a complete neurologic and neurovascular assessment to detect clinical manifestations associated with a diagnosis of meningitis or suspected meningitis as outlined in Chart 42-8. Signs and symptoms of meningitis result from meningeal irritation. Clinical manifestations of meningitis include fever, **nuchal rigidity** (neck stiffness), **photophobia** (light sensitivity), **phonophobia** (noise sensitivity), headache, **myalgia** (muscle aches), nausea, and vomiting. Confusion and altered consciousness may be present. A maculopapular rash is seen when the causative organism is an enterovirus. A petechial rash is associated with *N. meningitidis* meningitis. Although the classic nuchal rigidity (stiff neck) and positive Kernig's and Brudzinski's signs have been traditionally used to diagnose meningitis, these findings occur in only a small percentage of patients with a definitive diagnosis. Older adults, patients who are immunocompromised, and those who are receiving antibiotics may not have fever. Assess the patient for complications, including increased ICP. Left untreated, increased ICP can lead to herniation of the brain and death (see Chapter 45).

Chart 42-8 Key Features

Meningitis

- Decreased (or change in) level of consciousness
- Disoriented to person, place, and year
- Pupil reaction and eye movements:
  - Photophobia
  - Nystagmus
  - Abnormal eye movements
- Motor response:
  - Normal early in disease process
  - Hemiparesis, hemiplegia, and decreased muscle tone possible later
  - Cranial nerve dysfunction, especially CN III, IV, VI, VII, VIII
- Memory changes:
  - Attention span (usually short)
  - Personality and behavior changes
  - Bewilderment
- Severe, unrelenting headaches
- Generalized muscle aches and pain

- Nausea and vomiting
- Fever and chills
- Tachycardia
- Red macular rash (meningococcal meningitis)

Seizure activity may occur when meningeal inflammation spreads to the cerebral cortex. Inflammation can also result in abnormal stimulation of the hypothalamic area where excessive amounts of antidiuretic hormone (ADH) (vasopressin) are produced. Excess vasopressin results in water retention and dilution of serum sodium caused by increased sodium loss by the kidneys. This syndrome of inappropriate antidiuretic hormone (SIADH, Chapter 62) may lead to further increases in ICP.

Systemic inflammation (systemic inflammatory response syndrome or **SIRS**), a reaction to either endotoxin produced by infecting bacteria or activation of the immune cells by infecting organisms, can cause a rapidly falling blood pressure and tachycardia. Coagulopathy can occur as a result of systemic inflammation. Assess the patient's vascular status by:

- Observing the color and temperature of the extremities
- Determining the presence of peripheral pulses
- Identifying any indicators of abnormal bleeding

Thrombi may block circulation in the small vessels of the hands and feet, leading to gangrene. Coagulopathy from SIRS may lead to disseminated intravascular coagulation (DIC).

The most significant laboratory test used in the diagnosis of meningitis is the analysis of the *cerebrospinal fluid (CSF)*. Patients older than 60 years, those who are immunocompromised, or those who have signs of increased ICP usually have a CT scan before the lumbar puncture. If there will be a delay in obtaining the CSF, blood is drawn for culture and sensitivity. A broad-spectrum antibiotic should be given before the lumbar puncture. The CSF is analyzed for cell count, differential count, and protein. Glucose concentrations are determined, and culture, sensitivity, and Gram stain studies are performed. Table 42-2 compares the CSF findings in bacterial and viral meningitis.

TABLE 42-2

Cerebrospinal Fluid Findings in Bacterial and Viral Meningitis

FINDING	BACTERIAL MENINGITIS	VIRAL MENINGITIS
Appearance	Cloudy, turbid	Clear
White blood cells	Increased	Increased
Protein	Increased	Slightly increased
Glucose	Decreased	Most often normal, but may be decreased
CSF pressure	Elevated	Normal or elevated

CSF, Cerebrospinal fluid.

Counterimmunoelectrophoresis (CIE) may be performed to determine the presence of viruses or protozoa in the CSF. CIE is also indicated if the patient has received antibiotics before the CSF was obtained. To identify a bacterial source of infection, specimens for Gram stains and culture are obtained from the urine, throat, and nose when indicated.

A complete blood count (CBC) is performed. The white blood cell (WBC) count is usually elevated well above the normal value. Serum electrolyte values are also assessed so as to assess and maintain fluid and electrolyte balance.

X-rays of the chest, air sinuses, and mastoids are obtained to determine the presence of infection. A CT or MRI scan may be performed to identify increased ICP, hydrocephalus, or the presence of a brain abscess.

Interventions

Prevent meningitis by teaching people to obtain vaccination. Vaccines are available to protect against Haemophilus influenzae *type B (Hib), pneumococcal, mumps, varicella, and meningococcal organisms. Although many of these vaccines were developed to prevent respiratory illness, they have also reduced CNS infections. Mandatory vaccination programs for school enrollment and proof of vaccination as a prerequisite for group home or dormitory experiences have significantly reduced the incidence of meningitis.*

Maintain thorough handwashing. Teach visitors to wash hands before and after entering a patient's room. Preventing the transmission of infection through hand cleaning is a National Patient Safety Goal (The Joint Commission, 2014).

The most important nursing interventions for patients with meningitis are accurately monitoring and documenting their neurologic status. Best practices for nursing care are listed in Chart 42-9.

Chart 42-9 Best Practice for Patient Safety & Quality

Care QSEN

Care of the Patient with Meningitis

- Prioritize care to maintain airway, breathing, circulation.
- Take vital signs and perform neurologic checks every 2 to 4 hours, as required.
- Perform cranial nerve assessment, with particular attention to cranial nerves III, IV, VI, VII, and VIII, and monitor for changes.
- Manage pain with drug and nondrug methods.
- Perform vascular assessment, and monitor for changes.
- Give drugs and IV fluids as prescribed, and document the patient's response.
- Record intake and output carefully to maintain fluid balance and prevent fluid overload.
- Monitor body weight to identify fluid retention early.
- Monitor laboratory values closely; report abnormal findings to the physician or nurse practitioner promptly.
- Position carefully to prevent pressure ulcers.
- Perform range-of-motion exercises every 4 hours as needed.
- Decrease environmental stimuli:
  - Provide a quiet environment.
  - Minimize exposure to bright lights from windows and overhead lights.
  - Maintain bedrest with head of bed elevated 30 degrees.
- Maintain Transmission-Based Precautions per hospital policy (for bacterial meningitis).
- Monitor for and prevent complications:
  - Increased intracranial pressure
  - Vascular dysfunction
  - Fluid and electrolyte imbalance
  - Seizures
  - Shock

Nursing Safety Priority QSEN

Action Alert

For the patient with meningitis, assess his or her neurologic status and vital signs at least every 4 hours or more often if clinically indicated. *The priority for care is to monitor for early neurologic changes that may indicate increased ICP, such as decreased level of consciousness (LOC).* The

patient is also at risk for seizure activity. Care should be provided as discussed in Interventions on pp. 859-863 in the Seizures and Epilepsy section.

Cranial nerve testing is included as part of the routine neurologic assessment because of possible cranial nerve involvement. Particular attention is given to cranial nerves III, IV, VI, VII, and VIII, nerves involved in pupillary shape and accommodation to light (see Chapter 41). *A sixth cranial nerve defect (inability to move the eyes laterally) may indicate the development of* **hydrocephalus** *(excessive accumulation of CSF within the brain's ventricles).* Other indicators of hydrocephalus include signs of increased ICP and urinary incontinence. Urinary incontinence results from decreasing LOC.

To avoid life-threatening complications, the health care provider prescribes a broad-spectrum antibiotic until the results of the culture and Gram stain are available. After this information is available, the appropriate anti-infective drug to treat the specific type of meningitis is given. Treatment of bacterial meningitis generally requires a 2-week course of IV antibiotics. Drug therapy should begin within 1 to 2 hours after it is prescribed. Monitor and document the patient's response.

Drugs may be used to treat increased ICP or seizures, including mannitol, a hyperosmolar agent for ICP, and antiepileptic drugs (AEDs). Controversy exists as to whether steroids are helpful in the treatment of all adults with meningitis. They are, however, recommended for patients with *S. pneumoniae* meningitis.

People who have been in close contact with a patient with *N. meningitidis* should have prophylaxis (preventive) treatment with rifampin (Rifadin, Rofact), ciprofloxacin (Cipro), or ceftriaxone (Rocephin). Preventive treatment with rifampin may be prescribed for those in close contact with a patient with *H. influenzae* meningitis (Lilley et al., 2014).

Perform a complete vascular assessment every 4 hours or more often, if indicated, to detect early vascular compromise. Thrombotic or embolic complications are most often seen in circulation to the hand. Assess the patient's temperature, color, pulses, and capillary refill in the fingernails. If vascular compromise is not noticed and left untreated, gangrene can develop quickly, possibly leading to loss of the involved arm. The health care team monitors the patient for other complications, including septic shock, coagulation disorders, acute respiratory distress syndrome, and septic arthritis. These health problems are discussed elsewhere in this textbook.

Standard Precautions are appropriate for all patients with meningitis unless the patient has a bacterial type that is transmitted by droplets, such as *N. meningitides* and *H. influenzae.*

Nursing Safety Priority QSEN

Action Alert

Place the patient with bacterial meningitis that is transmitted by droplets on Droplet Precautions *in addition to* Standard Precautions. When possible, place the patient in a private room. Stay at least 3 feet from the patient unless wearing a mask. Patients who are transported outside of the room should wear a mask (see Chapter 23). Teach visitors about the need for these precautions and how to follow them.

Encephalitis

Pathophysiology

Encephalitis is an inflammation of the brain tissue and often the surrounding meninges. It affects the cerebrum, the brainstem, and the cerebellum. A viral agent most often causes the disease, although bacteria, fungi, or parasites may also be involved (e.g., malaria). The virus travels to the central nervous system (CNS) via the bloodstream, along peripheral or cranial nerves, or in the meninges (e.g., varicella zoster). Therefore viral encephalitis can be life threatening or lead to persistent neurologic problems such as learning disabilities, epilepsy, memory deficits, or fine motor deficits.

After the virus invades the brain tissue, it begins to reproduce, causing an inflammatory response. Unlike in meningitis, this response does not cause exudate (pus) formation. Inflammation extends over the cerebral cortex, the white matter, and the meninges, causing degeneration of the neurons of the cortex. Demyelination of axons occurs in the involved area because the white matter is destroyed. This destruction leads to hemorrhage, edema, necrosis (cell death), and the development of small lacunae (hollow cavities) within the cerebral hemispheres. Widespread edema can cause compression of blood vessels leading to a further increase in intracranial pressure (ICP). Death may occur from herniation and increased ICP.

Arboviruses can be transmitted to humans through the bite of an infected mosquito or tick. The most common types of encephalitis caused by arboviruses are Eastern or Western equine encephalitis, St. Louis

encephalitis, California encephalitis, and West Nile virus.

*West Nile virus h*as gained attention in the United States because it has spread rapidly throughout the country and is a potentially serious illness. This infection is typically mild, and usually the patient is asymptomatic. However, a small percentage of patients develop severe disease. The incubation period is 2 to 15 days after being bitten by an infected mosquito. Other possible sources of transmission include blood products, breast milk, or an organ transplant. Diagnostic tests to determine the presence of West Nile virus include enzyme-linked immunosorbent assay and West Nile virus–specific immunoglobulin M (IgM) antibody in the blood or CSF.

In mild cases of *West Nile virus,* the patient has no symptoms or has mild flu-like symptoms (e.g., fever, body aches, nausea, vomiting). Some people develop serious symptoms that may include high fever, severe headache, decreased level of consciousness, tremors, vision loss, seizures, and muscle weakness or paralysis. These manifestations may last for several weeks, and neurologic deficits may be permanent. A few patients die from the disease, especially those older than 50 years with a weakened immune system (Overstreet, 2011).

Echovirus, coxsackievirus, poliovirus, herpes zoster, and viruses that cause mumps and chickenpox are the common *enteroviruses* associated with encephalitis. *Herpes simplex virus type 1* (HSV1) encephalitis is the most common nonepidemic type of encephalitis in North America. Patients with this disease often have a history of cold sores. The mortality rates for HSV1 encephalitis are very high compared with those for other types of encephalitis.

Amebic meningoencephalitis is caused by the amebae *Naegleria* and *Acanthamoeba.* Both are found in warm freshwater areas and can enter the nasal mucosa of people swimming in ponds or lakes. The amebae may also be found in soil and decaying vegetation. Although this infection has not often been seen in the past, the incidence in North America is increasing, perhaps because ponds and lakes are becoming more polluted.

Patient-Centered Collaborative Care

Assessment

The typical patient with encephalitis has a high fever and reports nausea, vomiting, and a stiff neck. Assess for other clinical manifestations, including possible:

- Changes in mental status (e.g., agitation)

- Motor dysfunction (e.g., dysphagia [difficulty swallowing])
- Focal (specific) neurologic deficits
- Photophobia (light sensitivity) and phonophobia (noise sensitivity)
- Fatigue
- Symptoms of increased ICP (e.g., decreased LOC)
- Joint pain
- Headache
- Vertigo

Assess LOC using the Glasgow Coma Scale (see Chapter 41) or other agency-approved assessment tool. The patient may be lethargic, stuporous, or comatose. Mental status changes are more extensive in the patient with encephalitis than with meningitis. Changes include acute confusion, irritability, and personality and behavior changes (especially noted in the presence of herpes simplex). Signs of meningeal irritation include the presence of nuchal (neck) rigidity and motor changes that vary from a mild weakness to hemiplegia. The patient may have muscle tremors, spasticity, an ataxic gait (postencephalitic Parkinsonism), myoclonic jerks, and increased deep tendon reflexes. Seizure activity is common.

Observe for cranial nerve involvement, such as ocular palsies (paralysis), facial weakness, and nystagmus (involuntary lateral eye movements). The herpes zoster lesion affects cranial and spinal nerve root ganglia, which is clinically manifested by a rash, severe pain, itching, burning, or tingling in the areas innervated by these nerves.

Nursing Safety Priority QSEN

Critical Rescue

In severe cases of encephalitis, the patient may have increased ICP resulting from cerebral edema, hemorrhage, and necrosis of brain tissue. If the patient is nonverbal or comatose at baseline, then monitoring vital signs and pupils becomes essential for detecting worsening neurologic status and increased ICP. Changes in vital signs that require an immediate notification of the health care provider are a widened pulse pressure, new bradycardia, and irregular respiratory effort. Pupils that become increasingly dilated and less responsive to light are also communicated urgently. Left untreated, increased ICP leads to herniation of the brain tissue and possibly death (see Chapter 45).

Lumbar puncture (LP) is done to analyze the CSF for the specific

offending organism. A polymerase chain reaction (PCR) test may be used to detect viral DNA or ribonucleic acid (RNA) in the CSF. Specificity and sensitivity in diagnosing encephalitis are excellent, especially with herpes simplex virus (HSV). The test is rapid and noninvasive, replacing the brain biopsy for diagnosis.

An electroencephalogram is done to evaluate brain wave activity to detect seizures. Brain imaging in the form of a CT scan with and without contrast is performed to evaluate elevated intracranial pressure (ICP) or obstructive hydrocephalus.

Interventions

Teach people who live in mosquito-infested areas to protect themselves and their families from West Nile virus infections. Chart 42-10 lists measures for preventing this infection. There is no curative treatment for West Nile viral encephalitis.

Chart 42-10 Patient and Family Education: Preparing for Self-Management

Protecting the Patient and Family from West Nile Virus

- Limit your time outside between dusk and dawn when mosquitoes are out.
- Wear protective clothing, including long sleeves and pants.
- Use an insect repellent containing DEET when outdoors.
- Remove areas of standing water from flower pots, trash cans, and rain gutters.
- Check window and door screens for holes that need repair.
- Keep hot tubs and pools clean and properly chlorinated.

Acyclovir (Zovirax) is the antiviral drug of choice for the treatment of herpes encephalitis and is associated with a significantly lower mortality rate than vidarabine (Vira-A). Drug therapy is most effective if begun early, before the patient becomes stuporous or comatose. This neurologic decline usually occurs within 4 to 6 days after the initial neurologic symptoms. No specific drug therapy is available for infection by arboviruses or enteroviruses.

Nursing interventions for encephalitis are similar to those for meningitis with the exception of drug therapy. Supportive nursing care and prompt recognition and treatment of increased ICP are essential components of management. *Maintain a patent airway to prevent the*

development of atelectasis or pneumonia, which can lead to further brain hypoxia (lack of oxygen).

Provide supportive nursing care for the patient who is immobile, stuporous, or comatose. Delegate and supervise unlicensed assistive personnel (UAP) to turn, cough, and deep breathe the patient at least every 2 hours. Perform deep tracheal suctioning even in the presence of increased ICP if respiratory status is compromised. Assess vital signs and neurologic signs every 2 hours or more frequently if clinically indicated. Elevate the head of the bed 30 to 45 degrees unless contraindicated (e.g., after lumbar puncture or in the patient with severe hypotension). Keep the patient's room darkened and quiet to promote comfort and decrease agitation. Remind UAP to provide safety measures such as keeping the bed in the lowest position.

Provide patient and family support. Families need health teaching to understand how to care for their loved ones. They are often fearful that the patient may not return to his or her baseline. Collaborate with a certified chaplain, social worker, or case manager to provide additional emotional support and counseling.

Patients with encephalitis and permanent neurologic deficits are usually discharged to a rehabilitation setting or a long-term care facility. Those with minimal neurologic problems are discharged to the home setting.

Parkinson Disease

Pathophysiology

Parkinson disease (PD), also referred to as *Parkinson's disease* and *paralysis agitans,* is a progressive neurodegenerative disease that is the one of the most common neurologic disorders of older adults. It is a debilitating disease affecting motor ability and is characterized by four cardinal symptoms: tremor, muscle rigidity, **bradykinesia** or **akinesia** (slow movement/no movement), and postural instability. Most people have *primary,* or idiopathic, disease. A few patients have *secondary* parkinsonian symptoms from conditions such as brain tumors and certain anti-psychotic drugs.

Motor activity occurs as a result of integrating the actions of the cerebral cortex, basal ganglia, and cerebellum. The basal ganglia are a group of neurons located deep within the cerebrum at the base of the brain near the lateral ventricles. When the basal ganglia are stimulated, muscle tone in the body is inhibited and voluntary movements are refined. The secretion of two major neurotransmitters accomplishes this process: dopamine and acetylcholine (ACh).

Dopamine is produced in the substantia nigra, as well as in the adrenal glands, and is transmitted to the basal ganglia along a connecting neural pathway for secretion when needed. *ACh* is produced and secreted by the basal ganglia, as well as in the nerve endings in the periphery of the body. ACh-producing neurons transmit *excitatory* messages throughout the basal ganglia. Dopamine *inhibits* the function of these neurons, allowing control over voluntary movement. This system of checks and balances allows for refined, coordinated movement, such as picking up a pencil and writing.

Widespread degeneration of the *substantia nigra* then leads to a decrease in the amount of dopamine in the brain. When dopamine levels are decreased, a person loses the ability to refine voluntary movement. The large numbers of excitatory ACh-secreting neurons remain active, creating an imbalance between excitatory and inhibitory neuronal activity. The resulting excessive excitation of neurons prevents a person from controlling or initiating voluntary movement (McCance et al., 2014).

Not only does PD interfere with movement as a result of dopamine loss in the brain, it also reduces the sympathetic nervous system influence on the heart and blood vessels. This loss results in the orthostatic hypotension frequently seen in the patient with PD.

PD is separated into stages according to the symptoms and degree of

disability. Stage 1 is mild disease with unilateral limb involvement, whereas the patient with stage 5 disease is completely dependent in all ADLs. Other classifications refer simply to mild, moderate, and severe disease (Table 42-3).

TABLE 42-3

Stages of Parkinson Disease

Stage 1: Initial Stage
• Unilateral limb involvement • Minimal weakness • Hand and arm trembling
Stage 2: Mild Stage
• Bilateral limb involvement • Masklike face • Slow, shuffling gait
Stage 3: Moderate Disease
• Postural instability • Increased gait disturbances
Stage 4: Severe Disability
• Akinesia • Rigidity
Stage 5: Complete ADL Dependence

Although the exact cause of PD is not known, it is probably due to environmental and genetic factors. Exposure to pesticides, herbicides, and industrial chemicals and metals and drinking well water, being older than 40 years, and having reduced estrogen levels are known risk factors for the development of PD.

Genetic/Genomic Considerations

Patient-Centered Care QSEN

Primary Parkinson disease (PD) often has a familial tendency. The disease is associated with a variety of mitochondrial DNA (mtDNA) variations that often involve deletions in the genetic sequences that are used in CNS mitochondria, the energy powerhouses of cells. These variations ultimately cause destruction of neurons that produce dopamine in the substantia nigra. Mitochondrial dysfunction is a common observation in PD and other neurodegenerative diseases, indicating there is a disorder of energy regulation that contributes to cell death (Coskun et al., 2012).

As the population ages, the number of people affected by PD is

expected to dramatically increase. About 50% more men than women currently have the disease.

Patient-Centered Collaborative Care

Assessment

Collect data related to the time and progression of symptoms noticed by the patient or the family. The older adult, who may assume that these behaviors are normal changes associated with aging, may ignore early signs and symptoms such as *resting* tremors, bradykinesia (slowed movement), and problems with muscular rigidity. Tremors are usually noticed in the upper extremities first and may increase with stress. Slow voluntary movements and reduced automatic movements may be manifested by a change in the patient's handwriting. Some patients report "freezing" because they feel that they are stuck to the floor. Chart 42-11 summarizes the clinical manifestations of Parkinson disease. Assess the patient for *rigidity*, or resistance to passive movement of the extremities, which is classified as:

Chart 42-11 Key Features

Parkinson Disease

- Posture:
  - Stooped posture
  - Flexed trunk
  - Fingers abducted and flexed at the metacarpophalangeal joint
  - Wrist slightly dorsiflexed
- Gait:
  - Slow and shuffling
  - Short, hesitant steps
  - Propulsive gait
  - Difficulty stopping quickly
- Motor:
  - **Bradykinesia** (slow movement)
  - Muscular rigidity
  - Akinesia
  - Tremors
  - "Pill-rolling" movement
  - Masklike face
  - Difficulty chewing and swallowing

  - Uncontrolled drooling, especially at night
  - Fatigue
  - Difficulty getting into and out of bed
  - Reduced arm swinging on one side of the body when walking
  - Micrographia (change in handwriting or handwriting gets smaller)
- Speech:
  - Soft, low-pitched voice
  - **Dysarthria** (slurred speech)
  - **Echolalia** (automatic repetition of what another person says) and repetition of sentences
  - **Hypophonia** (soft voice), change in voice volume or articulation
- Autonomic dysfunction:
  - Orthostatic hypotension
  - Excessive perspiration
  - Oily skin
  - Seborrhea
  - Flushing
  - Changes in skin texture
  - Blepharospasm (eyelid spasm)
- Psychosocial assessment:
  - Emotionally labile
  - Depressed
  - Paranoid
  - Easily upset
  - Rapid mood swings
  - Impaired cognition (i.e., dementia or delirium)
  - Delayed reaction time
  - Sleep disturbances

- *Cogwheel,* manifested by a rhythmic interruption of the muscle movement
- *Plastic,* defined as mildly restrictive movement
- *Lead pipe,* or total resistance to movement

Rigidity is present early in the disease process and progresses over time. Observe the patient's ability to relax a muscle or move a selected muscle group.

Changes in facial expression or a *masklike face* with wide-open, fixed, staring eyes is caused by rigidity of the facial muscles (Fig. 42-1). This rigidity can lead to difficulties in chewing and swallowing, particularly if the pharyngeal muscles are involved. As a result, the patient may have inadequate nutrition. Uncontrolled drooling may occur. Some patients

develop dementia later as the disease progresses. In addition to changes in voluntary movement, many patients experience autonomic nervous system symptoms, such as excessive perspiration and orthostatic hypotension. Orthostatic hypotension is likely related to loss of sympathetic innervation in the heart and blood vessel response.

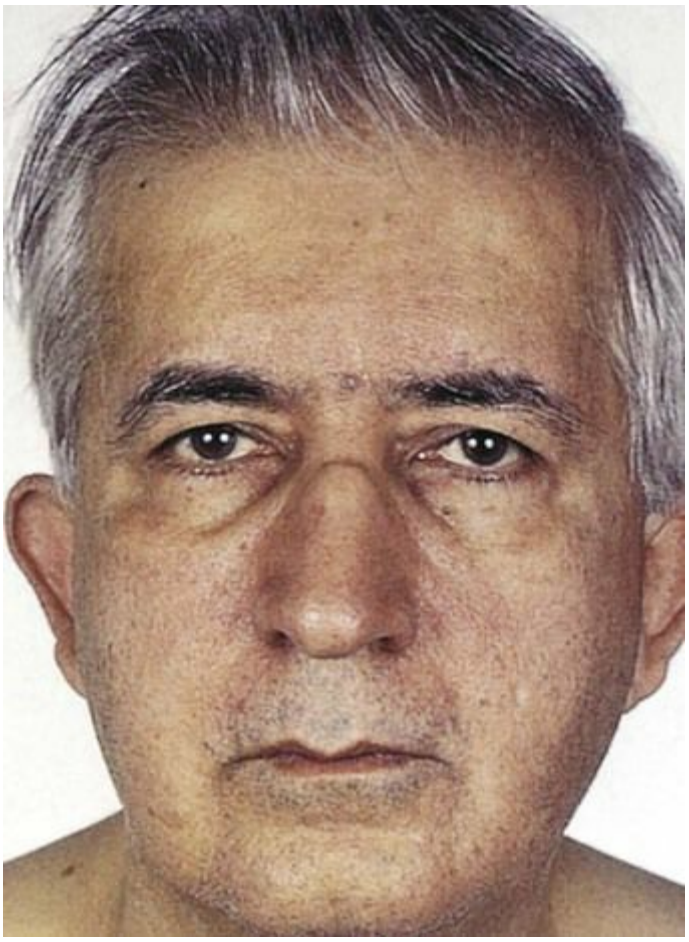


FIG. 42-1 The masklike facial expression typical of patients with Parkinson disease.

Patients can also develop emotional changes such as depression, irritability, pessimism, fear, and insecurity. These symptoms may develop because patients fear that they will not be able to cope with new situations.

Changes in speech pattern are common in PD patients. They may speak very softly, slur or repeat their words, use a monotone voice or a halting speech, hesitate before speaking, or exhibit a rapid speech pattern.

Bowel and bladder problems are commonly seen in PD due to malfunction of the autonomic nervous system, which regulates smooth muscle activity. Patients can exhibit symptoms of either urinary incontinence or difficulty urinating. Constipation can occur due to the

slow motility of the GI tract or because of poor dietary habits and poor fluid intake.

The diagnosis of PD is made based on clinical findings after other neurologic diseases are eliminated as possibilities. There are no specific diagnostic tests. Analysis of cerebrospinal fluid (CSF) may show a decrease in dopamine levels, although the results of other studies are usually normal. Other diagnostic tests may be done such as an MRI, single-photon emission computed tomography (SPECT), or a positron emission tomography (PET) to rule out other CNS health problems.

Interventions

In addition to the health care provider, physical and/or occupational therapist, speech-language pathologist, dietitian, and case manager, collaborate with the patient and family to develop a patient-centered plan of care. In some cases, palliative surgery may be performed to assist the patient to remain mobile for as long as possible. Chart 42-12 summarizes best practices for nursing management of the patient with PD.

Chart 42-12 Best Practice for Patient Safety & Quality Care QSEN

Care of the Patient with Parkinson Disease

- Allow the patient extra time to respond to questions.
- Administer medications promptly on schedule to maintain continuous therapeutic drug levels.
- Provide medication for pain, tingling in limbs, as needed.
- Monitor for side effects of medications, especially orthostatic hypotension, hallucinations, and acute confusional state (delirium).
- Collaborate with physical and occupational therapists to keep the patient as mobile and as independent as possible in ADLs.
- Allow the patient time to perform ADLs and mobility skills.
- Implement interventions to prevent complications of immobility, such as constipation, pressure ulcers, and contractures.
- Schedule appointments and activities late in the morning to prevent rushing the patient, or schedule them at the time of the patient's optimal level of functioning.
- Teach the patient to speak slowly and clearly. Use alternative communication methods, such as a communication board. Refer to speech-language pathologist.

- Monitor the patient's ability to eat and swallow. Monitor actual food and fluid intake. Collaborate with the dietitian.
- Provide high-protein, high-calorie foods or supplements to maintain weight.
- Recognize that Parkinson disease affects the patient's body image. Focus on the patient's strengths.
- Assess for depression and anxiety.
- Assess for insomnia or sleeplessness.

Nonsurgical Management.

Care for the patient with Parkinson disease includes drug therapy, exercise programs or physical therapy, strategies and collaboration to promote self-management, and psychosocial support. Ultimately, the goals of care are to preserve mobility, cognition, and quality of life.

Drug Therapy.

Drugs are prescribed to treat the symptoms of PD with the purpose of increasing the patient's functional abilities. An equally important desired outcome is to prescribe drugs with minimal long-term side effects. Many questions and controversies remain about which drugs to use, when to start therapy, and how to prevent complications. Drug administration is closely monitored, and the health care provider adjusts the dosage or changes therapy as the patient's condition requires. Teach the patient and family how to monitor for and report adverse effects of drug therapy.

Dopamine agonists mimic dopamine by stimulating dopamine receptors in the brain. They are typically the most effective during the first 3 to 5 years of use. The benefit of these agents is fewer incidents of **dyskinesias** (problems with movement) and "wearing off" phenomenon (loss of response to the drug) when compared with other drugs. This problem is characterized by periods of good mobility ("on") alternating with periods of poor mobility ("off"). Patients report that their most distressing symptom is "off time."

Examples of dopamine agonists are apomorphine (Apokyn [a morphine derivative]), pramipexole (Mirapex), and ropinirole (Requip). Another drug in this class, rotigotine, is available as a continuous transdermal patch (Neupro) to maintain a consistent level of dopamine.

 **Nursing Safety Priority** QSEN

Drug Alert

Dopamine agonists are associated with adverse effects such as orthostatic (postural) hypotension, hallucinations, sleepiness, and drowsiness. Remind patients to avoid operating heavy machinery or driving if they have any of these symptoms. Teach them to change from a lying or sitting position to standing by moving slowly. The health care provider should not prescribe drugs in this class to older adults because of their severe adverse drug effects.

Almost all patients are on Sinemet, a combination *levodopa-carbidopa* drug, at some point in their disease. It may be the initial drug of choice if the patient's presenting symptoms are severe or interfere with work or school. Both an immediate-release (IR) and controlled-release (CR) form of Sinemet in varying doses are available. The levodopa agents are less expensive than the dopamine agonists and are better at improving motor function. Long-term use leads to dyskinesia (inability to perform voluntary movement). Teach the patient and family to give the drug before meals to increase absorption and transport across the blood-brain barrier.

Catechol O–methyltransferases (COMTs) are enzymes that inactivate dopamine. Therefore COMT *inhibitors* block this enzyme activity, thus prolonging the action of levodopa. One example is entacapone (Comtan), which is often used in combination with levodopa. Stalevo is a combination of levodopa, carbidopa, and entacapone. The benefit of these combinations is that the disease is treated in several ways with one drug. However, they are not beneficial for those patients who need more specific dosages of individual drugs.

Monamine oxidase type B (MAO-B) inhibitors (MAOIs) are more popular for use in patients with early or mild symptoms of PD. Entacapone (Comtan) and selegiline (Deprenyl, Eldepryl) are often given with levodopa for early or mild disease. A newer MAOI-B for PD is rasagiline mesylate (Azilect), which can be given as a single drug or with levodopa. This drug has been reported to decrease "freezing" episodes (Cranwell-Bruce, 2010).

The MAOI-B drugs work by slowing the main type (B) of monamine oxidase in the brain, increasing dopamine concentrations and helping reduce the clinical manifestations of PD. They may also protect neurons in the brain (Cranwell-Bruce, 2010).

Nursing Safety Priority QSEN

Drug Alert

Teach patients taking MAOIs about the need to avoid foods, beverages, and drugs that contain tyramine, including cheese and aged, smoked, or cured foods and sausage. Remind them to also avoid red wine and beer to prevent severe headache and life-threatening hypertension (Lilley et al., 2014). Patients should continue these restrictions for 14 days after the drug is discontinued.

When other drugs are no longer effective, bromocriptine mesylate (Parlodel), a *dopamine receptor agonist,* may be prescribed to promote the release of dopamine. It may be used alone or in combination with carbidopa/levodopa (Sinemet). Some providers may prescribe Parlodel early in the course of treatment. It is especially useful in the patient who has experienced side effects such as dyskinesias or orthostatic hypotension while receiving Sinemet.

Amantadine (Symmetrel) is an *antiviral drug* that has anti-Parkinson benefits. It may be given early in disease to reduce symptoms. It is also prescribed with Sinemet to reduce dyskinesias. Rivastigmine (Exelon) is a *cholinesterase inhibitor* that is used only when patients with PD have dementia. This drug works to improve the transmission of acetylcholine in the brain by delaying its destruction by the enzyme *acetylcholinesterase.*

For severe motor symptoms such as tremors and rigidity, one of the older *anticholinergic* drugs may be prescribed, but they are rarely used as primary drugs of choice for Parkinson disease (PD) (Cranwell-Bruce, 2010). Examples are benztropine (Cogentin), trihexyphenidyl HCl (Artane), and procyclidine (Kemadrin). *These drugs should be avoided in older adults because they can cause acute confusion, urinary retention, constipation, dry mouth, and blurred vision. Newer and safer drugs are now available for this age-group.*

For the patient on any long-term drug therapy regimen, drug tolerance or *drug toxicity* often develops. Drug toxicity may be evidenced by changes in cognition such as delirium (acute confusion) or hallucinations and decreased effectiveness of the drug. Delirium may be difficult to assess in the patient who is already suffering from chronic dementia as a result of PD or another disease. If possible, compare the patient's current cognitive and behavioral status with his or her baseline before drug therapy began.

When drug tolerance is reached, the drug's effects do not last as long as previously. The treatment of PD drug toxicity or tolerance includes:

- A reduction in drug dosage

- A change of drug or in the frequency of administration
- A drug holiday (particularly with levodopa therapy)

During a **drug holiday,** which typically lasts up to 10 days, the patient receives no drug therapy for PD. Carefully monitor the patient for symptoms of PD during this time, and document assessment findings.

Many patients are on additional drugs to help relieve symptoms associated with the disease. For example, muscle spasms may be relieved by baclofen (Kemstro), drooling can be minimized by sublingual atropine sulfate (Atropair), and insomnia may require a sleeping aid like zolpidem tartrate (Ambien). If patients also become moderately to severely depressed, an antidepressant such as short-acting venlafaxine (Effexor) may be prescribed. This complicated drug regimen may be confusing to patients. A review by Vervloet and colleagues (2012) supports electronic reminders as effective in helping to educate patients and maintain drug adherence.

Other Interventions.

A freezing gait and postural instability are major problems for patients with PD. Nontraditional exercise programs, such as yoga and tai chi, may help elevate mood, as well as improve mobility, in the early stage of the disease. Early in the disease process, collaborate with physical and occupational therapists to plan and implement a program to keep the patient flexible, prevent falling, and retain mobility by incorporating active and passive range-of-motion (ROM) exercises, muscle stretching, and out-of-bed activity. Remind the patient to avoid concentrating on his or her feet when walking to prevent falls.

In collaboration with the rehabilitation team, encourage the patient to participate as much as possible in self-management, including ADLs. The team makes the environment conducive to independence in activity and as stress-free and safe as possible. Occupational and physical therapists provide training in ADLs and the use of adaptive devices, as needed, to facilitate independence. The occupational therapist (OT) evaluates the patient for the need for adaptive devices (e.g., special utensils for eating).

Patients with PD tend to not sleep well at night because of drug therapy and the disease itself. Some patients nap for short periods during the day and may not be aware that they have done so. This sleep misperception may put the patient at risk for injury. For example, he or she may fall asleep while driving an automobile. Therefore teach the patient and family to monitor the patient's sleeping pattern and discuss whether he or she can operate machinery or perform other potentially

high-risk tasks safely.

Collaborate with the dietitian, if needed, to evaluate the patient's food intake and ability to eat. The patient's intake of calcium, vitamin K, and other nutrients is evaluated, especially in the patient who has difficulty swallowing or is susceptible to injury from falling. The dietitian considers the patient's bowel habits and adjusts the diet if constipation occurs. If the patient has trouble swallowing, collaborate with the speech-language pathologist (SLP) for an extensive swallowing evaluation. Based on these findings and the patient interview, an individualized nutritional plan is developed. Usually a soft diet and thick, cold fluids, such as milk shakes, are more easily tolerated.

Small, frequent meals or a commercial powder, such as Thick-It, added to liquids may assist the patient who has difficulty swallowing. Elevate the patient's head to allow easier swallowing and prevent aspiration. Remind UAP and teach the family to be careful when serving or feeding the patient. The SLP can be very helpful in recommending specific feeding strategies. Be sure that UAP record food intake daily or as needed. The patient loses weight because of altered food intake and the increased number of calories burned secondary to muscle rigidity. Teach the family to weigh the patient once a week so that adjustments to the diet can be made as indicated. As the disease progresses and swallowing becomes more of a problem, supplemental feedings become the main source of nutrition to maintain weight, with meals and other foods taken as the patient can tolerate.

Collaborate with the SLP if the patient has speech difficulties. Together with the interdisciplinary health care team, patient, and family, develop a communication plan. The SLP teaches exercises to strengthen muscles used for breathing, speech, and swallowing. Remind the patient to speak slowly and clearly and to pause and take deep breaths at times during each sentence. Teach the family the importance of avoiding unnecessary environmental noise to increase the listener's ability to hear and understand the patient. Ask the patient to repeat words that the listener does not understand. Have the listener watch the patient's lips and nonverbal expressions for cues as to the meaning of conversation. Remind the patient to organize his or her thoughts before speaking and use facial expression and gestures, if possible, to assist with communication. In addition, he or she should exaggerate words to increase the listener's ability to understand. If the patient cannot communicate verbally, he or she can use alternative methods of communication, such as a communication board, mechanical voice synthesizer, computer, or handheld mobile device. The SLP assesses the

ability to use these devices before a decision is made about which method to use. Some older patients may not want to use electronic methods to communicate.

Psychosocial Support.

Although not all patients with PD have dementia, impaired cognition and memory deficits are common. Some patients also experience changes in gait and tremors that are uncontrollable. In the late stages of the disease, they cannot move without assistance, have difficulty talking, have minimal facial expression, and may drool. Patients often state that they are embarrassed and tend to avoid social events or groups of people. They should not be forced into situations in which they feel ashamed of their appearance. Encourage patients to undertake activities that do not require small-muscle dexterity, such as light, modified aerobic exercises.

Collaborate with the social worker or case manager to help the family with financial and health insurance issues, as well as respite care or permanent placement if needed. Refer the patient and family to social and state agencies, as well as support groups as needed (e.g., the National Parkinson Foundation [www.pdf.org]).

Teach the family to emphasize the patient's abilities or strengths and provide positive reinforcement when he or she meets expected outcomes. The patient, the family or significant other, and the rehabilitation team mutually set realistic expected outcomes that can be achieved.

The long-term management of PD presents a special challenge in the home care setting. A case manager may be required to coordinate interdisciplinary care and provide support for the patient and family. Impaired mobility affects the patient's daily lifestyle, including sexuality. The case manager or home care nurse uses a holistic approach to ensure that psychosocial, as well as physical, needs are addressed.

As the disease progresses and drug effectiveness decreases, refer the family to a palliative care organization or hospice. Referral sources can be obtained from the Center to Advance Palliative Care (www.capc.org), which advocates applying the principles of palliative care to chronic disease. Chapter 7 discusses palliative and hospice care in detail.

Clinical Judgment Challenge

Informatics QSEN

A 68-year-old man reports shaking of his arms, hands, and head that he cannot control. He has also noticed that he walks more slowly now

and thought it was part of the aging process. He is afraid that he won't be able to continue his job as an auto body worker, and he says he can't live on his monthly Social Security income. His mother had Parkinson disease for many years and died of complications before she was 70. He decided he should see his family practice physician to discuss the changes he is experiencing. He is accompanied by his wife of 45 years; they have two children who live out of town.

1. As the patient's intake nurse, what questions might you include in his history?
2. What physical assessment will you perform and why?
3. The physician places the patient on Sinemet. You realize that you need to look up information about this drug to provide accurate health teaching. What reliable resources might you use?
4. What health teaching will you need to provide for this patient and his wife regarding his drug and other aspects of his illness?

Surgical Management.

Several options are available if surgery for the patient with PD is needed. Surgery is a last resort when drugs are not effective in symptom management. The most common surgeries are stereotactic pallidotomy and thalamotomy, although newer surgical procedures are being tried. Deep brain stimulation may also be done.

Stereotactic Pallidotomy/Thalamotomy.

Stereotactic pallidotomy (opening into the pallidum within the corpus striatum) can be a very effective treatment for controlling the symptoms associated with PD. First, the target area within the pallidum is identified by a CT or MRI scan. Next, the stereotactic head frame is placed on the patient. IV sedation is given, and a burr hole is made into the cranium. An electrode or cylindric rod is inserted into the target area. The target area receives a mild electrical stimulation, and the patient's reaction is assessed for reduction of tremor and rigidity. If this result does not occur or if unexpected visual, motor, or sensory symptoms appear, the probe is repositioned. When the probe is in the ideal location, a permanent lesion (scarring) is made to destroy the tissue. The patient is monitored in the postanesthesia care unit (PACU) for about 1 hour and is then returned to the inpatient unit for continuing postoperative care.

As an alternative to stereotactic pallidotomy, the surgeon may perform a **thalamotomy** (opening into the thalamus of the brain for the stimulation) for treatment of tremor through thermocoagulation (high-

frequency currents to destroy tissue) of brain cells. This procedure is effective for a limited number of patients. Because bilateral procedures have increased surgical complication rates, only unilateral (one-sided) surgery is done to benefit the side of the body that is most affected by the disease.

Deep Brain Stimulation.

Deep brain stimulation (DBS) is approved as a treatment for Parkinson disease. In DBS, electrodes are implanted into the brain and connected to a small electrical device called a *pulse generator* that delivers electrical current. The generator is placed under the skin similar to a cardiac pacemaker device. The generator is externally programmed to deliver an electrical current to decrease involuntary movements known as **dyskinesias**, resulting in a reduced need for levodopa and related drugs. DBS also helps to alleviate fluctuations of symptoms and to reduce tremors, slowness of movements, and gait problems (National Institute of Neurological Disorders and Stroke [NINDS], 2014).

Fetal Tissue Transplantation.

Fetal tissue transplantation is an experimental and highly controversial ethical and political treatment. Fetal substantia nigra tissue, either human or pig, is transplanted into the caudate nucleus of the brain. Preliminary reports suggest that patients show clinical improvement in motor symptoms without dyskinesias after receiving the transplanted tissue. Long-term results are yet to be seen or studied.

Dementia

Pathophysiology

Dementia is a loss of brain function that is chronic and progressive. Dementia affects the ability to learn new information. It also impairs language, judgment, and behavior. Alzheimer's disease (AD) is the most common type of dementia, accounting for most of the chronic confusional states that occur in people older than 65 years. Vascular dementia is the second most common dementia and is associated with stroke. When dementia occurs in people in their 40s and 50s, it is referred to as *early dementia, Alzheimer type,* or *presenile dementia.* Although symptoms of dementia can vary greatly, at least two of these cognitive functions must be significantly impaired for a diagnosis of dementia:

- Memory
- Communication and language
- Attention span or ability to focus and pay attention
- Reasoning and judgment
- Visual perception

People with dementia often have problems with short-term memory such as keeping track of keys or personal items, paying bills, preparing meals, remembering appointments, or traveling out of the neighborhood. Many dementias are progressive and result in a chronic confusional state. Severe physical deterioration occurs over time, and death is usually associated with complications of immobility.

The brain of the older adult usually weighs less and occupies less space in the cranial vault than does the brain of a younger person. Other changes in the brain that occur with aging include widening of the cerebral sulci, narrowing of the gyri, and enlargement of the ventricles. In the presence of AD and vascular dementia, these normal changes are greatly accelerated. Brain weight is reduced further. Marked atrophy of the cerebral cortex and loss of cortical neurons occur. The cerebral sulci and fissures, as well as the ventricles, are enlarged more than those of persons of the same age without AD. These areas of the brain are particularly affected:

- Precentral gyrus of the frontal lobe
- Superior temporal gyrus
- Hippocampus
- Substantia nigra

Microscopic changes of the brain found in people with AD include

neurofibrillary tangles, amyloid-rich senile or neuritic plaques, and granulovascular degeneration. **Neurofibrillary tangles** are a classic finding at autopsy in the brains of patients with AD. They consist of tangled masses of fibrous tissue throughout the neurons (McCance et al., 2014).

Neuritic plaques are composed of degenerating nerve terminals and are found particularly in the hippocampus, an important part of the limbic system. Deposited within the plaques are increased amounts of an abnormal protein called *beta amyloid.* These peptides have a tendency to accumulate and form the neurotoxic plaques found in the brain (McCance et al., 2014).

Although *vascular degeneration* occurs in the normally aging brain, its presence is significantly increased in patients with dementia. Vascular degeneration accounts for at least partial loss of the ability of nerve cells to function properly. Cell deterioration and death may lead to hemorrhage. This pathologic change contributes to the mortality associated with this disorder.

In addition to the structural changes in the brain associated with AD and other dementias, abnormalities in the neurotransmitters (acetylcholine [ACh], norepinephrine, dopamine, and serotonin) may occur. High levels of beta amyloid are associated with significantly reduced ACh, which leads to a decrease in the amount of acetyltransferase in the hippocampus. This loss is major because the decrease in acetyltransferase interferes with cholinergic innervation to the cerebral cortex. This results in impaired cognition, recent memory, and the ability to acquire new memories. The specific role of reduced neurotransmitters in the development of AD is not well understood.

Etiology and Genetic Risk

The exact cause of AD is unknown. It is well established that *age, gender (women more than men), and family history are the most important risk factors*. Several other theories and risk factors have been studied, including chemical imbalances, environmental agents, immunologic changes, and ethnicity/race. Compared with Euro-Americans, African Americans have a greater risk for developing the disease and Hispanics tend to develop the disease earlier than other groups. The cause of these differences is not yet known.

Genetic/Genomic Considerations

Patient-Centered Care QSEN

There is little doubt that many patients with AD had a genetic predisposition to the development of the disease. The inheritance pattern is highly complex with both isolated and interactive genes identified from multiple sites such as the beta-amyloid precursor *(APP)*, the presenilin1 *(PSEN1)*, and presenilin2 *(PRESN2)* genes—all involved in the formation of the distinctive plaque and neurofibrillary tangles in AD. Other genes implicated in AD are apolipoprotein E *(APOE)* and clusterin *(CLU)* genes that code for products in lipid metabolism and inflammation. A third family of genes associated with AD progression is responsible for endocytosis and vesicle trafficking—intracellular processes that help deliver neurotransmitters. These genes are phosphatidylinositol-binding clathrin assembly protein *(PICALM)* and Bridging Integrator 1 *(BIN1)* (Bettens et al., 2013). The genetic studies in AD are an example of how genetics, genomics, and proteomics are not only finding genes associated with the condition but also illustrating the mechanisms of pathology in complex conditions.

Environmental agents, especially certain viruses such as herpes zoster and herpes simplex, and toxic metals such as zinc and copper have also been suggested as causes. Patients who have experienced a head injury or repeated head trauma (e.g., boxers) may be more at risk for AD and at an earlier age than others.

Incidence and Prevalence

There is a significant increase in both the incidence and prevalence of AD after 65 years of age, although it may affect anyone older than 40 years. The number of people in the United States with AD is estimated at 4.5 million and expected to triple in the next three decades (Mayeux & Stern, 2012). AD has a significant impact on health care costs, including direct and indirect medical and social service costs.

Health Promotion and Maintenance

There are no proven ways to prevent AD or other dementias. Current research activities are focusing on eating a balanced diet, eating dark-colored fruits and vegetables, using soy products, and consuming sufficient amounts of folate and vitamins B_{12}, C, and E. These substances have been reported to decrease the risk for developing AD, but study results are inconclusive and inconsistent. Walking, swimming, and other exercise not only increase tone and muscle strength but also may

decrease mental decline in AD, as well as other dementias. Avoiding lifestyle factors that contribute to stroke risk, including untreated hypertension, is also advocated.

Patient-Centered Collaborative Care

Assessment

History.

The patient with dementia and Alzheimer's disease (AD) often presents with cognitive impairment, although many other disorders, drugs, and environmental factors can cause changes in cognition. A thorough history and physical examination are necessary to differentiate AD from other, possibly reversible causes of cognitive impairment (Table 42-4). Obtain information from family members or significant others because the patient may be unaware of the problems, denying their existence or covering them up. Family members often do not recognize or may deny early changes in their loved one as well.

TABLE 42-4

Causes of Cognitive Impairment in the Older Adult

Neurologic Causes
• Vascular insufficiency • Infections • Trauma • Tumors • Normal-pressure hydrocephalus
Cardiovascular Causes
• Myocardial infarction • Dysrhythmias • Heart failure • Cardiogenic shock • Endocarditis • Stroke
Pulmonary Causes
• Infection • Pneumonia • Hypoventilation
Metabolic Causes
• Electrolyte imbalance • Acidosis/alkalosis • Hypoglycemia/hyperglycemia • Kidney failure • Fluid volume deficit • Urinary tract infection • Hepatic failure
Drug Intoxication
• Misuse of prescribed medications • Side effects of medications • Incorrect use of over-the-counter medications • Ingestion of heavy metals
Nutritional Deficiencies
• B vitamins • Vitamin C • Hypoproteinemia
Environmental Causes
• Hypothermia/hyperthermia • Unfamiliar environment • Sensory deprivation/overload
Psychological Causes
• Depression • Anxiety • Pain • Fatigue • Grief • Paranoia

The most important information to be obtained is the onset, duration, progression, and course of the symptoms. Question the patient and the family about changes in memory or increasing forgetfulness and about the ability to perform ADLs. Ask about current employment status, work history, and ability to fulfill household responsibilities, including cleaning, grocery shopping, and preparing meals. Inquire about changes in driving ability, ability to handle routine financial transactions, and

language and communication skills. In addition, document any changes in personality and behavior. Assessing functional status for complex chronic conditions such as dementia is a recommended core measure by the Centers for Medicare and Medicaid Services (www.cms.gov).

There is increasing evidence that an altered sense of smell is associated with the development of AD. Therefore ask about changes in the ability to smell or changes in the sense of smell. The history taking concludes with a review of the patient's medical history. Of particular importance is a history of head trauma, viral illness, or exposure to metal or toxic waste, as well as any family history of AD or Down syndrome.

Physical Assessment/Clinical Manifestations

Stages of Alzheimer's Disease.

The clinical manifestations associated with AD can be grouped into three broad stages based on the progress of the disease (Chart 42-13). The patient does not necessarily progress from one stage to the next in an orderly fashion. A stage may be bypassed, or he or she may exhibit symptoms of one or several stages. Each patient exhibits different disease stages and clinical manifestations. Consequently, most authorities now use broader terms such as *early (mild)*, *middle (moderate)*, and *late (severe)* stages.

Chart 42-13 Key Features

Alzheimer's Disease

Early (Mild), or Stage I (first symptoms up to 4 years)

- Independent in ADLs
- No social or employment problems initially
- Denies presence of symptoms
- Forgets names; misplaces household items
- Short-term memory loss; difficulty recalling new information
- Subtle changes in personality and behavior
- Loss of initiative; less engaged in social relationships
- Mild impaired cognition, problems with judgment
- Decreased performance, especially when stressed
- Unable to travel alone to new destinations
- Decreased sense of smell

Middle (Moderate), or Stage II (2 to 3 years)

- Impairment of all cognitive functions
- Problems with handling or unable to handle money and finances
- Disorientation to time, place, and event
- Possible depression, agitated
- Increasingly dependent in ADLs
- Visuospatial deficits: difficulty driving, gets lost
- Speech and language deficits: less talkative, decrease in use of vocabulary, increasingly non-fluent, and eventually aphasic
- Incontinent
- Wandering; trouble sleeping

Late (Severe), or Stage III

- Completely incapacitated; bedridden
- Totally dependent in ADLs
- Motor and verbal skills lost
- General and focal neurologic deficits
- Agnosia (loss of facial recognition)

The primary focus of the neurologic assessment of patients with AD is to identify abnormalities in cognition, including language, personality, and behavior. Physical manifestations of neurologic impairment (seizures, tremors, or ataxia) tend to occur late in the disease process.

Changes in Cognition.

Cognition refers to the ability of the brain to process, store, retrieve, and use information. Therefore assess the patient for deficits in these abilities:

- Attention and concentration
- Judgment and perception
- Learning and memory
- Communication and language
- Speed of information processing

One of the first symptoms of AD is short-term memory impairment. New memory and defects in information retrieval result from dysfunction in the hippocampal, frontal, or parietal region. Alterations in communication abilities, such as **apraxia** (inability to use words or objects correctly), **aphasia** (inability to speak or understand), **anomia** (inability to find words), and **agnosia** (loss of sensory comprehension), are due to dysfunction of the temporal and parietal lobes. Frontal lobe impairment causes problems with judgment, an inability to make decisions, decreased attention span, and a decreased ability to

concentrate. As the disease progresses to a later stage, the patient loses all cognitive abilities, is totally unable to communicate, and becomes less aware of the environment.

To more clearly identify the nature and extent of the patient's cognitive impairment, the neurologist or psychologist administers several neuropsychological tests. The tests selected depend on clinician preference and the ability of the patient to participate in testing. All of the tests focus on cognitive ability and may be repeated over time to measure changes. Folstein's Mini-Mental State Examination (MMSE) is an example of a tool used to determine the onset and severity of cognitive impairment. The MMSE is also known as the “mini-mental exam.” The MMSE assesses five major areas—orientation, registration, attention and calculation, recall, and speech-language (including reading). Fig. 42-2 lists examples of the questions asked on this test. The patient performs certain cognitive tasks that are scored and added together for a total score of 0 to 30. The lower the score is, the greater the severity of the dementia. It is not unusual for a patient with advanced AD to score below 5.

A

Orientation to Time
"What is the date?"

Registration
"Listen carefully, I am going to say three words. You say them back after I stop. Ready? Here they are... HOUSE (pause), CAR (pause), LAKE (pause). Now repeat those words back to me." [Repeat up to 5 times, but score only the first trial.]

Naming
"What is this?" [Point to a pencil or pen.]

Reading
"Please read this and do what it says." [Show examinee the words on the stimulus form.]

CLOSE YOUR EYES

FIG. 42-2 **A,** Examples of questions that are asked on the Mini-Mental State Examination (MMSE). **B,** Copying is one of the tasks on the MMSE.

Although the MMSE is used frequently by specialists and researchers outside of the acute care setting, it is a copyrighted tool and the patient must be able to read. For the patient who cannot read or for a quicker screening test, the "set test" can be used. The patient is asked to name 10 items in each of four sets or categories: fruits, animals, colors, and towns (FACT). Other categories can be used, if needed. The patient receives 1 point for each item for a possible maximum score of 40. Patients who score above 25 do not have dementia. Although this assessment is easy to administer, it should not be used for patients with hearing impairments or speech and language problems. Another brief tool to screen for dementia that has validity and reliability in acute care settings is the Short Blessed Test (www.mybraintest.org). In long-term care settings, the federally required Brief Interview for Mental Status (BIMS) is required as part of the Minimum Data Set 3.0 for Nursing Homes (Saliba et al., 2012).

Changes in Behavior and Personality.

One of the most difficult aspects of AD and dementia that families and caregivers cope with is the behavioral changes that can occur in advanced disease. Assess the patient for:

- Aggressiveness, especially verbal and physical abusive tendencies
- Rapid mood swings
- Increased confusion at night or when light is not adequate **(sundowning)** or in excessively fatigued patients

The patient may wander and become lost or may go into other rooms to rummage through another's belongings. Hoarding or hiding objects is also common. For example, patients may hoard washcloths in the long-term care setting.

For some patients with dementia, emotional and behavioral problems occur with the primary disease. They may experience paranoia (suspicious behaviors), delusions, hallucinations, and depression. Document these behaviors, and ensure the patient's safety. (Refer to a mental health/behavior health nursing textbook for a complete discussion of these disorders.)

Although drug therapy is not effective in treating dementia, certain drugs may help control the emotional and psychiatric manifestations (e.g., depression, anxiety, paranoia, aggression) associated with the primary disease.

Changes in Self-Management Skills.

Observe for changes in the patient's self-management skills, such as:

- Decreased interest in personal appearance
- Selection of clothing that is inappropriate for the weather or event
- Loss of bowel and bladder control
- Decreased appetite or ability to eat

Over time, the patient becomes less mobile and muscle contractures develop. He or she eventually becomes totally immobile and requires total physical care. The patient is then unable to meet the human needs of mobility and cognition.

Psychosocial Assessment.

In people with dementia, the cognitive changes and biochemical and structural dysfunctions affect personality and behavior. In the early stage, patients often recognize that they are experiencing memory or cognitive changes and may attempt to hide the problems. They begin the grieving process because of anticipated loss, experiencing denial, anger, bargaining, and depression at varying times. Older patients typically think the changes are part of “old age.”

When the patient and family receive the diagnosis, one or more family members may desire genetic testing. Support the patient's/family's decisions regarding testing, and assist them in finding credible resources for testing and professional genetics counseling.

As the disease progresses, patients begin to display major changes in emotional and behavioral affect. Of particular importance is the need for an assessment of the patients' reactions to changes in routine or environment. For example, a hospital admission is very traumatic for most patients with dementia. It is not unusual for them to exhibit a catastrophic response or overreact to any change by becoming excessively aggressive or abusive. This is referred to as *traumatic relocation syndrome.*

As patients become unaware of their behavior, the focus of the psychosocial assessment shifts to the family or significant others. The health care team assesses their ability to cope with the chronicity and progression of the disease and identifies possible support systems.

Laboratory and Imaging Assessment.

No laboratory test can confirm the diagnosis of AD. Definitive diagnosis is made on the basis of brain tissue examination at autopsy, which confirms the presence of neurofibrillary tangles and neuritic plaques.

Genetic testing, specifically for *apolipoprotein E4 (Apo E4),* may be helpful as an ancillary test (not a predictive test) for the differential diagnosis of AD. *Amyloid beta protein precursor (soluble)* (sBPP) may be measured for patients to diagnose AD and other types of dementia. A decrease in the patient's sBPP in the cerebrospinal fluid (CSF) supports the diagnosis because the amyloid tends to deposit in the brain and is not circulating in the CSF (Pagana & Pagana, 2014).

A variety of other laboratory tests may be performed to rule out other treatable causes of dementia or delirium, including:

- Complete blood count (CBC)
- Serum electrolyte levels, blood urea nitrogen, and glucose
- Vitamin B_{12} levels
- Folate levels
- Blood ammonia levels
- Blood gas analysis
- Cerebrospinal fluid (CSF) analysis
- Urinalysis
- Thyroid and liver function tests
- Serologic test for syphilis
- Toxicity screening tests; heavy metal screen

• Alcohol screening tests

A CT, PET, or SPECT scan may be performed to rule out other causes of disease. The CT scan typically shows cerebral atrophy and ventricular enlargement, wide sulci, and shrunken gyri in the later stages of the disease. An MRI scan can also rule out other causes of neurologic disease. The PET and SPECT scans show a significant decrease in metabolic activity in the brains of people with AD.

Analysis

The priority NANDA-I nursing diagnoses and collaborative problems for patients with Alzheimer's disease (AD) include:

1. Chronic Confusion related to neuronal degeneration in the brain (NANDA-I)
2. Risk for Injury related to wandering or elder abuse (NANDA-I)
3. Caregiver Role Strain related to the patient's prolonged progression of disability and the patient's increasing care needs (NANDA-I)

Planning and Implementation

The priority for interdisciplinary care is safety! Chronic confusion and physical deficits place the patient with AD at a high risk for injury.

Managing Chronic Confusion

Planning: Expected Outcomes.

In the very early stages of the disease, the patient with dementia is expected to maintain the ability to perform complex mental processes. As the disease progresses, patients cannot meet this outcome. Instead, the desired outcome is to maintain cognitive function for as long as possible to keep patients safe and increase their quality of life.

Interventions.

Although drug therapy may be used for patients with dementia or AD, nonpharmacologic interventions are the main focus of patient-centered collaborative management. Teach family members and significant others about the importance of being consistent in following the plan of care.

Nonpharmacologic Management.

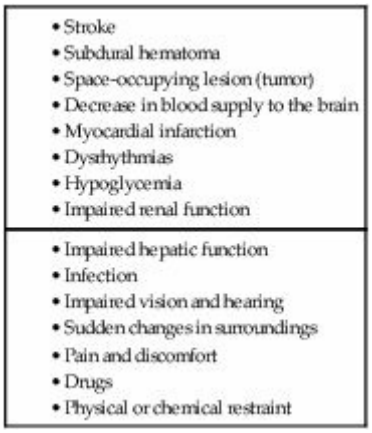
The health care provider should answer the patient's questions truthfully concerning the diagnosis of dementia or AD. In this way, the patient can more fully participate in the interdisciplinary plan of care. Interventions are the same whether he or she is cared for at home, in an adult day-care

center, in an assisted-living center, in a long-term care facility, or in a hospital admitted with another medical condition. The patient with memory problems always benefits best from a structured and consistent environment (Seitz et al., 2012).

Many factors, including physical illness and environmental factors, can exacerbate (worsen) the clinical manifestations of AD (Table 42-5). The patient with dementia frequently has other medical problems such as cardiovascular disease, arthritis, renal insufficiency, and pulmonary disease. Changes in vision and hearing also may be present. Managing these conditions helps the patient's functional abilities.

TABLE 42-5

Factors That Can Worsen Alzheimer's Disease and Dementia



Approaches to managing the patient who has Alzheimer's disease include:

- Cognitive stimulation and memory training
- Structuring the environment
- Orientation and validation therapy
- Promoting self-management
- Promoting bowel and bladder continence
- Promoting communication

The purpose of *cognitive stimulation and memory training* is to reinforce or promote desirable cognitive function and facilitate memory. An individualized cognitive therapy program may provide some benefit to the patient. Training in communication can help nurses and health care team members interact with better effect and compassion (Eggenberger et al., 2013; Johnson et al., 2013).

As the disease progresses, the patient may experience **prosopagnosia,** an inability to recognize oneself and other familiar faces. Encourage the family to provide pictures of family members and close friends that are

labeled with the person's name on the picture. In addition, advise the family to reminisce with the patient about pleasant experiences from the past (Subramaniam & Woods, 2012). Use *reminiscence therapy* while assisting the patient with ADLs or performing a treatment or assessment. Refer to a personal item in the room to help the patient begin to talk about its meaning in the present and in the past.

It is not unusual for the patient to talk to his or her image in the mirror. This behavior should be allowed as long as it is not harmful. If the patient becomes frightened by the mirror image, remove or cover the mirror. In some long-term care or assisted-living settings, a picture of the patient is placed on the room door to help with facial recognition and to help the patient locate his or her room. This picture also helps the staff locate the patient in case of elopement (running away).

Teach the family to keep environmental distractions and noise to a minimum. The patient's home, hospital room, or nursing home room should not have pictures on the wall or other decorations that could be misinterpreted as people or animals that could harm the patient. An abstract painting or wallpaper might look like a fire or an explosion and scare the patient. The room should have adequate, nonglare lighting and no potentially frightening shadows.

In addition to disturbed sleep, other negative effects of high noise levels include decreased nutritional intake, changes in blood pressure and pulse rates, and feelings of increased stress and anxiety. The patient with AD is especially susceptible to these changes and needs to have as much undisturbed sleep at night as possible. Fatigue increases confusion and behavioral manifestations such as agitation and aggressiveness.

Nursing Safety Priority QSEN

Action Alert

When a patient with Alzheimer's disease is in a new setting or environment, collaborate with the staff and admitting department to select a room that is in the quietest area of the unit and away from obvious exits, if possible. A private room may be needed if the patient has a history of agitation or wandering. The television should remain off unless the patient turns it on or requests that it be turned on.

Objects such as furniture, a hairbrush, and eyeglasses should be kept in the same place. Establish a daily routine, and follow it as much as possible. Arrange for a communication board for scheduled activities

and other information to promote orientation such as the day of the week, the month, and the year. Pictures of people familiar to the patient can also be placed on this board.

Explain changes in routine to the patient before they occur, repeating the explanation immediately before the changes take place. Clocks and single-date calendars also help the patient maintain day-to-day orientation to the environment in the early stages of the disease process. *For the patient with early disease, reality orientation is usually appropriate.* Teach family members and health care staff to frequently reorient the patient to the environment. Remind the patient what day and time it is, where he or she is, and who you are.

For the patient in the later stages of AD or dementia, reality orientation does not work and often increases agitation. *The health care team uses validation therapy for the patient with moderate or severe AD. In* **validation therapy,** *the staff member recognizes and acknowledges the patient's feelings and concerns.* For example, if the patient is looking for his or her mother, ask him or her to talk about what Mother looks like and what she might be wearing. This response does not argue with the patient but also does not reinforce the patient's belief that Mother is still living.

As the disease progresses, altered thought processes affect the *ability to perform ADLs*. Encourage the patient to perform as much self-care as possible and to maintain independence in daily living skills as long as possible. For example, in the home setting, complete clothing outfits that can be easily removed and put on (e.g., shirt, slacks, underwear, and socks) and placed on a single hanger are preferred for patient selection. When possible, the patient should participate in meal preparation, grocery shopping, and other household routines. Many patients cannot make purposeful movements as the disease progresses.

NCLEX Examination Challenge

Psychosocial Integrity

A client with moderate dementia asks the nurse to find her brother who is deceased. What is the nurse's best response?
A "Your brother died over 20 years ago."
B "We can call him in a little while if you want."
C "What did your brother look like?"
D "I'll ask your daughter to find him for you when she comes in."

Collaborate with the occupational and physical therapists to provide a complete evaluation and assistance in helping the patient become more independent. Adaptive devices, such as grab bars in the bathtub or shower area, an elevated commode, and adapted eating utensils, may enable him or her to maintain independence in grooming, toileting, and feeding. The physical therapist prescribes an exercise program to improve physical health and functionality.

The patient may remain continent of bowel and bladder for long periods if taken to the bathroom or given a bedpan or urinal every 2 hours. Toileting may be needed more often during the day and less frequently at night. Unlicensed assistive personnel (UAP) or home caregiver encourages the patient to drink adequate fluids to promote optimal voiding. A patient may refuse to drink enough fluids because of a fear of incontinence. Assure the patient that he or she will be toileted on a regular schedule to prevent incontinent episodes.

When patients with dementia are in the hospital or other unfamiliar place, avoid the use of restraints, including siderails. Serious injury can occur when a patient with dementia attempts to get out of bed with either limb restraints or siderail use. Use frequent surveillance, toileting every 2 hours, and other strategies to prevent falls. Restraint reduction has been associated with a reduced length of stay and fewer injuries (Kwok et al., 2012). In some cases, sitters may be used to help prevent patient injury (see the Evidence-Based Practice box). Chapter 2 discusses fall prevention in detail.

Evidence-Based Practice QSEN

Does the Use of Sitters Improve the Care of Older Adults with Dementia in Acute Care Settings?

Moyle, W., Borbasi, S., Wallis, M., Olorenshaw, R., & Gracia, N. (2011). Acute care management of older people with dementia: A qualitative perspective. *Journal of Clinical Nursing, 20*(3-4), 420-428.

This Australian study explored management for older people with dementia in an acute hospital setting using a descriptive qualitative approach. A total of 13 nurses participated in semi-structured audiotaped interviews. All nurses worked in acute medical or surgical wards in a large South East Queensland, Australia, hospital. The authors identified an inconsistent approach to care in that the most common intervention—providing a sitter—emphasized safety at the expense of well-being and dignity. Using untrained staff (i.e., a sitter or "patient

observers") to monitor a patient with dementia is a risk management strategy that reduces the use of restraints but does not incorporate other evidence-based approaches to care such as reminiscent therapy, mobility activities, or family member presence. The use of sitters does not individualize care, a hallmark of nursing care.

Level of Evidence: 3

The research was a small qualitative study.

Commentary: Implications for Practice and Research

Although this study occurred in Australia, sitters are commonly used in the United States. It may be that sitters need to be trained in communication and assisting in activities of daily living to provide safe and compassionate care that recognizes the dignity of hospitalized patients with dementia. The study needs to be repeated in the United States using a larger sample size.

Maintain a clear path between the bed and bathroom at all times. For patients who are too weak to walk to the bathroom, a bedside commode may be used. Some patients may void in unusual places, such as the sink or a wastebasket. As a reminder of where they should toilet, place a picture of the commode on the bathroom door.

Use **redirection** by attracting the patient's attention to promote communication. Keep the environment as free from distractions as possible. Speak directly to the patient in a distinct manner. Sentences should be clear and short. Remind the patient to perform one task at a time, and allow sufficient time for completion. It may be necessary to break each task down into many small steps (Chart 42-14).

Chart 42-14 Best Practice for Patient Safety & Quality Care QSEN

Promoting Communication with the Patient with Advanced Dementia or Alzheimer's Disease

- Ask simple, direct questions that require only a "yes" or "no" answer if the patient can communicate.
- Provide instructions with pictures in a place that the patient will see if he or she can read them.
- Use simple, short sentences and one-step instructions.
- Use gestures to help the patient understand what is being said.

- Validate the patient's feelings.
- Limit choices; too many choices cause frustration and increased confusion.
- Never assume that the patient is totally confused and cannot understand what is being communicated.
- Try to anticipate the patient's needs and interpret nonverbal communication.

As the disease progresses, the patient is unable to perform tasks when asked. Show the patient what needs to be done, or provide cues to remind him or her how to perform the task. When possible, explain and demonstrate the task that the patient is asked to perform.

Patients with dementia disorders typically have specific speech and language problems, such as:

- **Aphasia** (difficulty speaking and understanding language)
- **Anomia** (difficulty findings words to name an object)
- **Apraxia** (difficulty recognizing words)

Recognize that emotional and physical behaviors may be a form of communication. Interpret the meaning of these behaviors to address them. For example, restlessness may indicate urinary retention, pain, infection, or hypoxia (lack of oxygen to the brain).

Drug Therapy.

Cholinesterase inhibitors are drugs approved for treating AD symptoms. They work to improve cholinergic neurotransmission in the brain by delaying the destruction of acetylcholine (ACh) by the enzyme *acetylcholinesterase.* This action slows the onset of cognitive decline in some patients. None of these drugs alters the course of the disease. Examples include donepezil (Aricept), galantamine (Reminyl), and rivastigmine (Exelon).

Memantine (Namenda) is the first of a new class of drugs that is a low to moderate affinity ***N*-methyl-d-aspartate (NMDA) receptor antagonist.** Overexcitation of NMDA receptors by the neurotransmitter *glutamate* may play a role in AD. This drug therefore blocks excess amounts of glutamate that can damage nerve cells. It is indicated for advanced AD and has been shown to slow the pace of deterioration. Namenda may help maintain patient function for a few months longer. Some patients also have improved memory and thinking skills. This drug can be given with donepezil (Aricept), a cholinesterase inhibitor.

Some patients with AD develop depression and may be treated with **antidepressants.** Selective serotonin reuptake inhibitors (SSRIs), such as

paroxetine (Paxil) and sertraline (Zoloft), are usually prescribed. Tricyclic antidepressants, such as amitriptyline (Elavil, Levate), should not be used because of their anticholinergic effect, especially for older adults. Anticholinergic drugs frequently cause serious side effects, including increased confusion, urinary retention, and constipation.

Psychotropic drugs, also called *antipsychotic* or *neuroleptic drugs,* should be reserved for patients with emotional and behavioral health problems that sometimes accompany dementia, such as hallucinations and delusions. In clinical practice, however, these drugs are sometimes incorrectly used for agitation, combativeness, or restlessness. Psychotropic drugs are considered chemical restraints because they decrease mobility and patients' self-management ability. Therefore most geriatricians recommend that these drugs be used as a last resort and with caution in low doses for a specific emotional or behavioral health problem. The specific drug prescribed depends on side effects, the condition of the patient, and expected outcomes. Follow agency policy and The Joint Commission standards concerning the use of chemical restraints.

Preventing Injury

Planning: Expected Outcomes.

The patient with dementia is expected to remain free from physical harm and not injure anyone else.

Interventions.

Many patients with dementia tend to wander and may easily become lost. In later stages of the disease, some patients may become severely agitated and physically or verbally abusive to others. Teach the family the importance of a patient identification badge or bracelet. The badge should include how to contact the primary caregiver. In an inpatient setting, check the patient frequently and place him or her in a room that can be monitored easily. The room should be away from exits and stairs. Some health care agencies place large stop signs or red tape on the floor in front of exits. Others have installed alarm systems to indicate when a patient is opening the door or getting out of a bed or chair.

Teach the family to enroll the patient in the Safe Return Program—a national, government-funded program of the Alzheimer's Association (www.alz.org) that assists in the identification and safe, timely return of people with dementia. The program includes registration of the patient and a 24-hour hotline to be called to assist in finding a lost patient. If a

patient wanders and becomes lost, the family (or health care institution) should immediately notify the police department. An up-to-date picture of the patient makes it easier for local authorities, the public, and neighbors to identify the missing patient. Devices using radio wave beacons and a global positioning system (GPS) have been developed to help families and law enforcement officials find a lost patient more easily. These devices include shoes with a GPS unit implanted, jewelry that is hard to remove, and bracelets. Caution families that these devices are not foolproof. Just like cell phones, there are some areas where the signal from the patient may not be picked up easily if at all.

Restlessness may be decreased if the patient is taken for frequent walks. If the patient begins to wander, redirect him or her. For example, if the patient insists on going shopping for clothes, the patient is redirected to his or her closet to select clothing that will not be recognized as his or her own. This type of activity can be repeated a number of times because the patient has lost short-term memory. Best practices for preventing and managing wandering are listed in Chart 42-15.

Chart 42-15 Best Practice for Patient Safety & Quality Care QSEN

Approaches to Prevent and Manage Wandering in Hospitalized Patients

- Identify the patients most at risk for wandering through observation and history provided by family.
- Provide appropriate supervision, including frequent checks (especially at shift-change times).
- Place the patient in an area that provides maximum observation, but not in the nurses' station.
- Use family members, friends, volunteers, and sitters as needed to monitor the patient.
- Keep the patient away from stairs or elevators.
- Do not change rooms to prevent increasing confusion.
- Avoid physical or chemical restraints.
- Assess and treat pain.
- Use re-orientation methods and validation therapy, as appropriate.
- Provide frequent toileting and incontinence care as needed.
- If possible, prevent overstimulation, such as excessive noise; use soft music and nonglare lighting if possible.

In any setting, keep the patient busy with structured activities. In a health care agency, an activity therapist or volunteer may work with patients as a group or individually to determine the type of activity that is appropriate for the stage of the disease. Puzzles, board games, and art activities are often appropriate. Music and art therapy are nonpharmacologic approaches to managing patients with dementia (Seitz et al., 2012).

Nursing Safety Priority QSEN

Action Alert

In inpatient health care agencies, use physical restraints such as waist belts and geri-chairs with lapboards only as a last resort because they often increase patient restlessness and cause agitation. Federal regulations in long-term care facilities in the United States mandate that all residents have the right to be free of both physical and chemical restraints. All health care agencies accredited by The Joint Commission are required to use alternatives to restraints before resorting to any physical or chemical restraint.

Patients with dementia may be injured because they cannot recognize objects or situations as harmful. Remove or secure all potentially dangerous objects (e.g., knives, drugs, cleaning solutions). Patients are often unaware that their driving ability is impaired and usually want to continue this activity even if their driver's license has been suspended or they are unsafe. Automobile keys must be secured, but the patient should be told why they were taken. (See Chapter 2 for more discussion on older adult driving.)

Late in the disease process, the patient may experience seizure activity. If he or she is cared for at home, teach caregivers what action to take when a seizure occurs. (See discussion of Interventions on pp. 859-863 in the Seizures and Epilepsy section.)

Talking calmly and softly and attempting to redirect the patient to a more positive behavior or activity are effective strategies when he or she is agitated. Use calm, positive statements, and reassure the patient that he or she is safe. Statements such as “I'm sorry that you are upset,” “I know it's hard,” and “I will have someone stay with you until you feel better” may help.

Actions to *avoid* when the patient is agitated include raising the voice, confrontation, arguing, reasoning, taking offense, or explaining. Teach

the caregiver to not show alarm or make sudden movements out of the person's view. If the patient remains agitated, ensure his or her safety and leave the room after explaining that you will return later. Frequent visual checks must be done during this time. If the patient is connected to any type of tubing or other device, he or she may try to disconnect it or pull it out. These devices should be used cautiously in the patient with dementia. If IV access, for example, is needed, the catheter or cannula is placed in an area that the patient cannot easily see or it should be covered.

Another way to manage this problem is to provide a diversion. For example, if the patient is doing an activity or holding an item such as a stuffed animal or other special item, he or she might be less likely to pay attention to medical devices. Additional strategies to minimize behavioral problems, especially at home, are listed in Table 42-6.

TABLE 42-6

Minimizing Behavioral Problems for Patients with Alzheimer's Disease at Home

Carefully evaluate the patient's environment.
- Ensure environment is safe:
  - Remove small area rugs.
  - Consider replacing tile floors with non-slippery floors.
  - Arrange furniture and room decorations to maximize the patient's safety when walking.
  - Minimize clutter in all rooms in and outside of the house.
  - Install nightlights in patient's room, bathroom, and hallway.
  - Install and maintain smoke alarms, fire alarms, and natural gas detectors.
- Install safety devices in the bathroom such as handles for changing position (sit-to-stand).
- Install alarm system or bells on outside doors; place safety locks on doors and gates.
- Ensure that door locks cannot be easily opened by the patient.

Assist the patient to remain oriented.
- Place single-date calendars in patient's room and in kitchen.
- Use large-face clocks with a neutral background.

Communicate with the patient based on his or her ability to understand.
- Explain activity immediately before the patient needs to carry it out.
- Break complex tasks down to simple steps.

Encourage the patient to be as independent as possible in ADLs.
- Place complete outfits for the day on hangers; have the patient select one to wear.
- Develop and maintain a predictable routine (e.g., meals, bedtime, morning routine).

When a problem behavior occurs, divert patient to another activity.

Minimize excessive stimulation.
- Take the patient on outings when crowds are small.
- If crowds cannot be avoided, minimize the amount of time the patient is present in a crowd. For example, at family gatherings, provide a quiet room for the patient to rest throughout the visit.

Arrange for a day-care program to maintain interaction and provide respite for home caregiver.

Register the patient with the Alzheimer's Association Safe Return Program (www.alz.org).

Drugs may be used only if other modalities fail to control the patient's agitation and the behavior may lead to the patient or other being harmed. For example, atypical psychotics like risperidone (Risperdal), quetiapine (Seroquel), and olanzapine (Zyprexa) can help with aggressive and unsafe behaviors, although not all patients respond to these drugs.

Lorazepam (Ativan) should be used with particular caution because of significant sedation and reports of increased confusion.

Patients who are cared for at home are at high risk for neglect or abuse. The Joint Commission requires all patients to be assessed for neglect and abuse on admission to a health care facility. Patients with mild dementia may not report these concerns for fear of retaliation. Those with severe dementia may not have the ability to report the abuse. Asking questions such as "Who cooks for you?" "Do you get help when you need it?" or "Do you wait long for help to the bathroom?" may be less stressful for the patient to answer.

NCLEX Examination Challenge

Safe and Effective Care Environment

The nurse is caring for a client with dementia. Which nursing intervention is most appropriate when caring for this client?

A Provide a large clock and calendar at the nurses' station.
B Use removable restraints like a roll-waist belt to prevent wandering.
C Use incontinence pads or absorbent underwear to prevent complications from incontinence.
D Place the patient in a room close to the nurses' station for frequent observation.

Managing Caregiver Role Strain

Planning: Expected Outcomes.

The family or other caregivers of the patient with dementia are expected to plan time to care for themselves to promote a reasonable quality of life and satisfaction (Van Mierlo et al., 2012).

Interventions.

The patient with moderate or severe dementia requires continual 24-hour supervision and caregiving. Severe cognitive changes leave the patient unable to manage finances, property, or personal care. The family needs to seek legal counsel regarding the patient's competency and the need to obtain guardianship or a durable medical power of attorney when necessary. Refer the family to the local Alzheimer's or dementia support group for literature and information concerning the disease and related problems (Corbett et al., 2012).

Family members and other caregivers must be aware of their own

health and stress levels. Signs of stress include anger, social withdrawal, anxiety, depression, lack of concentration, sleepiness, irritability, and health problems. When signs of stress occur, the caregiver should be referred to his or her health care provider or should seek one on his or her own. It is not unusual for the caregiver to refuse to accept help from others, even for a few brief hours. Initially, the caregiver may be more comfortable accepting help for just a few minutes a day so he or she could shower, enjoy a cup of tea, or take a brief walk. Some caregivers find that eventually they need to place their loved one into a respite setting or unit so that they can re-energize.

Refer all families to their local chapter of the Alzheimer's Association (www.alz.org) in the United States or to the Alzheimer Society of Canada (www.alzheimer.ca). These organizations provide information and support services to patients and their families, including seminars, audiovisual aids, and publications.

Community-Based Care

Home Care Management.

AD is a chronic, progressive condition that eventually leaves the patient completely disoriented and totally dependent on others for all aspects of care. In the early stages, patients may be cared for at home with little need for outside intervention. Whenever possible, the patient and family should be assigned a case manager who can assess their needs for health care resources and find the best placement throughout the continuum of care.

The patient usually begins to withdraw from friends and social events as memory impairment and personality and behavior changes occur. The family may begin to decrease their own social activities as the demands of the patient's care take more of their time. Emphasize to the family the importance of maintaining their own social contacts and leisure activities. Many family members experience caregiver stress, which affects their physical, mental, and emotional health. Chart 42-16 lists strategies for reducing caregiver stress. Chapter 2 discusses caregiver role strain and interventions in more detail.

Chart 42-16 Best Practice for Patient Safety & Quality Care QSEN

Reducing Caregiver Stress

- Maintain realistic expectations for the person with Alzheimer's disease (AD).
- Take each day one at a time.
- Try to find the positive aspects of each incident or situation.
- Use humor with the person who has AD.
- Use the resources of the Alzheimer's Association, including attending local support group meetings.
- Explore alternative care settings early in the disease process for possible use later.
- Establish advance directives with the AD patient early in the disease process.
- Set aside time each day for rest or recreation away from the patient, if possible.
- Seek respite care periodically for longer periods of time.
- Take care of yourself by watching your diet, exercising, and getting plenty of rest.
- Be realistic about what you or they can do, and accept help from family, friends, and community resources.
- Use relaxation techniques.

It is now possible in most areas of the United States and Canada for families to arrange respite care. The patient may be placed in a respite facility or nursing home for the weekend or for several weeks to give the family a rest from the constant care demands. The family may also be able to obtain respite care in the home through a home care agency or assisted-living facility. Remind the family that respite care is for a short period—it is not permanent placement. Some health care agencies have opened adult day-care centers or specialty units for patients with AD. In the day-care center, patients spend all or part of the day at the facility and participate in activities as their condition permits. Although these centers are usually open only on weekdays, this arrangement allows the caregiver to work or participate in other activities. If patients require 24-hour care, they may be placed in a specialty unit of a long-term care or assisted-living facility.

Teach the family how to be prepared in case the patient becomes restless, agitated, abusive, or combative. In addition, the family can learn how to use reality orientation or validation therapy, depending on the stage of the disease.

Self-Management Education.

Usually patients with AD and dementia are cared for in the home until

late in the disease process unless they can afford private-pay care. Because health insurance coverage in the United States and family finances may not be sufficient to cover the services of a private duty nurse or home care aide, family members typically provide the care. The patient plan of care developed by the nurse or case manager, in conjunction with the family, must be reasonable and realistic for the family to implement.

Review how to assist with bathing, dressing, toileting, and other self-management activities. The occupational therapist teaches the family and the patient how to use adaptive equipment, such as a brace, a sling, a cane, or modified eating utensils. The patient may have difficulty chewing, swallowing, or tasting foods and may not be able to eat without assistance.

The family and the dietitian should develop a diet plan to increase the patient's nutritional intake. In the late stage of AD, the patient's intake often decreases and he or she loses weight.

Provide information to the family on what to do in the event of a seizure and how to protect the patient from injury. Instruct them to notify the health care provider if the seizure is prolonged or if the patient's seizure pattern changes.

Review with the family or other caregiver the name, time, and route of administration; the dosage; and the side effects of all drugs. Remind the family to check with the health care provider before using any over-the-counter drugs or herbs because they may interact with prescribed drug therapy.

Emphasis is placed on the need for the patient to have an established exercise program to maintain mobility for as long as possible, as well as to prevent complications of immobility. In collaboration with the family, the physical therapist (PT) develops an individualized exercise program. The PT may continue to work with the patient at home until goals are achieved, depending on the payer source.

Remind the family or other caregiver to take special precautions to maintain the patient safely at home. The environment must be uncluttered, consistent, and structured. All hazardous items (e.g., cooking range and oven, power tools) are removed, secured, or “locked out.” All electrical sockets not in use should be covered with safety plugs. Teach families to install handrails and grab bars in the bathroom. Handrails should be along all stairways, and a guardrail should be placed around porches or open stairwells. Because the patient may have a tendency to wander, especially at night, the family may want to install alarms to all outside doors, the basement, and the patient's bedroom. All

outside and basement doors should have deadbolt locks to prevent the patient from going outside unsupervised. Remind the family to adjust the temperature of the water to prevent accidental burns. Nightlights should be used in the patient's bedroom, hallway, and bathroom to prevent fear and to help with orientation.

Health Care Resources.

When the patient can no longer be cared for at home, referral to an assisted-living or long-term care facility may be needed. Early in the course of the disease, advise the family that placement might be needed in the late stages of the disease or sooner. This allows the family to begin to search for an appropriate facility before a crisis develops and immediate placement is needed. A number of facilities specialize in the care of patients with AD and other dementias. These units generally have a high staff-to-patient ratio and are architecturally designed to meet the special needs of this type of patient. The national office of the Alzheimer's Association publishes an outline of criteria for a dementia unit. In the advanced stage of the disease, the patient may need referral to hospice services for total care. (See the discussion of end-of-life and hospice care in Chapter 7.)

Evaluation: Outcomes

Evaluate the care of the patient with dementia based on the identified priority patient problems. The expected outcomes include that the patient and/or family will:

- Remain free from injury and have a safe home environment
- Sleep through the night and be awake at appropriate times
- Meet basic human needs (e.g., nutrition, mobility)
- Have a positive perception of his or her health status and life circumstances

Specific indicators for these outcomes are listed in the Planning and Implementation section (see earlier).

Clinical Judgment Challenge

Patient-Centered Care QSEN

A middle-aged man brings his 90-year old mother to the neurologist for re-evaluation of her Alzheimer's disease (AD). The patient was diagnosed with AD 2 years ago and continues to live alone most of the time in her home. One of her sons stays with her at night, but she cannot

bathe herself or prepare meals. She forgets to eat and take her medications for hypertension. Her weight is 98 pounds and she is 5′4″ tall.

1. As the nurse in the neurologist office, what questions might you ask the son about his mother's health?
2. What health assessment will you perform?
3. To promote the patient's safety, what options might you recommend for her caregiving?
4. What interventions are needed to improve the patient's nutritional status?
5. What health teaching is needed for the son at this time?

Huntington Disease

Pathophysiology

Huntington disease (HD) is a hereditary disorder transmitted as an autosomal dominant trait at the time of conception. HD is called an *autosomal dominant disorder* because only one copy of the defective gene, inherited from one parent, is necessary to produce the disease. This movement disorder causes both neurologic and behavioral symptoms that usually begin between the ages of 30 and 50 years and worsen during the next one to two decades. Patients typically die from pneumonia, heart failure, or other complication of immobility (Huntington's Disease Society of America [HDSA], 2014).

Genetic/Genomic Considerations

Patient-Centered Care QSEN

Huntington disease is a single gene disorder caused by a mutation in the HD gene *(IT15)* located on chromosome 4. The mutation is a multiple repeat of the specific base triplet *cytosine, adenine, guanine (CAG),* increasing the length of the gene. An autosomal dominant trait with high penetrance means that a person who inherits just one mutated allele has nearly a 100% chance of developing the disease (McCance et al., 2014). This gene mutation has different expressions, depending on whether it is inherited from the mother or the father. People who inherit the mutation from their father have an earlier onset and a shorter life expectancy than do those who inherit from their mother. In addition, there is some variation in the disease, depending on the size (length) of the mutation. The longer the mutation, the more severe the disease is at an earlier age.

It is estimated that 30,000 people in the United States have HD, and another 20,000 to 50,000 are thought to carry the gene (HDSA, 2014). Men and women are equally affected at a highly productive time in life. The clinical onset of HD is gradual. The two main symptoms of the disease are progressive mental status changes, leading to dementia, and **choreiform movements** (rapid, jerky movements) in the limbs, trunk, and facial muscles. Dementia is related to the destruction of neurons within the cerebral cortex. It may also be associated with excessive amounts of dopamine found within the cerebral cortex and limbic systems of those affected. Two structures within the basal ganglia are

involved in the development of HD: the caudate nucleus and the putamen. Both structures have close connections to the cerebral cortex and are closely associated with neurotransmitters. Neurotransmitters are secreted at the synapse, or junction, of one neuron with another, and it is through their specific excitation or inhibition of neurons that fine, controlled, integrated motor activity occurs.

In HD, there is a decrease in the amount of *gamma-aminobutyric acid (GABA),* an inhibitory neurotransmitter in the basal ganglia. GABA depletion causes increased activity of the thalamus and other parts of the brain. There may also be an increase in *glutamate,* a major excitatory neurotransmitter. The result of these chemical changes in the brain is brisk, jerky, purposeless movements, particularly of the hands, face, tongue, and legs, which the patient cannot stop (McCance et al., 2014).

There are three stages of HD, each lasting roughly 5 years, corresponding to the average 15-year course of the disease. Stage 1 is the onset of neurologic or psychological symptoms. Stage 2 is characterized by an increasing dependence on others for care. Stage 3 results in loss of independent function.

The diagnosis of HD is made on the basis of a family history of the disease and clinical assessment. The triad of dominant inheritance, choreoathetosis (neuromuscular symptoms), and dementia is the hallmark of the disease. The symptoms exhibited by the patient vary in range and severity, age of onset, and rate of progression. Observe for clinical manifestations, which include chorea (jerky movements), poor balance, hesitant or explosive speech, dysphagia (difficulty swallowing), impaired respiration, and bowel and bladder incontinence. Mental status changes include decreased attention span, poor judgment, memory loss, personality changes, and dementia (later in the disease process). Perform a complete neurologic assessment.

Patient-Centered Collaborative Care

There is no known cure or treatment for HD. The only way to prevent transmission of the gene is for those affected to avoid having biologic children. Genetic counseling is important for children of patients with the disease. People at risk for the disease can be tested to determine whether the gene mutation is present. Before the testing procedure is undertaken, counseling is necessary to ensure that the patient has voluntarily decided in favor of testing and is not being pressured by family or friends. In addition, counseling helps determine whether the benefits of knowing the results outweigh the risks of a positive result

(e.g., depression or suicide).

The first drug to be approved to decrease chorea associated with HD is tetrabenazine (Xenazine). It is given orally and is thought to work by depleting the monoamines (e.g., dopamine, serotonin) from nerve terminals. In some patients, it may increase the risk for suicide ideations and depression. Be sure to teach them and their families to report early signs of depression, including sleeplessness, decreasing appetite, and mood changes.

In other patients, psychotropic agents may be used to manage movement abnormalities that interfere with ADLs or are functionally disabling. They are also used to help control agitation, hallucinations, or psychotic delusions. Drug therapy may be used to treat other symptoms such as depression, anxiety, or obsessive-compulsive behaviors. Many of the drugs used to treat HD may cause side effects that may be difficult to differentiate from signs of HD.

A number of clinical trials are being conducted to find other drugs or supplements that may decrease HD symptoms. Examples include the CoQ10 enzyme, growth factors, glutamate blockers, and antidepressants, such as sertraline (Zoloft).

The care of the patient with HD is managed by the collaborative efforts of the family and health care team and includes:

- Speech-language pathologist (SLP) who helps with communication, swallowing, and drooling
- Dietitian who plans meals based on the SLP's recommendations and the patient's likes and dislikes
- Physical and occupational therapists who determine exercise conditioning and assistive devices
- Nurses or home health care aides who provide supportive care
- Case manager and social worker who coordinate care and help with referrals to community resources (e.g., Huntington's Disease Society of America [www.hdsa.org]) and health care agencies for placement as needed

Nursing Concepts and Clinical Judgment Review

What might you NOTICE if the patient is experiencing pain, impaired mobility, *or* altered cognition as a result of an acute or chronic brain disorder?

- Headache
- Acute or chronic confusion
- Sleepiness or lethargy

- Inability to perform ADLs
- Inability to ambulate or alteration in gait
- Reduced nutritional intake resulting in weight loss
- Inability to communicate effectively
- Report of photophobia or phonophobia
- One or more seizures
- Extremity tremors, rigidity, or jerky movements

What should you INTERPRET and how should you RESPOND to a patient experiencing pain, impaired mobility, and altered cognition as a result of an acute CNS infection or chronic brain disorder?

Perform and interpret physical assessment, including:

- Assessing neurologic status, especially level of consciousness (LOC)
- Taking vital signs (high fever may indicate infection)
- Performing a comprehensive pain assessment
- Assessing ability to communicate
- Assessing nutritional status

Respond by:

- Notifying health care provider or Rapid Response Team if seizure or sudden change in LOC or onset of an acute confusional state
- Ensuring an adequate airway
- Protecting patient from injury
- Managing pain
- Giving oxygen (during a seizure and for status epilepticus)
- Reorienting patient
- Assisting with ADLs if needed
- Collaborating with health care team members (e.g., PT, OT, SLP, dietitian)

On what should you REFLECT?

- Think about how you responded.
- Continue to monitor for improving mental status and changes in LOC.
- Assess triggers or other causes for acute event.
- Develop teaching plan for patient and family for self-management.
- Think about what resources the patient and family may need.

Get Ready for the NCLEX® Examination!

Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Provide a written summary of events during hospitalization and an oral report to the receiving caregiver during all transitions in care (e.g., from hospital to rehabilitation or home).
- Implement best practices for fall prevention and prevent injury from impaired cognition and immobility with frequent observation and interventions described in Table 42-6 and Charts 42-9, -12, -14, and -15. **Safety** QSEN
- Ensure that drugs have been reviewed with the patient and caregivers with each administration and that discharge drugs have been reconciled with a list of problems or indications. Provide written information about all home-going drugs. **Informatics** QSEN
- Collaborate with the health care team in discharge planning and health teaching for patients who have chronic seizures or neurodegenerative diseases such as PD, dementia, and HD. **Teamwork and Collaboration** QSEN
- Ensure a safe environment for a patient with seizure precautions by ensuring that suction and oxygen are available and that frequent observation occurs to detect seizure activity early. **Safety** QSEN
- Implement interventions for seizures as listed in Chart 42-6. Patients with status epilepticus have a life-threatening complication. Lorazepam and diazepam are the major drugs used for this emergency. **Evidence-Based Practice** QSEN
- For the patient with a chronic brain disorder, provide an environment that maximizes their mobility, including consultation with physical and occupational therapy. **Teamwork and Collaboration** QSEN

Health Promotion and Maintenance

- Teach patients with migraine headaches about triggers that could cause an attack, such as tyramine in wine, pickled products, and aged cheeses; nitrates and nitrites in processed and grilled meats; and other dietary or environmental triggers. **Patient-Centered Care** QSEN
- Teach patients with cluster headaches about precipitating factors, such as anger episodes, excitement, and excessive physical activity.
- In addition to prescribed drug therapy, encourage patients with

headaches to use complementary and alternative therapies to help relieve pain, such as ice, darkened room, and relaxation techniques. **Patient-Centered Care** QSEN

- Teach the patient with epilepsy to maintain seizure-free health or reduced seizure activity through using prescribed antiepileptic drugs (AEDs) and follow-up medical care. Additional instructions for the patient and family are listed in Chart 42-5.
- Document vaccination status and provide vaccination to prevent some types of infectious meningitis, particularly meningococcal vaccination to people who are in areas of high population density, such as university residences, military barracks, and crowded living areas. Vaccination is a core measure of health care effectiveness. **Evidence-Based Practice** QSEN

Psychosocial Integrity

- Remind caregivers of patients with chronic neurologic diseases, such as dementia, to find ways to cope with their own stress to remain physically and psychologically healthy, as suggested in Chart 42-16. **Patient-Centered Care** QSEN
- Teach caregivers of patients with dementia to use validation therapy rather than reality orientation. Acknowledge the patient's feelings and concerns.
- Involve families who care for patients with neurodegenerative diseases like Parkinson disease, dementia, or Huntington disease to develop a culturally appropriate continuing plan of care that reflects patient values and preferences.
- Adapt communication techniques for the patient with dementia as outlined in Chart 42-14. **Patient-Centered Care** QSEN
- Assist patients and family members to identify community resources that can assist with education and caregiver support, including consultation with social services or a case manager.

Physiological Integrity

- Assess patients with classic migraine headaches as listed in Chart 42-2.
- Compare migraine to cluster headache, recalling that the pain of cluster headaches is usually accompanied by ipsilateral (same side) eye tearing, rhinorrhea, congestion, ptosis, facial sweating, eyelid edema, and/or miosis. Migraine pain is characterized by throbbing pain that is unilateral and can be accompanied by nausea, light sensitivity, and

worsening symptoms with movement.

- Recognize that generalized seizures, such as the tonic-clonic seizure, involve both cerebral hemispheres. Partial seizures, also called *focal* or *local seizures,* usually involve only one hemisphere.
- During a seizure, document the patient's body movements and other assessments as described in Chart 42-7. **Informatics** QSEN
- Monitor for side and adverse effects of antiepileptic drugs (AEDs) as listed in Chart 42-4. **Safety** QSEN
- For patients who have had one or more seizures, place on "seizure precautions," which includes having oxygen delivery and suctioning equipment available and starting or maintaining IV access. **Safety** QSEN
- Assess for clinical manifestations of meningitis as listed in Chart 42-8. For patients with meningitis and encephalitis, carefully monitor neurologic status, including vital signs and neurologic and vascular checks. Observe for signs and symptoms of increased intracranial pressure (ICP), and communicate changes in level of consciousness immediately to the health care provider. **Safety** QSEN
- Assess for key features of Parkinson disease as described in Chart 42-11. Monitor for drug toxicity when patients are taking medications for Parkinson disease, especially levodopa combinations such as Sinemet. Delirium and decreased drug effectiveness are the most common indicators of toxicity. **Safety** QSEN
- Communicate worsening neurologic assessment findings immediately following electrode placement for deep brain stimulation and injection of stem cells when used to control symptoms of Parkinson disease.
- Document cognitive and functional abilities of the patient with dementia, recognizing that it is a progressive condition (e.g., Alzheimer stages are listed in Chart 42-13).
- For patients with dementia, recall that a few drugs improve function and cognition (cholinesterase inhibitors, such as donepezil [Aricept]) or slow the disease process (Memantine) but they do not cure the disease.
- Remember that Huntington disease is a chronic, hereditary illness that is transmitted as an autosomal dominant trait at the time of conception. Refer patients with the disease for genetic counseling. **Patient-Centered Care** QSEN
- Foster a collaborative communication, establish outcomes for care with health care team members, and review them regularly. Document communication to reduce complications and promote quality of life in patients. **Informatics** QSEN

CHAPTER 43

Care of Patients with Problems of the Central Nervous System

The Spinal Cord

Rachel L. Gallagher

PRIORITY CONCEPTS

- Mobility
- Sensory Perception
- Pain
- Inflammation
- Tissue Integrity
- Palliation
- Sexuality

Learning Outcomes

Safe and Effective Care Environment

1. Use best practices to teach strategies that reduce back and neck injury and pain.
2. Prioritize the nursing care of the patient with an acute spinal cord injury (SCI).
3. Collaborate with other health care team members to manage care for patients with spinal cord problems.
4. Establish patient values and preferences, including integration of advance directives, palliation, and managing distressing symptoms for patients with progressively debilitating spinal cord conditions.

Health Promotion and Maintenance

5. Identify with the patient behaviors that promote optimal weight.
6. Communicate with health care team members to establish outcomes for care and strategies to promote independence in ADLs.
7. Identify community resources for patients with spinal cord health problems and their families.

Psychosocial Integrity

8. Describe the impact of spinal cord conditions on the patient's sexuality.
9. Use therapeutic communication to assess the need for emotional, mental, and social support of patients with spinal cord health problems and their families.

Physiological Integrity

10. Perform a comprehensive assessment of the patient with a spinal cord injury.
11. Establish priorities in care for the patient with spinal cord–related problems of mobility, sensory perception, elimination, and skin tissue integrity.
12. Apply knowledge of pathophysiology when caring for a patient having autonomic dysreflexia.
13. Explain the pathophysiology of multiple sclerosis (MS) and amyotrophic lateral sclerosis (ALS).
14. Explain the role of drug therapy in managing patients with spinal cord problems.
15. Develop an evidence-based postoperative plan of care for patients having spinal cord surgery, including monitoring for complications.

 http://evolve.elsevier.com/Iggy/

The spinal cord relays messages to and from the brain. Besides injuries, the spinal cord can develop tumors, infections such as meningitis and poliomyelitis, inflammatory and autoimmune diseases, and degenerative diseases such as amyotrophic lateral sclerosis (ALS) and spinal muscular atrophy. The spinal cord itself may be damaged, or the spinal nerves leading from the cord to the extremities may be affected, often by chronic inflammation. In some cases, both the spinal cord and the nerves are involved. Symptoms vary but often include problems with mobility, sensory perception, and pain. As a result, the patients' ability to

perform ADLs, their skin tissue integrity, elimination patterns, and sexuality are often affected. Health care team members with expertise in symptom management can provide significant contributions to this population's quality of life by providing palliation of symptoms that are chronic and often progressive. Health care team members also can promote a safe environment, preventing complications from impaired mobility and sensory perception (Forrest et al., 2012). (See the Quality Improvement box.)

Quality Improvement QSEN

Reducing Falls and Harm from Falls

Forrest, G., Huss, S., Patel, V., Jeffries, J., Myers, D., Barber, C., et al. (2012). Falls on an inpatient rehabilitation unit: Risk assessment and prevention. *Rehabilitation Nursing, 37*(2), 56-61.

This quality improvement project had a twofold purpose. The first was to determine if a common measure of function used in a rehabilitation setting identified patients at increased risk for a fall. The second purpose was to determine if a comprehensive plan for fall reduction that used the functional assessment results to guide interventions was effective at reducing falls.

The strength of this project is the interdisciplinary team that designed the process of both assessment and care. This report also details the application of a quality improvement process to refine interventions as data became available about the usefulness of a functional assessment in identifying high-risk patients. Functional impairment was found to be associated with more falls. It is important to note that functional impairment was most often associated with Guillain-Barré, spinal cord injury, myopathy, and peripheral neuropathy. Neurologic diagnoses were then used to revise the screening tool that identified patients at increased risk for falls and develop novel interventions. Over time, falls were reduced by 50%—a significant improvement in patient safety.

Commentary: Implications for Practice and Research

This report illustrates several steps of a Plan-Do-Study-Act cycle in developing and sustaining a quality improvement project. First, the authors used information in the literature about fall reduction and then adapted that information to develop a protocol that met their patient population needs and hospital resources. Adding functional assessment provided essential information about high-risk patients in this setting. The report also illustrates the need for ongoing feedback to sustain

adherence to quality improvement (protocol) interventions that were successful in reducing falls.

Back Pain

Back pain affects as many of 80% of adults at some time in their life. It can be recurrent, and subsequent episodes tend to increase in severity. The prevalence of both acute and chronic back pain varies with age, lifestyle factors including obesity and osteoporosis, and certain types of physical activity such as heavy physical work and lifting. Low back pain is the leading cause of work disability (Costa-Black et al., 2010).

The lumbosacral (lower back) and cervical (neck) vertebrae are most commonly affected because these are the areas where the vertebral column is the most flexible. *Acute* back pain is usually self-limiting. If the pain continues for 3 months or if repeated episodes of pain occur, the patient has *chronic* back pain.

Low Back Pain (Lumbosacral Back Pain)

Pathophysiology

Low back pain (LBP) occurs along the lumbosacral area of the vertebral column. Acute pain is caused by muscle strain or spasm, ligament sprain, disk (also spelled "disc") degeneration (osteoarthritis), or herniation of the center of the disk, the nucleus pulposus, past the lateral vertebral border. A **herniated nucleus pulposus (HNP)** in the lumbosacral area can press on the adjacent spinal nerve (usually the sciatic nerve), causing severe burning or stabbing pain down into the leg or foot (Fig. 43-1). Herniated disks occur most often between the fourth and fifth lumbar vertebrae (L4-5) but may occur at other levels. The specific area of symptoms depends on the level of herniation.

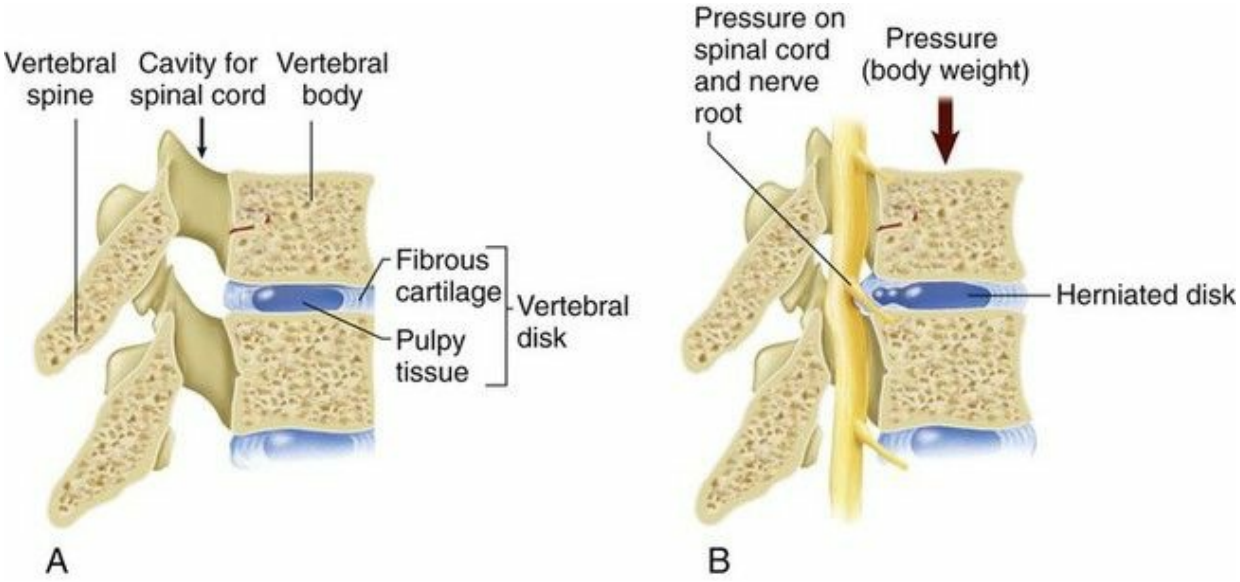


FIG. 43-1 Sagittal section of vertebrae showing (**A**) a normal disk and (**B**) a herniated disk.

In addition to pain, there may be both muscle spasm and numbness and tingling (paresthesia) in the affected leg because spinal nerves have both motor and sensory fibers. The HNP may press on the spinal cord itself, causing leg weakness. Bowel and bladder incontinence or retention may occur with motor nerve involvement and because sacral spinal nerves have parasympathetic nerve fibers that help control bowel and bladder function.

Back pain may also be caused by **spondylolysis,** a defect in one of the vertebrae usually in the lumbar spine. **Spondylolisthesis** occurs when one vertebra slips forward on the one below it, often as a result of spondylolysis. This problem causes pressure on the nerve roots, leading to pain in the lower back and into the buttocks. Pain or numbness may also occur in the leg and foot. **Spinal stenosis,** a narrowing of the spinal canal, nerve root canals, or intervertebral foramina is typically seen in people older than 50 years. This narrowing may be caused by infection, trauma, herniated disk, arthritis, and disk degeneration. Most adults older than 50 years have some degree of degenerative disk disease, although they may not be symptomatic.

Low back pain is most prevalent during the third to sixth decades of life but can occur at any time. Acute back pain usually results from injury or trauma such as during a fall, vehicular crash, or lifting a heavy object. The mechanisms of injury include repetitive flexion and/or extension and hyperflexion or hyperextension with or without rotation. Obesity places increased stress on the vertebral column and back muscles, contributing to risk for injury. Smoking has been linked to disk degeneration, possibly caused by constriction of blood vessels that supply the spine. Congenital

spinal conditions like scoliosis can also lead to LBP. Older adults are at high risk for both acute and chronic LBP. Vertebral fracture from osteoporosis contributes to LBP. Petite, Euro-American women are at high risk for both bone loss and subsequent vertebral fractures. Chart 43-1 provides a list of specific factors that can cause low back pain in the older adult. Vertebral compression fractures are discussed in detail in Chapter 51.

Chart 43-1 Nursing Focus on the Older Adult

Factors Contributing to Low Back Pain

- Changes in support structures
  - Spinal stenosis
  - Hypertrophy of the intraspinal ligaments
  - Osteoarthritis
  - Osteoporosis
- Changes in vertebral support and malalignment
  - Scoliosis
  - Lordosis
- Vascular changes
  - Diminished blood supply to the spinal cord or cauda equina caused by arteriosclerosis
  - Blood dyscrasias
- Intervertebral disk degeneration

Health Promotion and Maintenance

Many of the problems related to acute back pain can be prevented by recognizing the factors that contribute to tissue injury and taking appropriate preventive measures. For example, good posture and exercise can significantly decrease the incidence of low back pain. The U.S. Occupational Safety and Health Administration (OSHA) mandated that all industries develop and implement a plan to decrease musculoskeletal injuries among their workers. One way to meet this requirement is to develop an ergonomic plan for the workplace. **Ergonomics** is an applied science in which the workplace is designed to increase worker comfort (thus reducing injury) while increasing efficiency and productivity. An example is a celling lift designed to help nurses assist patients to get out of bed. A variety of equipment can be used to decrease injury related to moving patients. Professional guidelines and legislative rules promote safe patient handling for health care workers (www.nursingworld.org/rnnoharm). Chart 43-2 summarizes various ways to help prevent LBP related to lifting objects and handling

patients (ANA, 2013; Nelson et al., 2008).

Chart 43-2 Patient and Family Education: Preparing for Self-Management

Prevention of Low Back Pain and Injury

- Use safe manual handling practices, with specific attention to bending, lifting, and sitting.
- Assess the need for assistance with your household chores or other activities.
- Participate in a regular exercise program, especially one that promotes back strengthening, such as swimming and walking.
- Do not wear high-heeled shoes.
- Use good posture when sitting, standing, and walking.
- Avoid prolonged sitting or standing. Use a footstool and ergonomic chairs and tables to lessen back strain. Be sure that equipment in the workplace is ergonomically designed to prevent injury.
- Keep weight within 10% of ideal body weight.
- Ensure adequate calcium intake. Consider vitamin D supplementation if serum levels are low.
- Stop smoking. If you are not able to stop, cut down on the number of cigarettes or decrease the use of other forms of tobacco.

Patient-Centered Collaborative Care

Assessment

Physical Assessment/Clinical Manifestations.

The patient's primary concern is continuous pain. Some patients have so much pain that they walk in a stiff, flexed posture or they may be unable to bend at all. They may walk with a limp, indicating possible sciatic nerve impairment. Walking on the heels or toes often causes severe pain in the affected leg, the back, or both.

Conduct a complete pain assessment as discussed in Chapter 3. Record the patient's current pain score, as well as the worst and best score since the pain began. Ask about precipitating or relieving factors such as symptoms at night or during rest. Determine if a recent injury to the back has occurred. It is not unusual for the patient to say "I just turned around and felt my back go out."

Inspect the patient's back for vertebral alignment and tenderness.

Examine the surrounding anatomy and lower extremities for secondary injury (Patton & Thibodeau, 2014). Patients report stabbing, continuous pain in the muscle closest to the affected disk. They often describe a sharp, burning posterior thigh or calf pain that may radiate to the ankle or toes along the path of one or more spinal nerves. Pain usually does not extend the entire length of the limb. Patients may also report the same type of pain in the middle of one buttock. The pain is often aggravated by sneezing, coughing, or straining. Driving a vehicle is particularly painful.

Ask whether **paresthesia** (tingling sensation) or numbness is present in the involved leg. Both extremities may be checked for sensory perception by using a cotton ball and a paper clip for comparison of light and deep touch. The patient may feel sensory perception in both legs but may experience a stronger sensation on the unaffected side. Ask about urinary and fecal continence and difficulty in urination or constipation.

If the sciatic nerve is compressed, severe pain occurs when the patient's leg is held straight and lifted upward. Foot, ankle, and leg weakness may accompany lower back pain. To complete the neurologic assessment, evaluate the patient's muscle tone and strength. Muscles in the extremity or lower back can atrophy as a result of severe chronic back pain. The patient has difficulty with movement, and certain movements create more pain than others.

Other information that may indicate more serious neurologic problems includes a history of fever and chills, recurrent skin or urinary tract infections, progressive motor and sensory loss, and difficulty with urination or having a bowel movement (due to involvement of sacral nerves).

Imaging Assessment.

Imaging studies for patients who report mild nonspecific back pain may not be done depending on the nature of the pain. Patients with severe or progressive motor or sensory perception deficits or who are thought to have other underlying conditions (e.g., cancer, infection) require complete diagnostic assessment. X-rays of the spine can exclude fracture, spondylosis, or neoplasm as the causative agent. Flexion-extension views can be very useful to show instability of the spine. The imaging studies of choice are magnetic resonance imaging (MRI) or computerized tomography (CT) scanning. The MRI is usually the first test of choice because it is noninvasive. A CT myelogram is done when a better delineation of the bony anatomy and the specific nerve root involvement is needed.

Electro-diagnostic testing, such as electromyography (EMG) and nerve-

conduction studies, may help distinguish motor neuron diseases from peripheral neuropathies and **radiculopathies** (spinal nerve root involvement). These tests are especially useful in chronic diseases of the spinal cord or associated nerves. Chapter 41 describes these tests in more detail.

Interventions

Management of patients with back pain varies with the severity and chronicity of the problem. Most patients with acute LBP experience a spontaneous resolution of pain and other symptoms over the short term (i.e., less than 3-6 months). Other patients need a brief treatment regimen of at-home exercise or physical therapy and drugs to manage pain. In general, return to work, if safe, is beneficial for recovery and well-being. When motor function is abruptly lost, surgery may be needed. Some patients have continuous or intermittent chronic pain that must be managed for an extended period. Referral to an interdisciplinary team that specializes in pain or back pain can provide expert long-term management.

Nonsurgical Management.

Nonsurgical conservative management of LBP includes positioning, drug therapy, physical therapy, weight control, and smoking cessation.

Acute Low Back Pain.

The **Williams position** is typically more comfortable and therapeutic for the patient with LBP from a bulging or herniated disk. In this *position,* the patient lies in the semi-Fowler's position with a pillow under the knees to keep them flexed or sits in a recliner chair. This position relaxes the muscles of the lower back and relieves pressure on the spinal nerve root. Most patients also find that they need to change position frequently. Prolonged standing, sitting, or lying down increases back pain. If the patient must stand for a long time for work or other reason, shoe insoles or special floor pads may help decrease pain.

The health care provider prescribes acetaminophen or NSAIDs; muscle relaxants may also be used for acute LBP. Opioid analgesics are no more effective than non-opioid analgesics and should be avoided if at all possible. If they must be used, the course of therapy should be short to prevent adverse drug events. Short-term oral steroids in tapering doses may be prescribed for some patients to rapidly reduce inflammation.

Some patients may need an epidural injection for pain relief. A corticosteroid and an anesthetic are injected to reduce inflammation in the

affected area. During a facet joint injection, fluoroscopy is used to insert a needle into the epidural space surrounding the facet and a corticosteroid is injected to coat the nerve roots and outside lining of the joints.

Chronic Low Back Pain.

Patients having chronic low back pain (LBP) are treated with NSAIDs, opioids, and/or antidepressants (as adjunctive therapy). In a recent systematic review of drug treatment, the authors reported NSAIDs and opioids provided somewhat higher relief in pain in the short term as compared with placebo. However, these drugs are associated with significant adverse drug effects. Further, there were no differences in outcomes between antidepressants and placebo in patients with nonspecific chronic LBP (Kuijpers et al., 2011).

Nursing Safety Priority QSEN

Drug Alert

Teach older adults and their families to monitor for the adverse drug effects of opioids, including constipation, drowsiness, and acute confusion. Opioids can put older adults at increased risk for falls and injury. Instruct them to notify their health care provider to report these changes, and suggest a lower dose or change to a non-opioid pain drug.

Some patients with back pain may have temporary relief from *heat or cold* application. Heat increases blood flow to the affected area and promotes the healing of injured nerves. Moist heat from heat packs or hot towels applied for 20 to 30 minutes at least 4 times per day is often recommended. Hot showers or baths may also be beneficial, although data are insufficient to support the use of *superficial* heat/cold applications for low back pain (van Middelkoop et al., 2011).

The physical therapist (PT) may provide *deep* heat therapy, such as ultrasound treatments and diathermy. Some patients may receive **phonophoresis,** which is the application of a topical drug (e.g., Xylocaine, hydrocortisone) followed by continuous ultrasound for 10 minutes. **Iontophoresis** is a similar procedure in which a small electrical current and dexamethasone are typically used. Both procedures push the medication into the subcutaneous tissue and provide longer-lasting pain relief.

The PT also works with the patient to develop an individualized

exercise program. The type of exercises prescribed depends on the location and nature of the injury and the type of pain. The patient does not begin exercises until acute pain is reduced by other means. Several specific exercises for strengthening muscles to manage LBP are listed in Chart 43-3. A systematic review of 37 studies showed that there is low-quality evidence for the effectiveness of exercise for low back pain (van Middelkoop et al., 2010). Water therapy combined with exercise is helpful for some patients with chronic pain. The water also provides muscle resistance during exercise to prevent atrophy.

Chart 43-3 Patient and Family Education: Preparing for Self-Management

Typical Exercises for Chronic or Postoperative Low Back Pain

Extension Exercises

- **Stomach lying:** Lie face down with a pillow under your chest; lift legs straight up (alternate legs) (may not be tolerated).
- **Upper trunk extension:** Lie face down with your arms at your sides, and lift your head and neck.
- **Prone push-ups:** Lie face down on a mat and, keeping your body stiff, push up to extend your arms.

Flexion Exercises

- **Pelvic tilt:** Lying on your back with your knees bent, tighten your abdominal muscles to push your lower back against the mat.
- **Semi–sit-ups:** Lying on your back with your knees bent, raise your upper body at a 45-degree angle and hold this position for 5 to 10 seconds.
- **Knee to chest:** Lying on your back with your knees bent, tighten your abdominal muscles to push your lower back against the mat. Now bring one or both knees to your chest and hold this position for 5 to 10 seconds.

Weight reduction may help reduce chronic lower back pain by decreasing the strain on the vertebrae caused by excess weight. If the patient's weight exceeds the ideal by more than 10%, caloric restriction is recommended. Health care providers must be sensitive when reinforcing the need for patients to lose weight to prevent or to lessen chronic back pain. Behavioral approaches to weight loss and positive reinforcement are important for the nutrition plan.

Complementary and Alternative Therapies.

The patient may find that nontraditional and complementary therapies provide short-term pain relief. Patients with low back muscle injuries or mild nerve involvement may find relief of pain from chiropractic therapies, although there is insufficient evidence to support consistent use of this intervention (Parkinson et al., 2013). The purpose of chiropractic or spinal manipulative therapy (SMT) is to promote alignment and prevent or treat pressure on nerve roots (Bergman & Peterson, 2011).

Imagery, acupuncture, music therapy, massage, and herbal medicines are examples of other possible pain-relief therapies for acute and chronic back pain. A systematic review of research on the effectiveness of complementary and alternative medicine (CAM) for chronic back pain supported the use of acupressure and herbal therapies for short-term pain relief (Rubinstein et al., 2010).

As many as 20% of patients with back pain may use or be prescribed weighted traction, an intervention that applies a weighted pulley system and a girdle or other device to create a pulling force along the vertebrae. However, a recent review of the evidence for this therapy suggests that weighted traction provides little or no effect on pain intensity, function, or return to work (Wegner et al., 2013).

Surgical Management

Surgery is usually performed if conservative measures fail to relieve back pain or if neurologic deficits continue to progress. An orthopedic surgeon and/or neurosurgeon perform these surgeries. Two major types of surgery are used depending on the severity and exact location of pain: minimally invasive surgery (MIS) and conventional open surgical procedures. MIS is not done if the disk is pressing into the spinal cord (central cord involvement).

Preoperative Care.

Preoperative care for the patient preparing for lumbar surgery is similar to that for any patient undergoing surgery (see Chapter 14). Teach the patient about postoperative expectations, including:

- Techniques to get into and out of bed
- Turning and moving in bed
- Reporting immediately new sensory perception, such as numbness and tingling, or new motor impairment that may occur in the affected leg or in both legs

• Home care activities and restrictions

Many patients are discharged to home within 23 to 48 hours after surgery. Therefore, before surgery, teach family members or other caregiver how to assist the patient and what restrictions the patient must follow at home.

A bone graft is done if the patient has a *spinal fusion*. The surgeon explains from where the bone for grafting will be obtained. The patient's own bone is used whenever possible, but additional bone from a bone bank may be needed. The surgeon provides verbal and written information about the type and the source of bone for surgery. Be sure that the patient signs an informed consent form before surgery. While the bone graft heals, the patient may wear a back orthotic device for 4 to 6 weeks after surgery, but this is not common practice today. Provide information about the importance of wearing the brace as instructed during the healing process, how to take it off and put it on while maintaining spinal alignment, and how to clean it.

Operative Procedures.

Minimally invasive surgeries (MISs) have the advantage of being associated with minimal muscle injury, decreased blood loss, and decreased postoperative pain. The primary advantage of these surgical procedures is a shortened hospital stay and the possibility of an ambulatory care (same-day) procedure. Spinal cord and nerve complications are also less likely. Several specific procedures are commonly performed.

A local anesthetic is given for the *microscopic (or surgical) endoscopic diskectomy (MED)* or *percutaneous endoscopic diskectomy (PED).* The surgeon uses x-ray fluoroscopy to insert an endoscope (arthroscope) next to the affected disk. A special cutting tool or laser probe is threaded through the cannula for removal or destruction of the *disk pieces* that are compressing the nerve root. A newer procedure combines the PED with *laser thermodiskectomy* to also shrink the herniated disk before removal. Inpatient hospitalization is not necessary for this procedure.

A *microdiskectomy* involves microscopic surgery directly through a 1-inch incision. This procedure allows easier identification of anatomic structures, improved precision in removing small fragments, and decreased tissue trauma and pain.

Laser-assisted laparoscopic lumbar diskectomy combines a laser with modified standard disk instruments inserted through the laparoscope using an umbilical ("belly button") incision. The procedure may be used to treat herniated disks that are bulging but do not involve the vertebral

canal. The primary risks of this surgery are infection and nerve root injury. The patient is typically discharged in 23 hours but may go home sooner.

The most common *conventional open procedures* are diskectomy, laminectomy, and spinal fusion. These procedures involve a surgical incision to expose anatomic landmarks for extensive muscle and soft-tissue dissection. In patients with fragile vertebrae following major spine surgery, vertebroplasty (insertion of acrylic bone cement) is sometimes performed at the levels above and below surgery. This procedure strengthens adjacent vertebral bodies that will be more stressed. Major complications from spine surgery include nerve injuries, **diskitis** (disk inflammation), and dural tears (tears in the dura covering the spinal cord).

As the name implies, a *diskectomy* is removal of a herniated disk. A *laminectomy* involves removal of part of the laminae and facet joints to obtain access to the disk space. When repeated laminectomies are performed or the spine is unstable, the surgeon may perform a **spinal fusion (arthrodesis)** to stabilize the affected area. Chips of bone are removed, typically from the iliac crest, or obtained from donor bone and are grafted between the vertebrae for support and to strengthen the back. Metal implants (usually titanium pins, screws, plates, or rods) may be required to ensure the fusion of the spine. Before closing, the surgeon may give an **intrathecal** (spinal) or epidural dose of long-acting morphine (Duramorph) to decrease postoperative pain.

Interbody cage fusion is a newer spinal implant. A cagelike device is implanted into the space where the disk was removed. Bone graft tissue is packed around the device. As with instrumentation and fusion, the bone graft grows into and around the cage and creates a stable spine at that level.

An adjunct for patients for whom fusion may be difficult is the placement of an implantable **direct current stimulation (DCS)** device to promote bone fusion. External bone stimulators may also be effective for healing bone fusions.

Postoperative Care.

Postoperative care depends on the type of surgery that was performed. In the postanesthesia care unit (PACU), vital signs and level of consciousness are monitored frequently, the same as for any surgery. Best practices for PACU nursing care are discussed in Chapter 16.

Minimally Invasive Surgery.

Patients go home the same day or the day after surgery with a Band-Aid

or Steri-Strips over their small incision. Those having a microdiskectomy may also have a clear or gauze dressing over the bandage. Most patients notice less pain immediately after surgery, but mild oral analgesics are needed while nerve tissue heals over the next few weeks. In collaboration with the health care provider and physical therapist, teach the patient to follow the prescribed exercise program, which begins immediately after discharge. Patients should start walking routinely every day. Complications of MIS are rare.

Conventional Open Surgery.

Early postoperative nursing care focuses on preventing and assessing complications that might occur in the first 24 to 48 hours (Chart 43-4). As for any patient undergoing surgery, take vital signs at least every 4 hours during the first 24 hours to assess for fever and for hypotension, which could indicate bleeding or severe pain. Perform a neurologic assessment every 4 hours. Of particular importance are movement, strength, and sensory perception in the lower extremities.

Chart 43-4 Best Practice for Patient Safety & Quality Care QSEN

Assessing and Managing the Patient with Major Complications of Lumbar Spinal Surgery

COMPLICATION	ASSESSMENT/INTERVENTIONS
Cerebrospinal fluid (CSF) leakage	Observe for clear fluid on or around the dressing.
	If leakage occurs, place patient flat.
	Report CSF leakage immediately to the surgeon. (The patient is usually kept on flat bedrest for several days while the dural tear heals.)
Fluid volume deficit	Monitor intake and output; monitor drain output, which should not be more than 250 mL in 8 hours during the first 24 hours.
	Monitor vital signs carefully for hypotension and tachycardia.
Acute urinary retention	Assist the patient to the bathroom or a bedside commode as soon as possible postoperatively.
	Assist male patients to stand at the bedside as soon as possible postoperatively.
Paralytic ileus	Monitor for flatus or stool.
	Assess for abdominal distention, nausea, and vomiting.
Fat embolism syndrome (FES) (more common in people with spinal fusion)	Observe for and report chest pain, dyspnea, anxiety, and mental status changes (particularly common in older adults).
	Note petechiae around the neck, upper chest, buccal membrane, and conjunctiva.
	Monitor arterial blood gas values for decreased Pa_{O_2}.
Persistent or progressive lumbar radiculopathy (nerve root pain)	Report pain not responsive to opioids.
	Document the location and nature of pain.
	Administer analgesics as prescribed.
Infection (e.g., wound, diskitis, hematoma)	Monitor the patient's temperature carefully (a slight elevation is normal). Increased temperature elevation or a spike after the second postoperative day is possibly indicative of infection.
	Report increased pain or swelling at the wound site or in the legs.
	Give antibiotics as prescribed if infection is confirmed.
	Use clean technique for dressing changes.

Carefully check the patient's ability to void. Pain and a flat position in bed make voiding difficult, especially for men. An inability to void may indicate damage to the sacral spinal nerves, which control the detrusor muscle in the bladder. Opioid analgesics have also been associated with difficulty voiding. The patient with a diskectomy or laminectomy typically gets out of bed with assistance on the evening of surgery, which may help with voiding.

Pain control may be achieved with patient-controlled analgesia (PCA) with morphine. The route is changed to oral administration after the patient is able to take fluids or the next morning.

Nursing Safety Priority QSEN

Critical Rescue

For the patient after back surgery, inspect the surgical dressing for blood or any other type of drainage. Clear drainage may mean cerebrospinal fluid (CSF) leakage. The loss of a large amount of CSF may cause the patient to report having a sudden headache. Report signs of any drainage on the dressing to the surgeon immediately. Bulging at the incision site may be due to a CSF leak or a hematoma, both of which should also be reported to the surgeon.

Empty the surgical drain, usually a Jackson-Pratt or Hemovac, and record the amount of drainage every 8 hours. The surgeon usually removes the drain in 24 to 36 hours.

Correct turning of the patient in bed is especially important. Teach the patient to log roll every 2 hours from side to back and vice versa. In **log rolling,** the patient turns as a unit while his or her back is kept as straight as possible. A turning sheet may be used for obese patients. Either turning method may require additional assistance, depending on how much the patient can assist and on his or her weight. Instruct the patient to keep his or her back straight when getting out of bed. He or she should sit in a straight-back chair with the feet resting comfortably on the floor. As with all surgical patients, prevent atelectasis and iatrogenic pneumonia with deep breathing. Follow best practices to avoid venous thromboembolism (VTE) postoperatively with early mobility and intermittent sequential compression or pneumatic devices per The Joint Commission's Core Measures.

When a spinal fusion is performed in addition to a laminectomy, more care is taken with mobility and positioning. The nurse or unlicensed

assistive personnel (UAP) assist with log rolling the patient every 2 hours. For the conventional fusion, inspect both the iliac and spinal incision dressings for drainage and make sure they are intact. Remind the patient to avoid prolonged sitting or standing.

Community-Based Care

The patient with back pain who does not undergo surgery is typically managed at home. If back surgery is performed, the patient is usually discharged to home with support from family or significant others. For older adults without a community support system, a short-term stay in a nursing home or transitional care unit may be needed. Collaborate with the case manager or discharge planner, patient, and family to determine the most appropriate placement.

Home Care Management.

After *conventional open back surgery,* the patient may have activity restrictions such as limited daily stair climbing. Driving, lifting objects heavier than 5 pounds, pushing, and pulling (e.g., dog walking) are also restricted during home recovery for many weeks. However, daily walking is encouraged. The duration of home-based recovery depends on the nature of the job and the extent and type of surgery. Most patients return to work after 6 weeks; some patients may not return for 3 to 6 months if their jobs are physically strenuous.

Patients having any of the *MIS procedures* may resume normal activities within a few days up to 3 weeks after surgery, depending on the specific procedure that was done and the condition of the patient. He or she may take a shower on the third or fourth day after surgery. Teach the patient to remove the outer clear or gauze dressing, if any is in place, but leave the Steri-Strips in place for removal by the surgeon or until they fall off. Instruct the patient to contact the surgeon immediately if clear drainage seeps from the incision. Clear drainage usually indicates a meningeal tear and cerebrospinal fluid is leaking.

Self-Management Education.

The patient with an acute episode of back pain typically returns to his or her usual activities but may fear a recurrence. Remind the patient that he or she may never have another episode if caution is used. However, continuous or repeated pain can be frustrating and tiring. Encourage the patient and family members to plan short-term goals and take steps toward recovering each day.

After surgery, in collaboration with the physical therapist, instruct the

patient to:
- Continue with a weight-reduction diet, if needed.
- Stop smoking, if applicable.
- Perform strengthening exercises as instructed.

The physical therapist reviews and demonstrates the principles of body mechanics and muscle-strengthening exercises. The patient is then asked to demonstrate these principles (Chart 43-5). Formal physical therapy usually begins about 2 weeks after surgery. Teach the patient the importance of keeping all appointments and following the prescribed exercise plan.

Chart 43-5 Best Practice for Patient Safety & Quality Care QSEN

Prevention of Musculoskeltal Injuries

Use Best Practices to Prevent Back Injury when Moving Objects

- Avoid lifting objects of more than 10 pounds without assistance or aid until the surgeon approves.
- Push objects rather than pull them.
- Do not twist your back during movement.
- Use handles or grips to prevent unintended shifting of the object during movement.
- Avoid prolonged sitting or standing. Use a footstool to lessen back strain.
- Sit in chairs with good support.
- Avoid shoulder stooping; maintain proper posture.
- Do not walk or stand in high-heeled shoes for prolonged periods (for women).

Use Best Practices to Prevent Back Injury when Moving a Person

- Establish an interdisciplinary team responsible for reviewing and implementing OSHA guidelines for the prevention of musculoskeletal disorders. Originally developed for nursing homes, these guidelines provide guidance for education and practice and programs for health care workers and other stakeholders involved in patient handling, transfers, and movement.
- Build and support a culture of safety in health care settings that

protects staff as well as patients from injury.
- Improve communication channels among nurses, physical therapists, and family caregivers to facilitate safe patient handling and movement tasks.
- Develop policies and procedures for the therapeutic use of patient handling equipment:
  - Select equipment that first provides safety of patients, staff, and family caregivers.
  - Train all staff and family caregivers in the proper and safe operation of all ergonomic-appropriate equipment.
  - Encourage patient participation in the use of assistive equipment like sit and stand lifts that are used as an ambulation aid.
- Develop competency-based assessments that demonstrate proficiency for use of all patient handling approaches and equipment.
- Encourage quality improvement projects and research that support safe and effective patient handling and movement while maximizing patient-assisted or patient-independent movement. For example, investigate the cost-effectiveness of ergonomic interventions.

The health care provider may want the patient to continue taking anti-inflammatory drugs or, if muscle spasm is present, muscle relaxants. Remind the patient and family about the possible side effects of drugs and what to do if they occur.

In a few patients, back surgery is not successful. This situation, referred to as **failed back surgery syndrome (FBSS),** is a complex combination of organic, psychological, and socioeconomic factors. Repeated surgical procedures often discourage these patients, who must continue pain management after multiple operations. Nerve blocks, implantable spinal cord stimulators (neurostimulators), and other chronic pain management modalities may be needed on a long-term basis.

Spinal cord stimulation is an *invasive* technique that provides pain control by applying an electrical field over the spinal cord. A trial with a percutaneous epidural stimulator is conducted to determine whether or not permanent placement is appropriate. If the trial is successful, electrodes are surgically placed in the epidural space and connected to an external or implanted programmable generator. The patient is taught to program and adjust the device to maximize comfort. Spinal cord stimulation can be extremely effective in select patients but is reserved for intractable neuropathic pain syndromes that have been unresponsive to other treatments.

Nursing Safety Priority QSEN

Critical Rescue

For patients who have a spinal cord stimulator implanted in the epidural space, assess neurologic status below the level of insertion frequently. Monitor for early changes in sensory perception, movement, and muscle strength. Ensure that the patient can void without difficulty. *If any changes occur, document and report them immediately to the surgeon!*

Ziconotide (Prialt) is a drug used for severe chronic back pain. It is given by intrathecal (spinal) infusion with a surgically implanted pump. It is the first available drug in a new class called *N-type calcium channel blockers (NCCBs).* NCCBs seem to selectively block calcium channels on those nerves that usually transmit pain signals to the brain. Ziconotide is also used for patients with cancer, acquired immune deficiency syndrome (AIDS), and unremitting pain from other nervous system disorders.

Nursing Safety Priority QSEN

Drug Alert

Ziconotide can be given with opioid analgesics but should *not* be given to patients with severe mental health/behavioral health problems because it can cause psychosis. *If symptoms such as hallucinations and delusions occur, teach patients to stop the drug immediately and notify their health care provider.*

NCLEX Examination Challenge

Physiological Integrity

When providing discharge teaching to a client after a lumbar laminectomy, the nurse teaches the client to engage in which activities?
A Evening showers with hot water
B Vigorous stair climbing
C Return to work within 1-2 weeks
D Daily walking

Health Care Resources.

Assist the patient in identifying support systems (e.g., family, church groups, clubs) after back surgery or FBSS. For example, a spouse may

help the patient with exercises or perform the exercises with the patient. Members of a church group may help run errands and do household chores. The patient with back pain may continue physical therapy on an ambulatory basis after discharge. For unresolved pain, the patient may be referred to pain specialists or clinics, which are usually found in large metropolitan hospitals. A case manager may be assigned to the patient to help with resource management and utilization.

Cervical Neck Pain

Pathophysiology

Cervical neck pain most often results from a bulging or herniation of the nucleus pulposus (HNP) in an intervertebral disk, illustrated in Fig. 43-1. The disk tends to herniate laterally where the annulus fibrosus is weakest and the posterior longitudinal ligament is thinned. The result is spinal nerve root compression with resulting motor and sensory manifestations, typically in the neck, upper back (over the shoulder), and down the affected arm. The disk between the fifth and sixth cervical vertebrae (C5-6) is affected most often.

If the disk does not herniate, nerve compression may be caused by osteophyte (bony spur) formation from osteoarthritis. The osteophyte presses on the intervertebral foramen, which results in a narrowing of the disk and pressure on the nerve root. As with sciatic nerve compression, the patient with cervical nerve compression may have either continuous or intermittent chronic pain. When the disk herniates centrally, pressure on the spinal cord occurs.

Cervical pain—acute or chronic—may also occur from muscle strain, ligament sprain resulting from aging, poor posture, lifting, tumor, rheumatoid arthritis, osteoarthritis, or infection. The typical history of the patient includes a report of pain when moving the neck, which radiates to the shoulder and down the arm. The pain may interrupt sleep and may be accompanied by a headache or numbness and tingling in the affected arm. To determine the exact cause of the pain, a number of diagnostic tests may be used, including:

- Plain x-rays (show general arthritis changes and bony alignment)
- Computerized tomography (CT) scan (shows spinal bones, nerves, disks, and ligaments)
- Magnetic resonance imaging (MRI) (provides images of the spinal tissue, bones, spinal cord, nerves, ligaments, musculature, and disks)
- Bone scan (shows bone changes by injecting radioactive tracers, which attach to areas of increased bone production or show increased

vascularity associated with tumor or infection)
- Myelogram/post-myelogram CT (evaluates nerve root lesions and any other mass lesion or infection of the meninges or spinal cord)
- Electromyography/nerve conduction studies (help differentiate cervical radiculopathy, ulnar or radial neuropathy, carpal tunnel syndrome, or other peripheral nerve problems)

Patient-Centered Collaborative Care

Conservative treatment for acute neck pain is the same as described for low back pain except the exercises focus on the shoulders and neck. The physical therapist teaches the patient the correct techniques for performing "shoulder shrug," "shoulder squeeze," and "seated rowing." Some health care providers prescribe a soft collar to stabilize the neck, especially at night. Using the collar longer than 10 days can lead to decreased muscle strength and range of motion. For that reason, some health care providers do not recommend collars for cervical disk problems. Therapeutic manipulation (chiropractic interventions) alone or in combination with other interventions does not appear to cause harm, does not consistently reduce pain or disability, but does benefit some patients (Mior et al., 2013).

If conservative treatment is ineffective, surgery may be required, most often using a *conventional open surgical approach*. A neurosurgeon usually performs this surgery because of the complexity of the nerves and other structures in that area of the spine. Depending on the cause and the location of the herniation, either an anterior or posterior approach is used. An anterior cervical diskectomy and fusion (ACDF) is commonly performed. The patient is fitted with a large neck brace before surgery. Routine preoperative and postoperative care is the same as described in Chapters 14 and 16.

Nursing Safety Priority QSEN

Critical Rescue

The priority for care in the immediate postoperative period after an ACDF is maintaining an airway and ensuring that the patient has no problem with breathing. Swelling from the surgery can narrow the trachea, causing a partial obstruction. Surgery can also interfere with cranial innervation for swallowing, resulting in a compromised airway or aspiration.

Chart 43-6 summarizes best practices for postoperative care and discharge planning. Complications of ACDF can occur from the brace or the surgery itself. The initial brace is worn for 4 to 6 weeks, depending on the patient. When it is removed, a soft collar is worn for several more weeks, or longer if needed. Potential complications of the anterior surgical approach can be found in Chart 43-7.

Chart 43-6 Best Practice for Patient Safety & Quality Care QSEN

Care of the Patient After an Anterior Cervical Diskectomy and Fusion

Postoperative Interventions

- Assess **a**irway, **b**reathing, and **c**irculation (first priority!).
- Check for bleeding and drainage at the incision site.
- Monitor vital signs and neurologic status frequently.
- Check for swallowing ability.
- Monitor intake and output.
- Assess the patient's ability to void (may be a problem secondary to opiates or anesthesia).
- Manage pain adequately.
- Assist the patient with ambulation within a few hours of surgery, if he or she is able.

Discharge Teaching

- Be sure that someone stays with the patient for the first few days after surgery.
- Review drug therapy.
- Teach care of the incision.
- Review activity restrictions:
  - No lifting
  - No driving until physician permission
  - No strenuous activities
- Walk every day.
- Call the surgeon if symptoms of pain, numbness, and tingling worsen or if swallowing becomes difficult.
- Wear brace or collar per surgeon's prescription

Chart 43-7 Key Features

Postoperative Complications of Anterior Cervical Diskectomy and Fusion

- Hoarseness due to laryngeal injury; may be temporary or permanent
- Temporary dysphagia; may last few days to several months; usually not severe
- Esophageal, tracheal, or vertebral artery injury
- Wound infection
- Injury to the spinal cord or nerve roots
- Dura mater tears with associated cerebrospinal fluid leaks
- Pseudoarthrosis caused by nonunion of fusion
- Graft and screw loosening if a fusion was performed

Some patients may be candidates for minimally invasive surgery (MIS), such as percutaneous cervical diskectomy through an endoscope, with or without laser thermodiskectomy to shrink the herniated portion of the disk. The care for these patients is very similar to that for the patient with low back pain who has MIS (see discussion of surgical management of patients with low back pain on pp. 888-889). Patients may also benefit from the placement of an artificial disk, a surgical option that preserves movement of the vertebrae. Artificial disks are newly approved by the U.S. Food and Drug Administration (FDA); there is evidence of their safety but the long-term effects on patient health are not yet established.

Spinal Cord Injury

Caring for a patient with an SCI requires both a patient-centered and family-centered collaborative approach and involves every health care team member to help meet the patient's expected outcomes. Optimally, patients with a new SCI are quickly transported to a model SCI System Center. Because of the complexity of a spinal cord injury, discharge planning needs to begin the day of admission. The rehabilitation team must be consulted on the day of admission.

❖ Pathophysiology

Loss of motor function (mobility), sensory perception, reflex activity, and bowel and bladder control often result from an SCI. In addition, the patient may experience significant behavior and emotional problems as a result of changes in functional ability, body image, role performance, and self-concept. Addressing family member concerns and changes in family dynamics is also important to effective care

The SCIs are classified as complete or incomplete. A **complete spinal cord injury** is one in which the spinal cord has been damaged in a way that eliminates all innervation below the level of the injury. Injuries that allow some function or movement below the level of the injury are described as an **incomplete spinal cord injury.** Incomplete injuries are more common than complete SCIs.

Mechanisms of Injury

When enough force is applied to the spinal cord, the resulting damage causes many neurologic deficits. Sources of force include direct injury to the vertebral column (fracture, dislocation, and subluxation [partial dislocation]) or penetrating injury from violence (gunshot or knife wounds). Although in some cases the cord itself may remain intact, at other times the cord undergoes a destructive process caused by a contusion (bruise), compression, laceration, or transaction (severing of the cord, either complete or incomplete) (Nayduch, 2010).

The causes of SCI can be divided into primary and secondary mechanisms of injury. Five *primary* mechanisms may result in an SCI:

- Hyperflexion
- Hyperextension
- Axial loading, or vertical compression
- Excessive rotation
- Penetrating trauma

A **hyperflexion** injury occurs when the head is suddenly and forcefully

accelerated (moved) forward, causing extreme flexion of the neck (Fig. 43-2). This type of injury often occurs in head-on vehicle collisions and diving accidents. Flexion injury to the lower thoracic and lumbar spine may occur when the trunk is suddenly flexed on itself, such as occurs in a fall on the buttocks. The posterior ligaments can be stretched or torn, or the vertebrae may fracture or dislocate. Either process may damage the spinal cord, causing hemorrhage, edema, and necrosis.

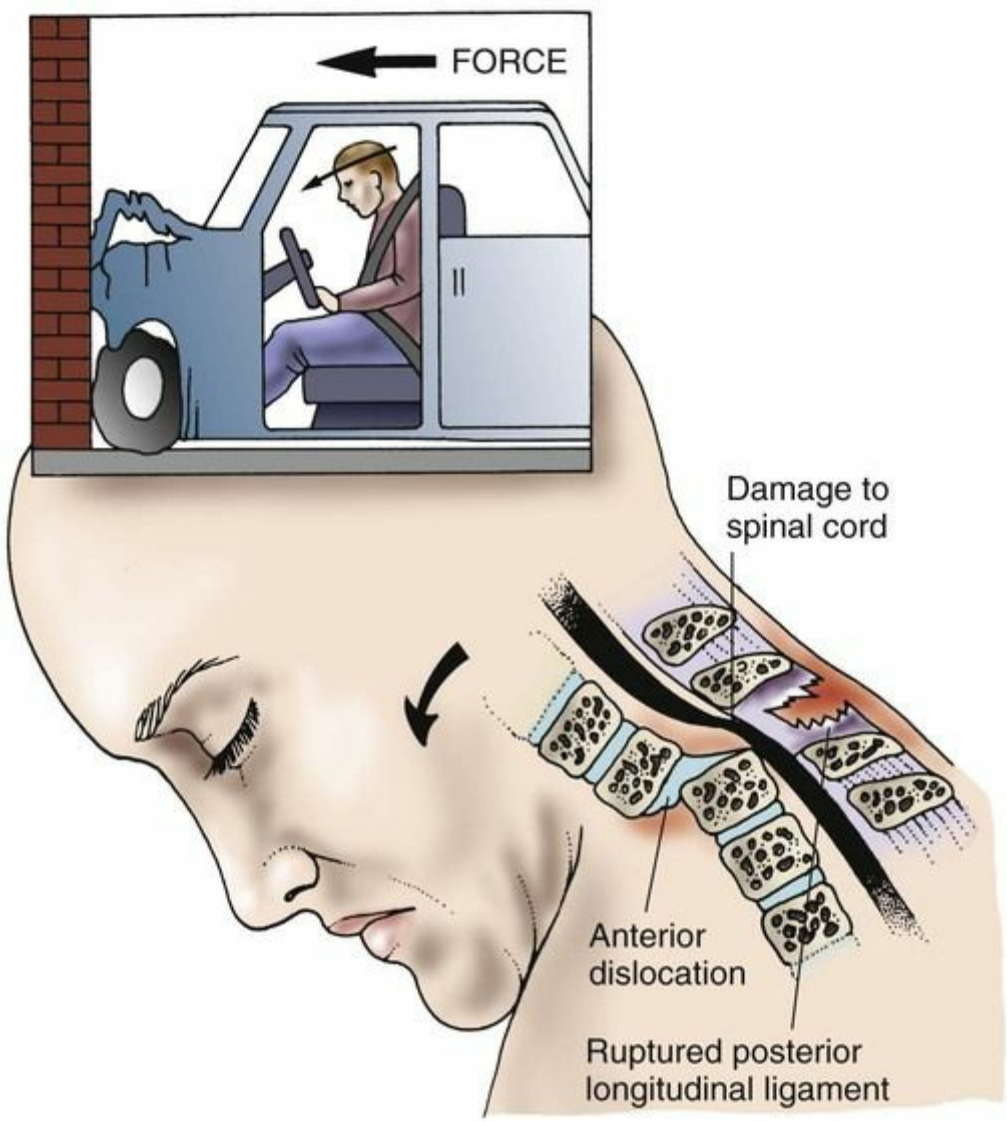

FIG. 43-2 Hyperflexion injury of the cervical spine.

Hyperextension injuries occur most often in vehicle collisions in which the vehicle is struck from behind or during falls when the patient's chin is struck (Fig. 43-3). The head is suddenly accelerated and then decelerated. This stretches or tears the anterior longitudinal ligament, fractures or subluxates the vertebrae, and perhaps ruptures an intervertebral disk. As with flexion injuries, the spinal cord may easily be

damaged.

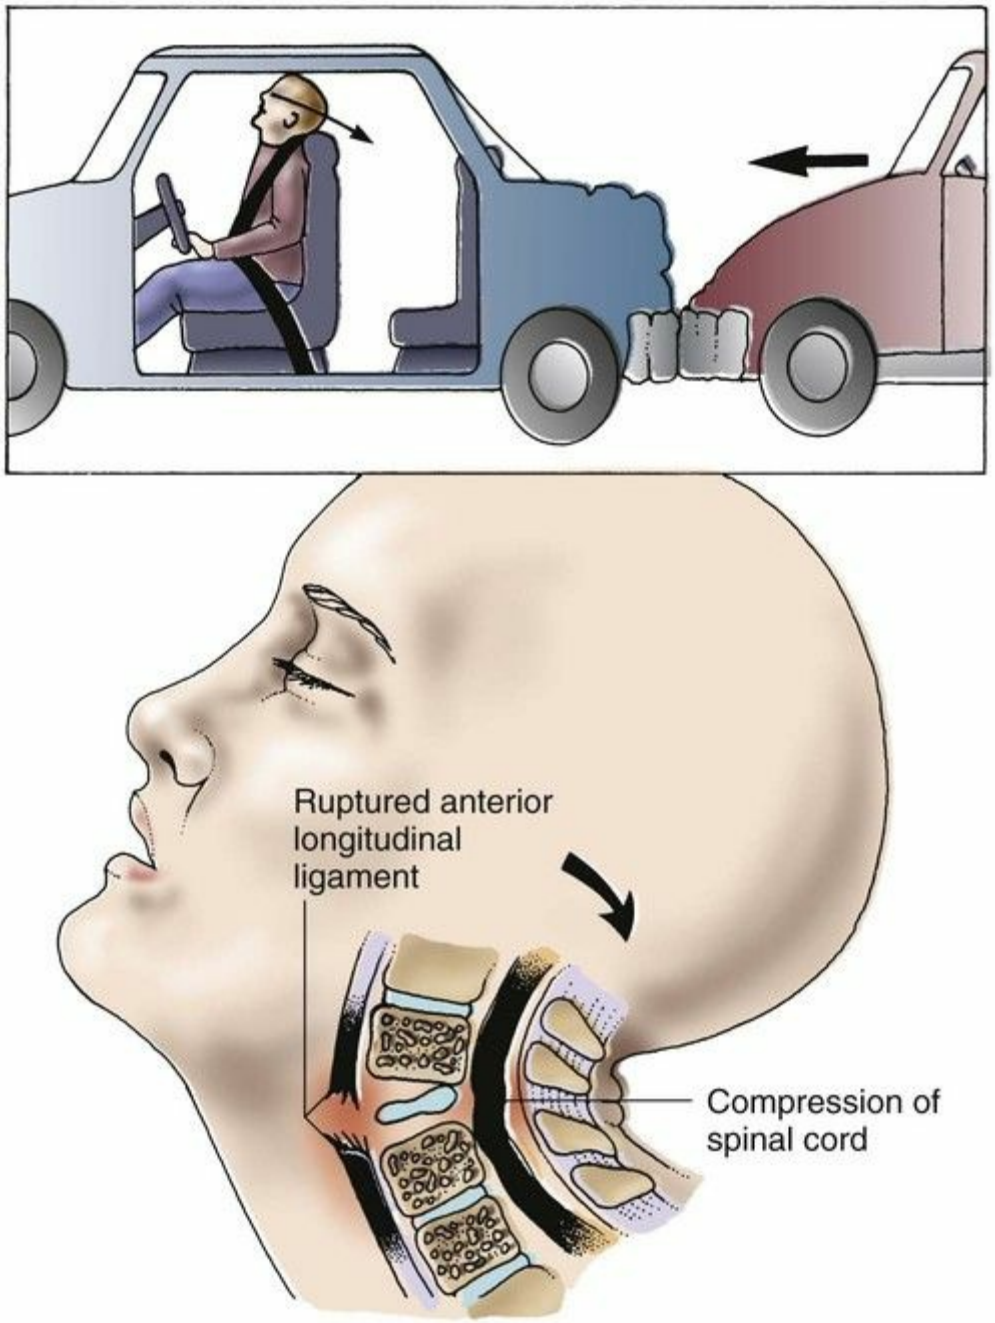

FIG. 43-3 Hyperextension injury of the cervical spine.

Diving accidents, falls on the buttocks, or a jump in which a person lands on the feet can cause many of the injuries attributable to **axial loading** (vertical compression) (Fig. 43-4). A blow to the top of the head can cause the vertebrae to shatter. Pieces of bone enter the spinal canal and damage the cord. **Rotation** injuries are caused by turning the head beyond the normal range.

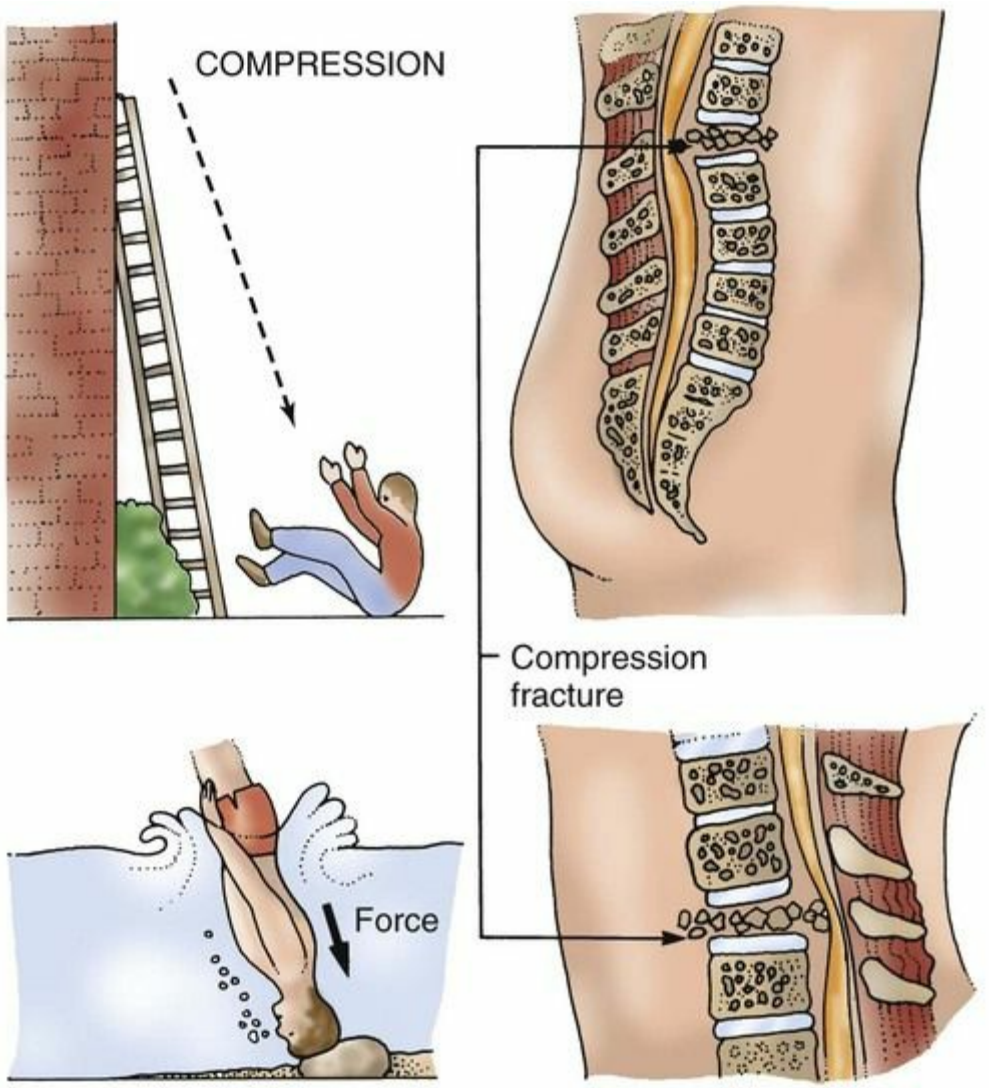

FIG. 43-4 Axial loading (vertical compression) injury of the cervical spine and the lumbar spine.

Penetrating trauma to the spinal cord is classified by the speed of the object (e.g., knife, bullet) causing the injury. Low-speed or low-impact injuries cause damage directly at the site or local damage to the spinal cord or spinal nerves. In contrast, high-speed injuries that occur from gunshot wounds cause both direct and indirect damage.

Secondary injury worsens the primary injury. Secondary injuries include:

- Hemorrhage
- Ischemia (lack of oxygen, typically from reduced/absent blood flow)
- Hypovolemia (decreased circulating blood volume)
- Impaired tissue perfusion form neurogenic shock (a *medical emergency*)
- Local edema

Hemorrhage into the spinal cord may be manifested by contusion or petechial leaking into the central gray matter and later into the white matter. Systemic hemorrhage can result in shock and decrease perfusion

to the spinal cord. Edema occurs with both primary and secondary injuries, contributing to capillary compression and cord ischemia. In neurogenic shock, loss of blood vessel tone (dilation) after *severe* cord injury may result in hypoperfusion (McCance et al., 2014).

Etiology

Trauma is the leading cause of spinal cord injuries (SCIs), with more than 35% resulting from vehicle crashes. Other leading causes are falls, acts of violence (usually gunshot wounds [GSWs]), and sport-related accidents (National Spinal Cord Injury Statistical Center, 2013). SCIs from falls are particularly likely among older adults. Spinal cord damage in adults can also result from nontraumatic vertebral fracture and diseases such as benign or malignant tumors.

Incidence and Prevalence

According to the National Spinal Cord Injury Statistical Center (2013), about 12,000 new SCIs occur every year in the United States. Almost 80% of all SCIs occur in young males, with the majority being Euro-American. Cervical cord injuries are more common than thoracic or lumbar cord injuries. The most common neurologic level of injury is C5. In paraplegia, T12 and L1 are the most common levels (Juknis et al., 2012).

❖ Patient-Centered Collaborative Care

◆ Assessment

History.

When obtaining a history from a patient with an acute SCI, gather as much data as possible about how the accident occurred and the probable mechanism of injury. Questions include the location and position of the patient immediately after the injury, the symptoms that occurred immediately with the injury, and the changes that have occurred subsequently. If possible, ask Emergency Medical Transport (EMT) rescue personnel about the type of immobilization devices used and whether any problems occurred during stabilization and transport to the hospital. Review the patient's medical record regarding the treatment given at the scene of injury or in the emergency department (ED) (e.g., drugs, IV fluids). Communicate with the ED nurse as he or she "hands off" the patient. Use the **s**ituation, **b**ackground, **a**ssessment, **r**ecommendation (SBAR) communication technique to collect valuable information for continuing patient care per The Joint Commission's National Patient

Safety Goals. (See Chapter 1 for how to use SBAR.)

Obtain the patient's medical history, including a history of osteoporosis or arthritis of the spine, congenital deformities, cancer, and previous injury or surgery of the neck or back. These health problems may cause or contribute to an SCI. A detailed history of any respiratory problems is particularly important if the patient has experienced a cervical SCI.

Physical Assessment/Clinical Manifestations

Initial Assessment.

Assessing the ABCs (**a**irway, **b**reathing, and **c**irculation) is the priority for any trauma patient. Therefore the first priority for the patient with an SCI is to assess the patient's airway, breathing pattern, and circulation status. The airway may be compromised because of foreign body obstruction from the tongue or teeth due to facial trauma, injury to the larynx, or mandibular (jaw) fracture. After an airway is established, assess the patient's breathing pattern. The patient with a cervical SCI is at high risk for respiratory compromise because the cervical spinal nerves (C3-5) innervate the phrenic nerve, controlling the diaphragm. A significant head injury, pneumothorax (air in the chest cavity), hemothorax (blood in the chest cavity), and/or fractured ribs may also cause respiratory distress or failure. Endotracheal intubation with mechanical ventilation may be necessary to prevent respiratory arrest.

To assess for circulation, evaluate pulse, blood pressure, and peripheral perfusion such as pulse strength and capillary refill. In the patient with traumatic SCI, multiple injuries may contribute to circulatory compromise from hemorrhage or hemorrhagic shock. Assess for indications of intra-abdominal *hemorrhage* or hemorrhage or bleeding around fracture sites. Indicators of significant blood loss compromising circulation include hypotension and tachycardia with a weak and thready pulse. In patients with known or potential cervical spinal cord injury, neurologic shock with profound vasodilation and bradycardia can occur resulting in hypotension. All symptoms of circulatory compromise or shock must be aggressively treated to preserve tissue perfusion to the spinal cord. Shock is discussed in detail in Chapter 37.

Use the Glasgow Coma Scale (see Chapter 41) or other agency-approved assessment tool to assess the patient's *level of consciousness (LOC).* Cognitive impairment as a result of an associated traumatic brain injury (TBI) or substance abuse can occur in patients with traumatic SCIs. Perform a detailed assessment of the patient's motor function and

sensory perception to determine the level of injury and establish baseline data for future comparison. The level of injury is the lowest neurologic segment with intact or normal motor and sensory function. **Tetraplegia** (also called *quadriplegia*) (paralysis) and **quadriparesis** (weakness) involve all four extremities, as seen with cervical cord and upper thoracic injury. **Paraplegia** (paralysis) and **paraparesis** (weakness) involve only the lower extremities, as seen in lower thoracic and lumbosacral injuries or lesions.

Spinal shock, also called **spinal shock syndrome,** occurs immediately as the cord's response to the injury. The patient has complete but temporary loss of motor, sensory, reflex, and autonomic function that often lasts less than 48 hours but may continue for several weeks (McCance et al., 2014). Muscle spasticity, reflex activity, and bladder function begin in patients with cervical or high thoracic injuries when spinal shock is resolved. Spinal shock is NOT the same as neurogenic shock.

Sensory and Motor Assessment.

Neurologic level defined by the American Spinal Injury Association (ASIA) refers to the highest neurologic level of normal function and is not the same as the anatomic level of injury. The neurologic level is determined by evaluation of the zones of sensory and motor function, known as *dermatomes* and *myotomes.* Follow the sensory distribution of the skin dermatomes (see Fig. 41-5), with the examination beginning in the area of reported loss of sensory perception and ending where sensory perception becomes normal. For example, sensation of the top of the foot and calf of the leg is spinal skin segment (dermatome) levels L3, L4, and L5. The area at the level of the umbilicus is T10, the clavicle (collarbone) is C3 or C4, and finger sensation is C7 and C8. The patient may report a complete sensory loss, **hypoesthesia** (decreased sensation), or **hyperesthesia** (increased sensation). In acute SCI, a decrease in sensation from baseline, especially in a proximal (upward) dermatome, is considered reason to urgently notify the neurosurgeon.

Many scales are available to measure motor function after SCI. ASIA recommends a six-point grading scale, with 0 being no movement and 5 being normal strength against full resistance. It is important to test all muscle groups for function. For example, patients with spinal injuries at the fifth or sixth cervical vertebra often can flex but not extend their arms. Extensive training is needed to fully assess a patient with SCI (Furlan et al., 2011b). New loss of motor function in a patient with recent SCI is an emergency and requires immediate communication with the

neurosurgeon.

The advanced practice nurse or health care provider may also test deep tendon reflexes (DTRs), including the biceps (C5), triceps (C7), patella (L3), and ankle (S1). It is not unusual for these reflexes, as well as all movement or sensation, to be absent immediately after the injury because of spinal shock. After shock has resolved, the reflexes may return if the lesion is incomplete.

Cardiovascular and Respiratory Assessment.

Cardiovascular dysfunction results from disruption of sympathetic fibers of the autonomic nervous system (ANS), especially if the injury is above the sixth thoracic vertebra. Bradycardia, hypotension, and hypothermia occur because of loss of sympathetic input. These changes may lead to cardiac dysrhythmias. *A systolic blood pressure below 90 mm Hg requires treatment because lack of perfusion to the spinal cord could worsen the patient's condition.* In addition, the lack of sympathetic or hypothalamic control causes the patient to lose thermoregulatory functions. As a result, the body tends to assume the temperature of the environment and attempts to compensate by increasing extracellular fluid.

A patient with a cervical SCI is at risk for *breathing* problems resulting from an interruption of spinal innervation to the respiratory muscles. In collaboration with the respiratory therapist (RT), if available, perform a complete respiratory assessment, including pulse oximetry for arterial oxygen saturation every 8 to 12 hours. An oxygen saturation 92% or less and adventitious breath sounds may indicate a complication like atelectasis or pneumonia. Hypercarbia measured by end-tidal carbon dioxide in an intubated patient may indicate circulatory or worsening respiratory failure. The RT should also evaluate vital capacity and minute volume and repeat the tests daily and during periods of worsening oxygenation during the acute phase. Early tracheostomy is recommend if the patient is likely to need prolonged (i.e., more than 7 days) mechanical ventilation.

Gastrointestinal and Genitourinary Assessment.

Assess the patient's *abdomen* for manifestations of internal bleeding, distention, or paralytic ileus. Hemorrhage may result from the trauma, or it may occur later from a stress ulcer or the administration of steroids. Monitor for abdominal pain and changes in bowel sounds. Paralytic ileus may develop within 72 hours of hospital admission. During the period of spinal shock, peristalsis decreases, leading to a loss of bowel sounds and to gastric distention. This disruption of the autonomic nervous system

may lead to a hypotonic bowel.

Consult with the registered dietitian for assessment to initiate early nutrition to meet caloric and protein needs. Assess serum glucose levels to avoid complications from hypoglycemia and sustained hyperglycemia. Assess the patient for swallowing difficulties such as weak gag reflex, drooling, or cough with oral intake. Collaborate with the speech-language specialist to evaluate swallowing for patients with cervical and high thoracic injury before starting oral intake and plan for appropriate diet and treatment when **dysphagia** is present. Monitor intake and output.

Autonomic dysfunction initially causes an areflexic (neurogenic) bladder (no reflex ability for bladder contraction), which later leads to urinary retention. Assess for bladder distention and urine stasis. The patient with an indwelling urinary catheter has increased risk for urinary tract infection. Start a bowel regimen congruent with best practices for paralyzed patients. Maintain bladder and bowel programs for patients with established SCI. One source for best practices is the Paralyzed Veterans of America (www.pva.org).

Assessment of Patients for Long-Term Complications.

Assess for skin tissue integrity with each turn or repositioning. Monitor for signs of VTE with vital signs. Monitor intake and output to maintain a normal volume of intravascular fluid (**euvolemia**). Assess glycemic and nutritional status including intake of protein, vitamins (A, C, E), zinc, and iron. Nursing management for neurogenic bowel care is usually started in rehabilitation. In patients with established SCI, assess baseline ability and encourage their participation in self-care and management (Furlan et al., 2011a). Encourage family participation in care, and support their effort to keep the patient engaged in family life.

Bones become *osteopenic* and *osteoporotic* without weight-bearing exercise, placing the long-term SCI patient at risk for fractures. Another complication of prolonged immobility is **heterotopic ossification (HO)** (bony overgrowth, often into muscle). Assess for swelling, redness, warmth, and decreased range of motion (ROM) of the involved extremity. The hip is the most common place where HO occurs (Zychowicz, 2013). Changes in the bony structure are not visible until several weeks after initial symptoms appear.

Laboratory and Imaging Assessment.

The health care provider requests laboratory studies for the patient with an SCI to establish baseline data or to prepare for surgery. Arterial blood

gas analysis is done to monitor the respiratory status of a patient at risk for respiratory insufficiency. The findings should be within normal limits unless the patient has a history of heavy smoking or pre-injury pulmonary disease. Respiratory failure is indicated by decreased oxygen levels, increased carbon dioxide levels, and respiratory acidosis. A complete blood count can help determine hemorrhage; blood in the urine may be another significant indication of hemorrhage. Check laboratory values for a low hemoglobin count, leukocytosis (increased white blood cells [WBCs]), lymphocytopenia (decreased lymphocytes), and thrombocytopenia (decreased platelets), which can occur in patients with cervical spine injuries. These abnormalities may be related to lack of autonomic innervation to the hematopoietic (blood-cell producing) system. Observe patients for clinical signs and symptoms of these changes, such as an increased bleeding tendency.

Computed tomography (CT) is obtained as soon as possible, especially for the patient who has sustained multiple trauma. Magnetic resonance imaging (MRI) is performed to determine the degree and extent of damage to the spinal cord and to detect the presence of blood and bone within the spinal column. The health care provider may also request a series of x-rays of the spine to identify vertebral fractures, subluxation, or dislocation.

Analysis

The priority NANDA-I nursing diagnoses and collaborative problems for patients with an acute spinal cord injury (SCI) include:

1. Risk for respiratory distress/failure related to aspiration or diaphragmatic denervation (e.g., impaired phrenic nerve impulses in patients with cervical injury)
2. Potential for cardiovascular instability related to loss or interruption of sympathetic innervation or hemorrhage
3. Potential for secondary spinal cord injury related to hypoperfusion, edema, or delayed spinal column stabilization
4. Impaired Physical Mobility related to spinal compression and edema (NANDA-I)
5. Spastic or flaccid bladder and bowel related to direct neurologic damage or disruption in nerve impulses
6. Risk for Compromised Resilience from injury requiring need for life change (NANDA-I)

Planning and Implementation

The desired outcomes of patient-centered collaborative care following

acute SCI are to stabilize the vertebral column, manage damage to the spinal cord, and prevent secondary injuries. Systemic hypothermia is an experimental approach to provide neuroprotection in the first 24 to 48 hours after SCI wherein the patient is cooled to 32° to 34° C (89° to 93.2° F) (Ahmad et al., 2013). Therapeutic hypothermia is described in Chapter 34 in conjunction with treatment for cardiac arrest. Although stem cell therapies have significant potential to treat SCI, they are not yet established as an intervention to restore damaged neurons or neuron function.

Many patients with previous spinal cord injuries (SCIs) are admitted to the acute care or long-term care setting for complications of immobility, such as pressure ulcers or fractures resulting from osteoporosis. Pressure ulcers contribute to local infection, including osteomyelitis and septicemia. Priorities in care may need to be re-evaluated as complications occur and resolve.

Nursing management strategies that promote high level of patient participation in care are associated with patient outcomes of higher life satisfaction, mobility, and return to occupation (Bailey et al., 2012). Preventing complications of immobility and infection following SCI is an effort that requires patient, family, and health care team communication, collaboration, and individualized intervention.

Managing the Airway and Improving Breathing

Planning: Expected Outcomes.

The patient with an SCI is expected to have a patent airway and adequate ventilation.

Interventions.

Airway management is the priority for a patient with cervical spinal cord injury! Patients with injuries at or above T6 are especially at risk for respiratory complications and pulmonary embolus during the first 5 days after injury. These complications are due to impaired functioning of the intercostal muscles and decreased mobility. Depending on the level of injury, intubation or tracheotomy with mechanical ventilation may be needed.

Nursing Safety Priority QSEN

Action Alert

Assess breath sounds every 2 to 4 hours during the first few days after SCI, and document and report any adventitious or diminished sounds. Monitor vital signs with pulse oximetry. Watch for changes in respiratory pattern or airway obstruction, and intervene when there are decreases in pulse oximetry values.

Respiratory secretions are managed with manually assisted coughing, pulmonary hygiene, and suctioning. Implement strategies to prevent ventilator-associated pneumonia (VAP) when the patient needs continuous mechanical ventilation as discussed in Chapter 32.

Teach the patient who is tetraplegic to coordinate his or her cough effort with an assistant. The nurse, or other assistant, places his or her hands on the upper abdomen over the diaphragm and below the ribs. Hands are placed one over the other, with fingers interlocked and away from the skin. If the patient is obese, an alternate hand placement is one hand on either side of the rib cage. Have the patient take a breath and cough during exhalation. The assistant locks his or her elbows and pushes inward and upwards as the patient coughs. This technique is sometimes called "assisted coughing," "quad cough," or **"cough assist."** Repeat the coordinated effort, with rest periods as needed, until the airway is clear.

Encourage the patient to use an incentive spirometer. The nurse and respiratory therapist perform a respiratory assessment at least every 8 hours to determine the effectiveness of these strategies. In some cases it may be necessary to perform oral or nasal suctioning if the patient cannot clear the airway of secretions effectively.

Monitoring for Neurogenic Shock and Hemorrhagic/Hypovolemic Shock

Planning: Expected Outcomes.

The patient is expected to not develop neurogenic shock. If signs and symptoms of this potentially life-threatening complication occur, the patient is expected to receive prompt intervention.

Interventions.

Maintain adequate hydration through IV therapy and oral fluids as appropriate, depending on the patient's overall condition. Carefully observe for manifestations of **neurogenic shock,** which may occur within 24 hours after injury most commonly in patients with injuries above T6. This potentially life-threatening problem results from disruption in the

communication pathways between upper motor neurons and lower motor neurons.

Nursing Safety Priority QSEN

Critical Rescue

Monitor the patient with acute spinal cord injury at least hourly for:

- Pulse oximetry (Spo_2) <90% or symptoms of aspiration (e.g., stridor, garbled speech, or inability to clear airway)
- Symptomatic bradycardia, including reduced level of consciousness and deceased urine output
- Hypotension with systolic blood pressure (SBP) <90 or mean arterial pressure (MAP) <65 mm Hg

Notify the physician immediately if these symptoms occur, because this problem is an emergency! Respiratory compromise from aspiration may be treated with intubation or bronchial endoscopy. Neurogenic shock is treated symptomatically by providing fluids to the circulating blood volume, adding vasopressor intravenous therapy, and providing supportive care to stabilize the patient.

Preventing Secondary Spinal Cord Injury

Planning: Expected Outcomes.

The patient with an *acute* SCI is expected to demonstrate adequate spinal cord stabilization as evidenced by no further deterioration in neurologic status.

Interventions.

If the patient has a fractured vertebra, the primary concern of the health care team is to reduce and immobilize the fracture to prevent further damage to the spinal cord from bone fragments. Nonsurgical techniques include external fixation or orthotic devices, but surgery is usually needed to stabilize the spine and prevent further spinal cord damage.

Assess the patient's neurologic status, particularly focusing on sensory and motor function, vital signs, pulse oximetry, and pain, at least every 1 to 4 hours depending on the patient's overall condition. See Chart 43-8 for elements of a focused motor assessment related to spinal cord injury. *Document your assessments carefully and in detail, particularly changes in motor or sensory function. Failure to do so may prevent other staff members from quickly recognizing deterioration in neurologic status.*

Chart 43-8 Best Practice for Patient Safety & Quality Care QSEN

Assessing Motor Function in the Patient with a Spinal Cord Injury

- To assess C4-5, apply downward pressure while the patient shrugs his or her shoulders upward.
- To assess C5-6, apply resistance while the patient pulls up his or her arms.
- To assess C7, apply resistance while the patient straightens his or her flexed arms.
- To assess C8, make sure the patient is able to grasp an object and form a fist.
- To assess L2-4, apply resistance while the patient lifts his or her legs from the bed.
- To assess L5, apply resistance while the patient dorsiflexes his or her feet.
- To assess S1, apply resistance while the patient plantarflexes his or her feet.

Regardless of the level of SCI, keep the patient in proper body alignment to prevent further cord injury or irritability. Devices such as traction, orthoses, or collars may be used to keep the spine immobilized during healing and rehabilitation.

Spinal Immobilization and Stabilization.

During the immediate care of the patient with a suspected or confirmed cervical spine injury, a hard cervical collar, such as the Miami J or Philadelphia, is placed immediately and maintained until a specific order indicates it can be removed. A daily inspection of skin beneath the collar is recommended while a health care provider assists with maintaining neck alignment when the collar is removed. Padding at pressure points beneath and at the edges of the collar, particularly at the occiput, may be necessary to sustain tissue integrity. Until the spinal column is stabilized, a jaw-thrust maneuver is preferable to a head-tilt maneuver to open the airway should the patient need an airway intervention. Maintain spinal alignment at all times with log rolling to change position from supine to side-lying. Log rolling may also be prescribed in the initial period following surgical stabilization. Provide ongoing spinal alignment by using a slider board to transfer the patient between surfaces such as

placement on a computerized tomography (CT) scanner table.

The patient may be placed in fixed skeletal traction to realign the vertebrae, facilitate bone healing, and prevent further injury, often after surgical stabilization. The most commonly used device for immobilization of the *cervical spine* is the halo fixation device, which is worn for 8 to 12 weeks. The device is affixed by the physician into the outer aspect of the skull. For patients not having surgery, the addition of traction helps reduce the fracture.

The **halo fixator** is a static traction device (Fig. 43-5). Four pins (or screws) are inserted into the skull. The metal halo ring may be attached to a plastic vest or cast when the spine is stable, allowing increased patient mobility.

FIG. 43-5 Halo fixation device with jacket.

Nursing Safety Priority QSEN

Action Alert

Never move or turn the patient by holding or pulling on the halo

device. Do not adjust the screws holding it in place. Check the patient's skin frequently to ensure that the jacket is not causing pressure. Pressure is avoided if one finger can be inserted easily between the jacket and the patient's skin. Monitor the patient's neurologic status for changes in movement or decreased strength. A special wrench is needed to loosen the vest in emergencies such as cardiopulmonary arrest. Tape the wrench to the vest for easy and consistent accessibility. Do not use sharp objects (e.g., coat hangers, knitting needles) to relieve itching under the vest; skin damage and infection will slow recovery.

Common complications of the halo device are pin loosening, local infection, and scarring. More serious complications include osteomyelitis (cranial bone infection), subdural abscess, and instability. Hospital policy is followed for pin site care, which may specify the use of solutions such as saline. Vaseline dressings may also be used. *Monitor vital signs for indications of possible infection (e.g., fever, purulent drainage from the pin sites), and report any changes to the physician immediately. Discharge teaching related to halo fixator management is described in* Chart 43-9.

Chart 43-9 Patient and Family Education: Preparing for Self-Management

Use of a Halo Device*

- Be aware that the weight of the halo device alters balance. Be careful when leaning forward or backward.
- Wear loose clothing, preferably with hook and loop (Velcro) fasteners or large openings for head and arms.
- Bathe in the bathtub, or take a sponge bath. (Some physicians allow showers.)
- Wash under the lambs wool liner of the vest to prevent rashes or sores; use powders or lotions sparingly under the vest.
- Have someone change the liner if it becomes odorous.
- Support the head with a small pillow when sleeping to prevent unnecessary pressure and discomfort.
- Try to resume usual activities to the extent possible; keep as active as possible. (The weight of the device may cause fatigue or weakness.) However, avoid contact sports and swimming.
- Do not drive because vision is impaired with the device.
- Keep straws available for drinking fluids.
- Cut meats and other food into small pieces to facilitate chewing and

swallowing.
- Before going outside in cold temperatures, wrap the pins with cloth to prevent the metal from getting cold.
- Have someone clean the pin sites as recommended by physician or hospital protocol.
- Observe the pin sites daily for redness, drainage, or loosening; report changes to the physician.
- Increase fluids and fiber in the diet to prevent constipation.
- Use a position of comfort during sexual activity.

*Home care instructions may vary depending on hospital or physician preference.

Nonsurgical treatment of *thoracic and lumbosacral injuries* is often challenging. Most health care providers choose to refer the patient for surgery and then immobilize the spine with lightweight, custom-fit thoracic lumbar sacral orthoses (TLSOs) to prevent prolonged periods of immobility.

NCLEX Examination Challenge

Safe and Effective Care Environment

A client was admitted this morning with an incomplete cervical spinal cord injury and is placed in a halo fixator. Halo fixation is used to reduce motion of the cervical spine. Which assessment finding will the nurse report immediately to the health care provider?

A A new-onset heart rate of 48 beats/min
B Mean arterial pressure of 90 mm Hg
C Pain level of 2 on a 0-to-10 pain scale
D Oxygen saturation of 95% on room air

Drug Therapy.

Dextran, a plasma expander, may be used to increase capillary blood flow within the spinal cord and to prevent or treat hypotension. *Atropine sulfate* is used to treat bradycardia if the pulse rate falls below 50 to 60 beats per minute. Hypotension, if severe, is treated with continuous intravenous sympathomimetic agents such as *dopamine* or other vasoactive agent.

Centrally-acting skeletal muscular relaxants, such as *tizanidine* (Zanaflex, Sirdalud), may help control severe muscle spasticity. However,

these drugs cause severe drowsiness and sedation in most patients and may not be effective in reducing spasticity. As an alternative to these drugs, *intrathecal baclofen (ITB) (Lioresal)* therapy may be prescribed. This drug is administered through a programmable, implantable infusion pump and intrathecal catheter directly into the cerebrospinal fluid. The pump is surgically placed in a subcutaneous pouch in the lower abdomen. Monitor for common adverse effects, which include sedation, fatigue, dizziness, and changes in mental status. *Seizures and hallucinations may occur if ITB is suddenly withdrawn.*

Other drugs to prevent or treat complications of immobility may be needed *later* during the rehabilitative phase. For example, celecoxib (Celebrex) may be prescribed to prevent or treat **heterotopic ossification** (bony overgrowth). Calcium and bisphosphonates may prevent the osteoporosis that results from lack of weight-bearing or resistance activity. Osteoporosis can cause fractures in later years. Early and continued exercise may help decrease the incidence of these complications.

Surgical Management.

Surgery within 24 hours of injury to stabilize the vertebral spinal column, particularly if there is evidence of spinal cord compression, results in decreased secondary complications (Stahel et al., 2012). Emergent surgery also removes bone fragments, hematomas, or penetrating objects such as a bullet. Typical procedures include wiring and spinal fusion for cervical injuries and the insertion of steel or metal rods (e.g., Harrington rods) to stabilize thoracic and lumbar spinal injuries. During a cervical fusion, the surgeon reduces the fracture by placing the bone ends in proper alignment. Metal wiring is then used to secure bone chips (bone graft) taken from the patient's hip. The patient wears a halo vest to immobilize the spine during the healing process. For thoracic and lumbar fusions, metal or steel rods (e.g., Harrington rods) are used to keep the bone ends in alignment after fracture reduction. After surgery, the patient usually wears a molded plastic support (cervical or thoracic-lumbar or both) to keep the injured and operative areas immobilized during recovery. Postoperative care occurs as described in Chapter 16.

Nursing Safety Priority QSEN

Action Alert

After surgical spinal fusion, assess the patient's neurologic status and

vital signs at least every hour for the first 4 to 6 hours and then, if the patient is stable, every 4 hours. Assess for complications of surgery, including worsening of motor or sensory function at or above the site of surgery.

Managing Impaired Mobility

Planning: Expected Outcomes.

The patient with an SCI is expected to be free from complications of immobility and perform ADLs as independently as possible with or without assistive/adaptive devices.

Interventions.

The patient with an SCI is especially at risk for pressure ulcers (impaired skin tissue integrity), venous thromboembolism (VTE), contractures, orthostatic hypotension, and fractures related to osteoporosis. Patients with high SCIs are also at risk for orthostatic hypotension. Frequent and therapeutic positioning not only helps prevent complications but also provides alignment to prevent further spinal cord injury or irritability. Assess the condition of the patient's skin, especially over pressure points, with each turn or repositioning. Reduce pressure on any reddened area, and monitor it with the next turn. Reposition patients frequently (every 1-2 hours). When sitting in a chair, the patient is repositioned or taught to reposition himself or herself more often than every hour. Paraplegic patients usually perform frequent "wheelchair push-ups" to relieve skin pressure. Use a pressure-reducing mattress and wheel chair or chair pad to help prevent skin breakdown. Prevent pressure ulcers using best practices as described in Chapter 25. Prevent VTE including using interventions of intermittent pneumatic compression stockings and low–molecular-weight heparin (LMWH). Document pressure ulcer and VTE prophylaxis in accordance with Core Measures developed by the Centers for Medicare and Medicaid Services and The Joint Commission (www.jointcommision.org).

Contractures may be prevented or minimized with splints. Consult with the PT and occupational therapist (OT) for optimal scheduling for placing/removing splints (typically individually molded to the patient's extremity), trigger points to relieve spasticity, and positioning to maintain joint function. Administer antispasmodic drugs, and monitor the patient's response.

Patients with cervical cord injuries are especially at high risk for orthostatic (postural) hypotension, but anyone who is immobilized may

have this problem. If the patient changes from a lying position to a sitting or standing position too quickly, he or she may experience hypotension, which could result in dizziness and falls. Because of interrupted sympathetic innervation caused by the spinal cord injury, the blood vessels do not constrict quickly enough to push blood up into the brain. The resulting vasodilation causes dizziness or light-headedness and possible falls with syncope ("blackout"). Consult with the registered dietitian to optimize diet for general health and to reduce osteoporosis from reduced daily weight-bearing activities. Provide out-of-bed activity in collaboration with the PT and OT. Resistance exercise, if it can be performed, promotes bone health.

Promote self-management with regular communication with the patient, family, and interdisciplinary health care team members. Help identify and set realistic expected outcomes on the basis of the patient's mobility and functional level. Even patients with a cervical SCI often learn how to perform most ADLs independently in specialized rehabilitation programs, and the majority of patients with SCI return home.

Managing Risk for Autonomic Dysreflexia

Planning: Expected Outcomes.

The patient with an SCI is expected to be free from episodes of autonomic dysreflexia (AD). If this complication of a high SCI occurs, the patient is expected to receive prompt interventions

Interventions.

Autonomic dysreflexia (AD), sometimes referred to as *autonomic hyperreflexia,* is a potentially life-threatening condition in which noxious visceral or cutaneous stimuli cause a sudden, massive, uninhibited reflex sympathetic discharge in people with high-level SCI. AD primarily affects men more than women. The signs and symptoms of AD are listed in Chart 43-10 (Gunduz & Binak, 2012). The sudden rise in blood pressure can result in end-organ damage, including stroke.

Chart 43-10 Key Features

Autonomic Dysreflexia

- Sudden, significant rise in systolic and diastolic blood pressure, accompanied by bradycardia
- Profuse sweating above the level of lesion—especially in the face, neck,

and shoulders; rarely occurs below the level of the lesion because of sympathetic cholinergic activity
- Goose bumps above or possibly below the level of the lesion
- Flushing of the skin above the level of the lesion—especially in the face, neck, and shoulders
- Blurred vision
- Spots in the patient's visual field
- Nasal congestion
- Onset of severe, throbbing headache
- Flushing about the level of the lesion with pale skin below the level of the lesion
- Feeling of apprehension

People with a cervical or high-thoracic SCI face lifelong abnormalities in systemic arterial pressure control (Krassioukov, 2012). Be aware that the sudden rise in blood pressure in AD is usually associated with bradycardia. Normal systolic blood pressure (SBP) for SCI above T6 is 90 to 110 mm Hg; a SBP 20 to 40 mm Hg above the reference range for patients with established SCI may be a sign of AD. Patients with AD may display no symptoms other than an elevated blood pressure.

The causes of AD are typically gastrointestinal (GI), gynecologic-urologic (GU), and vascular stimulation as well as skin and bone injury. Conditions associated with AD onset are bladder distention, urinary tract infection, epididymitis or scrotal compression, bowel distention or impaction from constipation, or irritation of hemorrhoids. Pain, circumferential constriction of the thorax, abdomen, or an extremity (e.g., tight clothing), contact with hard or sharp objects, and temperature fluctuations can also cause AD.

Certain procedures and pathologic conditions are also associated with AD. Anticipate the need for frequent assessment to detect AD early and intervene before blood pressure becomes dangerously elevated. For example, inflammation or injury in the GI system from gallstones, ulcers, gastritis, appendicitis, or other pathology is associated with the onset of AD. Stimulation of the GU system from menses, vaginitis, sexual penetration, ejaculation, and pregnancy (especially labor) can lead to AD. Venous thromboembolism can also cause AD. Acute and deep skin or mucosal injury from insect bites, blistering, pressure ulcers, and invasive instrumentation (e.g., cystoscopy, urodynamic testing, central line placement, and surgical procedures) can initiate AD. Heterotopic bone (i.e., bone tissue formed outside of the skeleton due to derangements in bone metabolism in patients confined to bed) and fractures can lead to

AD. There have been case reports of ingrown toenails leading to AD.

Awareness of the causes of AD assists the nurse in prioritizing assessment and using best practices to avoid conditions that contribute to the onset and severity of AD. For example, proper bladder and bowel care to prevent fecal impaction and bladder distention are essential. *AD is a neurologic emergency and must be promptly treated to prevent a hypertensive stroke!* Chart 43-11 lists emergency care for autonomic dysreflexia.

Chart 43-11 Best Practice for Patient Safety & Quality Care QSEN

Emergency Care of the Patient Experiencing Autonomic Dysreflexia: Immediate Interventions

- Place patient in sitting position (first priority!), or return to previous safe position.
- Page/notify care provider.
- Assess for and treat the cause:
- Check for urinary retention or catheter blockage:
- Check the urinary catheter tubing (if present) for kinks or obstruction.
- If a urinary catheter is not present, check for bladder distention and catheterize immediately if indicated:
- Consider using anesthetic ointment on tip of catheter before catheter insertion to reduce urethral irritation.
- Determine if a urinary tract infection or bladder calculi (stones) are contributing to genitourinary irritation.
- Check the patient for fecal impaction or other colorectal irritation, using anesthetic ointment at rectum. Disimpact if needed.
- Examine skin for new or worsening pressure ulcer symptoms.
- Monitor blood pressures every 10 to 15 minutes.
- Give nifedipine or nitrate as prescribed:
- Patients with recurrent autonomic dysreflexia may receive an alpha blocker prophylactically.

Managing Urinary and Bowel Elimination

Planning: Expected Outcomes.

The patient with an SCI is expected to achieve control of elimination of urine and stool without complications, if possible.

Interventions.

Patients with SCIs have reflex or neurogenic loss of bowel and bladder control. Many can become continent if they rigorously adhere to an established program. The type of program depends on the usual elimination pattern and whether the injury involved cervical or lower motor neurons (LMNs). A urologic evaluation may be needed to identify bladder type.

Patients with injuries to the lumbosacral area usually have a flaccid bladder and bowel. Patients with a **flaccid bladder** may achieve emptying of the bladder by performing a Valsalva maneuver or tightening the abdominal muscles. These techniques are not successful for all LMN injuries. To determine the effectiveness of these maneuvers, use a bedside **bladder ultrasound** or bladder scan device to measure bladder residual. This use of this device is discussed in Chapter 65.

Some patients rely on intermittent catheterization 2 or 3 times daily to empty the bladder. Obese patients and those with thoracic and cervical SCIs may need an indwelling urinary catheter for a period of time. External urinary catheters connected to a leg bag may be used for men.

The patient with *any* SCI is at risk for long-term kidney complications, such as hydronephrosis, acute and chronic kidney disease, and kidney stones. Urinary tract infections (UTIs) are common because organisms are introduced into the urinary tract by urinary catheters. Patients with an SCI may not be aware of the infection because they cannot feel dysuria, urgency, or back pain. They must rely on other signs and symptoms, such as foul-smelling urine or fever.

Teach the patient that the essential elements of a bowel program include stool softeners, fluid intake sufficient to result in clear, light yellow urine (unless medically contraindicated), high-fiber diet, and a consistent time for elimination. *Rectal digital stimulation is done only if requested by the health care provider because it could cause a vagal response, manifested by severe bradycardia and syncope.*

Adjusting to Major Life Change, Promoting Resilience

Planning: Expected Outcomes.

The patient with an SCI is expected to adapt to a significant life change.

Interventions.

Information obtained from the psychosocial assessment is used by the interdisciplinary team to identify strategies to help the patient adjust to the disability. Help the patient set realistic goals and verbalize feelings

about the injury and his or her future. Invite the patient to ask questions, and answer them openly and honestly. Questions about prognosis and potential for complete recovery are referred to the health care provider because the timing and extent of recovery are different for each patient.

Collaborate with the case manager or discharge planner for a review of the patient's insurance and financial status. Many insurance policies cover rehabilitation services but for a limited time each year. The discharge coordinator or financial counselor may be able to assist the patient or family to locate other sources for adapting the home or funding an adapted car, such as private foundations and community organizations.

Community-Based Care

Case managers are ideal care coordinators to act as SCI patient advocates. In some settings, case managers begin working with patients in the emergency department to establish a positive image of SCI rehabilitation. Rehabilitation begins in the acute or critical care unit when patients are hemodynamically stable. They are usually transferred from the acute care setting to a rehabilitation setting, where they learn more about self-care, mobility skills, and bladder and bowel retraining. One promising therapy in rehabilitation is functional electrical stimulation (FES). FES uses small electrical pulses to paralyzed muscles to restore or improve their function. FES is commonly used for exercise but also to assist with breathing, grasping, transferring, standing, and walking.

Psychosocial adaptation is one of the critical factors in determining the success of rehabilitation. The case manager or acute care nurse can help the patient and family members prepare for discharge or transfer to a rehabilitation hospital. Assist in verbalizing feelings and fears about body image, self-concept, role performance, self-esteem, and sexuality. The patient should be told about the expected reactions of those outside the security of the hospital environment. Role-playing or anticipating responses to potential problems is helpful. For example, the patient can practice answering questions from children about why he or she is in a wheelchair or cannot move certain parts of the body.

Particularly among young men, who are the most common patients with SCI, sexuality is a major issue. Many patients are concerned about their ability to have sexual intercourse and have children. Most hospitals do not have psychological social workers or counselors to discuss sexuality issues. Rehabilitation programs often include a sexuality/intimacy counselor as part of the interdisciplinary team

approach to patient care.

Home Care Management.

If the patient is discharged home or returns home for a weekend visit from the rehabilitation setting, the environment must be assessed to ensure that it is free from hazards and can accommodate the patient's special needs (e.g., a wheelchair). The occupational or physical therapist, in collaboration with rehabilitation and the home care nurse, usually assesses the patient's temporary or permanent home environment. Ease of accessibility is particularly important at the entrance of the home as well as the bathroom, kitchen, and bedroom. The height of the patient's bed may need to be adjusted to allow a smooth transfer into and out of the bed.

All adaptive devices that the patient will use at home should be requested and delivered to the rehabilitation facility. This enables the nurse and other therapists to ensure that the items fit correctly and that the patient and family know how to use them correctly.

Self-Management Education.

The teaching plan for the patient with an SCI includes:

- Mobility skills
- Pressure ulcer prevention
- ADL skills
- Bowel and bladder program
- Education about sexuality and referral for counseling to promote sexual health
- Prevention of autonomic dysreflexia with appropriate bladder, bowel, and skin care practices and recognition of early signs or symptoms of autonomic dysreflexia

This information should be reinforced with written handouts, CDs, DVDs, or other patient education material that the patient and family members can use after discharge to the home. Chart 43-12 provides information about aging for middle-aged and older adults with a spinal cord injury.

Chart 43-12 Nursing Focus on the Older Adult

What Patients Need to Know About Aging with Spinal Cord Injury

NURSING INTERVENTION	RATIONALES
Follow guidelines for adult vaccination, particularly influenza and pneumococcus vaccination recommendations.	Respiratory complications are the most common cause of death after spinal cord injury (SCI). The vaccine to prevent herpes zoster (shingles) can help prevent skin breakdown.
For women, have Papanicolaou (Pap) smears and mammograms as recommended by the American Cancer Society or your health care provider.	Limitations in movement may make breast self-examination difficult.
Take measures to prevent osteoporosis, such as increasing calcium intake, avoiding caffeine, and not smoking. Exercise against resistance can maintain muscle strength and slow bone loss.	Women older than 50 years often lose bone density, which can result in fractures. Men can also have osteoporotic fractures as a result of immobility.
Practice meticulous skin care, including frequent repositioning, using pressure-reduction surfaces in bed and chairs/wheelchairs, and applying skin protective products like Mepilex.	As a person ages, skin becomes dry and less elastic, predisposing the patient to pressure ulcers.
Take measures to prevent constipation, such as drinking adequate fluids, eating a high-fiber diet, adding a stool softener or bowel stimulant daily, and establishing a regular time for bowel elimination.	Constipation is a problem for most patients with SCI, and bowel motility can slow, contributing to constipation later in life.
Modify activities if joint pain occurs; use a powered rather than a manual wheelchair. Ask the health care provider about treatment options.	Arthritis occurs in more than half of people older than 65 years. Patients with SCI are more likely to develop arthritis as a result of added stress on the upper extremities when using a wheelchair.

A full-time caregiver or personal assistant is sometimes required if the patient with tetraplegia returns home. The caregiver may be a family member or a nursing assistant employed to help provide care and companionship. A patient who is paraplegic is often able to function without assistance after an appropriate rehabilitation program.

ADL training for the patient with an SCI includes a structured exercise program to promote strength and endurance. The occupational therapist instructs the patient in the correct use of all adaptive equipment. In collaboration with the therapists, instruct family members or the caregiver in transfer skills, feeding, bathing, dressing, positioning, and skin care as discussed briefly in this chapter and in more detail in Chapter 6.

Nursing Safety Priority QSEN

Drug Alert

Teach the SCI patient and his or her family or other caregiver about the name, purpose, dosage, timing of administration, and side effects of all *drugs*. Make sure they understand the possible interaction of prescribed drugs with over-the-counter drugs or alcohol and illegal drugs.

Sexuality is associated with sexual and reproductive function. Sexual function after spinal cord injury depends on the level and extent of injury. Incomplete lesions allow some control over sensory perception and motor ability. Complete lesions disconnect the messages from the brain to the rest of the body, and vice versa. However, men with injuries above T6 are often able to have erections by stimulating reflex activity. For example, stroking the penis will cause an erection. Ejaculation is less predictable and may be mixed with urine. However, urine is sterile, so the patient's partner will not get an infection. To prevent AD, prophylactic administration of a vasodilator may be needed prior to intercourse (Courtois et al., 2012).

Women with an SCI have a different challenge because they have indwelling urinary catheters more commonly than men with an SCI. However, some women do become pregnant and have full-term children. For others, ovulation stops in response to the injury. In this case, alternate methods for pregnancy, such as *in vitro* fertilization, may be an option. Some women also report vaginal dryness. Recommend a water-soluble lubricant for both partners to promote comfort.

For patients who choose not to have intercourse, intimate pleasure can be achieved in other ways, including kissing, hugging, fondling, masturbation, and oral sex. Variations in positioning may be needed to accommodate weak or paralyzed parts of the body. An understanding partner can help the patient adjust to his or her physical changes.

Clinical Judgment Challenge

Safety; Evidence-Based Practice; Teamwork and Collaboration QSEN

A 52-year-old man who has had a T-10 spinal cord injury for 10 years is admitted for septicemia. He has a 3 × 2–centimeter discoloration on his left buttock that is classed as an unstageable pressure ulcer. He has an indwelling urinary catheter. The patient has been living alone and states that he has no family or friends. He has had a variety of health problems and wishes he would die. An antidepressant was prescribed for the

patient 3 years ago, but he does not take it because it makes him tired.

1. What priority problems does this patient have at this time? Which problems need immediate action and why? What other data do you need to help formulate your answer?
2. With what members of the interdisciplinary and nursing team should you collaborate to provide quality care for this patient?
3. What may be causing the patient's septicemia? What are the evidence-based interventions for the care of patients with septicemia? Use a reliable electronic database to help you answer this question.
4. Use the SBAR method to communicate your concerns about this patient to another nurse who will be continuing his care.

Health Care Resources.

Refer the patient and family to local, state or province, and national organizations for more information and support for patients with SCI. These organizations include the National Spinal Cord Injury Association (www.spinalcord.org) in the United States and Spinal Cord Injury Canada (www.sci-can.ca). Many excellent consumer-oriented books, journals, and DVDs are also available. Support groups may help the patient and family adjust to a changed lifestyle and provide solutions to commonly encountered problems.

The primary purpose of rehabilitation is to enable patients to function independently in their communities. However, many physical barriers still exist in some communities that prevent the patient in a wheelchair from finding a parking place, using sidewalks, and attending activities or utilizing resources (Fig. 43-6). The use of Photovoice (sometimes referred to as *Photo Voice*) projects can be very helpful in making positive changes in the community for people who are disabled.

FIG. 43-6 Community physical barrier example: A curb prevents the patient in a wheelchair from getting onto the sidewalk.

Photovoice is a combination of photographs, videos, and storytelling that allows disabled people in the community to "**v**oice **o**ur **i**ndividual and **c**ollective **e**xperiences" in an organized way. This process can allow groups of patients with SCIs to work together to record and discuss their community's strengths and concerns. The collective desired outcome for Photovoice is to influence policymakers to make changes that remove or change their community's barriers. Newman (2010) described a Photovoice project to create a database of community environmental barriers and facilitators in a large city in the southeastern United States. Over 500 facilitators and over 500 barriers were identified. The authors produced a YouTube video and concluded that this type of community-based participatory project was extremely valuable to help wheelchair-bound SCI patients.

Evaluation: Outcomes

Evaluate the care of the patient with an SCI based on the identified priority patient problems. The expected outcomes are that the patient:

- Exhibits no deterioration in neurologic status
- Maintains a patent airway, a physiologic breathing pattern, and

adequate ventilation
- Is free from complications of immobility
- Performs basic ADLs as independently as possible with or without the use of assistive/adaptive devices
- Achieves control of regular elimination of stool and urine
- Adapts to a significant life change

Spinal Cord Tumors

Pathophysiology

Primary spinal cord tumors make up only a small percentage of all central nervous system neoplasms. Most spinal cord tumors are secondary or metastatic. Common primary cancers that metastasize (spread) to the spinal cord are lungs, breasts, prostate, colon, and uterus. Spinal cord tumors, whether primary or secondary, occur most often in the thoracic area, but they can occur in the lumbar and cervical areas. Signs and symptoms depend on the location of the tumor and its speed of growth. In addition, tumors in the spinal area can involve the vertebrae, and this location for bone cancer is usually as a result of metastasis from other areas of the body.

The pathologic effects of a spinal cord tumor are more often related to compression of the cord rather than the tumor itself. As the tumor expands, it compresses the cord or the spinal nerve roots. A large tumor may affect the blood supply to the cord causing ischemia or obstruct the normal flow of cerebrospinal fluid (CSF). Venous occlusion by the tumor may lead to spinal cord congestion and infarction (tissue death).

The appearance of neurologic signs and symptoms is related to the rate of tumor growth. With a slow-growing tumor, the cord may become significantly misshapen and displaced but the patient has surprisingly few symptoms. However, a rapidly growing tumor quickly leads to spinal cord compression, edema, and the development of neurologic symptoms, such as numbness and paralysis.

Primary spinal cord tumors can be extradural or intramedullary. Their cause is unknown. **Intramedullary tumors** are within the cord in the central gray matter or glial cells of the spinal cord. Intramedullary tumors are usually cancerous and grow rapidly and invasively. **Extramedullary tumors,** representing 90% of primary spinal cord tumors, are found within the spinal dura but outside the cord. They are further defined anatomically as extradural and intradural tumors. *Extradural or epidural* tumors occur between the vertebrae and the spinal dura. They develop in the surrounding bone and cause destruction of the vertebral bodies. *Intradural* tumors are located within the dura and originate from the pia-arachnoid, spinal roots, or ligaments. Most extramedullary tumors (e.g., schwannomas, neurofibromas, and meningiomas) do not exhibit the signs of uncontrolled growth and organ invasion of cancerous tumors.

Patient-Centered Collaborative Care

Assessment

The clinical manifestations of a spinal cord tumor depend on its location (Chart 43-13) and rate of growth. The most common problem is non-mechanical back pain. Pain results from spinal cord compression, infiltration of the spinal tracts, or irritation of the spinal roots. Assess the quality, severity, and intensity of the pain. In addition, ask the patient to describe factors that worsen and relieve the pain. **Radicular** (nerve root) pain is stabbing or dull, with intermittent episodes of sharp, piercing pain. The pain may increase during coughing, straining, or sneezing. Lying flat may increase the pain as a consequence of stretching the involved spinal nerve roots.

Chart 43-13 Key Features

Spinal Cord Tumors

General Manifestations
• Pain • Sensory loss or impairment • Motor loss or impairment • Sphincter disturbance (bladder before bowel)
Cervical Manifestations
High Cervical
• Respiratory distress • Diaphragm paralysis • Occipital headache • Quadriparesis • Stiff neck • Nystagmus • Cranial nerve dysfunction
Low Cervical
• Pain in the arms and the shoulders • Weakness • Paresthesia • Motor loss • Horner's syndrome • Increased reflexes
Thoracic Manifestations
• Sensory loss • Spastic paralysis • Positive Babinski's sign • Bladder and bowel dysfunction • Pain in the chest and the back • Muscle atrophy • Muscle weakness in the legs • Foot drop
Lumbosacral Manifestations
• Low back pain • Paresis • Spastic paralysis • Sensory loss • Bladder and bowel dysfunction • Sexual dysfunction • Decreased-to-absent ankle and knee reflexes

Involvement of the corticospinal tract may lead to mobility problems. Assess for weakness, clumsiness, spasticity, and hyperactive reflexes, and compare responses on both sides of the body. Other presenting signs include ataxia (staggered gait), hypotonia (decreased muscle tone), and a positive Babinski's reflex. Spastic paralysis occurs most often, although a flaccid paralysis may be present in a tumor that affects the spinal roots, an intramedullary tumor in the lumbosacral area, or an extramedullary tumor.

Determine sensory perception on each side of the body, and compare the responses. Early symptoms include a slowly progressive numbness or tingling, pain, and temperature loss. The sensory deficit is further marked by a decreased touch perception, an inability to sense vibration, and a loss of position sense. The patient often reports a tight, bandlike feeling around the trunk.

Loss of bladder control often occurs before a loss of bowel control. Assess for urinary hesitancy, dribbling, incontinence, urgency, or acute retention. Bowel dysfunction is manifested by constipation. Keep in mind that the patient is often embarrassed to admit to bladder or bowel dysfunction.

A lesion in the sacral area may cause a decrease in genital sensation and thus affect the patient's sexual function and enjoyment. Men may be unable to have an erection or to ejaculate.

Diagnostic Assessment.

Radiographic examinations or scans of the spine are obtained to detect a narrowing of the spinal canal, destruction of the vertebrae, or the presence of calcification. An MRI scan with and without contrast medium provides more detail of the pathologic condition of the spinal cord than either a CT scan or myelography. Electromyography (EMG) may help make a differential diagnosis to rule out multiple sclerosis (MS) or amyotrophic lateral sclerosis (ALS) or when spinal cord symptoms indicate an incomplete block. It indicates the level, extent, and boundaries of a tumor. This test is being performed less today because of newer imaging techniques.

A biopsy may be done to diagnose the specific type of tumor using a CT/MRI–guided needle. If the tumor is malignant, a biopsy assists in determining the cancer's type, which will subsequently determine treatment options. A biopsy is not needed for tumors that result from metastases if cancer has been diagnosed in another site of the body.

Interventions

Nursing care of the patient with a spinal cord tumor focuses on careful monitoring of vital signs and neurologic status at least every 4 hours or more often if clinically indicated.

Nursing Safety Priority QSEN

Critical Rescue

For the patient with a spinal cord tumor, report any change in motor and sensory status immediately to the physician or Rapid Response Team. Swelling or tumor invasion can damage the spinal nerves that help control the diaphragm, and respiratory failure can result.

The primary management of a spinal cord tumor is *surgery*. The

desired outcome of surgical intervention is to remove as much of the tumor as possible. Often this is not possible and other treatment is needed (e.g., radiation therapy). *Emergency surgery is performed if the patient has a rapid loss of motor and sensory function or a loss of bladder and bowel control. Surgical decompression may be performed to maintain bladder, bowel, or motor function and to preserve quality of life—even with a poor prognosis.*

The neurosurgeon performs a laminectomy and surgical total or partial resection of the tumor to remove the source of spinal cord compression. Depending on the extent of the tumor, a spinal fusion may be necessary. Experts in palliative care can provide interventions to relieve pain. Rarely, a cordotomy or a palliative sectioning of sensory roots is done to control intractable pain.

After surgery, assess the patient's vital signs and neurologic status every 1 to 2 hours until they are stable and then every 4 hours. Help turn the patient as a unit (log roll) and reposition every 2 hours. Inspect the incision site for drainage, especially for cerebrospinal fluid (CSF), and signs of infection. Carefully monitor the patient with a cervical cord tumor for respiratory compromise. Postoperative nursing care for a patient undergoing a laminectomy is discussed on pp. 888-889 in the Back Pain section of this chapter.

Radiation therapy may be necessary, depending on the tumor type. It is usually used with low-grade malignant tumors that are not completely removed, with metastatic tumors, or with recurrent tumors when there is no other treatment option. The spinal cord cannot tolerate high doses of radiation. Overexposure to radiation may lead to spinal damage, which can develop as long as 6 to 12 months after therapy. Radiation overdose is manifested by progressive spinal cord degeneration and neurologic deficits. With time, the patient experiences spastic paralysis, loss of sensory perception, and bowel and bladder dysfunction. Death may occur. Care of the patient undergoing radiation therapy is described in detail in Chapter 22.

The use of chemotherapy in the treatment of spinal cord tumors is very limited. The drugs that are given tend to be alkylating agents, which are effective for some CNS tumors because they cross the barrier formed in the CNS by unique capillary characteristics and glial cells similar to the blood-brain barrier in the skull. Chemotherapy may also be used as an adjunctive therapy for tumors that have metastasized to the spinal cord from other primary sites, such as the breast. Meningeal involvement may benefit from intrathecal (spinal) chemotherapy. Chapter 22 describes the general nursing care associated with giving chemotherapy.

Community-Based Care

Collaborate with the patient and his or her family members or significant others to identify and suggest ways to eliminate potential hazards in the home. If needed, make a referral to a home care nurse, social worker, or case manager to assess the need for structural alterations to the home. Alterations may be needed to accommodate ambulatory aids (e.g., a walker) and to help the patient perform ADLs.

Depending on the prognosis, some patients are discharged from the acute care hospital to a rehabilitation setting, where they can learn to function as independently as possible. Chapter 6 describes rehabilitation in detail.

The teaching plan for the patient with a spinal cord tumor depends on his or her level of dysfunction. With decompression of the tumor, the severity of the patient's symptoms often lessens. Deficits that may remain include mobility and sensory perception. Learning mobility skills can enable the patient to negotiate movement on sidewalks, carpeting, and other flooring surfaces. The patient must also be able to negotiate sidewalk curbs independently. The physical or occupational therapist instructs the patient in the correct use of all adaptive equipment. Review the individualized bowel and bladder program with the patient, family member, or other caregiver. Chapter 6 describes these programs and the rehabilitation process in detail.

The interventions related to sexuality are usually focused on education in the acute care setting. The nurse answers questions and corrects any misinformation. Unless the nurse has had specific training or experience in sexual counseling of people with spinal cord tumors or injuries, more detailed questions should be directed to a sexual counselor.

The prognosis for the patient with malignant tumors or metastatic tumors is poor. Determine what the physician and family members have told the patient about diagnosis and prognosis. Encourage the patient to verbalize feelings and fears about prognosis, body image, self-concept, role performance, and self-esteem.

Refer patients and family members to local, state or province, and national organizations for people with spinal cord injuries. These groups often have information and support groups for patients with spinal cord tumors. Refer patients with a malignancy to the American Cancer Society (www.cancer.org). Referral to support groups may also assist families with helping the patient adapt to lifestyle changes. The Canadian Cancer Society (www.cancer.ca) offers similar services.

Multiple Sclerosis

Multiple sclerosis (MS) is a life-long inflammatory disease of unknown etiology that affects the brain and spinal cord. It is one of the leading causes of neurologic disability in young adults. This chronic disease is characterized by periods of remission and **exacerbation** (flare), which is commonly referred to as a *relapsing-remitting course.* Patients progress at different rates and over different lengths of time. However, as the severity and duration of the disease progress, the periods of exacerbation become more frequent. Patients with MS have a normal life expectancy as long as the effects of the disease are treated.

A major concern reported by most patients is how long it takes to establish a diagnosis of MS. Many patients go to several health care providers, are given varying diagnoses and treatment, and/or are told that their symptoms are related to stress and anxiety. Often times, young adults will present with weakness, fatigue, or changes in vision and are diagnosed with exhaustion and advised to get more sleep. The patient and family are often relieved to have a definite diagnosis but may express anger and frustration that it took a long time to start appropriate treatment. Therefore establish open and honest communication with the patient, and allow him or her to share frustrations, anger, and anxiety.

❖ Pathophysiology

Multiple sclerosis is characterized by an inflammatory process causing **demyelination** and axonal injury. Diffuse random or patchy areas of *plaque* in the white matter of the CNS is the definitive finding. Initially, remyelination takes place to some degree, and clinical symptoms decrease. Over time, however, new lesions develop and neuronal injury and atrophy occurs. Myelin is responsible for the electrochemical transmission of impulses between the brain and spinal cord and the rest of the body, and demyelination can result in slowed or stopped impulse transmission. The white fiber tracts that connect the neurons in the brain and spinal cord are generally involved in MS. The areas particularly affected include optic nerves, pyramidal tracts, posterior columns, brainstem nuclei, and the ventricular region of the brain. Eventually, with repeated exacerbations of the disease, damage to the axons becomes permanent.

The four major types of MS include (McCance et al., 2014):

- Relapsing-remitting
- Primary progressive
- Secondary progressive

• Progressive-relapsing

The classic picture of the **relapsing-remitting** type of **MS (RRMS)** occurs in most cases of multiple sclerosis. The course of the disease may be mild or moderate, depending on the degree of disability. Symptoms develop and resolve in a few weeks to months, and the patient returns to baseline. During the relapsing phase, the patient reports loss of function and the continuing development of new symptoms.

Primary progressive MS (PPMS) involves a steady and gradual neurologic deterioration without remission of symptoms. The patient has progressive disability with no acute attacks. Patients with this type of MS tend to be between 40 and 60 years of age at onset of the disease.

Secondary progressive MS (SPMS) begins with a relapsing-remitting course that later becomes steadily progressive. About half of all people with RRMS developed SPMS within 10 years. The current addition of disease-modifying drugs as part of disease management may decrease the development of SPMS.

Progressive-relapsing MS (PRMS) is characterized by frequent relapses with partial recovery but not a return to baseline. This type of MS is seen in only a small percentage of patients. Progressive, cumulative symptoms and deterioration occur over several years.

Etiology

The exact cause of MS remains unknown and is very complex. Research continues on viral, immunologic, genetic, and environmental etiologic factors. Viruses are well recognized as causes of demyelination and inflammation. Therefore it may be possible that a virus or other infectious agent is the triggering factor in MS. Although a number of viruses have been studied, no single virus has been identified as causing MS in genetically predisposed people. The environment may also contribute to the development of MS. The disease is seen more often in the colder climates of the northeastern, Great Lakes, and Pacific northwestern states, as well as in Canada. MS is common in areas inhabited by people of northern European ancestry (National Multiple Sclerosis Society, 2013a).

Genetic/Genomic Considerations

Patient-Centered Care QSEN

Large genome studies of families have helped identify familial patterns of multiple sclerosis (MS). For example, having a first-degree

relative such as a parent or sibling with MS increases a person's risk for developing the disease. Recent research also confirms the association of MS with the interleukin (IL)-7 and IL-2 receptor genes. Other interleukin genes, B-lymphocytes, and B-cells play a role in more progressive forms of the disease (McCance et al., 2014). These data help guide development of targeted drug therapies that may cure or better manage MS.

Incidence and Prevalence

MS usually occurs in people between the ages of 20 and 40 years, but cases may occur in those younger than 15 years and older than 50 years. About 400,000 people in the United States have MS, and women are affected about twice as often as men. The disease affects over 2 million people worldwide. Although MS tends to occur more frequently among whites, it affects people of all races (Frankel & James, 2011).

Patient-Centered Collaborative Care

Assessment

History.

Multiple sclerosis (MS) often looks like other neurologic diseases, which can make the diagnosis difficult and prolonged. As a result, patients often see many health care providers and undergo a variety of diagnostic tests and treatments. Obtaining a thorough history is essential for accurate diagnosis. Ask about a history of vision, mobility, and sensory perception changes, all of which are early indicators of MS. Symptoms are often vague and nonspecific in the early stages of the disease and may disappear for months or years before returning. Ask about the progression of symptoms. Pay particular attention to whether the symptoms are intermittent or are becoming progressively worse. Document the date (month and year) when the patient first noticed the clinical manifestations.

Next, ask about factors that aggravate the symptoms, such as fatigue, stress, overexertion, temperature extremes, or a hot shower or bath. Ask the patient and the family about any personality or behavioral changes that have occurred (e.g., euphoria [very elated mood], poor judgment, attention loss). In addition, determine whether there is a family history of MS or autoimmune disease.

Physical Assessment/Clinical Manifestations.

Multiple sclerosis produces a wide variety of manifestations (Chart 43-

14). Any myelinated fibers of the brain and spinal cord may be affected. To determine a patient's specific manifestations, perform a comprehensive neurologic assessment as described in Chapter 41.

Chart 43-14 Key Features

Multiple Sclerosis

- Muscle weakness and spasticity
- Fatigue
- Intention tremors
- Dysmetria (inability to direct or limit movement)
- Numbness or tingling sensations (paresthesia)
- Hypalgesia (decreased sensitivity to pain)
- Ataxia (decreased motor coordination)
- Dysarthria (slurred speech)
- Dysphagia (difficulty swallowing)
- Diplopia (double vision)
- Nystagmus (involuntary eye movements)
- Scotomas (changes in peripheral vision)
- Decreased visual and hearing acuity
- Tinnitus (ringing in the ears), vertigo (dizziness)
- Bowel and bladder dysfunction
- Alterations in sexual function, such as impotence
- Cognitive changes, such as memory loss, impaired judgment, and decreased ability to solve problems or perform calculations
- Depression

First, assess the patient's ability to move. The patient often reports increased fatigue and stiffness of the extremities, particularly the legs. Fatigue is one of the most disabling manifestations, affecting almost all patients with MS. Unlike fatigue in other patients, MS fatigue is associated with continuous sensitivity to temperature.

Flexor spasms at night may awaken the patient from sleep. Further examination reveals increased or hyperactive deep tendon reflexes, positive Babinski's reflex, and absent abdominal reflexes. Gait may be unsteady because of leg weakness and spasticity due to cerebral motor strip damage.

Significant *cerebellar* findings include **intention tremor** (tremor when performing an activity), **dysmetria** (inability to direct or limit movement), and dysdiadochokinesia (inability to stop one motor impulse and

substitute another). Motor movements are often clumsy. The patient may lose balance easily and may exhibit signs of poor coordination.

During examination of the *cranial nerves* and brainstem function, ask the patient if he or she has or has had episodes of tinnitus (ringing in the ears), vertigo (dizziness), and hearing loss. Assess for facial weakness and dysphagia. Speech problems include dysarthria, such as slurred words resulting from weak muscles of the tongue, lips, cheek, or mouth. Scanning is also a type of dysarthria common in MS. Scanning is an abnormal speech pattern with long pauses between words or syllables.

Typical clinical findings from assessment of the patient's visual acuity, visual fields, and pupils include:

- Blurred vision
- **Diplopia** (double vision)
- Decreased visual acuity
- **Scotomas** (changes in peripheral vision)
- **Nystagmus** (involuntary rapid eye movements)

Sensory findings include hypalgesia (diminished sensitivity to pain), paresthesia, facial pain, and decreased temperature perception. The patient may report numbness, tingling, burning, or crawling sensations. Some patients with RRMS, especially women, report pain (Newland, et al., 2010) (see the Evidence-Based Practice box). Perform a complete pain assessment for all patients with MS as described in Chapter 3.

Evidence-Based Practice QSEN

Are There Differences in Pain Between Women with Multiple Sclerosis and Healthy Women?

Newland, P.K., Riley, M.A., Fearing, A.D., Neath, A.A., & Gibson, D. (2010). Pain in women with relapsing-remitting multiple sclerosis and healthy women: Relationship to demographic variables. *MEDSURG Nursing, 19*(3), 177-182.

The purpose of this descriptive study was to determine if there is a relationship among aspects of pain and demographic variables in women with relapsing-remitting multiple sclerosis (RRMS) and healthy women. The researcher used data from a previous study consisting of 40 women with RRMS and 40 healthy women in the Midwest. Subjects were volunteers from one hospital. They were primarily Caucasian, married, and highly educated.

Findings revealed that pain prevalence was higher in women with RRMS when compared with healthy women. As years of education

increased, prevalence and intensity of pain decreased. Pain also increased significantly in women who did not work. Conversely, for healthy women there was not a significant relationship with years of experience and pain prevalence or intensity.

Level of Evidence: 4

The study was a descriptive study that used a small convenience sample but with comparative groups.

Commentary: Implications for Practice and Research

When caring for patients with MS, especially women, medical-surgical nurses need to assess for the presence and intensity of their pain. When providing health teaching, patients may have special learning needs due to possible cognitive impairment. In addition, if possible, women should be encouraged to work or stay active to prevent increased pain.

This research used only Caucasian women in the study. Therefore the findings cannot be generalized to men or to any other racial or ethnic group. The research needs to be duplicated using male patients with MS and/or using a larger sample size of both men and women to compare with healthy men and women of mixed racial/ethnic origin.

If demyelination of the *spinal cord* has occurred, the patient may experience bowel and bladder dysfunctions. The patient may have an areflexic bladder or may experience frequency, urgency, or nocturia. Ask the patient if he or she has constipation or incontinence. Inquire about problems with sexuality, including impotence, difficulty sustaining an erection, and decreased vaginal secretions.

Psychosocial Assessment.

Assess the patient for mental status changes. Cognitive changes are usually seen late in the course of the disease and include decreased short-term memory, concentration, and ability to perform calculations; inattentiveness; and impaired judgment.

After the initial diagnosis of MS, the patient is often anxious. Apathy and emotional lability are common problems that occur later. Depression may occur at the time of diagnosis and can also occur later with disease progression. The patient may be euphoric or giddy, either as a result of the disease itself or because of the drugs used to treat the disease. Assess the patient's previously used coping and stress-management skills in preparing him or her for a chronic, usually debilitating disease. Secondary depression is the most frequent mental health disorder

diagnosed in people with MS.

Assess the impact of bowel and bladder problems. Managing fecal incontinence or constipation can be time-consuming and embarrassing. The authors of a single site study found that elimination problems affected quality of life as much as mobility difficulties (Norton & Chelvanayagam, 2010).

Sexuality can be affected in people with multiple sclerosis, and sexual dysfunction can have a major impact on quality of life. Assess the patient's fatigue level and pattern, since fatigue contributes to sexual dysfunction. Be sensitive when asking about the patient's sexual practices and orientation. Women report impaired genital sensation, diminished orgasm, and loss of sexual interest. Men most often report difficulty in achieving and maintaining an erection and delayed ejaculation. If able, answer the patient's questions, or refer the patient to a counselor or urologist with experience in the field of sexuality, intimacy, and disability.

MS affects the entire family due to the unpredictability and uncertainty of the course of the disease. Chronic fatigue and pain may also prevent the patient from participating in family and community activities. CNS stimulants such as amantadine (Symmetrel), aerobic exercise as tolerated, and energy-conservation strategies may help manage fatigue. Assess coping strategies of family members or other caregivers, and help them identify support systems that can assist them as they live with the patient with MS.

Laboratory Assessment.

No single specific laboratory test is definitively diagnostic for MS. However, the collective results of a variety of tests are usually conclusive. Abnormal cerebrospinal fluid (CSF) findings include an elevated protein level and a slight increase in the white blood cell count. CSF electrophoresis reveals an increase in the myelin basic protein and the presence of increased immunoglobulins, especially immunoglobulin G (IgG). IgG bands are seen in most patients with MS.

Other Diagnostic Assessment.

MRI of the brain and spinal cord demonstrates the presence of plaques and is considered diagnostic for MS. MRI with contrast shows active plaques and reveals older lesions not associated with current symptoms.

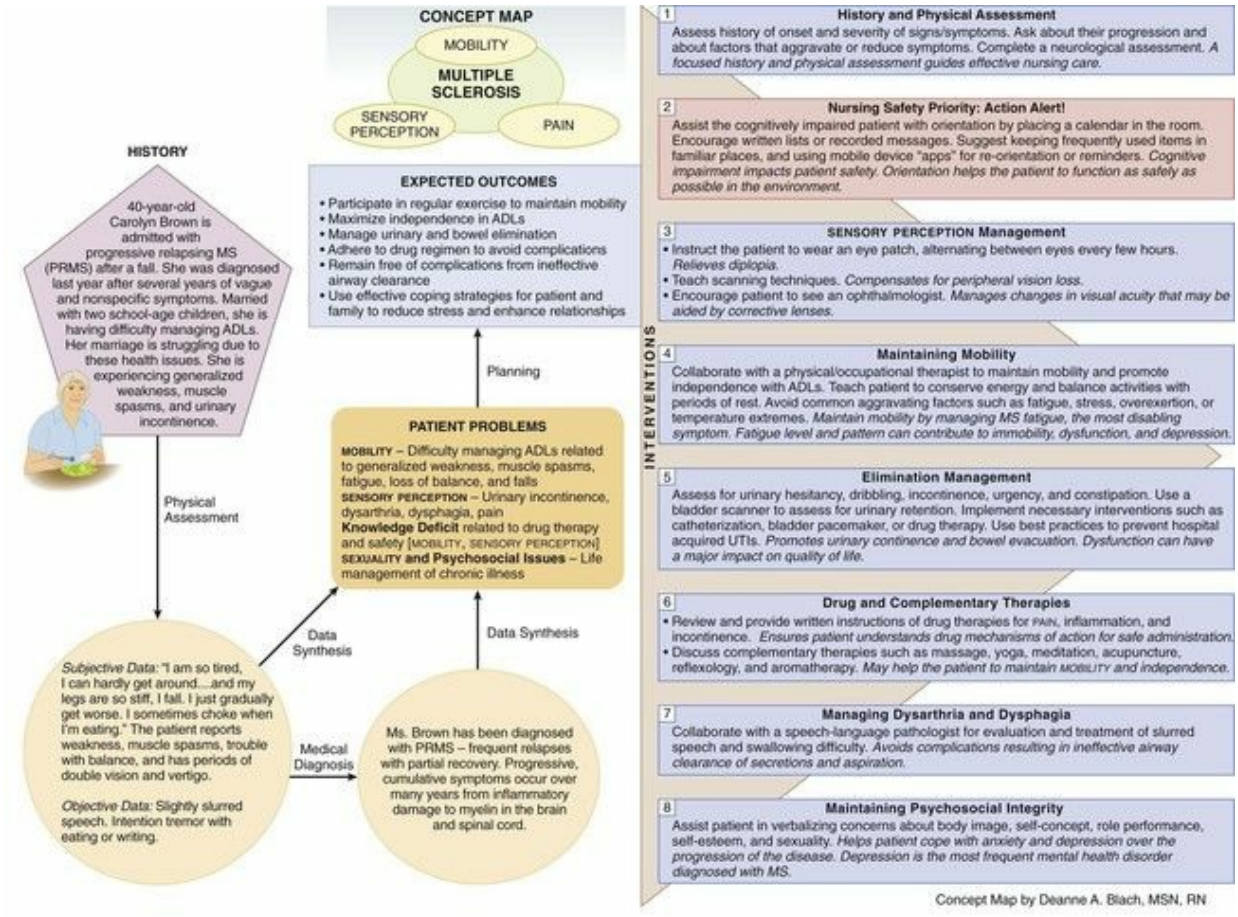
A complete history and physical examination is necessary to exclude other disease diagnoses. In general, assessment of cranial nerve function, coordination, strength, reflexes, and sensation are needed to diagnose MS, and a variety of neurologic tests are used to evaluate the many areas

in which dysfunction from MS plaques can occur. Results of visual, auditory, and brainstem evoked potential studies are often abnormal. Electromyography (EMG) findings may be grossly abnormal in people with advanced disease.

Interventions

The purpose of management is to modify the disease's effects on the immune system, prevent exacerbations, manage symptoms, and improve function. As with other spinal cord diseases, care of the patient with MS requires the collaborative efforts of the interdisciplinary team.

The patient with MS is often weak and easily fatigued. The Concept Map on p. 907 illustrates the priority problems and interventions for the patient with MS. Teach the patient the importance of planning activities and allowing sufficient time to complete activities. For example, the patient should check that all items needed for work are gathered before leaving the house. Items used on a daily basis should be easily accessible.



Drug Therapy.

Current therapies are based on emerging evidence that MS is an autoimmune disorder. A variety of drugs are used to treat and control the disease, decrease specific symptoms, and attempt to slow its progression.

One or more of these drugs is recommended for treatment of relapsing types of MS:

- Interferon-beta-1a (Avonex or Rebif)—immunomodulators that *modify* the course of the disease and have antiviral effects
- Interferon-beta-1b (Betaseron, Extavia)—another immunomodulator with antiviral properties
- Glatiramer acetate (Copaxone)—a synthetic protein that is similar to myelin-based protein
- Mitoxantrone (Novantrone)—an antineoplastic agent and anti-inflammatory used to resolve relapses but with risks for leukemia and cardiotoxicity
- Natalizumab (Tysabri)—the first monoclonal antibody approved for MS that binds to WBCs to prevent further damage to the myelin
- Fingolimod (Gilenya), teriflunomide (Aubagio), or dimethyl fumarate (Tecfidera)—newer oral immunomodulating drugs
- Mitoxantrone (Novantrone) for patients with worsening disease or increased frequency of relapses
- Corticosteroid (methylprednisolone [Solu-Medrol], dexamethasone, or prednisone) for acute exacerbation or onset
- Other immunosuppressants (e.g., cyclophosphamide, methotrexate, azathioprine, cladribine, and cyclosporine) can reduce symptoms of MS and suppress the number of circulating immune cells to slow the autoimmune process and neuronal damage

The interferons and glatiramer acetate are subcutaneous injections that patients can self-administer.

Nursing Safety Priority QSEN

Drug Alert

Teach patients how to give and rotate the site of interferon-beta and glatiramer acetate injections because local injection site (skin) reactions are common. The first dose of these drugs is given under medical supervision to monitor for allergic response, including anaphylactic shock. Teach patients receiving these drugs to avoid crowds and people with infections. Remind them to report any sign or symptom associated with infection immediately to their health care provider.

Natalizumab, a humanized monoclonal antibody, is a controversial drug because it can cause many adverse events. It is given as an IV infusion in an infusion clinic under careful supervision. The patient is monitored carefully for allergic or anaphylactic reaction when each dose is given because the drug tends to build up in the body. *Patients receiving this drug are at a high risk for* **progressive multifocal leukoencephalopathy (PML).** This opportunistic viral infection leads to death or severe disability. Monitor for neurologic changes, especially changes in mental state, such as disorientation or acute confusion. PML is confirmed by an MRI and examining the cerebrospinal fluid for the causative pathogen. Natalizumab also causes damage to hepatic cells. Carefully monitor liver enzymes and teach patients to have frequent laboratory tests to assess for changes.

Mitoxantrone (Novantrone), a chemotherapy drug, has been shown to be effective in reducing neurologic disability. It also decreases the frequency of clinical relapses in patients with secondary progressive, progressive-relapsing, or worsening relapsing-remitting MS.

Fingolimod (Gilenya) was the first oral immunomodulator approved for the management of MS. The capsules may be taken with or without food. Teach patients to monitor their pulse every day because the drug can cause bradycardia, especially within the first 6 hours after taking it (Duddy et al., 2011). Two newer oral immunomodulating drugs have been approved for MS—teriflunomide (Aubagio) and dimethyl fumarate (Tecfidera). Like fingolimod, these drugs inhibit immune cells and have antioxidant properties that protect brain and spinal cord cells. Teach the patient that the two most common side effects of all the oral drugs are facial flushing and GI disturbances (Lilley et al., 2014). Remind the patient to keep follow-up appointments for laboratory monitoring of the white blood cell (WBC) count because the oral drugs can cause a decrease in WBCs, which can predispose the patient to infection.

Another oral drug, dalfampridine (also known as fampridine) (Ampyra), was approved several years ago to improve walking ability in patients with MS. However, half of patients taking the drug have experienced seizures. The FDA has issued a warning to limit patients who are eligible to take the drug. For example, patients older than 50 years, those with renal impairment, and those with a history of seizures should not take dalfampridine. For these reasons, the drug is not widely prescribed.

Immunosuppressive therapy with a combination of cyclophosphamide (Cytoxan) and methylprednisolone (Solu-Medrol) may be used for some patients to stabilize the disease process and decrease inflammation. IV

adrenocorticotropic hormone (ACTH) may be given instead of methylprednisolone and tapered gradually over 2 to 4 weeks.

Promoting Mobility and Managing Symptoms.

The symptoms of MS include spasticity, tremor, worsening of symptoms triggered by increased body temperature (i.e., Uhthoff phenomenon), pain, cognitive impairment, dysphagia, dysarthria, bladder and bowel dysfunction, oculomotor symptoms (e.g. diplopia, nystagmus), sexual dysfunction, and fatigue. Referral to rehabilitative services can help manage functional deficits from MS symptoms. A multidisciplinary approach is important to provide pharmacotherapy, physiotherapy, and psychotherapy as well as attain patient-centered goals for care.

For spasticity, the health care provider may prescribe baclofen (Lioresal), tizanidine (Zanaflex), diazepam (Valium, Apo-Diazepam), or dantrolene sodium (Dantrium) to lessen muscle spasticity. Dalfampridine (Ampyra), a potassium channel blocker, is a new oral drug that can be prescribed to improve walking ability and speed. Dalfampridine is not given to patients with a history of seizures or renal disease.

Severe muscle spasticity may be treated with intrathecal baclofen (ITB) administered through a surgically implanted pump. Paresthesia may be treated with carbamazepine (Tegretol) or tricyclic antidepressants. Propranolol hydrochloride (Inderal) and clonazepam (Klonopin) have been used to treat cerebellar ataxia. If fatigue cannot be controlled through the use of nonpharmacologic measures, amantadine hydrochloride (Symmetrel) may be prescribed.

In collaboration with physical and occupational therapists, plan an exercise program that includes range-of-motion (ROM) exercises and stretching and strengthening exercises to manage spasticity and tremor. Beta-blockers (e.g., propranolol [Inderal]) and neurosurgery (e.g., thalamotomy or deep brain stimulation) can provide some relief from tremors.

Emphasize the importance of avoiding rigorous activities that increase body temperature. Increased body temperature may lead to increased fatigue, diminished motor ability, and decreased visual acuity resulting from changes in the conduction abilities of the injured axons.

Pain and paresthesia are often problems for the MS patient. Antispasmodics, antiepileptic drugs (AEDs), analgesics, NSAIDs, tranquilizers, or antidepressants may be used, depending on the cause of the pain and the patient's response. Teach patients about side and adverse effects for drugs that they may need to help increase their quality

of life.

Cognitive impairment may occur early in the disease process. Many patients have some degree of neuropsychological dysfunction during the course of their disease. Areas affected include attention, memory, problem solving, auditory reasoning, handling distractions, visual perception, and use of speech.

Nursing Safety Priority QSEN

Action Alert

For the patient with MS who has cognitive impairment, assist with orientation by placing a single-date calendar in his or her room. Give or encourage the patient to use written lists or recorded messages. To maintain an organized environment, encourage him or her to keep frequently used items in familiar places. Applications for handheld devices like mobile phones and electronic tablets can also be used for re-orientation, reminders, and behavioral cues.

If the patient experiences dysarthria (slurred speech), refer him or her to the speech-language pathologist (SLP) for evaluation and treatment. It is not unusual for the patient with dysarthria also to have dysphagia (difficulty swallowing). The SLP performs a swallowing evaluation, but further diagnostic testing may be indicated.

The patient may experience a variety of bladder problems. Bladder dysfunction (detrusor hyperreflexia) may be treated with anticholinergic agents. Other measures include an intermittent self-catheterization program, indwelling urinary catheter, or insertion of a bladder pacemaker. When the patient activates the control on the pacemaker, the bladder is stimulated and voiding is initiated. Patients with MS are at increased risk for urinary tract infections. Prophylactic antibiotics may be prescribed by the health care provider. Remind the patient to drink plenty of fluids unless contraindicated by other medical conditions.

Bowel symptoms can include constipation that can be treated with increased physical activity, adequate fluid intake of 1.5 to 2 liters daily, and increased dietary fiber to 25 to 35 g daily. Osmotic agents such as magnesium oxide may be used. Prokinetic agents such as lubiprostone may be used to increase motility. Enemas or suppositories may also be used.

An eye patch that is alternated from eye to eye every few hours usually relieves **diplopia** (double vision). For peripheral visual deficits, teach

scanning techniques by having the patient move his or her head from side to side. Changes in visual acuity may be assisted by corrective lenses.

Sexual dysfunction may benefit from counseling. Prostaglandin-5 inhibitors (sildenafil, vardenafil, tadalafil) can be used to help men with erectile dysfunction. Penile prostheses are also used for men. The EROS Clitoral Therapy Device is a FDA-approved therapy for women with impaired sexual response.

Patients with MS who experience fatigue may limit their professional and social interactions. Depression can be manifested by fatigue, so screen for both of these symptoms. There are no licensed therapies for MS-related fatigue. Physiotherapy and occupational therapy can help reduce effort and fatigue. Depression can be managed with cognitive therapy and antidepressant drugs.

Complementary and Alternative Therapies.

Patients with MS have reported a number of complementary and alternative medicine (CAM) therapies that have been successful in decreasing their symptoms. Consultation with a health care provider certified in palliative care may also provide strategies for effective symptom management. Some of the CAM therapies used by patients with MS are:

- Reflexology
- Massage
- Yoga
- Relaxation and meditation
- Acupuncture
- Aromatherapy

Marijuana has been used by some patients to relieve the pain of muscle spasms and is now legal for medical use in over 20 U.S. states and in Canada.

Community-Based Care

Home Care Management.

To help the patient maintain maximum strength, function, and independence, continuity of care by an interdisciplinary team in both the rehabilitation and home setting is necessary. Admission to a rehabilitation center is brief but provides a program to improve functional ability. In collaboration with the case manager and occupational therapist, assess the patient's home before discharge for

any hazards. Any items that might interfere with mobility (e.g., scatter rugs) are removed. In addition, care must be taken to prevent injury resulting from vision problems. Teach the patient and family to keep the home environment as structured and as free from clutter as possible. As the disease progresses, the home may need to be adapted for wheelchair accessibility. Adaptation in the kitchen, bedroom, and bathroom may also be needed to promote self-management. Any necessary assistive/adaptive device should be readily available before discharge from the hospital.

Self-Management Education and Health Care Resources.

The health care provider explains to the patient and family the development of MS and the factors that may exacerbate the symptoms. Emphasize the importance of avoiding overexertion, stress, extremes of temperatures (fever, hot baths, use of sauna baths and hot tubs, overheating, and excessive chilling), humidity, and people with infections. Explain all medications to be taken on discharge, including the time and route of administration, dosage, purpose, and side effects. Teach the patient how to differentiate expected side effects from adverse or allergic reactions, and provide the name of a resource person to call if questions or problems occur. Provide written instructions as a resource for the patient and caregivers at home.

The physical therapist develops an exercise program appropriate for the patient's tolerance level at home. The patient is instructed in techniques for self-care, daily living skills, and the use of required adaptive equipment, such as walkers and electric carts. Include information related to bowel and bladder management, skin care, nutrition, and positioning techniques. Chapter 6 describes in detail these aspects of chronic illness and rehabilitation.

Teach patients about conservation strategies that balance periods of rest and activity, including regular social interactions. Remind them to use assistive devices and modify the environment to avoid fatigue. Explore strategies to manage stress and avoid undue stress. Often patients are anxious and worry about how long the remission will last or when the disease will progress.

Because personality changes are not unusual, teach the family or significant others strategies to enable them to cope with these changes. For example, the family may develop a nonverbal signal to alert the patient to potentially inappropriate behavior. This action avoids embarrassment for the patient.

Resources required by the patient depend on the course of the disease

and the complications that occur. Patients often are able to live completely independently, but they may need some assistance. In severe disease, placement in an assisted-living or long-term care facility may be the best alternative. The population of young and middle-aged residents in these settings is increasing as people with chronic, disabling diseases live longer. Refer the patient and family members or significant others to the local chapter of the National Multiple Sclerosis Society (www.nationalmssociety.org). Other community resources include meal delivery services (e.g., Meals on Wheels), transportation services for the disabled, and homemaker services.

Amyotrophic Lateral Sclerosis

Pathophysiology

Amyotrophic lateral sclerosis (ALS), also known as **Lou Gehrig's disease,** is an upper and lower motor neuron disease of adult onset. It is characterized by progressive weakness, muscle wasting, and spasticity that eventually lead to paralysis. Beginning in one area of the body, motor weakness and deterioration spread until the entire body is involved, including the ability to talk, swallow, and breathe. As a result of loss of lower motor neurons (LMNs) found in the spinal cord and brainstem, the muscles to which they connect weaken, atrophy, and die.

Loss or death of upper neurons (found in the brain) breaks their connections with LMNs, and spasticity occurs in the muscles. Death typically occurs within 3 years of diagnosis due to respiratory failure (McCance et al., 2014). There is no known cause, no cure, no specific treatment, no standard pattern of progression, and no method of prevention. Unlike with many other neural degenerative diseases, the sensory and autonomic nervous systems are not involved. Cognitive and behavioral dysfunction may occur, although the exact cause and extent of this has not been established.

Amyotrophic lateral sclerosis commonly affects people between the ages of 40 and 60 years, but it may also begin in younger and older age-groups. The incidence increases with each decade of life. ALS affects about 5 of every 100,000 people worldwide and is more common in men than in women. The cause of the disease is unknown but is likely due to multiple genetic and cell biologic hits and interactions of genetic, viral, and environmental factors (Ludolph et al., 2012).

Patient-Centered Collaborative Care

Assessment

The clinical manifestations of ALS include fatigue, muscle atrophy, and weakness. Early symptoms are listed in Chart 43-15.

Chart 43-15 Key Features

Early Clinical Manifestations of Amyotrophic Lateral Sclerosis

- Tongue atrophy
- Weakness of the hands and arms
- Beginning muscle atrophy of the arms

- **Fasciculations** (twitching) of the face or tongue
- Difficulty controlling crying or laughing (emotional incontinence)
- Nasal quality of speech
- **Dysarthria** (slurred speech)
- **Dysphagia** (difficulty swallowing)
- Fatigue while talking
- Stiff or clumsy gait
- Abnormal reflexes

In addition to motor changes, cognitive changes may affect the thinking and planning processes. As the disease progresses, muscle atrophy, particularly of the trapezius and sternocleidomastoid muscles, develops. Eventually the respiratory muscles become involved, leading to respiratory compromise, pneumonia, and death.

Diagnosis is based on clinical and diagnostic test findings and by ruling out other causes of the motor changes. There is no specific test to diagnose ALS, but creatine kinase (CK) is increased. The electromyogram (EMG) demonstrates fibrillations and fasciculations of the muscles. The use of ultrasound to visualize fasciculation particularly in deep muscles can lead to earlier diagnosis (de Carvalho & Swash, 2011). A muscle biopsy specimen typically demonstrates small, angulated, atrophic fibers. Other diagnostic studies reveal motor strength deficits in serial muscle testing; abnormal pulmonary function test results, such as a decreased vital capacity (<2 L); and dysphagia (difficulty swallowing).

Interventions

There is no known cure for ALS, but an interdisciplinary approach is needed for maintaining optimum functioning and end-of-life care. Interdisciplinary care can prolong survival and enhance quality of life in this population (Miller et al., 2009).

Riluzole (Rilutek) is the only drug approved by the Food and Drug Administration for use with ALS patients (Miller et al., 2012). It is not a cure, but it does extend survival time. Remind patients to take the drug when the stomach is empty. Teach the patient how to detect signs and symptoms of liver toxicity, such as vomiting and jaundice, that the drug may cause. Instruct them to have frequent liver enzyme tests, such as alanine aminotransferase (ALT) and aspartate aminotransferase (AST), as directed by the health care provider.

The health care provider also prescribes drug therapy for pain, fatigue, spasticity, excessive secretions, sleep disturbances, and other complications as they occur (Andersen et al., 2012). The interdisciplinary

health care team collaborates with the patient and family to develop an individualized plan of care and palliation of symptoms. The physical therapist and occupational therapist evaluate the patient's home and recommend modifications as the disease progresses. An exercise program is developed, and special equipment is obtained as needed to help with ADLs and mobility. Other interventions are directed toward preventing complications of immobility and promoting comfort.

The speech-language pathologist (SLP) evaluates the patient for speech and swallowing problems and makes recommendations as needed. The SLP teaches patients various adaptive strategies, such as techniques to help them speak louder and more clearly. He or she works with the patient and family to develop a communication system to be used when the patient can no longer verbally communicate.

A nutrition consult may be needed to help with planning meals that the patient can swallow when dysphagia occurs. The family is taught how to ensure that the patient obtains sufficient nutrients, fiber, and fluids. When the patient can no longer swallow, a feeding tube may be placed, depending on the patient's decision or advance directives. The dietitian can recommend the appropriate enteral feedings.

For symptomatic treatment of dyspnea and/or intractable pain, opioids alone or in combination with benzodiazepines if anxiety is present may be prescribed. Titrating the dose against the clinical symptoms is less likely to cause life-threatening respiratory depression. For palliation of terminal restlessness and confusion because of hypercapnia, neuroleptics may be used (e.g., chlorpromazine [Thorazine, Chlorpromanyl] 12.5 mg orally, IV, or rectally every 4 to 12 hours).

As the patient's condition worsens, he or she will require respiratory support. Intermittent positive-pressure ventilation (IPPV) or bi-level positive airway pressure (BiPAP) may be used to aid breathing during sleep or full time. Some patients may be a candidate for diaphragmatic pacing (Scherer & Bedlack, 2012). **Diaphragmatic pacing**, also known as *phrenic nerve pacing*, is a pacemaker-like application of electrical impulses to the diaphragm, resulting in inhalation. Another option is invasive mechanical ventilation. None of these options prolong life. For this reason, many patients elect not to be placed on a mechanical ventilator, according to their wishes or advance directives. Teach the patient about the need for advance directives, such as a living will. Chapter 7 discusses end-of-life issues and hospice services in detail.

Nursing Safety Priority QSEN

Action Alert

Refer the patient with amyotrophic lateral sclerosis to palliative care for symptom management. The palliative team collaborates with the health care provider to ensure that the patient has effective interventions to manage pain, fatigue, and dyspnea. Focusing care on symptom management is not restricted to patients who are at the end of life and can significantly improve quality of life in complexly ill patients and their family caregivers.

Other community resources include clinics and other support services run by the ALS Association (www.alsa.org) or the Muscular Dystrophy Association (www.mda.org).

Nursing Concepts and Clinical Judgment Review

What might you NOTICE if the patient is experiencing impaired mobility and sensory perception as a result of spinal cord health problems?

- Weakness or paralysis of one or more extremities
- Report of decreased sensation in one or more extremities
- Muscle spasticity or flaccidity
- Forward bent position when ambulating
- Limp or altered gait
- Bladder incontinence or retention
- Bowel incontinence or retention
- Report of pain at or above the site of injury along the spinal column and/or in one or more extremities
- Difficulty breathing

What should you INTERPRET and how should you RESPOND to a patient experiencing inadequate mobility and sensory perception as a result of spinal cord health problems?

Perform and interpret physical assessment, including:

- Assessing airway patency and breathing pattern
- Assessing use of accessory muscles, pattern of respiratory effort, and rate and depth of breathing
- Assessing level of consciousness
- Taking vital signs
- Performing a complete physical assessment
- Performing a complete neurologic assessment

Respond by:

- Establishing an airway as needed
- Stabilizing the spine by positioning until surgery or other treatment is provided
- Preparing for imaging assessment tests
- Inserting an indwelling urinary catheter
- Collaborating with the health care team, especially the physical therapist and the occupational therapist, if needed

On what should you REFLECT?

- Monitor the patient for changes in condition, including deterioration of neurologic status.
- Consider how to best collaborate with the health care team when caring for patients with spinal cord injury or illness.
- Think about family reaction to the injury or illness and what additional resources could have been used or should be used in the future.

Get Ready for the NCLEX® Examination!

Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Use safe object and patient handling practices to prevent back injury as described in Chart 43-5. **Safety** QSEN
- Assess airway and breathing *first* for patients with an acute SCI. **Evidence-Based Practice** QSEN
- Integrate team meetings into care of patients with long-term or degenerating spinal cord conditions.
- Identify patient and family values and preferences as the foundation for regular communication and collaboration with health care team members, including the physician, physiatrist, advanced practice provider, physical therapist, occupational therapist, sexual counselor, registered dietitian, respiratory therapist, and case manager. **Teamwork and Collaboration** QSEN
- Ask the patient about advance directives and palliative care/symptom management to promote patient-centered care. **Patient-Centered Care** QSEN

Health Promotion and Maintenance

- Use community resources and behavioral strategies to assist overweight and obese patients in losing weight to reduce back pain and strain.
- Collaborate with physical and occupation therapy to promote self-management, including the provision of adaptive/assistive devices for independence in ADLs. **Teamwork and Collaboration** QSEN
- Include community resources in discharge planning and teaching for patients with SCI, MS, ALS, and cancer that involves the spine or vertebrae. There are specialty organizations for each of these spinal conditions.

Psychosocial Integrity

- Refer patients to appropriate resources, such as a sexual counselor or urologist, for sexual dysfunction resulting from illness or disease. Counsel them as needed about sexuality. **Teamwork and Collaboration** QSEN
- Recognize that spinal cord injury and progressive neurologic diseases,

such as MS, require the patient and family to make major adjustments to roles and goals. **Patient-Centered Care** QSEN
- Include the family in planning for rehabilitation and discharge when spinal disorders occur or worsen.
- Determine patient and family coping strategies to help patients adjust to spinal trauma or disease. **Patient-Centered Care** QSEN

Physiological Integrity

- Assess pain level in patients with back injury, including the nature of the pain and location.
- Provide complete neurologic assessment of patients with spinal cord health problems, with ongoing focused motor assessment as described in Chart 43-8.
- Implement effective drug and non-drug interventions for back pain, including analgesics, NSAIDs, and adjunctives such as heat and exercise.
- Implement interventions to prevent complications associated with immobility, including turning; VTE prophylaxis; early ambulation or transfers out of bed; and airway and breathing management such as bedside suctioning equipment, incentive spirometry, and Aspiration Precautions. **Safety** QSEN
- Monitor patients with cervical spinal injuries for manifestations of autonomic dysreflexia (see Chart 43-10). Provide a bowel and bladder regimen to prevent retention of stool and urine because these common problems can initiate autonomic dysreflexia. **Evidence-Based Practice** QSEN
- Provide emergency care for patients who experience autonomic dysreflexia as listed in Chart 43-11. **Safety** QSEN
- Explain that the pathophysiology of MS is a demyelination syndrome of the brain and spinal neurons.
- Explain the pathophysiology of ALS is unknown. Neurons that conduct nerve impulses from the spinal or brain to muscles degenerate. Without motor neuron input, the muscles atrophy and the patient becomes weak and then paralyzed.
- Monitor respiratory status carefully in patients with ALS. Patients experience respiratory failure as the disease progresses. **Safety** QSEN
- Assess patients with multiple sclerosis for clinical manifestations as listed in Chart 43-14. Fatigue is the most common symptom.
- For patients who have surgery to manage vertebral or spinal cord conditions, observe the incision site for bleeding and cerebrospinal

fluid leakage (clear fluid).
- Log roll during repositioning, especially during acute spinal cord injury or following surgical fusion of vertebrae.
- Provide postoperative care and discharge teaching for patients having cervical neck surgery as listed in Chart 43-6.

CHAPTER 44

Care of Patients with Problems of the Peripheral Nervous System

Rachel L. Gallagher

PRIORITY CONCEPTS

- Mobility
- Sensory Perception
- Pain
- Inflammation
- Gas Exchange

Learning Outcomes

Safe and Effective Care Environment

1. Collaborate with interdisciplinary health care team members when providing care for patients with Guillain-Barré syndrome (GBS) and myasthenia gravis (MG) to avoid pain or complications from reduced sensory perception.

Health Promotion and Maintenance

2. Provide information to patients and families on common side effects and administration of drugs for peripheral nervous system (PNS) disorders to ensure safety.
3. Identify community resources for PNS disorders for patients and families.

Psychosocial Integrity

4. Plan interventions for patients with GBS and MG for promoting communication based on patient preferences.

Physiological Integrity

5. Describe how to perform focused neurologic assessments for patients with PNS disorders.
6. Compare and contrast the pathophysiology of GBS and MG, including the roles of inflammation and autoimmunity.
7. Prioritize evidence-based nursing interventions for the patient with GBS or MG to maintain mobility, reduce pain, and promote gas exchange.
8. Differentiate between a myasthenic crisis and a cholinergic crisis. Assess patients having a thymectomy for postoperative complications.
9. Plan and implement evidence-based postoperative care for the patient undergoing peripheral nerve repair.
10. Compare trigeminal neuralgia and facial paralysis assessment findings.

http://evolve.elsevier.com/Iggy/

There are over 100 peripheral nerve disorders. Although only a few require treatment in an acute care setting, many peripheral nerve disorders are present in patients admitted with an unrelated diagnosis. For example, neuropathies caused by systemic diseases like diabetes, chronic kidney disease, or cancers are common and interfere with mobility, alter sensory perception, and cause pain. Generally, peripheral nervous system disorders have symptoms that start gradually and then get worse. Often symptoms include:

- Pain, burning, or tingling
- Muscle weakness
- Either increased or reduced sensitivity to touch

The peripheral nervous system (PNS) is composed of the spinal nerves, cranial nerves, and part of the autonomic nervous system. Its function is to provide communication from the brain and spinal cord to other parts of the body. *Neuropathy* or *peripheral neuropathy (PN)* is a global word that refers to any disease, disorder, or damage to the PNS. These health problems may be acute, such as Guillain-Barré syndrome (GBS), or chronic, such as myasthenia gravis (MG). Secondary PN may result from disorders such as peripheral vascular disease and diabetes mellitus. These health problems are discussed elsewhere in this text.

Guillain-Barré Syndrome

Pathophysiology

Guillain-Barré syndrome (GBS) is an acute inflammatory polyradiculoneuropathy that affects the axons and/or myelin of the peripheral nervous system, causing motor weakness and abnormalities in sensory perception. It is an uncommon disorder, affecting males slightly more than females and peaking after age 55 years (Sejvar et al., 2011).

GBS may be referred to by a variety of other names, such as *acute idiopathic polyneuritis, acute inflammatory demyelinating polyneuropathy (AIDP), acute motor axonal neuropathy (AMAN),* and *acute motor and sensory axonal neuropathy* (Arcila-Londono & Lewis, 2012). In some forms of GBS, primarily the axons are affected. In other forms, **demyelination** (destruction of the myelin sheath) of the peripheral nerves occurs. Symptoms are the same: progressive motor weakness and abnormal sensory perception. In demyelinating GBS, symptoms typically begin in the legs and spread to the arms and upper body. This is referred to as an *ascending paralysis.* Paralysis can increase in intensity until the muscles cannot be used at all and the patient is almost totally immobile. As a result, some patients require mechanical ventilation because of a weak or paralyzed diaphragm and accessory muscles for respiration. Healing occurs in reverse; the neurons affected last are the first to recover.

GBS is the result of immune-mediated pathology. Antibodies attack the myelin sheath that surrounds the axons of the peripheral nerves. On microscopic examination, groups of lymphocytes are seen at the points of myelin breakdown. In some instances, secondary damage to the cell body, the neurilemma, or the axon occurs. Neurilemma and axonal injury can delay recovery or result in permanent neurologic defects. Segmental demyelination (the destruction of myelin between the nodes of Ranvier) is the major pathologic finding in most variants of GBS. This destruction slows the transmission of impulses from node to node. Damaged motor neurons result in weakness. Damaged sensory nerves send fewer messages to the brain, affecting the patient's sensory perception.

Three stages make up the *acute* course of GBS:

- The *acute or initial period* (1 to 4 weeks), which begins with the onset of the first symptoms and ends when no further deterioration occurs
- The *plateau period* (several days to 2 weeks)
- The *recovery phase* (gradually over 4 to 6 months, maybe up to 2 years), which is thought to coincide with remyelination and axonal regeneration (Some patients do not completely recover and have

permanent neurologic deficits, referred to as *chronic GBS*.)

GBS is associated with bacterial infection, especially infection with *Campylobacter jejuni*. Influenza, Epstein-Barr, and cytomegalovirus viral infections have also been associated with GBS. There are other anecdotal and case reports from patients with surgery, trauma, and pregnancy who also developed GBS, but numbers are not sufficient to establish a causal relationship. There are also reports of some vaccines increasing the risk for GBS slightly, but epidemiologic evidence is weak (Centers for Disease Control and Prevention [CDC], 2014). It is believed that the precipitating infection or event sensitizes the T-cells to the patient's myelin, resulting in production of a demyelinating autoantibody.

Patient-Centered Collaborative Care

Assessment

Obtain a complete health history. Ask the patient to describe GBS symptoms in chronologic order, if possible. Inquire about the presence of pain, numbness, and **paresthesias** (unpleasant sensations such as burning, stinging, and prickly feeling).

Although features vary, most people report a sudden onset of muscle weakness (Chart 44-1). The common symptoms of GBS are loss of reflexes in the arms and legs; low blood pressure or poor blood pressure control; muscle weakness or paralysis; numbness; uncoordinated movement, clumsiness, and falls; blurred or double vision; difficulty moving facial muscles; and palpitations (Simmons, 2010). Typically, the disease does not affect level of consciousness, cognition, or pupillary constriction or dilation. The clinical variations of GBS reflect the areas of earliest or most severe involvement (Arcila-Londono & Lewis, 2012).

Chart 44-1 Key Features

Guillain-Barré Syndrome

Motor Manifestations
• Ascending symmetric muscle weakness → flaccid paralysis without muscle atrophy • Decreased or absent deep tendon reflexes (DTRs) • Respiratory compromise (dyspnea, diminished breath sounds, decreased tidal volume, reduced peripheral oxygenation [Sp_{O_2}] and vital capacity) and respiratory failure • Loss of bowel and bladder control (less common) • Ataxia
Sensory Manifestations
• Paresthesias • Pain (cramping)
Cranial Nerve Manifestations
• Facial weakness • Dysphagia • Diplopia • Difficulty speaking
Autonomic Manifestations
• Labile blood pressure • Cardiac dysrhythmias • Tachycardia

With any of the variants, *cranial nerve* involvement most often affects the facial nerve (cranial nerve [CN] VII). Assess the patient's ability to smile, frown, whistle, or drink from a straw. Assess the patient for dysphagia (difficulty swallowing), which involves CNs V, VII, X, XI, and XII. The patient's inability to cough, gag, or swallow results from the involvement of CNs IX and X. Monitor the patient closely for varying blood pressure (hypertensive and hypotensive episodes or orthostatic hypotension), bradycardia, heart block, and, possibly, asystole. These symptoms are part of *autonomic dysfunction,* which is linked to vagus nerve (CN X) deficit. Assess CN XI (accessory) by asking the patient to shrug the shoulders. Hypoglossal nerve (CN XII) deficit is manifested by an inability to stick the tongue out straight.

In addition to determining the usual roles and responsibilities, occupation, motivation, and available support systems, assess the patient's ability to cope with this devastating illness and the accompanying fear and anxiety. In general, GBS is self-limiting and the paralysis is temporary. It is not unusual for the patient to have depression throughout the recovery period or feel significant powerlessness.

Although no single clinical or laboratory finding confirms the diagnosis of GBS, the health care provider may perform a lumbar puncture (LP) to evaluate *cerebrospinal fluid (CSF).* An increase in CSF protein level can occur from inflammatory plasma proteins, myelin breakdown, and damage to nerve roots. However, high protein levels may not occur until after 1 to 2 weeks of illness, reaching a peak in 4 to 6 weeks. The CSF lymphocyte count is normal.

Peripheral blood tests may show a moderate *leukocytosis* early in the illness. The number of leukocytes rapidly returns to normal if there are

no complications or concurrent illness.

Electrophysiologic studies (EPSs) demonstrate demyelinating neuropathy. The degree of abnormality found on testing does not always correlate with clinical severity. Within 3 weeks of symptoms, nerve conduction velocities are depressed. In some cases, denervated potentials (fibrillations) develop later in the illness. Electromyographic (EMG) findings, which reflect peripheral nerve function, are normal early in the illness. Electrophysiologic changes appear only after denervation of muscle has been present for 4 weeks or longer. Nerve conduction velocity (NCV) testing is performed with the EMG. Nerve damage or disease may still exist despite normal NCV results. A magnetic resonance imaging (MRI) or computed tomography (CT) scan may be requested to rule out other causes of motor weakness. These tests are described in Chapter 41.

Respiratory function manifested by poor gas exchange is often compromised in patients with GBS. Therefore vital capacity or tidal volume may be decreased and respiratory rate increased. Arterial blood gas (ABG) values may be abnormal with a decreased partial pressure of arterial oxygen (Pa_{O_2}), increased partial pressure of arterial carbon dioxide (Pa_{CO_2}), or decreased pH.

Interventions

Managing Drug Therapy and Plasmapheresis.

The health care provider follows the most recent best practice guidelines from the American Academy of Neurology (Patwa et al., 2012) for the treatment of GBS. The patient may receive either plasma exchange (also known as *plasmapheresis* or *apheresis*) or IV immunoglobulin (IVIG). There is no benefit to combining these treatments (Rajabally, 2012). Corticosteroids are not used unless medically necessary to treat other associated diseases.

Plasmapheresis removes the circulating antibodies thought to be responsible for the disease. In this procedure, plasma is selectively separated from whole blood. The blood cells are returned to the patient without the plasma. Plasma usually replaces itself, or the patient is transfused with a colloidal substitute such as albumin. Fresh frozen plasma is generally not used because of the associated risk for infection and allergic pulmonary edema. Plasmapheresis should be done within several days after the onset of the illness, although some patients benefit up to 30 days after the onset of symptoms. The patient usually receives three or four treatments, 1 to 2 days apart. Some patients may require a second round of treatment if they deteriorate after the first

plasmapheresis.

Nursing interventions for the patient undergoing plasmapheresis include providing information and reassurance, weighing the patient before and after the procedure, and caring for the shunt or venous access site and preventing complications described in Chart 44-2 (Kaplan, 2012).

Chart 44-2 Best Practice for Patient Safety & Quality Care QSEN

Preventing and Managing Complications of Plasmapheresis

COMPLICATION	NURSING INTERVENTIONS
Treatment-Related Complications	
Citrate-induced hypocalcemia	Monitor electrolytes before and after therapy. Communicate abnormal results appropriately to the health care provider. Anticipate calcium replacement therapy (Chapter 11).
Urticarial (skin) reactions from proteins in replacement fluids	Obtain order and administer diphenhydramine (Benadryl) or corticosteroid as premedications when urticaria occurred with previous exchange.
Depletion coagulopathy	Monitor complete blood count and coagulation panel before and after treatment. Communicate abnormal values to the health care provider in an urgent time frame.
Risk for infection from immunoglobulin depletion	Assess and document vital signs, including temperature 3 times daily. Report symptoms of infection, fever, or abnormal vital signs to the health care provider promptly.
Fluid shift or depletion	Monitor fluid status and vital signs during treatment and at least twice in the first hour following treatment.
Sensitivity reaction (including potential anaphylaxis with incorrect crossmatch or administration) when fresh frozen plasma is used in replacement fluid	Follow institution policy for safe, effective administration of blood products like fresh frozen plasma.
Site-Related Complications	
Trauma to skin and blood vessels from large-bore needles for access or catheter-related trauma	Teach the patient rationale for and how to monitor access site as described below.
Bleeding, phlebitis, or infection at access site	Anchor tubing securely during treatment. Minimize patient agitation, if present, during treatment. Assess access site immediately following cessation of treatment and at regular intervals (every 4 hours or more often). Assessment includes appearance of site or dressing, palpation of thrill, and auscultation of bruit.
Clotting at access site	Report loss of thrill or bruit, uncontrolled or large volume bleeding, and presence of redness (particularly along venous pathway), drainage, and swelling to provider immediately.

Nursing Safety Priority QSEN

Action Alert

If a shunt is used for plasmapheresis, be sure to:

- Check shunt patency by assessing the presences of bruit or thrill every 2 to 4 hours
- Keep double bulldog clamps at the bedside
- Observe the access site for bleeding or ecchymosis (bruising)

IVIG has been shown to be as effective as plasmapheresis and is immediately available in most settings. Side effects of immunoglobulin therapy range from minor discomforts (e.g., chills, mild fever, myalgia, and headache) to major complications (e.g., anaphylaxis, aseptic

meningitis, retinal necrosis, acute renal failure). Infuse IVIG slowly when it is started. Observe for and document side and adverse effects, and report their occurrence to the health care provider. The rate of administration can be increased based on the patient's tolerance and on agency protocol.

Managing Respiratory and Cardiac Status.

Frequent and focused monitoring of both the respiratory and cardiovascular systems can prevent complications from GBS as well as identify patients in need of critical rescue interventions.

Inability to maintain an airway is a high risk and potentially fatal consequence of rapidly ascending GBS. The priority nursing intervention of *airway management* is to promote airway patency and adequate gas exchange. Consider implementing Aspiration Precautions that include elevating the head of the bed to 45 degrees or higher and testing for dysphagia prior to restarting oral drugs or nutrition. Have suctioning equipment available and follow institution procedure for oral or oral-tracheal suctioning if the airway becomes compromised with secretions or food. Monitor the color, consistency, and amount of secretions obtained. Chest physiotherapy, often performed by the respiratory therapist (RT), and frequent position changes are combined with breathing exercises (coughing and deep breathing) and the use of an incentive spirometer to prevent pneumonia and atelectasis. Oxygen may be administered by nasal cannula at a flow rate prescribed by the health care provider.

Nursing Safety Priority QSEN

Action Alert

In the initial phase of Guillain-Barré syndrome, monitor the patient closely with each interaction for signs of respiratory distress, such as dyspnea, air hunger, adventitious breath sounds, decreased oxygen saturation, and cyanosis. In addition, assess respiratory rate, rhythm, and depth every 1 to 2 hours. In collaboration with the respiratory therapist (RT), check vital capacity every 2 to 4 hours and auscultate the lungs at 4-hour intervals. Monitor the patient's ability to cough and swallow for any change. Assess cognitive status, especially in older adults; a decline in mental status often indicates hypoxia.

Monitor ABG values or end-tidal carbon dioxide for signs of respiratory

failure; pulse oximetry reveals decreasing oxygen saturation. A decrease in vital capacity to less than 15 to 20 mL/kg (or less than two thirds of the patient's normal) and the inability to clear secretions may be indications for elective intubation.

Both the sympathetic and parasympathetic systems may be affected. A patient with acute GBS may require cardiac monitoring because of the risk for dysrhythmias. Monitor trends in vital signs closely. Report significant changes in heart rate and blood pressure to the health care provider in an urgent time frame. Hypertension is treated with a beta blocker or nitroprusside (Nitropress). Hypotension is treated with IV fluids and placing the patient in a supine position unless he or she is in extreme respiratory distress. Atropine may be prescribed to treat bradycardia.

Improving Mobility and Preventing Complications of Immobility.

Collaborate with the patient, family, physical and occupational therapists (PT/OT), speech-language pathologist (SLP), and dietitian to develop interventions that prevent complications of immobility and to address deficits in self-care. Assess the patient's motor (muscle) strength every 2 to 4 hours as part of the neurologic assessment. The interventions prescribed for mobility and self-management and to prevent complications depend on the degree of motor deficit. The PT and OT provide assistive devices and instructions for their use.

To ensure safety, assist the patient with walking, transfers from bed to chair, position changes, and maintenance of proper body alignment until he or she is able to perform these activities independently. Encourage maximum independence. Perform active or passive range-of-motion (ROM) exercises at least daily, or delegate this activity to unlicensed assistive personnel (UAP) with supervision. Teach family members these techniques. See Chapter 6 for detailed discussion of ways to promote self-management and prevent complications of immobility. Monitor the patient's responses, including fatigue level. Provide adequate rest periods between activities.

Decreased gastric motility, dysphagia, and depression can cause malnutrition. Collaborate with the dietitian to develop caloric and protein intake goals. The patient may require assistance with feeding. If he or she cannot safely swallow food or liquids, enteral nutrition is prescribed. Weigh the patient 3 times a week, and monitor serum prealbumin each week to evaluate nutritional status.

Immobility and malnutrition place patients at risk for pressure ulcers. Assess skin integrity at least daily and with any assisted mobility

intervention. While bedbound, ensure the patient is turned a minimum of every 2 hours. Consider the use of pressure-relieving supports after a turn or special mattress or overlay. Document the skin assessment daily. Consult with the skin or wound care expert when changes occur that contribute to pressure ulcer formation (see Chapter 25).

Because venous thromboembolism (VTE) and pulmonary emboli are common complications of immobility, the health care provider may prescribe prophylactic anticoagulant therapy, such as subcutaneous low–molecular-weight heparin. Sequential pneumatic compression devices for legs may be used to promote venous return. Ensure documentation of starting and maintaining VTE prophylaxis; this is a Joint Commission Core Measure of high-quality health care delivery in acute and critical care units.

Managing Pain.

Assess the severity and nature of the patient's pain, which is often worse at night. The patient may have paresthesia or hyperesthesia (extreme sensitivity to touch), deep muscle aches, and muscle stiffness. The typical pain experienced is severe and requires opioids at least initially for management. Other drugs that are given include gabapentin (Neurontin) or tricyclic antidepressants (Cranwell-Bruce, 2011).

Nursing Safety Priority QSEN

Drug Alert

Older adults should not receive tricyclic drugs because they cause serious anticholinergic effects such as urinary retention, blurred vision, and confusion. These adverse drug events can contribute to cognitive impairment, falls, and injury (see Chapter 2).

Other pain control measures include frequent repositioning, massage, ice, heat, relaxation techniques, guided imagery, hypnosis, and distractions (e.g., music, visitors). Chapter 3 discusses these modalities and other pain-relief measures in detail.

NCLEX Examination Challenge

Physiological Integrity

A client is admitted to the critical care unit with possible Guillain-Barré syndrome. Which symptom of neurologic impairment will require

priority nursing interventions? **Select all that apply.**
A New adventitious breath sounds
B A respiratory rate of 12
C Rapid, shallow breathing pattern
D A peripheral oxygen saturation (Spo_2) of 90%
E New-onset nausea following a position change

Promoting Communication.

The patient may have difficulty communicating because the muscles required for the production of speech are weak or he or she may be mechanically ventilated. In either case, collaborate with the speech-language pathologist to develop a communication system. A simple technique involves eye blinking or moving a finger to indicate "yes" and "no." A communication board or flash cards can be used with the letters of the alphabet or a list of common requests, such as the need to be repositioned or the need for pain medication. Computer or handheld mobile devices may also be used, depending on functional ability.

Providing Psychosocial Support.

Teach the patient and family about the illness, and explain all diagnostic tests and treatments. Assess the patient and family for verbal and nonverbal behaviors that indicate powerlessness, anxiety, fear, and isolation (Simmons, 2010). Encourage the patient to verbalize feelings about the illness and its effects, if possible, while fostering hope. Assess previous decision-making patterns, roles, and responsibilities. To help identify personal factors that influence coping ability, ask the patient and/or family to describe their usual lifestyles and the situations in which they coped effectively. Sleep disturbances related to pain and altered autonomic function may affect the patient's sleep-wake cycle. Allow for regularly scheduled rest periods (Simmons, 2010).

Refer patients who need further psychosocial support to the social worker, certified hospital chaplain or appropriate spiritual resource, and local support groups. If necessary, obtain a psychological consultation for further evaluation and intervention.

Community-Based Care

The severity and course of GBS are variable, which makes the prognosis difficult to predict. The most likely residual deficits at discharge are related to mobility, self-management, altered sensory perception, and disturbed self-concept. For patients who have total quadriparesis (weakness in all

four extremities) or respiratory paralysis, the course of the rehabilitation phase is even more variable and may require weeks to years. The expected outcome of the recovery phase is to move from dependence to independence (Khan & Amatya, 2012).

Planning for discharge begins on admission. Include a family member in the education process throughout the patient's hospitalization and in the discharge process. Provide them with both oral and written instructions to improve adherence to the plan of care and promote continuity during care transitions. The patient may transition to home or skilled care. In collaboration with the discharge planner or case manager (CM), the nurse communicates patient status and summarizes the hospital stay to provide safe transitions in care to a rehabilitation or long-term care setting. If the patient is discharged to home, consider referral to a home health care agency or support group. If assistive devices are needed at home, the CM in collaboration with the interdisciplinary health care team makes certain that the necessary equipment has been delivered after evaluating the home setting. Home care management for patients with GBS is similar to that for those who have had a stroke or spinal cord injury, depending on the nature of the neurologic deficit.

Self-help and support groups for patients with chronic illness are common. Refer the patient and family to these groups, if indicated. For example, the Guillain-Barré Syndrome Foundation International (www.gbs-cidp.org) provides resources and information for patients and their families. The psychosocial adjustment needed may be minimal or dramatic, depending on the patient's residual deficit, age, gender, usual roles and responsibilities, usual coping strategies, available support systems, and occupation. Help the patient identify other support systems, such as church members, friends, or spiritual resources.

Clinical Judgment Challenge

Patient-Centered Care; Safety QSEN

A female patient is admitted to the critical care unit with Guillain-Barré syndrome. She has ascending paralysis to the level of the waist.

1. What is the priority for this patient's care?
2. What health teaching will you provide for this patient about her disease?
3. What options for treatment will she have during this acute phase?
4. What other care will you include in your health teaching?

Myasthenia Gravis

Pathophysiology

Myasthenia gravis (MG) is an acquired autoimmune disease characterized by muscle weakness. There are two types of MG: ocular and generalized. About two thirds of patients initially present with reports about vision that arise from disturbances of the ocular muscles. MG may take many forms—from mild disturbances of the cranial and peripheral motor neurons to a rapidly developing, generalized weakness that may lead to death from respiratory failure. MG can present at any age, and the incidence is slightly higher among men. It is a progressive disease.

MG is caused by distorted acetylcholine receptors (AChRs) in the muscle motor end plate membranes. Antibodies are attached to the AChRs. As a result, nerve impulses are reduced at the neuromuscular junction; nerve impulses do not result in muscle contraction. MG and hyperplasia (abnormal growth) of the thymus gland are related because **thymoma** (encapsulated thymus gland tumor) occurs in a few cases.

There are five main classes and several subclasses of MG (Liang & Han, 2013):

- Class I: Any ocular muscle weakness; may have weakness of eye closure; all other muscle strength is normal
- Class II: Mild weakness affecting other than ocular muscles; may also have ocular muscle weakness of any severity:
  - Class IIa: Predominantly affecting limb, axial muscles, or both; may also have lesser involvement of oropharyngeal muscles
  - Class IIb: Predominantly affecting oropharyngeal, respiratory muscles, or both; may also have lesser or equal involvement of limb, axial muscles, or both
- Class III: Moderate weakness affecting other than ocular muscles; may also have ocular weakness of any severity:
  - Class IIIb: Predominantly affecting oropharyngeal, respiratory muscles, or both; may also have lesser or equal involvement of limb, axial muscles, or both;
- Class IV: Severe weakness affecting other than ocular muscles; may also have ocular muscle weakness of any severity:
  - Class IVa: Predominantly affecting limb, axial muscles, or both; may also have lesser involvement of oropharyngeal muscles
  - Class IVb: Predominantly affecting oropharyngeal, respiratory muscles, or both; may also have lesser or equal involvement of limb, axial muscles, or both; use of a feeding tube to avoid aspiration and

maintain nutrition

- Class V: Defined by the need for intubation, with or without mechanical ventilation, except when used during routine postoperative management

Patient-Centered Collaborative Care

Assessment

Physical Assessment/Clinical Manifestations.

In addition to the biographic data and history, ask the patient about specific muscle weakness (Abbott, 2010). Although the onset of MG is usually insidious (slow), some instances of fairly rapid development have been caused by infection, pregnancy, or anesthesia. A temporary increase in weakness may be noted after vaccination, menstruation, and exposure to extremes in environmental temperature. The course of the disease may have periods of exacerbation or flares when symptoms worsen. Ask the patient when symptoms worsen, specifically noting the affected muscle groups and any limitation or inability in performing ADLs. Anticipate worsening symptoms with repetitive muscle use. Determine the reason for admission to plan care. Patients with MG are typically hospitalized for diagnostic evaluation, myasthenic or cholinergic crisis resulting in respiratory failure, or periods of exacerbation when gas exchange is threatened.

Additional areas of inquiry include any history of **ptosis** (drooping eyelids), **diplopia** (double vision), or **dysphagia** (difficulty chewing or swallowing) and the type of diet best tolerated. Assess the patient about a history of respiratory difficulty, choking, or voice weakness. Other areas of assessment include asking about any difficulty holding up the head, brushing teeth, combing hair, or shaving. Assess for the presence of paresthesias or aching in weakened muscles. Finally, ask about a history of thymus gland tumor. The most common symptoms of MG are related to involvement of the levator palpebrae or extraocular muscles (Chart 44-3). These symptoms may last only a few days at the onset and then resolve, only to return weeks or months later. Pupillary responses to light and accommodation are usually normal.

Chart 44-3 Key Features

Myasthenia Gravis

Motor Manifestations

- Progressive (proximal) muscle weakness that worsens with repetitive use and usually improves with rest
- Poor posture
- Ocular palsies
- Ptosis; incomplete eyelid closure
- Diplopia
- Respiratory compromise
- Loss of bowel and bladder control
- Fatigue

Sensory Manifestations

- Muscle achiness
- Paresthesias
- Decreased sense of smell and taste

For most patients, the muscles of facial expression, chewing, and speech are affected (**bulbar** involvement). Note the patient's smile, which may be transformed into a snarl. The jaw may hang so that the patient must prop it up with the hand. Chewing and swallowing difficulties, choking, and regurgitation of fluids through the nose may lead to considerable weight loss. Ask about the patient's nutritional intake and any recent weight loss. He or she may have more difficulty eating after talking. After extended conversations, the voice may become weaker or exhibit a nasal twang. In some patients, the tongue has fissures (ulcers).

Less often involved are the muscles of the shoulders, the flexors of the neck, and the hip flexors. Because limb weakness is more often *proximal* (closer to the body), the patient may have difficulty climbing stairs, lifting heavy objects, or raising the arms overhead. Neck weakness may be mild or severe enough to cause difficulty in holding the head erect. Among the trunk muscles, the erector spinae are most commonly affected, causing difficulty maintaining a sitting or walking posture.

In the most advanced cases of MG, all muscles are weakened, including those associated with respiratory function and the control of bladder and bowel. In these severe cases, ask about bowel and bladder function. Assess respiratory rate, depth, pattern, and Spo_2 frequently to ensure adequate gas exchange.

Muscle atrophy, although rarely severe, occurs in a small percentage of patients with MG. The tendon reflexes should be assessed, but they are not often affected. Assess for pain, although this is seldom a major

concern. Some patients report that their weakened muscles ache. If present, paresthesias (painful tingling sensations) affecting the muscles of the face, hands, and thighs are not associated with any loss of sensation. Lost or decreased sensations of smell and taste have been reported. Consciousness is not altered.

In **Eaton-Lambert syndrome**, a form of myasthenia often seen with small cell carcinoma of the lung, the muscles of the trunk and the pelvic and shoulder girdles are most commonly affected. Although weakness increases after exertion, muscle strength may temporarily increase during the first few contractions, followed by rapid decline. Diagnosis is confirmed by electromyography (EMG). Management differs somewhat from that of other types of MG. Treatment includes removing the tumor, managing the cancer, and administering drug therapy to release acetylcholine (ACh). Additional therapies may include plasmapheresis and immunosuppressive therapy (discussed later).

Diagnostic Assessment.

Because the incidence of MG is rare, diagnosis may be delayed or missed (Abbott, 2010). An experienced clinician can diagnose the disease from the history and physical examination findings. MG may be immediately confirmed by the patient's response to cholinergic drugs. A standard series of laboratory studies is usually performed for patients with known or suspected MG. *Thyroid function* should be tested because **thyrotoxicosis** (excessive thyroid hormone) is present in a small number of myasthenic patients. *Serum protein electrophoresis* evaluates the patient for immunologic disorders. Immunologic-based diseases, such as rheumatoid arthritis, systemic lupus erythematous, and polymyositis, may be associated with the disease (Pagana & Pagana, 2014).

Several types of antibodies are found in the majority of patients with MG and include forms directed against the acetylcholine receptor (AChR) and the enzyme *muscle-specific receptor tyrosine kinase* (MuSK). However, whereas a positive antibody test confirms the diagnosis, a negative finding does not rule out the disease.

Some patients with MG have a thymoma, and therefore patients are assessed for this condition. The thymus, an H-shaped gland located in the upper mediastinum beneath the sternum, is where B- and T-cells interact, refining self-recognition of these white blood cells. It is hypothesized that thymic abnormalities cause the breakdown in tolerance that causes the immune-mediated attack on AChR in myasthenia gravis. A thymoma can be seen on a chest *x-ray* or a *CT scan*.

The most common electrodiagnostic test performed to detect MG is

repetitive nerve stimulation (RNS) of proximal nerves. Each nerve studied is electrically stimulated 6 to 10 times at 2 or 3 Hertz. The compound muscle action potential (CMAP) is recorded with surface electrodes over muscle. In MG, there is a progressive decline in CMAP amplitude (force, or strength) with the first 4 or 5 stimuli. This test diagnoses most cases of generalized MG but far fewer cases of ocular MG.

During *electromyography* (EMG) to diagnose MG, a recording electrode is placed into skeletal muscle and the electrical activity of skeletal muscle can be monitored in a way similar to electrocardiography (ECG) (Pagana & Pagana, 2014). A progressive decrease in the amplitude of the electrical waveform is a classic sign of MG. This study can be combined with nerve conduction studies and may be called an *electromyoneurography*. It can be performed at the bedside by a technician.

Single-fiber EMG (SFEMG) is a newer and most sensitive form of electromyography in detecting defects of neuromuscular transmission. This test compares the stability of the firing of one muscle fiber with that of another fiber innervated by the same motor neuron. The time interval between the two firings normally shows a minor degree of variability, called *jitter.* Defective transmission increases jitter or actually blocks successive discharges. This test can diagnose almost all cases of generalized and ocular MG.

Pharmacologic tests with the cholinesterase inhibitors *edrophonium chloride (Tensilon)* and *neostigmine bromide (Prostigmin)* may be performed. This older test is often referred to as a *Tensilon challenge test.* Tensilon is used most often for testing because of its rapid onset and brief duration of action. This drug inhibits the breakdown of ACh at the postsynaptic membrane, which increases the availability of ACh for excitation of postsynaptic receptors. To perform the test, the health care provider first estimates the strength of cranial muscles. Initially, 2 mg (0.2 mL) is injected IV; if this is tolerated, an additional 8 mg (0.8 mL) is injected after 30 seconds. Within 30 to 60 seconds of the first dose, most myasthenic patients show a marked improvement in muscle tone that lasts 4 to 5 minutes. False-positive test results may be caused by increased muscle effort by the patient. False-negative findings may be seen if the tested muscle is extremely weak or refractory to the drug.

Tensilon testing may be used also to help determine whether increasing weakness in the previously diagnosed myasthenic patient is due to a **cholinergic crisis** (too much cholinesterase inhibitor drugs) or a **myasthenic crisis** (too little cholinesterase inhibitor drugs). In a cholinergic crisis, muscle tone does not improve after giving Tensilon. Instead, weakness may actually increase, and **fasciculations** (muscle

twitching) may be seen around the eyes and face.

Nursing Safety Priority QSEN

Drug Alert

The Tensilon test can cause cardiac dysrhythmias and cardiac arrest, but these reactions rarely occur. Be sure that atropine sulfate, the antidote for Tensilon, is available in case these complications occur.

Interventions

MG is one of the most treatable neurologic disorders. The classic presentation of MG is muscle weakness that increases when the patient is fatigued and limits his or her mobility and ability to participate in activities. Management for this disease falls into two categories:

- Treatment that affects the symptoms of MG without influencing the actual course of the disease (anticholinesterases or cholinergic drugs)
- Therapeutic efforts for inducing remission, such as the administration of immunosuppressive drugs or corticosteroids, plasmapheresis, and thymectomy (removal of the thymus gland)

Nonsurgical Management.

Although not all patients with MG have respiratory compromise, ongoing assessment and maintenance of respiratory gas exchange are nursing care priorities.

Providing Respiratory Support.

Both myasthenic crisis and cholinergic crisis increase muscle weakness and the patient's risk for respiratory compromise. The diaphragm and intercostal muscles may be affected, which inhibits the patient's ability to maintain adequate gas exchange, breathe deeply, and cough effectively. In addition, dysphagia may result in the aspiration of foods, fluids, or saliva, which worsens the respiratory problems. Because of their respiratory muscle involvement, many of these patients have an increased risk for lung infections.

The patient who cannot cough effectively may require oropharyngeal or nasopharyngeal suctioning. If needed, teach the assisted-cough technique, similar to that used by patients who are quadriplegic. Collaborate with the respiratory therapist (RT) to provide chest physiotherapy consisting of postural drainage, percussion, and vibration to mobilize secretions and improve gas exchange.

Nursing Safety Priority QSEN

Critical Rescue

Keep a bag-valve-mask setup (e.g., Ambu), equipment for oxygen administration, and suction equipment at the bedside of the patient with myasthenia gravis in case of respiratory distress.

Because breathing difficulty or the inability to breathe easily is frightening, be aware of the patient's mental and emotional status during periods of respiratory compromise. Monitor his or her response to drug therapy for muscle weakness. Monitor for pulmonary congestion that can lead to respiratory complications like pneumonia and atelectasis.

Noninvasive mechanical ventilation (NIMV) can be used to support patients with acute respiratory failure from MG crisis while awaiting improvement from IV immunoglobulin (IVIG) therapy or plasma exchange. Chapter 32 explains further about NIMV.

Promoting Mobility.

Assess the patient's muscle strength before and after periods of activity. Provide assistance as necessary to prevent the patient from becoming fatigued. Schedule him or her for tests, treatments, and other activities early in the day or during the energy peaks after giving the prescribed drugs. Assist the patient in planning the periods of rest.

During periods of maximum weakness, provide assistance with positioning and activity. Assess for skin breakdown with each repositioning intervention. Pressure-reducing devices or mattresses are used to help prevent pressure ulcers. Collaborate with the physical and occupational therapists to develop a program for the patient to assist with mobility, self-care, and energy conservation techniques. Chapter 6 discusses rehabilitation as one strategy to improve functional ability after a period of immobility, and Chapter 25 describes strategies to prevent and manage pressure ulcers.

Administering Drug Therapy.

Two groups of drugs are typically prescribed for the treatment of myasthenia gravis (MG): anticholinesterases and immunosuppressants. Be sure to *give these drugs on time to maintain blood levels and thus improve muscle strength*. Monitor and document the patient's response to drug therapy. Provide information for the patient and the family about the indications for, effectiveness of, and side effects of the drugs used in the

treatment of MG.

Cholinesterase Inhibitor Drugs.

Cholinesterase (ChE) inhibitor drugs are the first-line management of MG. These drugs are also referred to as *anticholinesterase drugs* or *antimyasthenics.* They enhance neuromuscular impulse transmission by preventing the decrease of ACh by the enzyme *ChE.* This increases the response of the muscles to nerve impulses and improves muscle strength. The ChE inhibitor drug of choice is pyridostigmine (Mestinon, Regonol). Expect a day-to-day variation in dosage depending on the patient's changing symptoms.

Administer ChE inhibitors with a small amount of food to help alleviate GI side effects.

Nursing Safety Priority QSEN

Drug Alert

Instruct the patient to eat meals 45 minutes to 1 hour after taking ChE inhibitors to avoid aspiration. This is especially important if the patient has bulbar involvement. Drugs containing magnesium, morphine or its derivatives, curare, quinine, quinidine, procainamide, or hypnotics or sedatives should be avoided because they may increase the patient's weakness. Antibiotics such as neomycin and certain tetracyclines impair transmitter release and also increase myasthenic symptoms (Lilley et al., 2014).

A potential adverse effect of ChE inhibitors is cholinergic crisis. Sudden increases in weakness accompanied by hypersalivation, sweating, and increased bronchial secretions help identify this as a cholinergic crisis rather than a myasthenic crisis. A cholinergic crisis is more likely to be associated with nausea, vomiting, and diarrhea. Teach the patient and family to monitor for these two types of crises:

1. Myasthenic crisis—an exacerbation (flare-up or worsening) of the myasthenic symptoms caused by not enough anticholinesterase drugs
2. Cholinergic crisis—an acute exacerbation of muscle weakness caused by too many anticholinesterase drugs

Because myasthenic and cholinergic crises have many common characteristics, the type of crisis the patient is experiencing must be identified for effective treatment to be provided (Table 44-1). Monitor carefully for early detection of these emergencies if the patient is in a

health care setting.

TABLE 44-1

Characteristics of Myasthenic and Cholinergic Crises

Myasthenic Crisis	Cholinergic Crisis	Features Common to Both
Increased pulse and respiration	Flaccid paralysis	Apprehension
Rise in blood pressure	Hypersecretion: salivation, tearing, and sweating	Restlessness
Bowel and bladder incontinence	Nausea	Dyspnea
Decreased urine output	Vomiting	Dysphagia (difficult swallowing)
Absence of cough and swallow reflex	Diarrhea	Generalized weakness
Improvement of symptoms with Tensilon test*	Abdominal cramps	Respiratory failure
	Miosis, blurred vision	
	Pallor	
	Worsening of symptoms with Tensilon test	

*Tensilon test: Edrophonium (Tensilon) is given intravenously; muscle movement improves immediately in patients with myasthenia or myasthenia crisis.

Emergency Care: Myasthenic Crisis.

Myasthenic crisis is often caused by some type of infection. For other patients, increasing muscle weakness leads to an overdose of anticholinesterase drugs. As a result, the patient may experience a *mixed* crisis. The Tensilon test (described on p. 919), although not always conclusive, is an important procedure for differentiation. *Tensilon produces a temporary improvement in myasthenic crisis but worsening or no improvement of symptoms in cholinergic crisis.*

The priority for nursing management of the patient in myasthenic crisis is maintaining adequate respiratory function to promote gas exchange. The acutely ill patient may need intensive nursing care for monitoring. He or she may require mechanical ventilation or other technologic support. Cholinesterase-inhibiting drugs are withheld because they increase respiratory secretions and are usually ineffective for the first few days after the crisis begins. Drug therapy is restarted gradually and at lower dosages.

Emergency Care: Cholinergic Crisis.

In *cholinergic* crisis, do not give anticholinesterase drugs while the patient is maintained with mechanical ventilation. Atropine 1 mg IV may be given and repeated, if necessary. When atropine is prescribed, observe the patient carefully. Secretions can be thickened by the drug, which causes more difficulty with airway clearance and possibly the development of mucus plugs. Unless complications such as pneumonia or aspiration develop, the patient in crisis improves rapidly after the

appropriate drugs have been given. Continue to provide assistance as necessary because he or she tires easily after minimal exertion.

Immunosuppressants.

Immunosuppression may be accomplished with the use of corticosteroids, methotrexate, a chemotherapeutic agent, or rituximab, a biologic agent effective against B-cells (Diaz-Manera et al., 2012). B-cells are lymphocytes active in antibody formation (see Chapter 17). For ocular MG, corticosteroid treatment that does not cause significant systemic complications may significantly reduce the prevalence of generalized myasthenia gravis after 2 years on the drug. IV immunoglobulins (IVIGs) may also be used for acute disease management or as a long-term option for disease refractory to other treatment.

Other Interventions.

Plasmapheresis is a method by which antibodies are removed from the plasma to decrease symptoms. This is used as short-term management of an exacerbation. Six exchanges occur over a 2-week period with follow-up exchanges weekly or monthly as needed, usually as an ambulatory care patient. Nursing management of the patient undergoing plasmapheresis is presented in the earlier discussion of Guillain-Barré syndrome, p. 915, and Chart 44-2.

Generalized weakness and fatigue affect the patient's ability to participate in ADLs. Impaired fine motor control and shoulder weakness, which results in difficulty raising the arms, can compound the problem. Self-care deficits may be complete or partial depending on the severity of the illness or the patient's response to drugs.

Assess the patient's ability to perform ADLs. Although he or she is encouraged to perform activities as independently as possible, assistance is provided as needed to avoid frustration and fatigue. *For maximizing independence and making attempts at self-management successful, plan activities to follow the administration of medication.* Monitor and document the patient's response to or tolerance of activity, providing periods of rest after an activity. *Rest is critical because repetitive movement can precipitate a crisis*. Occupational and physical therapists evaluate patients for assistive-adaptive devices. In collaboration with the nurse, they also teach the patient and family energy conservation techniques and ideas for making work and self-management easier after discharge from the hospital.

Weakness of the speech and facial muscles often results in dysarthric (slurred) and nasal speech. In collaboration with the speech-language

pathologist (SLP), determine the patient's ability to communicate. Instruct the patient to speak slowly while attempting to lip-read. Repeat what the patient says to check that it is correct. Questions that can be answered with "yes" or "no" or by gestures may be used along with other communication systems such as eye blinking, notebook and pencil, computer, handheld mobile devices, and picture, letter, or word boards.

The patient with myasthenia gravis (MG) may have difficulty maintaining an adequate intake of food and fluid because the muscles needed for chewing and swallowing become weakened and tire easily. In collaboration with the dietitian, occupational therapist, and speech-language pathologist, evaluate the patient's nutritional status and his or her ability to receive adequate oral nutrition. High-calorie snacks are often well tolerated. Monitor the effectiveness of the nutrition program by recording the patient's calorie counts, intake and output, serum prealbumin levels, and daily weights (Chart 44-4). If he or she cannot swallow, a feeding tube may be used.

Chart 44-4 Best Practice for Patient Safety & Quality Care QSEN

Improving Nutrition in Patients with Myasthenia Gravis

- Assess the patient's gag reflex and ability to chew and swallow.
- Provide frequent oral hygiene as needed.
- Collaborate with the dietitian, speech-language pathologist, and occupational therapist to plan and implement meals that the patient can eat and enjoy.
- Cut food into small bites or request a soft or edentulous diet, and encourage the patient to eat slowly.
- Observe the patient for choking, nasal regurgitation, and aspiration.
- Provide high-calorie snacks or supplements (e.g., puddings).
- Keep the head of the bed elevated during meals and for 30 to 60 minutes after the patient eats.
- Consider thickening liquids to avoid choking or aspiration.
- Monitor caloric and food intake.
- Weigh the patient daily.
- Monitor serum prealbumin levels.
- Administer anticholinesterase drugs as prescribed, usually 45 to 60 minutes before meals.

The patient's inability to completely close the eyes may lead to corneal

abrasions and further decrease vision and comfort. During the day, apply artificial tears to keep the corneas moist and free from abrasion. A lubricant gel and shield may be applied to the eyes at bedtime to provide more extensive coverage. To help relieve diplopia, cover the eyes with a patch for 2 to 3 hours at a time, one eye at a time. At times, patients tape their eyes shut at night.

Surgical Management.

For patients with MG, **thymectomy** (removal of the thymus gland) is usually performed early in the disease. The procedure is not always immediately effective. Those who have surgery within 2 years of the onset of myasthenic symptoms show the most improvement, but many patients do not experience a change in status despite thymectomy.

Provide routine preoperative care as discussed in Chapter 14. Because there is no way to predict whether remission or improvement will occur, it is important to avoid making promises but be optimistic. Immediately before surgery, pyridostigmine (Mestinon) may be given with a small amount of water to keep the patient stable during and after surgery. If steroids have been used, they are also given before surgery and are tapered during the postoperative period. Antibiotics are administered immediately before or during the surgery. Plasmapheresis may be used before and after surgery to decrease circulating antibodies.

One of two surgical approaches may be used: the transcervical incision (minimal access technique) or the sternal split. The *transcervical approach* is becoming more popular because it allows more rapid recovery with less discomfort after surgery, especially if done using the video-assisted thoracoscopic surgery (VATS) technique. However, this procedure is used only for patients who do not have a thymoma. Only a small dressing and an IV line are needed after surgery.

The older *sternal split* procedure is preferred when patients have a thymoma. It allows the surgeon to directly see the mediastinum and areas around the thymus. When thymoma is present, all surrounding involved structures (i.e., the pericardium, the innominate vein, a portion of the superior vena cava, and a portion of the lung) are removed. A single chest tube is placed in the anterior mediastinum. The patient is usually admitted to the critical care unit after surgery. Thymoma should be considered as a potentially malignant tumor requiring prolonged follow-up. The presence of myasthenic weakness can still complicate its management.

Although patients with adequate respiratory effort and gas exchange may be extubated immediately after surgery, most require a gradual weaning

from the ventilator. Prolonged ventilatory assistance is rare. *After the patient is extubated, pay special attention to respiratory status and maintaining a patent airway.* Encourage the patient to turn, breathe deeply 3 to 6 times every 15 to 30 minutes in the hours after extubation, and use incentive spirometry.

Nursing Safety Priority QSEN

Critical Rescue

For the patient having a thymectomy, monitor respiratory effort and promote effective gas exchange. Observe for signs of pneumothorax or hemothorax, including:

- Chest pain
- Sudden shortness of breath
- Diminished or delayed chest wall expansion
- Diminished or absent breath sounds
- Restlessness or a change in vital signs (decreasing blood pressure or a weak, rapid pulse)

If respiratory distress or symptoms of ineffective gas exchange occur, provide oxygen to the patient and raise the head of the bed to at least 45 degrees. Then report any of these signs and symptoms to the surgeon or Rapid Response Team immediately!

For the sternal surgical technique, provide chest tube care (see Chapter 32). Both surgical approaches require sterile technique for wound care. Observe the patient for signs of infection, such as increasing or purulent drainage; redness, warmth, or swelling around the wound; and elevated temperature. Patient and family teaching about follow-up care is needed before discharge from the hospital.

Community-Based Care

The patient with myasthenia gravis (MG) may be cared for in a variety of settings, including the home, long-term acute care facility, rehabilitation setting, or skilled nursing facility. The patient discharged from the hospital may require the assistance of a family member, home care nurse, physical therapist (PT), occupational therapist (OT), and/or home care aide.

Home Care Management.

Patients with MG are often managed at home. Unless the patient requires

new assistive devices, little preparation of the home setting is required. In collaboration with physical and occupational therapists, the case manager (CM) and nurse make certain that the necessary equipment has been delivered and properly installed. Teach the patient and family members how to use the equipment safely. If the patient becomes wheelchair dependent, the discharge planner, CM, or OT checks on any necessary modifications to the home (e.g., the installation of ramps or widening of doorways) that have been completed. Home health care can provide assistance in transitioning from acute to home care.

Self-Management Education.

The patient and family need to know about the disease and the drugs used for treatment. Discuss the episodic nature of the disease, including factors that increase the risk for exacerbation, such as infection, stress, surgery, hard physical exercise, sedatives, and enemas or strong cathartics (Table 44-2). Teach the patient the importance of collaborating with the health care team to monitor muscle strength, ability to perform ADLs, and the need to evaluate and adjust drug therapy.

TABLE 44-2

Factors Precipitating or Worsening Myasthenia Gravis

• Various drugs, including: • Strong cathartics • Antidysrhythmics • Beta-blocking agents • Aminoglycosides and other antibiotics • Antirheumatic drugs • Antispasmodics, including quinine • Antihistamines • Opioids • Phenytoin (Dilantin) • Antidepressants (tricyclics)
• Rheumatoid arthritis • Alcohol • Hormonal changes • Stress • Infection • Seasonal temperature changes • Heat • Surgery • Enemas

Stress the importance of lifestyle adaptations such as avoiding heat (e.g., sauna, hot tubs, sunbathing), crowds, overeating, erratic changes in sleep habits, or emotional extremes. Teach the signs of exacerbation, such as increased weakness, increased diplopia, ptosis, and problems with chewing or swallowing. Remind the patient to plan activities to allow for

rest periods and to conserve energy.

Provide the drug regimen in a written format that includes the names, purposes, dosages, scheduled dosage times, and side effects of the drugs. Explain that the drugs are normally taken before activities such as eating, participating in sports, or working. Stress the importance of maintaining therapeutic blood levels by taking the medications on time and as prescribed and not missing or postponing doses (Chart 44-5). In addition, inform the patient of the side effects of anticholinesterase drugs and drugs that can worsen symptoms, such as corticosteroids, narcotics, antidysrhythmics, and antimalarials. Check with the pharmacist before starting or stopping drugs. In preparing the patient for discharge, explain the signs and symptoms of myasthenic and cholinergic crises and the need to contact the health care provider whenever either type of crisis is suspected.

Chart 44-5 Patient and Family Education: Preparing for Self-Management

Helpful Hints for Teaching Patients with Myasthenia Gravis About Drug Therapy

- Keep prescribed drugs and a glass of water at your bedside if you are weak in the morning.
- Wear a watch with an alarm function (or beeper) to remind you to take your drugs.
- Post your drug schedule so others know it.
- Plan strenuous activities, when possible, when the drug peaks.
- Keep a secure supply of drugs in your car or at work.
- Check with your health care provider before using any over-the-counter drugs.

Nursing Safety Priority QSEN

Action Alert

Because respiratory compromise often occurs in myasthenic patients, encourage family members to learn resuscitation procedures. A manual resuscitation bag, suctioning equipment, and oxygen should be available in the home for patients susceptible to crises. Teach family members in the proper use of equipment.

The episodic and progressive nature of MG, the potential or actual loss

of independence, and body image changes (e.g., the inability to smile) affect the patient's adjustment. During discharge planning, the CM considers factors such as age, gender, usual roles and responsibilities, available support systems, occupation, and financial status. Because the patient's and family's need for psychosocial adjustment may range from minimal to dramatic, the CM remains sensitive to their needs and provides information and support. Encourage family members or significant others to discuss their feelings with one another.

Health Care Resources.

In collaboration with the health care provider, patient, and family, the staff nurse or CM may initiate referrals to home care agencies and to local self-help groups for people who have chronic illnesses and their families. The Myasthenia Gravis Foundation (www.myasthenia.org) provides education and research programs and assistance with financial aid and community resources. Support groups are also available. Teach the patient the importance of obtaining and wearing a medical alert (MedicAlert) bracelet or necklace and to carry a medical alert identification card at all times.

Peripheral Nerve Trauma

❖ Pathophysiology

The peripheral nerves are subject to injuries associated with mechanical injury, vehicular crashes, sports, the injection of particular drugs, military conflicts or wars, and acts of violence (e.g., knife or gunshot wounds). Most commonly affected are the median, ulnar, and radial nerves of the arms and the peroneal, femoral, and sciatic nerves of the legs (Fig. 44-1). Specific mechanisms of injury to a peripheral nerve include:

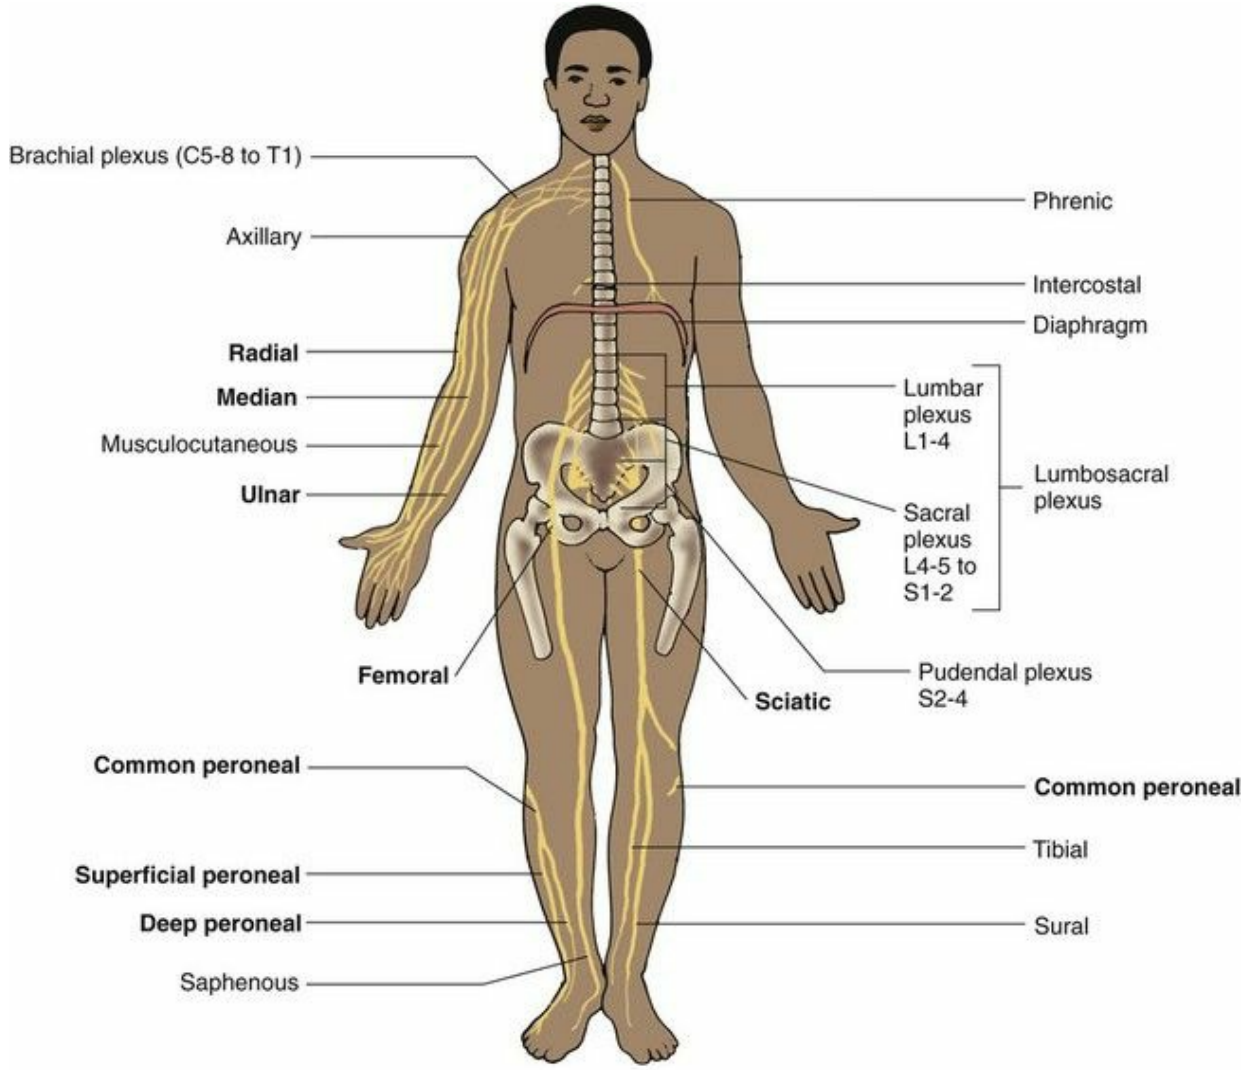


FIG. 44-1 Distribution of selected peripheral nerves in the body. The nerves most commonly affected by trauma are highlighted in bold type.

- Partial or complete severance
- Contusion, stretching, constriction, or compression
- Ischemia

- Electrical, thermal, or radiation exposure

Six degrees of peripheral nerve injury can occur (Novak, 2012):

- First-degree nerve injury (neuropraxia) involves a temporary conduction block with demyelination of the nerve at the site of injury. EMG study results are normal above and below the level of injury, and no denervation muscle changes are present. Once the nerve has remyelinated at that area, complete recovery occurs. Recovery may take up to 12 weeks.
- Second-degree nerve injury (axonotmesis) results from a more severe trauma or compression. This causes degeneration distal to the level of injury and proximal axonal degeneration to at least the next node of Ranvier. In more severe traumatic injuries, the proximal degeneration may extend beyond the next node of Ranvier. EMG studies demonstrate denervation changes in the affected muscles. In cases of reinnervation, motor unit potentials (MUPs) are present. Axonal regeneration occurs at the rate of 1 mm/day or 1 inch/month and can be monitored by the physiatrist or physical therapist.
- Third-degree injury is more severe than a second-degree injury and causes degeneration. EMG studies demonstrate denervation changes with fibrillations in the affected muscles. In cases of reinnervation, MUPs are present. Regeneration occurs at 1 mm/day. However, with the increased severity of the injury, regenerating axons may not reinnervate their original motor and sensory targets. The pattern of recovery is mixed and incomplete. Reinnervation occurs only if sensory fibers grow into a different area within the nerve's sensory distribution. If the muscle target is a long distance from the site of injury, nerve regeneration may occur. The muscle may not be completely reinnervated because of the long period of denervation.
- Fourth-degree injury results in a large scar at the site of nerve injury and prevents any axons from advancing distal to the level of nerve injury. EMG studies reveal denervation changes in the affected muscles. No improvement in motor function is noted, and the patient requires surgery to restore neural continuity, thus permitting axonal regeneration and motor and sensory reinnervation.
- Fifth-degree injury is a complete transection (cutting across) of the nerve. Similar to a fourth-degree injury, it requires surgery to restore neural continuity. EMG findings are the same as those for a fourth-degree injury.
- Sixth-degree injury describes a mixed nerve injury that combines the other degrees of injury. This commonly occurs when some fascicles of the nerve are working normally while other fascicles may be

recovering. Other fascicles may require surgical intervention to permit axonal regeneration.

Injuries to the peripheral nerves may result in loss of motor function (reduced mobility), sensory function (impaired sensory perception), or both. After a nerve is cut or damaged, the nerve distal to the injury degenerates and retracts within 24 hours. Motor and sensory dysfunction below the injury coincides with the loss of electrical excitability. Recovery occurs as Schwann cells of the neurilemma regenerate from both the proximal and distal stumps. Dividing mitotically, these cells form neurilemmal cords, which act as guidelines for the regenerating axon. Tiny unmyelinated sprouts are generated at the proximal axon and grow daily. Some can cross a transected gap through guidance by the neurilemma and reattach to the distal stump. The better aligned the union, the more normal the physical functional ability return (Fig. 44-2). Reinnervation is always a slow process.

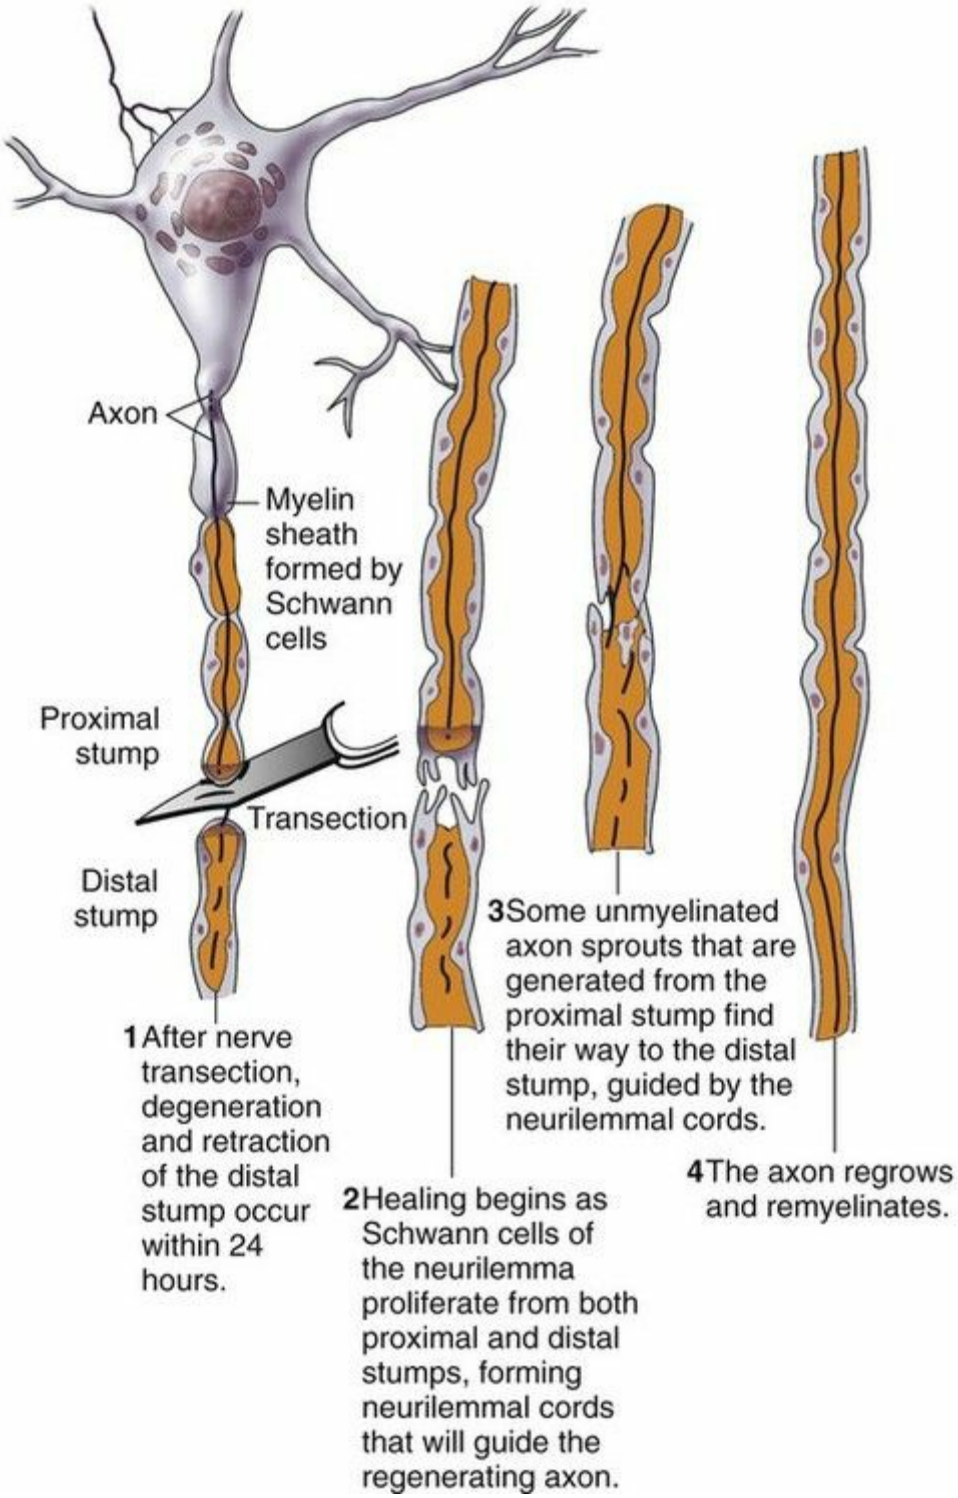

FIG. 44-2 Regeneration of peripheral nerve after injury.

Successfully realigned nerves remyelinate, grow to their former size, and eventually have conduction velocities near their former capacity. Successful reinnervation is slowed by infection and increasing age. Disorganization of the nerve or mismatched realignments may result in functional weakness, unintentional muscle movements, and poor sensation.

Some sensory perception may return before the regeneration process can occur. This return occurs because nerves above the injured neurons are

stimulated to produce collateral innervation to the affected areas. These collaterals occur before the injured axon has regenerated sufficiently.

Patient-Centered Collaborative Care

Assessment

The patient may relate a history of extremity or pelvic trauma, penetrating injury, recent surgery, or compression. Peripheral nerve trauma is especially common from combat-acquired injuries. In addition to weakness or flaccid *paralysis,* the patient may report *burning sensations* below the trauma or pain that increases with touch or environmental stimulation. Observe for skin and nail changes of the affected extremities.

Perform a physical assessment to determine physical function. In acute trauma, the injury should first be evaluated by the health care provider to determine whether movement is contraindicated. If movement is not contraindicated, the patient's motor function is assessed by putting the limb through the normal range of motion. Any abnormal movements, tremor, atrophy, contractions, paresis or paralysis, and weak or absent deep tendon reflexes are documented. Ask the patient about abnormal sensations.

After complete denervation, the extent of vasomotor function is reflected in skin temperature, skin color, and edema. A warm phase and a cold phase have been identified. During the **warm phase**, the extremity is warm and the skin appears flushed or rosy. Over 2 to 3 weeks, this phase is gradually superseded by a **cold phase**, during which the skin appears cyanotic, mottled, or reddish blue and feels cool compared with the unaffected extremity. Use the dorsal surface of your hand to compare skin temperatures because the abundance of temperature receptors in this area provides more accurate assessments. Edema may be noted immediately after injury or later as a result of surgical procedures. Record any observations of trophic changes (e.g., scaling of skin, brittleness of nails, and loss of body hair). This initial assessment serves as the baseline for comparison during subsequent examinations, which are performed every 2 to 4 hours or less frequently as the patient's condition indicates.

Interventions

Interventions for the patient with peripheral nerve trauma depend on the location as well as the type and degree of injury. If the nerve trauma results from a primary lesion, such as a tumor, the underlying problem is

addressed first (Walsh, 2012).

The health care provider may prescribe immobilization of the involved area by splint, cast, or traction to provide the rest needed to limit and resolve any inflammation. The purpose of surgical management is to restore the function of the damaged nerve. There are usually no special preoperative interventions for the patient undergoing peripheral nerve repair. Chapter 14 describes the general care of the patient before surgery.

If the nerve is lacerated or transected, surgery may be indicated. Restorative procedures include resecting and suturing to realign the severed nerve ends, nerve grafts, and nerve and tendon transplants.

The timing of procedures to repair nerves has been controversial. In the past, a repair delay of 3 to 8 weeks after injury allowed associated injuries to heal, after which the surgeon could better assess the extent of nerve damage. Although microsurgery and the use of lasers now allow primary nerve repair at the time of injury, the surgeon's judgment in selecting the optimal time and surgical procedure remains crucial.

After an injury, the two severed nerve segments contract and may form scar tissue. Before surgical anastomosis, the surgeon dissects these stumps to remove any damaged nerve tissue. This further decreases the lengths of the ends to be joined. To compensate for this shortening and to avoid excessive tension on the sutured nerve, the involved extremity is positioned in exaggerated flexion. The surgeon aligns the segments under magnification, bringing the nerve fiber ends together, and then sutures the nerve tissue.

After suturing, the extremity is placed in a cast to maintain the flexed position and to avoid tension on the suture line. Ten to 14 days after nerve repair, the entire dressing is removed, the joint flexion is eased, and a new splint may be applied for an additional 2 weeks. At that time, a removable splint may be applied and physical therapy begun. Protection of the nerve sutures is continued for a minimum of 6 weeks.

If a large segment of nerve has been damaged and direct anastomosis would be impossible without stretching the nerve, the surgeon may insert a *nerve graft*. Motor and sensory axons may regenerate through the graft, joining the nerve segments through the two sites of anastomosis. The results of grafting are not usually as favorable as with direct anastomosis. Immobilization by splints or casts to facilitate healing of the surgical sites is essential.

Splints are usually held in place with elastic wrapping or hook-and-loop (Velcro) closures, which can become too tight if edema develops.

Nursing Safety Priority QSEN

Critical Rescue

Perform frequent neurovascular assessments after surgical nerve repair, including checking the skin around the splints and casts (hourly, initially) for tightness, warmth, and color. If the patient reports discomfort, tingling, or coolness or if the color is blanched, the cast or splint may be too tight (constricted). *Inform the health care provider immediately about constriction and any indication of drainage under a splint or cast!*

Skin care is essential. Atrophy of the epidermis and underlying tissue causes the skin to become more fragile and more susceptible to injury and breakdown. Decreased skin nutrition and vascularity associated with denervation cause delayed healing, which further worsens the problem. Thoroughly examine the skin for signs of irritation or injury, and assist or instruct the patient to wash and dry the involved areas carefully. If the skin is dry, lanolin or cocoa butter may be used as a lubricant. *Because sensation may be absent or inhibited, teach the patient to protect the involved areas from temperature extremes and other sources of potential trauma.*

Physical or occupational therapy is the major approach for rehabilitation after surgical repair. Reinforce and help the patient perform the exercises learned in these therapy sessions. Because the regeneration of nerves and subsequent return of sensory and motor function may be extremely slow and produce pain, the patient may become discouraged and depressed. If the disability is permanent, he or she needs encouragement and assistance to cope with the changes in body image, self-esteem, and lifestyle.

Restless Legs Syndrome

Pathophysiology

Restless legs syndrome (RLS) is characterized by leg paresthesias (burning, prickly sensation) associated with an irresistible urge to move. Over 10% of the population in the United States have the problem, and women are affected twice as often as men (National Institute of Neurological Disorders and Stroke, 2013a). RLS occurs most often in middle-aged and older adults. Stress can exacerbate this condition. RLS is related to a dysfunction in the brain circuits that use the neurotransmitter *dopamine.* Many of those affected with *primary RLS* have a positive family history, indicating a possible genetic basis. The incidence is higher in patients who have diabetes mellitus type 2; chronic kidney disease; iron deficiency; Parkinson disease; peripheral neuropathy; use of certain medications such as caffeine, calcium channel blockers, lithium, or neuroleptics; and withdrawal from sedatives. Although not a cause of hospitalization, restless leg syndrome may be a comorbidity that complicates recovery from other conditions.

Patient-Centered Collaborative Care

Assessment

The patient reports intense burning or "crawling-type" sensations in the legs and therefore feels the need to move them repeatedly. These symptoms are worse in the evening and at night and when the patient is still for a period of time. Patients feel they need to move to relieve the symptoms. Many move their legs periodically while sleeping. For that reason, they often refer to themselves as "night walkers."

Interventions

The management of RLS is symptomatic and involves treating the underlying cause or contributing factor, if known. Both nonpharmacologic measures and drug therapy are used. Teach patients to avoid as many risk factors as possible or make lifestyle modifications. Examples are avoiding caffeine and alcohol, quitting smoking, losing weight, and exercising.

Strategies to relieve the symptoms of RLS include walking, stretching, moderate exercise, or a warm bath. Refer them to The Restless Legs Foundation (www.rls.org) as an excellent resource for information and patient and family support.

Many of the drugs prescribed for RLS are also used for either Parkinson disease (PD) or epilepsy. *Dopamine agonists* such as pramipexole (Mirapex) and ropinirole (Requip) are oral drugs used extensively. Gabapentin enacarbil (Horizant) is an *antiepileptic drug (AED)* that is also approved by the U.S. Food and Drug Administration (FDA) for RLS. These agents are usually taken at bedtime because they may cause daytime sleepiness. Teach patients to be cautious of driving or operating heavy equipment when taking these drugs (Silber, 2013). Correcting iron and magnesium deficiencies can reduce RLS symptoms, and ongoing supplementation of these minerals may be needed.

Some patients have had success with *Sinemet*, a combination of levodopa and carbidopa. This drug is often given with other medications to be more effective in reducing the symptoms of the disease. Other classes of drugs for managing RLS include *benzodiazepines, such as diazepam (Valium), and opioids* as a last resort. Two other AEDs, carbamazepine (Tegretol) and gabapentin (Neurontin), have been particularly effective and are taken in divided doses throughout the day. For insomnia from RLS, *melatonin* may be effective for many people, especially older adults. However, the focus of treatment should be on RLS, not insomnia. Teach patients to inform their health care providers when adding these supplements.

Diseases of the Cranial Nerves

Patients with cranial nerve disease may be seen in any practice setting. The cranial nerves may be affected in association with other disorders of the nervous system or as a result of trauma. The most common disorders, those affecting cranial nerves V (trigeminal) and VII (facial), are discussed here.

Trigeminal Neuralgia

❖ Pathophysiology

Trigeminal neuralgia (TN) is also known as *tic douloureux.* The trigeminal nerve has three branches: the first branch controls sensation in a person's eye, upper eyelid, and forehead; the second branch controls sensation in the lower eyelid, cheek, nostril, upper lip, and upper gum; and the third branch controls sensations in the jaw, lower lip, lower gum, and some of the muscles used for chewing.

According to the National Institute of Neurological Disorders and Stroke (2013b), trigeminal neuralgia has these characteristics:

- Affects the trigeminal (fifth cranial) nerve
- Occurs more often in people older than 50 years and in women more often than men
- Causes a specific type of facial pain, which occurs in sudden, intense facial spasms
- Is usually provoked by minimal stimulation of a trigger zone (like dental procedures)
- Is unilateral (one-sided) and confined to the area innervated by the trigeminal nerve, most often the second and third branches (Fig. 44-3)

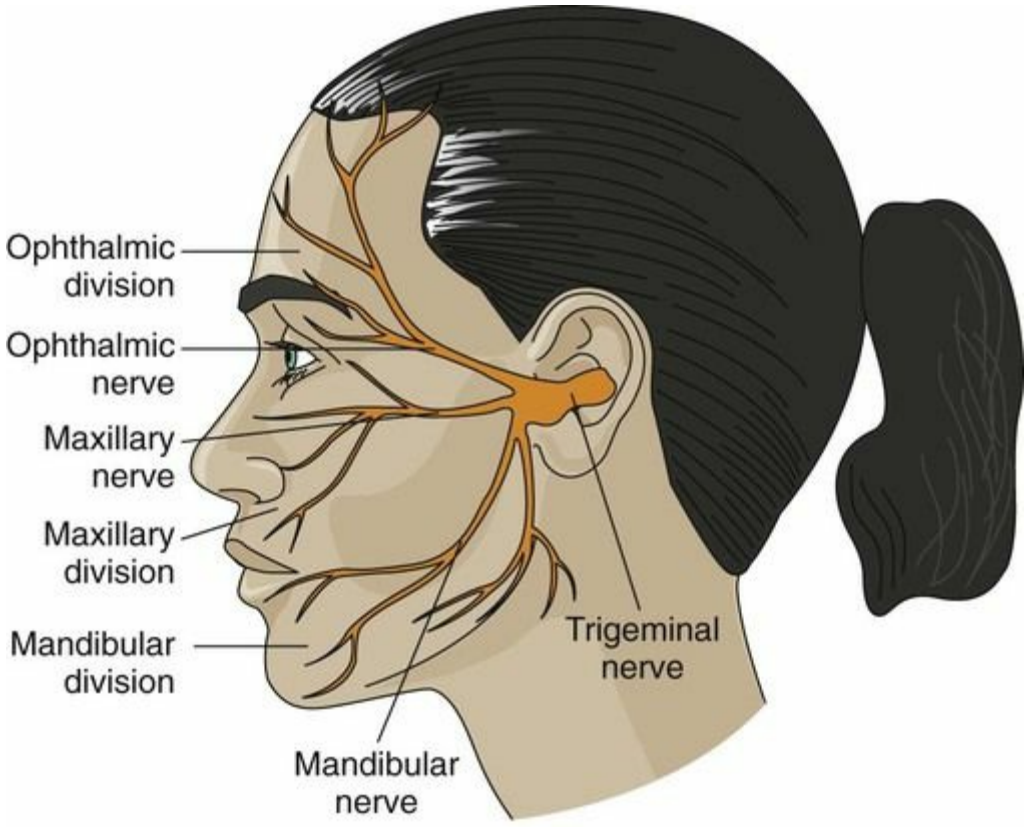

FIG. 44-3 Distribution of the trigeminal nerve and its three divisions: ophthalmic, maxillary, and mandibular.

- Is familial due to an inherited pattern of blood vessel formation

The cause of trigeminal neuralgia is thought to be related to impaired inhibitory mechanisms in the brainstem caused by excessive firing of irritated fibers in the trigeminal nerve. Trauma and infection of the teeth, jaw, or ear may be contributing factors. Patients younger than 30 years with pain in more than one branch of the trigeminal nerve may be further evaluated to rule out the possibility of a tumor or multiple sclerosis.

Patient-Centered Collaborative Care

Assessment

TN is a chronic pain syndrome. It can be categorized into two types of pain: classic and atypical. When describing trigeminal pain, patients use terms such as "excruciating," "sharp," "shooting," "piercing," "burning," and "jabbing." Atypical pain descriptions may include migraine-like headache. Between bursts of pain, which last from seconds to minutes, there is usually no pain. Often no sensory or motor deficits are found on examination. Pain can be initiated by light touch, a change in facial expression (e.g., smiling), or chewing. The fear of precipitating agonizing attacks often causes patients to avoid talking, smiling, eating, or

attending to hygienic needs such as shaving, washing the face, and brushing the teeth. The pain can cause uncontrollable facial twitching. The course of TN involves bouts of classic pain for several weeks or months followed by spontaneous remissions. The length of these remissions may vary from days to years, but attack-free periods tend to become shorter as the patient grows older.

The patient suspected of TN usually has a CT scan and MRI to determine whether there is a reversible cause of trigeminal compression or inflammation. The diagnosis is made based on patient history and the results of these imaging tests.

Interventions

The priority for care of the patient with TN is pain management. Specific interventions are determined by the amount of pain he or she is experiencing. Drug therapy is the first choice, but surgery can provide satisfactory pain relief in patients who do not respond to drug management or who experience profound adverse drug reactions (Ibrahim, 2012).

Drug Therapy and Radiosurgery.

The first choice for drug therapy is carbamazepine (CBZ, Tegretol), an antiepileptic drug (AED) (Ibrahim, 2012). Other drugs, such as gabapentin (Neurontin), pregabalin (Lyrica), and baclofen (Lioresal, Kemstro), a muscle relaxant, may be used. Some patients also achieve pain relief with complementary therapies, such as acupuncture (Lui et al., 2010).

Microvascular decompression, radiosurgery techniques such as a peripheral chemical nerve block with ropivacaine, or stereotactic radiation treatments with the Gamma Knife are surgical approaches to disrupt trigeminal neuralgia. These minimally invasive procedures prevent the complications of major surgery. Surgical interventions are often combined with drug therapy for pain management of this challenging condition.

In some cases, a **percutaneous stereotactic rhizotomy (PSR)** is performed as an ambulatory care procedure under general anesthesia. The surgeon passes a hollow needle through the inside of the patient's cheek into the trigeminal nerve fibers. A heating current (radiofrequency thermocoagulation) goes through the needle to destroy some of the fibers. As an option to heat, a balloon microcompression of the trigeminal nerve root may be performed. A glycerol injection may also be used as an option, but it is not done as commonly as thermocoagulation.

The entire nerve is not destroyed. The advantages of this procedure include long-term pain relief, absence of facial paralysis, and preservation of the sensation of touch. Puncturing the internal carotid artery is a possible complication. The affected side is permanently insensitive to pain.

After the PSR procedure, apply an ice pack to the PSR operative site on the cheek and jaw for 3 to 4 hours. Perform a focused cranial nerve assessment to assess whether other nerves have been damaged (e.g., facial nerve). Discourage the patient from chewing on the affected side until paresthesias resolve. A soft diet is usually prescribed.

Nursing Safety Priority QSEN

Action Alert

Teach the patient who has had percutaneous stereotactic rhizotomy to avoid rubbing the eye on the affected side because the protective mechanism of pain will no longer warn of injury. Instruct him or her to inspect the eye daily for redness or irritation and report to the health care provider any change or blurred vision. Stress the importance of regular dental examinations because the absence of pain may not warn the patient of potential problems.

Surgical Management.

In addition to the general preoperative care provided to all patients, the surgeon thoroughly explains the surgical benefits and any expected neurologic deficits. Ensure that the patient understands the procedure to be performed and any risks or complications.

In some patients, a small artery compresses the trigeminal nerve as it enters the pons. Surgical relocation of this artery **(microvascular decompression)** may relieve the pain of TN without compromising facial sensation. This procedure is more invasive, requiring a craniotomy. Though not common, complications include aseptic meningitis, cerebrospinal fluid leak, ataxia, **ipsilateral** (same side) hearing loss, and facial nerve damage. Older adults and patients with other medical problems may not be candidates for this procedure.

In addition to general post-craniotomy care for patients as described in Chapter 45, monitor the patient who has microvascular decompression for signs of complications including headache, cranial nerve dysfunction, and bleeding. Assess his or her corneal reflex, extraocular muscles, and facial nerve, and report abnormal findings to the surgeon. Document all

changes promptly.

Psychosocial considerations for the patient with trigeminal neuralgia include disappointment with ineffective drug protocols or surgical procedures, as well as the fear that the pain may recur with any activity. The patient may fail to move the face in an attempt to prevent pain. This behavior may be misinterpreted by others as withdrawal or depression. Refer patients and their families to the TNA—Facial Pain Association (www.fpa-support.org) for more information and support. TNA of Canada (www.catna.ca) is the national organization in Canada that advocates and informs patients and their families about trigeminal neuralgia.

Facial Paralysis

❖ Pathophysiology

Facial paralysis, or **Bell's palsy,** is an acute paralysis of cranial nerve VII but may also affect cranial nerves V (trigeminal) and VIII (vestibulocochlear [auditory]). The condition is also known as *cranial polyneuritis.* Although the incidence may be slightly higher among people with diabetes, Bell's palsy occurs in all ages; however, it is more commonly seen in young adults.

Acute maximum paralysis occurs over 2 to 5 days in almost all patients with this condition. pain behind the ear or on the face may occur a few hours or even days before paralysis. The disorder involves a drawing sensation and paralysis of all facial muscles on the affected side. The patient cannot close his or her eye, wrinkle the forehead, smile, whistle, or grimace. Tearing may stop or become excessive. The face appears masklike and sags. Taste is usually impaired to some degree, but this symptom seldom persists beyond the second week of paralysis. Tinnitus (ringing in the ears) may also occur. Most patients go into remission within 3 months.

The cause of Bell's palsy is believed to be the result of inflammation triggered by a formerly dormant herpes simplex virus type 1 (HSV-1). Infection, immunosuppression, or exposure to cold may trigger the HSV-1 re-activation. Patients are rarely hospitalized, but the nurse may encounter them in clinics, office settings, or emergency departments.

❖ Patient-Centered Collaborative Care

Medical management usually includes corticosteroids, 30 to 60 mg daily, during the first week after the onset of symptoms. Antiviral drugs such

as acyclovir (Zovirax), famciclovir (Famvir), or valacyclovir (Valtrex) may be prescribed for 7 to 10 days after symptoms begin. Mild analgesics may help relieve the pain. Nursing care is directed toward managing the major neurologic deficits and providing psychosocial support. Because the eye does not close, the cornea must be protected from drying and subsequent ulceration or abrasion. Teach the patient to manually close the eyelid at intervals and to instill artificial tears during the day. An ointment to supply moisture can be used at night. The eye may be patched or taped closed at bedtime.

The patient may be unable to chew, sip fluids through a straw, or control drooling on the affected side, creating difficulties at mealtimes. Encourage the patient to eat and drink using the unaffected side of the mouth. High-calorie snacks may supplement meals, and patients may require a soft diet. Explain how to use massage; the application of warm, moist heat; and facial exercises to manage pain and paralysis. In some cases, physical therapy is prescribed. As muscle tone improves, teach the patient to grimace, wrinkle the brow, force the eyes closed, whistle, and blow air out of the cheeks 3 or 4 times daily for 5 minutes.

Nerve block to manage pain may be performed, but it is not common. Surgery is reserved for patients with complete, severe Bell's palsy to decompress the facial nerve. In some cases, cosmetic surgery is done.

Although most patients recover fully within a few weeks or months, some may experience permanent neurologic deficits. For chronic pain, gabapentin (Neurontin) may be prescribed. Patients with Bell's palsy may require psychosocial support because body image and self-esteem are affected. Provide both information and psychosocial support. Refer patients and their families to the Bell's Palsy Research Foundation for information (www.angelfire/az/BellsPalsy.com). The Bell's Palsy Association in the United Kingdom is also a good source of web-based information (www.bellspalsy.org.uk).

NCLEX Examination Challenge

Safe and Effective Care Environment

The nurse is caring for a client with Bell's palsy. Which potential problem requires assessment by the nurse to ensure client safety?
A Risk for falls from balance impairment
B Risk for communication difficulties from impaired hearing
C Risk for eye ulceration or abrasion from inability to close eyelid
D Risk for adverse drug effects from pain management therapy

Nursing Concepts and Clinical Judgment Review

What might you NOTICE if a patient is experiencing impaired mobility, altered sensory perception, or pain as a result of acute or chronic peripheral nervous system disorders?

- Report of muscle weakness in face, arms, or legs
- Inability to swallow or clear the upper airway
- Changes in respiratory rate and pattern indicating respiratory compromise or failure
- Loss of sensation in face or extremities
- Report of burning, tingling sensations in face or extremities
- Report of pain in extremities or face
- Ptosis and either dry eye or excessive tearing

What should you INTERPRET and how should you RESPOND to a patient experiencing impaired mobility, and/or sensory perception, and/or pain as a result of peripheral nervous system disorders?

Perform and interpret physical assessment, including:

- Completing a neurologic assessment
- Assessing a patient's airway and breathing ability
- Performing a comprehensive pain assessment (see Chapter 3)

Respond by:

- Notifying health care provider or contacting Rapid Response Team if patient has problems with breathing or experiences a sudden change in neurologic status
- Establishing an airway and promoting ease in breathing (e.g., put patient in sitting position, provide oxygen, set up suction)
- Having emergency equipment like ventilator and tracheostomy set available for patient who has respiratory compromise
- Assisting with ADLs as needed
- Providing analgesics and other pain-relief measures

On what should you REFLECT as you assess and manage care for a patient with problems of the peripheral nervous system?

- Continue to observe patient for changes in functional ability and gas exchange.
- Consider multiple approaches to managing pain.
- Think about ways to promote independence in mobility and self-care.
- Think about health care team members with whom you will need to collaborate to improve mobility.

- Consider how to provide a safe environment for patients with decreased sensory perception.
- Develop a teaching plan for the patient and family for continuing care.

Get Ready for the NCLEX® Examination!

Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Collaborate with members of the interdisciplinary team, including the health care provider, physical and occupational therapists, speech-language pathologist, and dietitian, to establish goals for care and individualized interventions for patients with Guillain-Barré syndrome (GBS) and myasthenia gravis (MG). **Teamwork and Collaboration** QSEN

Health Promotion and Maintenance

- Reinforce the need for patients with MG to take their drugs on time. **Safety** QSEN
- Assess patient response to drugs to control pain related to peripheral nerve conditions; opioids, AEDs, and antidepressants have the potential to cause significant adverse effects.
- Refer patients with peripheral nervous system (PNS) disorders to community support groups and health care organizations, such as The Restless Legs Syndrome Foundation and the Myasthenia Gravis Foundation.

Psychosocial Integrity

- Provide alternatives to promote communication for patients with GBS and MG, including speaking slowly, lip-reading, and using communication boards or electronic technology. **Patient-Centered Care** QSEN

Physiological Integrity

- Assess for changes related to gas exchange and functional ability for patients with PNS disorders.
- Recall that patients with GBS have ascending paralysis, sensory changes, cranial nerve involvement, and autonomic manifestations as a result of demyelination of neurons (see Chart 44-1).
- Note that patients with MG have an autoimmune disease in which muscle weakness, including ocular symptoms, is the result of attacks on the acetylcholine receptors at neuromuscular junctions (see Chart

44-3).

- Teach patients about factors that can worsen (exacerbate) MG as listed in Table 44-2. **Evidence-Based Practice** QSEN
- Remember that the priority for care for patients with GBS and MG is respiratory monitoring and airway management. **Safety** QSEN
- Prevent complications of immobility for patients with GBS and MG, such as pressure ulcers and venous thromboembolic events.
- Teach patients on cholinesterase inhibitor drugs and their families about clinical manifestations of cholinergic and myasthenic crises as listed in Table 44-1. **Safety** QSEN
- For patients having a thymectomy, maintain adequate gas exchange and observe for complications such as pneumothorax or hemothorax (e.g., chest pain, shortness of breath). **Evidence-Based Practice** QSEN
- Perform frequent neurovascular assessments for patients having a peripheral nerve repair.
- Teach patients with restless legs syndrome to minimize risk factors for the disorder, including exercising, losing weight, and quitting smoking. **Evidence-Based Practice** QSEN
- Recall that trigeminal neuralgia (TN) affects primarily the fifth cranial nerve (although others may be involved) and does not typically involve paralysis or changes in sensation other than excruciating pain along the cranial nerve tract. Facial paralysis (Bell's palsy) affects cranial nerve VII and involves unilateral facial muscle paralysis.
- Prioritize pain management for the care of the patient with TN. **Patient-Centered Care** QSEN

CHAPTER 45

Care of Critically Ill Patients with Neurologic Problems

Chris Winkelman and Rachel L. Gallagher

PRIORITY CONCEPTS

- Mobility
- Sensory Perception
- Cognition
- Perfusion

Learning Outcomes

Safe and Effective Care Environment

1. Prioritize airway, breathing, and circulation during the initial care of a patient with acute and critical neurologic illness to avoid complications from inadequate gas exchange or low perfusion
2. Explain the importance of collaborating with health care team members when planning and providing care for critically ill patients with neurologic problems.
3. Discuss strategies to provide safe, effective transitions in care following acute management of patients with a stroke, traumatic brain injury (TBI), or brain tumor.

Health Promotion and Maintenance

4. Develop a teaching plan about risk factors for having a stroke.
5. Describe strategies to prevent secondary brain injury.

Psychosocial Integrity

6. Discuss how to support the patient and family coping with life changes

that result from stroke, TBI, or brain tumor.

Physiological Integrity

7. Perform a neurologic assessment of patients who are experiencing acute neurologic events of stroke, TBI, or cranial surgery, with a focus on changes in cognition, mobility, and sensory perception.
8. Prioritize evidence-based care for a patient with acute neurologic changes indicating a stroke or TBI.
9. Assess the patient after fibrinolytic therapy for ischemic stroke for potential adverse effects.
10. Describe elements of care for common patient responses to acute stroke, TBI, or brain tumor.
11. Explain the role of chemotherapy, radiation, and surgery in the management of patients with a brain tumor.

 http://evolve.elsevier.com/Iggy/

Many acute neurologic problems are associated with high mortality and severe morbidity and create significant and enduring impact upon patients, their families, and the wider society. Early recognition and comprehensive care of adult patients with acute neurologic compromise by the nurse can reduce mortality and disability. Acute neurologic problems from stroke, brain trauma, and malignancy cause varying degrees of impaired mobility, sensory perception, cognition, and perfusion.

Transient Ischemic Attack

Ischemic strokes often follow warning signs such as a **transient ischemic attack (TIA).** Temporary neurologic dysfunction resulting from a *brief* interruption in cerebral blood flow is easy to ignore or miss, particularly if symptoms resolve by the time the patient reaches the emergency department (ED). Typically, symptoms of a TIA resolve within 30 to 60 minutes (Chart 45-1). TIAs may damage the brain tissue with repeated insults, as seen on MRI or CT scan. Single TIAs indicate a high stroke risk; recurrent and multiple TIAs increase the risk for permanent brain damage.

Chart 45-1 Key Features

Transient Ischemic Attack

Symptoms resolve typically within 30 to 60 minutes.

Visual Deficits

- Blurred vision
- Diplopia (double vision)
- Blindness in one eye
- Tunnel vision

Motor Deficits

- Weakness (facial droop, arm or leg drift, hand grasp)
- Ataxia (gait disturbance)

Sensory Perception Deficits

- Numbness (face, hand, arm, or leg)
- Vertigo

Speech Deficits

- Aphasia
- Dysarthria (slurred speech)

Upon admission to the ED, a complete neurologic assessment is performed and laboratory tests, electrocardiogram (ECG), and CT scan are performed. If no neurologic deficit is identified, the patient may be admitted for further diagnostic testing to evaluate the risk for stroke, including an MRI of carotid and cerebral blood vessels and brain tissue. Treatment focuses on preventing another TIA or stroke and may include:

- Reducing high blood pressure, the most common risk factor for stroke, by adding or adjusting drugs to lower blood pressure
- Taking aspirin or another antiplatelet drug (e.g., clopidogrel [Plavix]) to prevent strokes (Aw & Sharma, 2012)
- Controlling diabetes and keeping blood sugar levels in a target range, typically 100-180 mg/dL
- Promoting lifestyle changes such as quitting smoking, eating heart-healthy foods, and being more active

As part of the discharge processes to meet The Joint Commission's National Patient Safety Goals and Core Measures for Venous Thromboembolism (VTE), ensure that the patient taking antiplatelet drugs is aware of precautions and actions to take if bleeding occurs. Anticoagulant therapy is discussed in detail in Chapter 36 under the VTE section. Reinforce the need to follow up with the health care provider and to complete any diagnostic tests requested on an ambulatory care basis.

Stroke (Brain Attack)

Pathophysiology

A **stroke** is caused by an interruption of perfusion to any part of the brain. The National Stroke Association uses the term **brain attack** to convey the urgency for acute stroke care similar to that provided for acute myocardial infarction. *A stroke is a medical emergency, and it should be treated immediately to reduce permanent disability*. About 14% of patients in hospitals in the United States have a stroke while in the hospital (Mink & Miller, 2011a).

Stroke is the third leading cause of death in the United States and is considered a major cause of disability worldwide. According to the Centers for Disease Control and Prevention (CDC), about 137,000 Americans die each year from stroke (CDC, 2013b) On average, one American dies from stroke every 4 minutes (CDC, 2013b).

Pathophysiologic Changes in the Brain

The brain cannot store oxygen or glucose and therefore must receive a constant flow of blood to provide these substances for normal function. In addition, blood flow is important for the removal of metabolic waste (e.g., carbon dioxide, lactic acid). If blood supply to any part of the brain is interrupted for more than a few minutes, cerebral tissue dies **(infarction).** The result is disability, depending on the location and amount of brain tissue affected. Brain metabolism and blood flow after a stroke are affected around the infarction as well as in the **contralateral** (opposite side) hemisphere. Effects of a stroke on the contralateral (nonaffected) side may be due to brain edema or global changes in perfusion in the brain. As a result of brain edema, patients may develop increased intracranial pressure and secondary brain damage.

Types of Strokes

Strokes are generally classified as ischemic (occlusive) or hemorrhagic (Fig. 45-1). Acute ischemic strokes are either thrombotic or embolic in origin (Table 45-1). Most strokes are ischemic.

TABLE 45-1

Differential Features of the Types of Stroke

FEATURE	ISCHEMIC		HEMORRHAGIC
	THROMBOTIC	EMBOLIC	
Evolution	Intermittent or stepwise improvement between episodes of worsening symptoms	Abrupt development of completed stroke	Usually abrupt onset
	Completed stroke	Steady progression	
Onset	Gradual (minutes to hours)	Sudden	Sudden, may be gradual if caused by hypertension
Level of consciousness	Preserved (patient is awake)	Preserved (patient is awake)	Deepening stupor or coma
Contributing associated factors	Hypertension Atherosclerosis	Cardiac disease	Hypertension Vessel disorders
Prodromal symptoms	Transient ischemic attack		
Neurologic deficits	Deficits during the first few weeks Slight headache Speech deficits Visual problems Confusion	Maximum deficit at onset Paralysis Expressive aphasia	Focal deficits Severe, frequent
Cerebrospinal fluid	Normal; possible presence of protein	Normal	Bloody
Seizures	No	No	Usually
Duration	Improvements over weeks to months Permanent deficits possible	Rapid improvements	Variable Permanent neurologic deficits possible

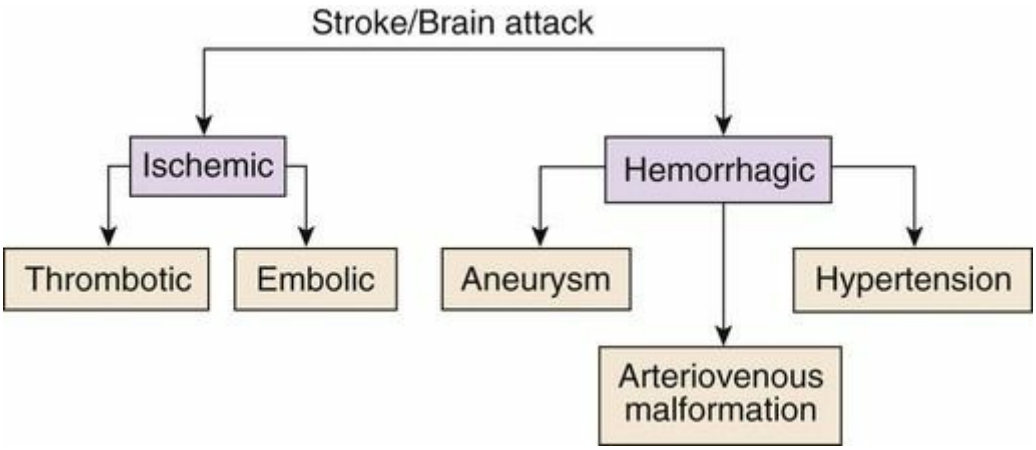

FIG. 45-1 Types of stroke/brain attack.

Ischemic Stroke.

An acute **ischemic stroke** is caused by the occlusion (blockage) of a cerebral artery by either a thrombus or an embolus. A stroke that is caused by a **thrombus** (clot) is referred to as a **thrombotic stroke,** whereas a stroke caused by an **embolus** (dislodged clot) is referred to as an **embolic stroke.**

Thrombotic strokes account for more than half of all strokes and are commonly associated with the development of atherosclerosis in either intracranial or extracranial arteries (usually the carotid arteries).

Atherosclerosis is the process by which fatty plaques develop on the inner wall of the affected arterial vessel. Chapter 36 describes this health problem, including its pathophysiology, in detail.

Rupture of one or more plaques promotes clot formation. When the clot is of sufficient size, it interrupts blood flow to the brain tissue supplied by the vessel, causing an ischemic (occlusive) stroke. The **bifurcation** (point of division) of the common carotid artery and the vertebral arteries at their junction with the basilar artery are the most common sites involved in atherosclerotic plaque formation. Because of the gradual nature of clot formation when atherosclerotic plaque is present, thrombotic strokes tend to have a *slow* onset, evolving over minutes to hours.

An *embolic stroke* is caused by a thrombus or a group of thrombi that break off from one area of the body and travel to the cerebral arteries via the carotid artery or vertebrobasilar system. The usual source of emboli is the heart. Emboli can occur in patients with atrial fibrillation, heart valve disease, mural thrombi after a myocardial infarction (MI), or a prosthetic heart valve. Another source of emboli may be plaque or clot that breaks off from the carotid sinus or internal carotid artery. Emboli tend to become lodged in the smaller cerebral blood vessels at their point of bifurcation or where the lumen narrows.

The middle cerebral artery (MCA) is most commonly involved in an embolic stroke. As the emboli occlude the vessel, ischemia develops and the patient experiences the clinical manifestations of the stroke. However, the occlusion may be temporary if the embolus breaks into smaller fragments, enters smaller blood vessels, and is absorbed. For these reasons, embolic strokes are characterized by the *sudden* development and rapid occurrence of neurologic deficits. The symptoms may resolve over several hours or a few days. Conversion of an occlusive stroke to a hemorrhagic stroke may occur because the arterial vessel wall is also vulnerable to ischemic damage from blood supply interruption. Sudden hemodynamic stress may result in vessel rupture, causing bleeding directly within the brain tissue.

Hemorrhagic Stroke.

The second major classification of stroke is hemorrhagic stroke. In this type of stroke, vessel integrity is interrupted and bleeding occurs into the brain tissue or into the subarachnoid space.

Intracerebral hemorrhage (ICH) describes bleeding into the brain tissue generally resulting from severe or sustained hypertension. Elevated blood pressure (BP) leads to changes within the arterial wall that leave it

likely to rupture. Damage to the brain occurs from bleeding, causing edema, distortion, and displacement, which are direct irritants to brain tissue. Cocaine use is one example of a trigger for sudden, dramatic blood pressure elevation leading to hemorrhagic stroke.

Subarachnoid hemorrhage (SAH) is much more common and results from bleeding into the subarachnoid space—the space between the pia mater and arachnoid layers of the meninges covering the brain. This type of bleeding is usually caused by a ruptured aneurysm or arteriovenous malformation (Mink & Miller, 2011b). It can also be caused by trauma.

An **aneurysm** is an abnormal ballooning or blister along a normal artery, which usually develops in a weak spot on the artery wall, typically along the posterior circulation such as the basilar artery, vertebral artery, or the superior cerebral artery. Larger aneurysms are more likely to rupture than smaller ones.

An **arteriovenous malformation (AVM)** is an uncommon abnormality that occurs during embryonic development. It is a tangled collection of malformed, thin-walled, dilated vessels without a capillary network (Fig. 45-2). Normally the capillary network lowers the pressure between the arterial and venous systems. In the absence of the capillary network, the thin-walled veins are subjected to arterial pressure. The abnormal vessels may eventually rupture, causing bleeding into the intracerebral tissue or spaces.

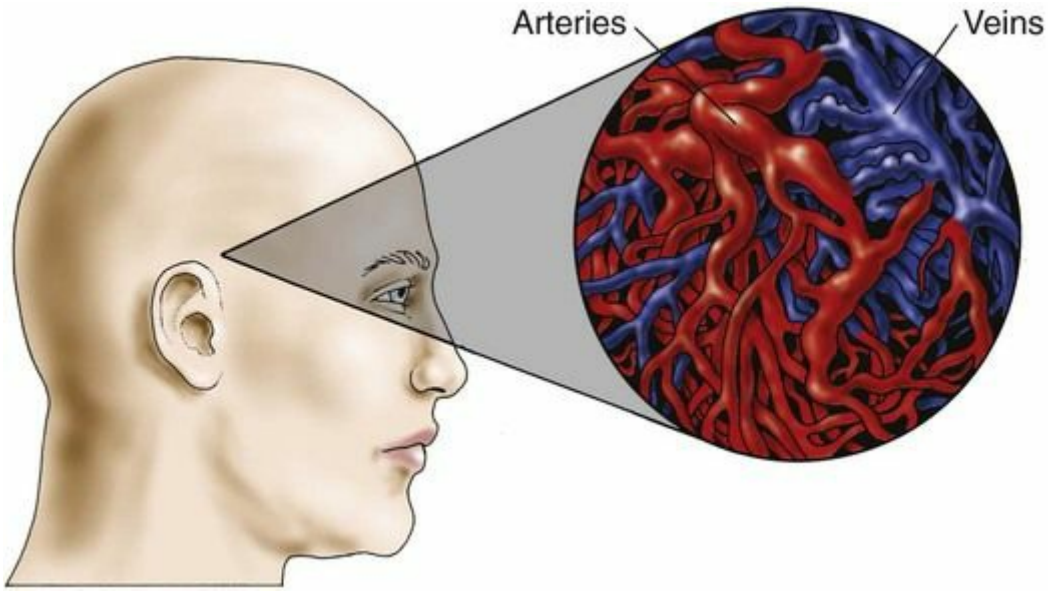

FIG. 45-2 Appearance of an arteriovenous malformation. Note the dilated, entangled blood vessels.

Vasospasm, a sudden and periodic constriction of a cerebral artery, often follows SAH or bleeding from an aneurysm or AVM rupture. Blood

flow to distal areas of the brain supplied by the damaged cerebral vessel is markedly diminished. Reduced perfusion from vasospasm contributes to secondary cerebral ischemia and infarction and further neurologic dysfunction.

Etiology and Genetic Risk

As with many health problems, the causes of stroke are likely a combination of genetic and environmental risk factors. Major risk factors increase the likelihood of strokes and can be divided into those that can be modified and those that cannot (nonmodifiable factors) (see Health Promotion and Maintenance section on p. 933). Many of these factors have a familial or genetic predisposition and are discussed elsewhere in this text. For example, the first-order relative (mother, father, sister, brother) stroke risk increases with a strong family history of hypertension, atherosclerotic disease, and a diagnosis of aneurysm. Relatives of a patient with an aneurysm, regardless of vessel location, may be at higher risk for intracranial aneurysms and should consider diagnostic testing and follow-up.

Incidence and Prevalence

It is estimated that there are more than 4.7 million stroke survivors in the United States. About 795,000 Americans have strokes each year, but deaths have declined over the past 15 years. The number of strokes occurring in the younger adult population is increasing (Lee et al., 2012). Strokes are associated with illicit drug use because many street drugs cause hypercoagulability, spasm of cerebral vessels, or hypertensive crisis.

Health Promotion and Maintenance

Risk factors that contribute to stroke are divided into three groups: risk factors that cannot be changed, risk factors that can be changed with medical treatment, and risk factors that can be changed by lifestyle modification.

People with predisposing health conditions should be aware that lifestyle habits contribute to stroke. Many of these factors contribute to other health problems. Teach them the importance of seeking professional health care and adhering to the recommended treatment plan. Recommend a diet high in fruits and vegetables and low in saturated fats. Light to moderate alcohol consumption may reduce the risk for stroke, but a higher consumption may increase it. Chart 45-2

describes common risk factors that can be changed (modifiable).

Chart 45-2 Patient and Family Education: Preparing for Self-Management

Common Modifiable Risk Factors for Developing a Stroke

- Smoking
- Substance use (particularly cocaine)
- Obesity
- Sedentary lifestyle
- Oral contraceptive use
- Heavy alcohol use
- Use of phenylpropanolamine (PPA), found in antihistamine drugs

Cultural Considerations

Patient-Centered Care QSEN

American Indian/Alaskan Native groups have the highest prevalence of stroke. Black men and women have more strokes than white men and women. Hispanic or Latino men have more strokes than non-Hispanic men. About half of the excess stroke risk in blacks between ages 45 and 65 years is attributable to traditional risk factors such as elevated systolic blood pressure and socioeconomic factors. These data suggest a critical need to study the role that nontraditional risk factors play in stroke development and severity in this group (Howard et al., 2011; Lakoski et al., 2011).

NCLEX Examination Challenge

Health Promotion and Maintenance

Which statements by a client or family member about preventing stroke indicate a need for further teaching by the nurse? **Select all that apply.**

A "I will adjust my aspirin drug dose depending on whether I have pain."
B "I have cut down on smoking to only a half-pack daily."
C "I need to walk at least 30 minutes most days of the week."
D "I need to consider salt content in the foods I eat at restaurants."
E "I don't need to worry about fat calories in what I eat—my heart is

fine!”

Patient-Centered Collaborative Care

Assessment

History.

Although an accurate history is important in the diagnosis of a stroke, *the first priority is to ensure the patient is transported to a stroke center.* A stroke center is designated by The Joint Commission for its ability to rapidly recognize and effectively treat strokes. At the center, the patients are evaluated for their eligibility to receive fibrinolytic therapy. Obtaining a history should not delay the patient's arrival to either the stroke center or interventional radiology within the stroke center. A focused history to determine if the patient has had a recent bleeding event or is taking an anticoagulant is an important part of the rapid stroke assessment protocol.

A more extensive history, after either fibrinolytic therapy or determination that the patient is unable to receive this therapy, assists in identifying the cause of the stroke and the area of brain involved. If possible, obtain a history of the patient's activity when the stroke began. Hemorrhagic strokes tend to occur during activity. Next ask the patient or a family member how the symptoms progressed. Be sure to document the history of the stroke's onset. Symptoms of a hemorrhagic stroke tend to occur abruptly, whereas thrombotic strokes generally have a more gradual progression. Determine the severity of the symptoms, such as whether they worsened after the initial onset or began to improve.

During the interview, observe the patient's level of consciousness (LOC) and assess for indications of cognitive or memory impairments and difficulties with speech or hearing. When LOC is suddenly decreased or altered, immediately determine if hypoglycemia or hypoxia is present because these conditions may mimic emergent neurologic disorders. Hypoglycemia and hypoxia are easily treated and reversed, unlike brain injury from poor perfusion or trauma.

Question the patient or family member about the presence of sensory perception deficits or motor changes, visual problems, problems with balance or gait, and changes in reading or writing abilities.

In addition, ask about the patient's medical history with specific attention directed toward a history of head trauma, diabetes, hypertension, heart disease, anemia, and obesity. Obtain a list of current medications, including prescribed drugs, over-the-counter (OTC) drugs,

herbal and nutritional supplements, and recreational (illicit) drugs. To complete the history, obtain data about the patient's social history, including education, employment, travel, leisure activities, and personal habits (e.g., smoking, diet, exercise pattern, drug and alcohol use).

The patient with a SAH, particularly when the hemorrhage is from a leaking aneurysm, often reports the onset of a sudden, severe headache described as "the worst headache of my life." Additional symptoms of SAH or cerebral aneurysmal and AVM bleeding are nausea and vomiting, photophobia, cranial neuropathy, stiff neck, and change in mental status. There may also be a family history of aneurysms.

Physical Assessment/Clinical Manifestations.

First-responder personnel (e.g., paramedics, emergency medical technicians) perform an initial neurologic examination using well-established stroke assessment tools.

Nursing Safety Priority QSEN

Critical Rescue

In the ED, assess the stroke patient within 10 minutes of arrival. This same standard applies to patients already hospitalized for other medical conditions who have a stroke. The priority is assessment of ABCs —**a**irway, **b**reathing, and **c**irculation. Many hospitals have designated stroke teams and centers that are expert in acute stroke assessment and management.

Nurses also perform a complete neurologic assessment on admission to the ED. The National Institutes of Health Stroke Scale (NIHSS) is a commonly used valid and reliable assessment tool that nurses complete as soon as possible after the patient arrives in the ED (Table 45-2). The NIHSS includes 11 areas of assessment (Mink & Miller, 2011a).

TABLE 45-2

NIH Stroke Scale

CATEGORY AND MEASUREMENT	SCORE*
1a. Level of Consciousness (LOC)	_____
0 = Alert; keenly responsive. 1 = Not alert; but arousable by minor stimulation to obey, answer, or respond. 2 = Not alert; requires repeated stimulation to attend or is obtunded and requires strong or painful stimulation to make movements (not stereotyped). 3 = Responds only with reflex motor or autonomic effects or totally unresponsive, flaccid, and areflexic.	
1b. LOC Questions	_____
0 = Answers two questions correctly. 1 = Answers one question correctly. 2 = Answers neither question correctly.	
1c. LOC Commands	_____
0 = Performs two tasks correctly. 1 = Performs one task correctly. 2 = Performs neither task correctly.	
2. Best Gaze	_____
0 = Normal. 1 = Partial gaze palsy; gaze is abnormal in one or both eyes, but forced deviation or total gaze paresis is not present. 2 = Forced deviation, or total gaze paresis not overcome by the oculocephalic maneuver.	
3. Visual	_____
0 = No visual loss. 1 = Partial hemianopia. 2 = Complete hemianopia. 3 = Bilateral hemianopia (blind including cortical blindness).	
4. Facial Palsy	_____
0 = Normal symmetrical movements. 1 = Minor paralysis (flattened nasolabial fold, asymmetry on smiling). 2 = Partial paralysis (total or near-total paralysis of lower face). 3 = Complete paralysis of one or both sides (absence of facial movement in the upper and lower face).	
5. Motor (Arm)	Right arm: _____ Left arm: _____
0 = No drift; limb holds 90 (or 45) degrees for full 10 seconds. 1 = Drift; limb holds 90 (or 45) degrees, but drifts down before full 10 seconds; does not hit bed or other support. 2 = Some effort against gravity; limb cannot get to or maintain (if cued) 90 (or 45) degrees, drifts down to bed, but has some effort against gravity. 3 = No effort against gravity; limb falls. 4 = No movement. Untestable = Amputation or joint fusion.	
6. Motor (Leg)	Right leg: _____ Left leg: _____
0 = No drift; leg holds 30-degree position for full 5 seconds. 1 = Drift; leg falls by the end of the 5-second period but does not hit bed. 2 = Some effort against gravity; leg falls to bed by 5 seconds, but has some effort against gravity. 3 = No effort against gravity; leg falls to bed immediately. 4 = No movement. Untestable = Amputation or joint fusion.	
7. Limb Ataxia	_____
0 = Absent. 1 = Present in one limb. 2 = Present in two limbs. Untestable = Amputation or joint fusion.	
8. Sensory	_____
0 = Normal; no sensory loss. 1 = Mild-to-moderate sensory loss; patient feels pinprick is less sharp or is dull on the affected side; or there is a loss of superficial pain with pinprick, but patient is aware of being touched. 2 = Severe-to-total sensory loss; patient is not aware of being touched in the face, arm, and leg.	
9. Best Language	_____
0 = No aphasia; normal. 1 = Mild-to-moderate aphasia; some obvious loss of fluency or facility of comprehension, without significant limitation on ideas expressed or form of expression. 2 = Severe aphasia; all communication is through fragmentary expression; great need for inference, questioning, and guessing by the listener. 3 = Mute, global aphasia; no usable speech or auditory comprehension.	
10. Dysarthria	_____
0 = Normal. 1 = Mild-to-moderate dysarthria; patient slurs at least some words and, at worst, can be understood with some difficulty. 2 = Severe dysarthria; patient's speech is so slurred as to be unintelligible in the absence of or out of proportion to any dysphasia, or is mute/anarthric. Untestable = Intubated or other physical barrier.	
11. Extinction and Inattention (Neglect)	_____
0 = No abnormality. 1 = Visual, tactile, auditory, spatial, or personal inattention or extinction to bilateral simultaneous stimulation in one of the sensory modalities. 2 = Profound hemi-inattention or extinction to more than one modality; does not recognize own hand or orients to only one side of space.	

*The patient can have a score of 0 to 40, with 0 having no neurologic deficits and 40 being the most deficits.

Modified from National Institutes of Health Stroke Scale, 2013. www.ninds.nih.gov/doctors/NIH_stroke_scale.pdf.

As the patients are transitioned from the ED to other settings, the most important area to assess is the patient's level of consciousness (LOC). Use the Glasgow Coma Scale (see Fig. 41-10) to frequently monitor for changes in LOC throughout the patient's acute care. Specific patient manifestations of stroke should also be monitored. Stroke symptoms depend on the extent and location of the ischemia and the arteries involved as described in Chart 45-3.

Chart 45-3 Key Features

Stroke Syndromes

Middle Cerebral Artery Strokes

- Contralateral hemiparesis: arm > leg
- Contralateral sensory perception deficit
- Homonymous hemianopsia
- Unilateral neglect or inattention
- Aphasia, anomia, alexia, agraphia, and acalculia
- Impaired vertical sensation
- Spatial deficit
- Perceptual deficit
- Visual field deficit
- Altered level of consciousness: drowsy to comatose

Posterior Cerebral Artery Strokes

- Perseveration (word or action repetition)
- Aphasia, amnesia, alexia, agraphia, visual agnosia, and ataxia
- Loss of deep sensation
- Decreased touch sensation
- Stupor, coma

Internal Carotid Artery Strokes

- Contralateral hemiparesis
- Sensory perception deficit
- Hemianopsia, blurred vision, blindness
- Aphasia (dominant side)
- Headache

- Bruit

Anterior Cerebral Artery Strokes

- Contralateral hemiparesis: leg > arm
- Bladder incontinence
- Personality and behavior changes
- Aphasia and amnesia
- Positive grasp and sucking reflex
- Perseveration
- Sensory perception deficit (lower extremity)
- Memory impairment
- Apraxic gait

Vertebrobasilar Artery Strokes

- Headache and vertigo
- Coma
- Memory loss and confusion
- Flaccid paralysis
- Areflexia, ataxia, and vertigo
- Cranial nerve dysfunction
- Disconjugate gaze
- Visual deficits (uniorbital) and homonymous hemianopsia
- Sensory loss: numbness

Stroke symptoms can appear at any time of the day or night (Beal, 2010). The five most common symptoms are (CDC, 2013b):

- Sudden confusion or trouble speaking or understanding others
- Sudden numbness or weakness of the face, arm, or leg
- Sudden trouble seeing in one or both eyes
- Sudden dizziness, trouble walking, or loss of balance or coordination
- Sudden severe headache with no known cause

Cognitive Changes.

The patient may have a variety of cognitive problems in addition to changes in LOC. LOC varies depending on the extent of increased intracranial pressure (ICP) caused by the stroke and on the location of the stroke. Assess for:

- Denial of the illness
- Spatial and proprioceptive (awareness of body position in space) dysfunction
- Impairment of memory, judgment, or problem-solving and decision-

making abilities
- Decreased ability to concentrate and attend to tasks

Dysfunction in one or more of these areas may be severe depending on the hemisphere involved (Chart 45-4).

Chart 45-4 Key Features

Left and Right Hemisphere Strokes

Feature	Left Hemisphere*	Right Hemisphere
Language	Aphasia Agraphia Alexia	Impaired sense of humor
Memory	Possible deficit	Disorientation to time, place, and person Inability to recognize faces
Vision	Inability to discriminate words and letters Reading problems Deficits in the right visual field	Visual spatial deficits Neglect of the left visual field Loss of depth perception
Behavior	Slowness Cautiousness Anxiety when attempting a new task Depression or a catastrophic response to illness Sense of guilt Feeling of worthlessness Worries over future Quick anger and frustration Intellectual impairment	Impulsiveness Lack of awareness of neurologic deficits Confabulation Euphoria Constant smiling Denial of illness Poor judgment Overestimation of abilities (risk for injury)
Hearing	No deficit	Loss of ability to hear tonal variations

*Location for speech in all but 5% to 20% of people.

The *right* cerebral hemisphere is more involved with visual and spatial awareness and **proprioception** (sense of body position). A person who has a stroke involving the right cerebral hemisphere is often unaware of any deficits and may be disoriented to time and place. Personality changes include impulsivity (poor impulse control) and poor judgment. The *left* cerebral hemisphere, the dominant hemisphere in all but about 15% to 20% of the population, is the center for language, mathematic skills, and analytic thinking. Therefore a left hemisphere stroke results in **aphasia** (inability to use or comprehend language), **alexia** or **dyslexia** (reading problems), **agraphia** (difficulty with writing), and **acalculia** (difficulty with mathematic calculation). A complete assessment of these problems is performed by a speech-language pathologist (SLP).

Motor Changes.

The motor examination provides information about which part of the brain is involved. A *right* **hemiplegia** (paralysis on one side of the body) or **hemiparesis** (weakness on one side of the body) indicates a stroke involving the *left* cerebral hemisphere because the motor nerve fibers cross in the medulla before entering the spinal cord and periphery. On the other hand, a *left* hemiplegia or hemiparesis indicates a stroke in the *right* cerebral hemisphere. If the brainstem or cerebellum is affected, the patient may experience hemiparesis or quadriparesis and **ataxia** (gait disturbance).

In collaboration with the physical therapist (PT) and occupational therapist (OT), assess the patient's muscle tone. The patient with **hypotonia,** or **flaccid paralysis,** cannot overcome the forces of gravity, and the extremities tend to fall to the side. The extremities feel heavy, and muscle tone is inadequate for balance, equilibrium, or protective mechanisms. **Hypertonia (spastic paralysis)** tends to cause fixed positions or contractures of the involved extremities. Range of motion (ROM) of the joints is restricted, and shoulder subluxation may easily occur from either spasticity or flaccidity. Also assess head and trunk control, balance, coordination, and gait. The patient who has had a stroke may also be unable to use an object correctly **(agnosia)** or carry out a purposeful motor activity or speech **(apraxia).**

Loss of neurologic control by the cerebral cortex causes a spastic (upper motor neuron) uninhibited bladder. Bowel function may also be affected. Assess the patient for incontinence (most common) or retention of urine and stool. Some patients have both problems.

Sensory Changes.

The sensory examination evaluates the patient's response to touch and painful stimuli. In addition to diminished motor function, decreased sensation typically occurs on the affected side of the body.

Evaluate for indications of **unilateral body neglect syndrome,** which is particularly common with strokes in the *right* cerebral hemisphere. In this syndrome, the patient is unaware of the existence of his or her left or paralyzed side. The typical picture is that of the patient sitting in a wheelchair and leaning to the left with the arm caught in the wheelchair wheel. When questioned, the patient often states that everything is fine and believes that he or she is sitting up straight in the chair. The patient may wash or dress only one side of the body or eat from only one side of a plate.

Another important part of the nursing assessment focuses on visual ability. Infarction or ischemia involving the carotid artery may cause

pupil constriction or dilation, **ptosis** (eyelid drooping), visual field deficits, or pallor and petechiae of the conjunctiva. **Amaurosis fugax,** a brief episode of blindness in one eye, results from retinal ischemia caused by ophthalmic or carotid artery insufficiency. **Hemianopsia,** or blindness in half of the visual field, results from damage to the optic tract or occipital lobe. Usually this deficit occurs as **homonymous hemianopsia,** in which there is blindness in the same side of both eyes (Fig. 45-3). The patient with this condition must turn his or her head to scan the complete range of vision. Otherwise, he or she does not see half of the visual field. For example, the patient eats only half of a meal because that is the only portion seen. Patients with brainstem or cerebellar damage may have abnormal eye movements, such as **nystagmus** (involuntary movements of the eyes).

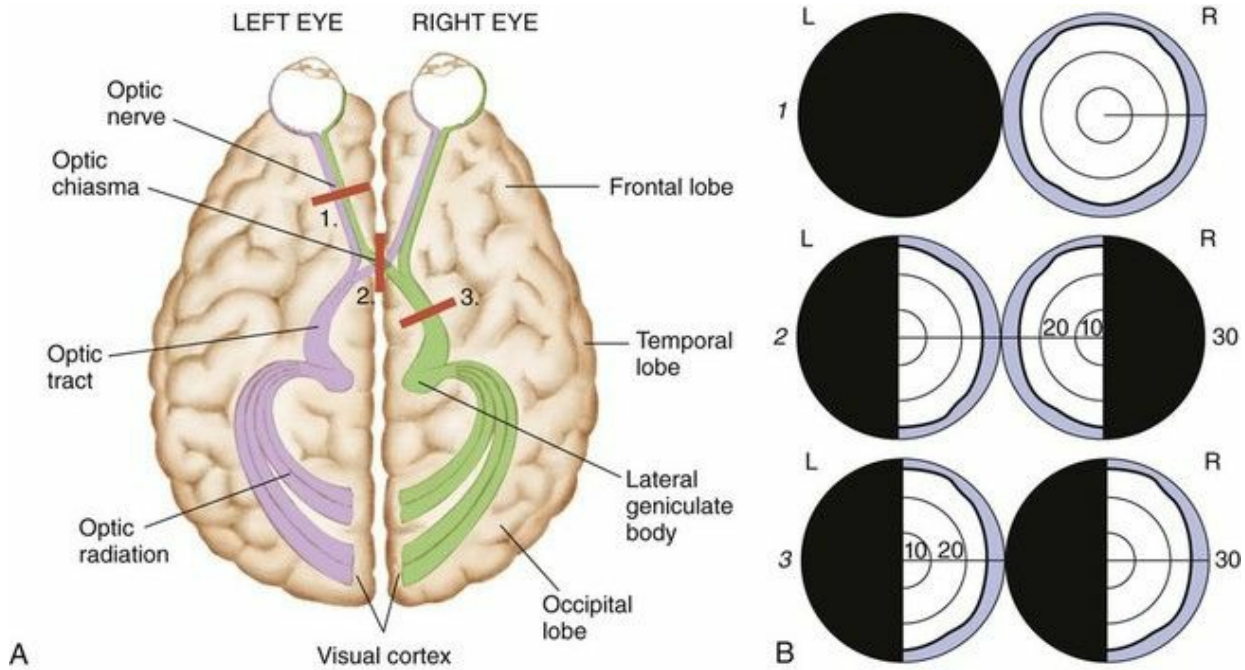

FIG. 45-3 **A,** Site of lesions causing visual loss. *1,* Total blindness left eye; *2,* Bitemporal hemianopia; *3,* Left homonymous hemianopia. **B,** Visual fields corresponding to lesions shown in **A.** *1,* Total blindness left eye; *2,* Bitemporal hemianopia; *3,* Left homonymous hemianopia.

Cranial Nerve Function.

Assess the patient's ability to chew, which reflects the function of cranial nerve (CN) V. Assessment of the patient's ability to swallow reflects the function of CNs IX and X. In addition, note any facial paralysis or paresis (CN VII), absent gag reflex (CN IX), or impaired tongue movement (CN

XII). The patient who has difficulty chewing or swallowing foods and liquids **(dysphagia)** is at risk for aspiration pneumonia and may become constipated or dehydrated from inadequate fluid intake.

Cardiovascular Assessment.

Patients with embolic strokes may have a heart murmur, dysrhythmias (most often atrial fibrillation), or hypertension. It is not unusual for the patient to be admitted to the hospital with a blood pressure greater than 180 to 200/110 to 120 mm Hg. Although a somewhat higher blood pressure of 150/100 mm Hg is needed to maintain cerebral perfusion after an acute ischemic stroke, pressures above these values may lead to another stroke.

Psychosocial Assessment.

The typical patient with a stroke is older than 60 years, is hypertensive, and has varying degrees of motor weakness and level of consciousness. Language and cognitive deficits, as well as behavior and memory problems, may also occur.

Assess the patient's reaction to the illness, especially in relation to changes in body image, self-concept, and ability to perform ADLs. In collaboration with the patient's family and friends, identify any problems with coping or personality changes.

Ask about the patient's financial status and occupation, because they may be affected by the residual neurologic deficits of the stroke. Patients who do not have disability or health insurance may worry about how their family will cope financially with the disruption in their lives. Early involvement of social services, certified hospital chaplain, or psychological counseling may enhance coping skills.

Assess for **emotional lability,** especially if the frontal lobe of the brain has been affected. In such cases, the patient laughs and then cries unexpectedly for no apparent reason. Explain these uncontrollable emotions to the family or significant others so they do not feel responsible for these reactions.

Laboratory Assessment.

Clinical history and presentation are usually enough to identify a stroke once it has occurred. No definitive laboratory tests confirm its diagnosis. Elevated hematocrit and hemoglobin levels are often associated with a severe or major stroke as the body attempts to compensate for lack of oxygen to the brain. An elevated white blood cell (WBC) count may indicate the presence of an infection, possibly subacute bacterial

endocarditis, or a response to physiologic stress or inflammation. Cardiac enzymes may be elevated in patients who have a cardiac cause for their stroke.

The health care provider typically requests a prothrombin time (PT) or international normalized ratio (INR) and a partial thromboplastin time (PTT) to establish baseline information in case anticoagulation therapy is started. These diagnostic tests may also provide supportive evidence that a hemorrhagic stroke has occurred.

Imaging Assessment.

Brain imaging is the most important tool for confirming the diagnosis of a stroke. *CT* without contrast is the standard for initial diagnosis (Mink & Miller, 2011b). Cerebral aneurysms or AVM may also be identified. For a patient with an ischemic or occlusive stroke, the head CT is usually initially negative, indicating a thrombotic or embolic stroke rather than intracerebral hemorrhage. After the first 24 hours, CT shows progressive changes of ischemia, infarction, and associated cerebral edema. This test establishes baseline information for future comparison in case the patient's condition deteriorates. In addition, the scan enables the physician to identify pathologic changes that may mimic a stroke, such as a brain tumor or cerebral hematoma, both of which may be unrelated to cerebrovascular disease.

MRI demonstrates ischemic brain injury earlier than CT. *Magnetic resonance angiography (MRA)* and multimodal techniques such as perfusion-weighted imaging enhance the sensitivity of the MRI to detect early changes in the brain, including confirming blood flow. *Ultrasonography* (carotid duplex scanning) and *echocardiography* help determine additional cardiovascular risks.

Other Diagnostic Assessment.

To assist in the determination of a cardiac cause of a stroke, the health care provider may request a 12-lead electrocardiogram (ECG) and an evaluation of cardiac enzymes. As with other cardiovascular diseases, it is not unusual to find these changes on the ECG: inverted T wave, ST depression, and prolongation of the QT interval in the cardiac cycle.

Analysis

The priority NANDA-I nursing diagnoses and collaborative problems for patients with a stroke include:

1. Inadequate perfusion to the brain related to interruption of arterial

blood flow and a possible increase in ICP
2. Impaired Swallowing related to neuromuscular impairment (NANDA-I)
3. Impaired Physical Mobility and self-care deficit related to neuromuscular impairment or cognitive impairment (NANDA-I)
4. Aphasia or dysarthria related to decreased circulation in the brain or facial muscle weakness
5. Urinary and/or Bowel Incontinence related to reflex bladder and bowel (NANDA-I)
6. Sensory perception deficits from altered neurologic reception, transmission, and perception
7. Unilateral Neglect related to disturbed perceptual abilities or hemianopsia (NANDA-I)

Planning and Implementation

Improving Cerebral Perfusion

Planning: Expected Outcomes.

The patient with a stroke is expected to have an adequate blood flow to the brain and through the cerebral blood vessels to maintain brain function and prevent further brain injury.

Interventions.

Interventions for patients experiencing strokes are determined primarily by the type and extent of the stroke. For patients having ischemic strokes, the standard of practice is to start two IV lines with non-dextrose isotonic saline (Hughes, 2011). Consider placing the patient in a supine position with a low head-of-bed elevation to maximize cerebral perfusion. The immediate primary role of the nurse is to manage the patient receiving treatment and continuously assess for increasing intracranial pressure.

Nonsurgical Management.

Nursing interventions are initially aimed at monitoring for neurologic changes or complications associated with stroke and its treatment. The two major treatment modalities for patients with acute ischemic stroke are systemic fibrinolytic therapy and endovascular interventions. Regardless of the immediate management approach used, once the patient is stable, provide ongoing supportive care. Provide interventions to prevent and/or monitor for early signs of complications, such as hyperglycemia, urinary tract infection, and pneumonia. Implement

interventions to prevent patient falls. These health problems are discussed in appropriate chapters in this textbook.

Fibrinolytic Therapy.

For select patients with ischemic strokes, early intervention with systemic fibrinolytic therapy ("clot-busting drug") is the standard of practice to improve blood flow to or through the brain. The success of fibrinolytic therapy for a stroke depends on the interval between the time symptoms begin and available treatment. It also depends on where the treatment is given. Hospitals with stroke centers or specialized stroke teams who care for numerous stroke patients have lower mortality rates than those hospitals that care for fewer of these patients (Hughes, 2011).

Intravenous (systemic) fibrinolytic therapy (also called *thrombolytic therapy*) for an acute ischemic stroke dissolves the cerebral artery occlusion to re-establish blood flow and prevent cerebral infarction. Alteplase (Activase) is the only drug approved at this point for the treatment of acute ischemic stroke. It is a fibrinolytic that activates plasminogen to degrade the thrombus. The most important factor in whether or not to give alteplase is the time between symptom onset and time seen in the stroke center. In 2009, the American Stroke Association recommended an expanded time interval from 3 to 4.5 hours to administer this fibrinolytic for patients unless they fall into these categories:

- Age older than 80 years
- Anticoagulation with an international normalized ratio less than or equal to 1.7
- Baseline National Institutes of Health Stroke Scale score greater than 25
- History of both stroke and diabetes

Gender Health Consideratons

Patient-Centered Care QSEN

Previous studies have suggested that being a female is a risk factor for delay in recognizing early symptoms of stroke and may contribute to ineligibility for fibrinolytic therapy. Current data show that women arrive at the ED at the same speed as men after acute ischemic stroke, so the delay in treatment does not appear to be related to transport time once the emergency medical transport system is called. Woman may be less likely to demonstrate focal symptoms, leading to diagnostic or treatment delay (Beal, 2010). Women have greater functional

impairments at 3 months and 12 months after stroke and stroke treatment despite similar pre-stroke functional ability and admission score of stroke severity (Knauft et al., 2010).

Fibrinolytic therapy is explained to the patient and/or family member, and informed consent is obtained. The dosage of the drug is based on the patient's actual weight. Each hospital has strict protocols for mixing and administering the fibrinolytic drug and for monitoring the patient before and after fibrinolytic drug administration.

Nursing Safety Priority QSEN

Drug Alert

In addition to frequent monitoring of vital signs, carefully observe for signs of intracerebral hemorrhage and other signs of bleeding during administration of fibrinolytic drug therapy. Other best practice interventions are listed in Chart 45-5.

Chart 45-5 Best Practice for Patient Safety & Quality Care QSEN

Nursing Interventions During and After IV Administration of Alteplase

- Perform a double check of the dose. Use a programmable pump to deliver the initial dose of 0.9 mg/kg (maximum dose 90 mg) over 60 minutes with 10% of the dose given as a bolus over 1 minute. Do not manually push this drug.
- Admit the patient to a critical care or specialized stroke unit.
- Perform neurologic assessments, including vital signs, every 10 to 15 minutes during infusion and every 30 minutes after that for at least 6 hours; monitor hourly for 24 hours after treatment. Be consistent regarding the device used to obtain blood pressures because blood pressures can vary when switching from a manual to a noninvasive automatic to an intra-arterial device.
- If systolic blood pressure is 180 mm Hg or greater or diastolic is 105 mm Hg or greater, give antihypertensive drugs as prescribed.
- To prevent bleeding, do not place invasive tubes, such as nasogastric (NG) tubes or indwelling urinary catheters, until the patient is stable.
- Discontinue the infusion if the patient reports severe headache or has severe hypertension, bleeding, nausea, and/or vomiting; notify the

health care provider immediately.
- Obtain a follow-up CT scan after treatment before starting antiplatelet or anticoagulant drugs.

NCLEX Examination Challenge

Physiological Integrity

A client begins to have severe epistaxis after completing a dose of alteplase. In order of priority, what are the nurse's actions?
A Obtain vital signs.
B Assess the airway, and set up suction at bedside.
C Draw blood for anticoagulation studies.
D Call the health care provider.

Endovascular Interventions.

Endovascular procedures include intra-arterial thrombolysis using drug therapy, mechanical **embolectomy** (clot removal), and carotid stent placement. *Intra-arterial thrombolysis* has the advantage of delivering the fibrinolytic agent directly into the thrombus within 6 hours of the stroke's onset. It is particularly beneficial for some patients who have an occlusion of the middle cerebral artery or those who arrive in the ED after the window for rtPA. If the patient arrives in less than 8 hours, the interventional neuroradiologist may perform mechanical embolectomy using special instrumentation systems that can remove the clot by suction or other method (Mink & Miller, 2011a). Patients having either fibrinolytic therapy or endovascular interventions are admitted to the critical care setting for intensive collaborative monitoring.

Carotid artery angioplasty with stenting is common to *prevent* or, in some cases, help manage an acute ischemic stroke. This interventional radiology procedure is usually done under moderate sedation. It may be performed by a cardiovascular surgeon or interventional radiologist. A technique using a distal/embolic protection device has made this procedure very safe. The device is placed beyond the stenosis through a catheter inserted into the femoral artery (groin). The device catches any clot debris that breaks off during the procedure. Placement of a carotid stent is performed to open a blockage in the carotid artery typically at the division of the common carotid artery into the internal and external carotid arteries. Throughout the procedure, the patient's neurologic and cardiovascular statuses are assessed.

Nursing Safety Priority QSEN

Action Alert

Before discharge after carotid stent placement, teach the patient to report these symptoms to the health care provider as soon as possible:

- Severe headache
- Change in level of consciousness or cognition (e.g., drowsiness, new-onset confusion)
- Muscle weakness or motor dysfunction
- Severe neck pain
- Neck swelling
- Hoarseness or difficulty swallowing (due to nerve damage)

When the stroke is hemorrhagic and the cause is related to an AVM or cerebral aneurysm, the patient is evaluated for the optimal procedure to stop bleeding. The goal of treatment is to embolize abnormal vessels or the aneurysm itself. Some procedures can be used to prevent bleeding in an AVM or aneurysm that is discovered *prior* to symptom onset or SAH. Procedures occur in the interventional radiology suite or operating room. The different approaches used by the interventional neuroradiologist or neurosurgeon to embolize the vessel defect and nursing implications during postprocedure recovery are summarized in Table 45-3. How a brain aneurysm or AVM is treated depends on the size of the aneurysm, whether it has ruptured (bled), where in the brain it is located, and the age and overall health of the patient. Fig. 45-4 illustrates a common approach to manage an intact (non-ruptured) AVM.

TABLE 45-3

Surgical and Interventional Radiologic Procedures to Manage Intracranial Aneurysms and Arteriovenous Malformations

PROCEDURE	DESCRIPTION	NURSING IMPLICATIONS
Surgical ligation or resection	A neurosurgeon performs a full or micro-craniectomy. Once the defective vessels are located, they are separated from brain tissue and removed. A graft may be placed to preserve blood flow of the parent vessel. Surgical elimination of arteriovenous malformation (AVM) or aneurysm depends on the size of the defect, the risk for major brain damage during resection, the absence	Ligation and clip placement can be done simultaneously. Preoperative and postoperative care are similar to that for patients undergoing a craniotomy as described in this chapter. Perioperative care described in Chapters 14-16 is also essential.

	of bleeding, and the condition of the patient preoperatively.	
Clip	Clips are small devices, similar to a paperclip, that are clamped over the aneurysm base to isolate it from the parent vessel circulation. The neurosurgeon performs a full craniotomy or micro-craniotomy to visualize the aneurysm in the operating room. A contrast agent is injected into the vessel to determine the degree of aneurysm occlusion and parent vessel patency. Micro-Doppler ultrasonography can also be used to evaluate the placement of the clips intraoperatively.	Older clips have metal components, preventing use of magnetic resonance imaging postprocedure. It is possible for clips to move, and movement is greatest immediately postplacement. Movement may occur as late as 2-5 years after placement. Patients require care as outlined under the perioperative chapters with close neurologic assessment to detect early rebleeding or migration of the clip. Changes in cognition or new focal neurologic deficits must be communicated urgently to the neurosurgeon.
Coil —With stent assist —With balloon assist	Detachable coils are placed under fluoroscopy to occlude the aneurysm without interrupting main vessel flow. Coils are platinum, and some are coated with polymers to promote fibrosis. Stents are used to enhance vessel stability and are an adjunct prior to vessel rupture. Balloon-assisted coil placement is thought to enhance endovascular remodeling and decrease postprocedure rebleeding when the aneurysm is intact before the procedure.	Up to 20% of patients experience bleeding or rebleeding after coil placement, with the greatest risk for bleeding occurring in the year following the procedure. As a result, patients are advised to avoid drugs that interfere with clotting during recovery. Patients return for re-evaluation typically at 3, 6, and 12 months to determine the extent of embolization. Full embolization is the goal for this type of procedure; it is possible to undergo a second placement of coils to achieve best results. Teach the patient to maintain an ongoing relationship with the neurosurgeon to evaluate the effectiveness of the procedure over time. Perform frequent neurologic assessments in the first 24 hours postprocedure to detect intracranial bleeding early.
Flow diversion	These stent-like devices look like a braided cylindric mesh and are delivered under fluoroscopy to the neck of an aneurysm, shifting blood flow away from the vessel defect and resulting in a thrombosed (clotted) aneurysm over 5-6 months. An example is the pipeline embolization device (PED).	These are the newest devices for treatment of intracranial aneurysms. Full embolization takes 5-12 months, so ongoing monitoring by the neurosurgery staff in community health settings (office or clinic) is common postprocedure. Encourage the patient to avoid strenuous activity or situations that create hypertension while the prolonged embolization occurs.
Liquid polymer embolization	This procedure is reserved for AVMs. It is used either preoperatively to reduce the size of the AVM or as a permanent treatment for a small	This procedure is often used prior to surgical ligation or stereotactic surgery to reduce the size of the AVM and decrease the number of branches of the

	AVM. Treatment can occur once or over several stages to achieve maximum AVM reduction.	tangled, defective vessel. Help the patient understand that this procedure may not provide definitive treatment if it is either staged or planned to precede surgery. Perform frequent neurologic assessment in the 24 hours postprocedure to detect early signs of bleeding.
Stereotactic surgery	Under the simultaneous supervision of the neurosurgeon, radiologist, and physicist, microwave or radio beams are directed to the defective vessel(s) to obliterate the defect.	Stereotactic surgery requires that the patient undergo extensive diagnostic study and be placed in a brace that will hold the head fixed while the beam is directed toward the abnormal vessel. Swelling around the beam site may alter neurologic status. Perform neurologic assessment with each opportunity to take vital signs, and inform the neurosurgeon of any deterioration in consciousness or new focal weakness or sensory changes.

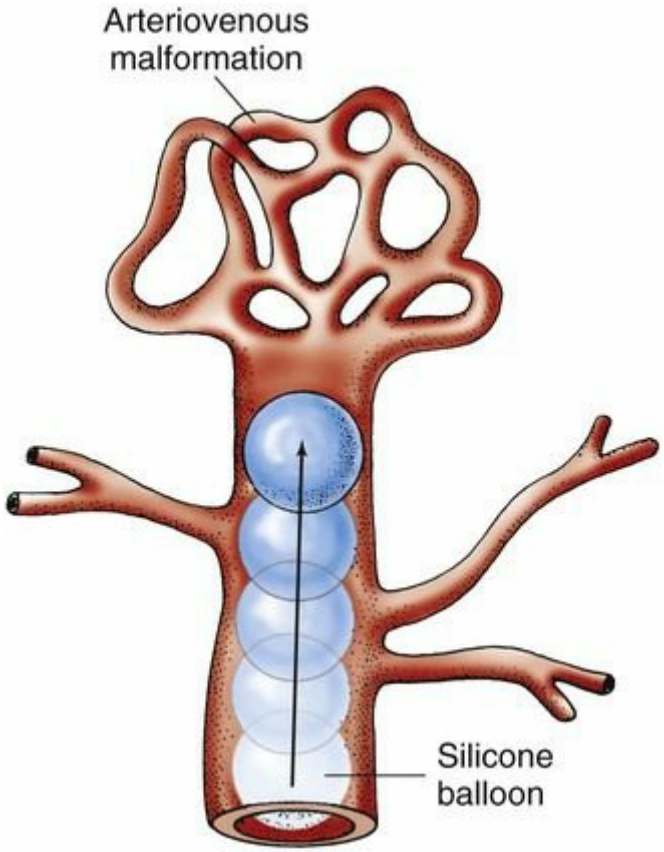

FIG. 45-4 Embolization procedure to treat an arteriovenous malformation. The liquid embolic agent causes vessel thrombosis.

Following endovascular procedures, a rare postprocedure

complication, hyperperfusion syndrome, has a high morbidity and mortality rate. This syndrome is thought to be the result of an impaired autoregulation of cerebral blood flow that results from long-standing decreased cerebral perfusion pressure resulting from carotid artery disease. The signs and symptoms include severe temporal headache, hypertension, seizures, and focal neurologic deficits. This syndrome may be associated with intracranial hemorrhage and may occur within 1 hour postprocedure up to 24 hours or even 1 week later (Oran & Oran, 2010).

Monitoring for Increased Intracranial Pressure.

The patient is most at risk for increased ICP resulting from edema during the first 72 hours after onset of the stroke. Some patients may have worsening of their neurologic status starting within 24 to 48 hours after their endovascular procedure from increased ICP (Chart 45-6). Reassess patients with stroke and with endovascular treatment of stroke symptoms every 1 to 4 hours depending on severity of the condition. Use the approved assessment strategy and documentation tools.

Chart 45-6 Key Features

Increased Intracranial Pressure (ICP)

- Decreased level of consciousness (LOC) (lethargy to coma)
- Behavior changes: restlessness, irritability, and confusion
- Headache
- Nausea and vomiting (may be projectile)
- Change in speech pattern
  - Aphasia
  - Slurred speech
- Change in sensorimotor status
  - Pupillary changes: dilated and nonreactive pupils ("blown pupils") or constricted and nonreactive pupils
  - Cranial nerve dysfunction
  - Ataxia
- Seizures (usually within first 24 hours after stroke)
- Cushing's triad
  - Severe hypertension
  - Widened pulse pressure
  - Bradycardia
- Abnormal posturing:
  - Decerebrate (extensor)

■ Decorticate (flexion)

Nursing Safety Priority QSEN

Critical Rescue

Be alert for symptoms of increased ICP in the stroke patient, and report any deterioration in the patient's neurologic status to the health care provider immediately! *The first sign of increased ICP is a declining level of consciousness (LOC).*

The best head-of-bed (HOB) positioning has not yet been determined; more studies are needed to determine best practice. A reduced head elevation of less than 25 degrees can improve perfusion pressure to damaged brain in ischemic conditions like most strokes. However, a HOB elevation greater than 30 degrees can improve oxygenation and reduce aspiration risk. Provide oxygen therapy to prevent hypoxia for patients with oxygen saturation less than 93%. Maintain the head in a midline, neutral position to help promote venous drainage from the brain. In collaboration with other team members, avoid sudden and acute hip or neck flexion during positioning. Extreme hip flexion may increase intrathoracic pressure, leading to decreased cerebral venous outflow and elevated ICP. Extreme neck flexion also interferes with venous drainage from the brain and intracranial dynamics.

Additional nursing considerations include avoiding the clustering of nursing procedures (e.g., giving a bath followed immediately by changing the bed linen). When multiple activities are clustered in a narrow time period, the effect on ICP can be dramatic elevation. Hyperoxygenating the patient before suctioning may also be appropriate to avoid even transient hypoxemia and resultant ICP elevation from dilation of cerebral arteries. Coughing and suctioning increase ICP. Careful attention to airway management can reduce unnecessary increases in ICP.

A quiet environment is particularly important for the patient experiencing a headache, which is common with a cerebral hemorrhage or increased ICP. The patient may have **photophobia** (sensitivity to light). Therefore keep the room lights very low.

Close physiologic monitoring of blood pressure, heart rhythm, oxygen saturation, blood glucose, and body temperature may prevent secondary brain injury and promote good outcomes after stroke. High quality evidence is not available on how to manage blood pressure in patients

with hemorrhagic strokes, but for many patients, severe hypertension is the cause of their stroke (Mink & Miller, 2011b). Assessing vital signs (VS) regularly and communicating concerning changes from baseline promote quality and safety for both individualized and system-wide outcomes.

Monitor vital signs closely, at least every 1 to 2 hours. Notify the health care provider if the blood pressure or core temperature does not meet a prescribed range of values. Although the optimal blood pressure range after stroke is controversial, the health care provider may allow the patient with *acute ischemic stroke* to be slightly hypertensive with a systolic blood pressure (SBP) between 140 and 150 mm Hg to promote cerebral tissue perfusion. A SBP greater than 180 mm Hg or a diastolic BP greater than 110 mm Hg is generally considered dangerous, contributing to a risk for hemorrhagic stroke or rebleeding of an aneurysm (if present). Carefully monitor the patient's temperature because fever may extend the area of injury in the brain.

Nursing Safety Priority QSEN

Critical Rescue

If the stroke patient's SBP is more than 180 mm Hg, notify the health care provider immediately and anticipate prescription of an IV antihypertensive medication. Monitor the patient's BP and mean arterial pressure (MAP) every 5 minutes until the SBP is between 140 and 150 mm Hg to maintain brain perfusion. Avoid a sudden SBP drop to less than 120 mm Hg with drug administration.

Monitoring for Other Complications.

Monitor the patient with an aneurysm or arteriovenous malformation (AVM) as well as patients following repair of these vessel malformations for signs and symptoms of hydrocephalus and vasospasm. **Hydrocephalus** (increased cerebrospinal fluid [CSF] within the ventricular and subarachnoid spaces) may occur as a result of blood in the CSF. This prevents CSF from being reabsorbed properly by the arachnoid villi. Cerebral edema, which interferes with the flow of CSF out from the ventricular system, may also develop. Eventually the ventricles become enlarged. If hydrocephalus is left untreated, increased intracranial pressure (ICP) results. Observe for clinical manifestations of hydrocephalus, which are similar to those of ICP elevation, including a change in the LOC. Clinical findings may also include headache, pupil

changes, seizures, poor coordination, gait disturbances (if ambulatory), and behavior changes.

If blood is in the subarachnoid space, the patient is at risk for cerebral vasospasm. Clinical manifestations of vasospasm may include decreased LOC, motor and reflex changes, and increased neurologic deficits (e.g., cranial nerve dysfunction, motor weakness, and aphasia). The symptoms may fluctuate with the occurrence and degree of vasospasm present. Hemorrhage-related cerebral vasospasm can result in permanent vascular changes and irreversible neurologic impairment.

Rebleeding or rupture is a common complication for the patient with an aneurysm or AVM. Recurrent hemorrhage may occur within 24 hours of the initial bleed or rupture and up to 7 to 10 days later. About 20% of patients experience a second episode of bleeding after a repair of vessel malformations. Assess for severe headache, nausea and vomiting, a decreased LOC, and additional neurologic deficits. Potential consequences of a second cerebral hemorrhagic event may be catastrophic.

Patients admitted to a critical care unit are observed for dysrhythmias with cardiac monitoring. The nurse performs a cardiac assessment, with particular attention to identify the presence of cardiac murmurs or atrial fibrillation (AF). Cardiac valve disorders, manifested by a murmur or AF, place the patient at increased risk for emboli.

Both hyperglycemia and hypoglycemia are associated with new, secondary brain damage. Too high or too low blood sugar values increase the area of primary brain damage and contribute to greater disability from stroke. Monitor the patient's finger stick blood sugars (FSBS) frequently. Perform an FSBS when there is any unexplained decrease in level of consciousness for the patient admitted with a central nervous system injury or insult. Ensure daily communication with the health care team members to share desired glycemic outcomes and interventions to achieve them.

Ongoing Drug Therapy.

Ongoing drug therapy depends on the type of stroke and the resulting neurologic dysfunction. In general, the purposes of drug therapy are to prevent further thrombotic episodes (anticoagulation) and to protect the neurons from hypoxia.

The use of aspirin or other antiplatelet drug is considered for treatment following acute ischemic strokes or for preventing future strokes when risk factors of prodromal symptoms (TIA) occur (Bousser, 2012). Sodium heparin and other anticoagulants, such as warfarin

(Coumadin, Warfilone), are used in the presence of atrial fibrillation. *Anticoagulants are high-alert drugs that can cause bleeding, including intracerebral hemorrhage.*

An *initial* dose of 325 mg of aspirin (Ecotrin, Ancasal) is recommended within 24 to 48 hours after stroke onset. Aspirin should not be given within 24 hours of rtPA administration. Low-dose aspirin is an antiplatelet drug and reduces blood clotting by reducing platelet adhesiveness (clumping). Aspirin can cause bruising, hemorrhage, and liver disease over a long-term period. Teach the patient to report any unusual bruising or bleeding to the health care provider.

A calcium channel blocking drug that crosses the blood-brain barrier such as nimodipine (Nimotop) may be given to treat or prevent cerebral vasospasm after a subarachnoid hemorrhage. Vasospasm, which usually occurs between 4 and 14 days after the stroke, slows blood flow to the area and worsens ischemia. Nimodipine works by relaxing the smooth muscles of the vessel wall and reducing the incidence and severity of the spasm. Neurologic functioning may improve, and further deterioration from ischemia is then prevented. In addition, this drug dilates collateral vessels to ischemic areas of the brain.

Stool softeners, analgesics for pain, and antianxiety drugs may also be prescribed as needed for symptom management. Stool softeners also prevent the Valsalva maneuver during defecation to prevent increased ICP.

Surgical Management.

Few patients are candidates for immediate surgery once a stroke occurs. A neurosurgeon may perform a decompressive craniectomy (explained on p. 956) to manage refractory intracranial hypertension in a patient with a massive stroke.

Following recovery from a stroke or to prevent a TIA from progressing to a stroke, the patient may have surgery to improve cerebral circulation. In an **extracranial-intracranial bypass**, the surgeon performs a craniotomy (surgical opening into the brain through the skull) and bypasses the blocked artery by making a graft or a bypass from the first artery to the second artery. This procedure establishes blood flow around the blocked artery and re-establishes blood flow to the involved areas. The two most common techniques are the superficial temporal artery–to–middle cerebral artery (STA-MCA) graft and the occipital–to–posterior inferior cerebellar artery (PICA) bypass.

Whenever possible, an AVM is also totally removed via a craniotomy. The surgeon cuts and separates the group of vessels and removes the

defect. Radiosurgery (Gamma Knife) can also be used by the neurosurgeon. Radiation delivered during surgery results in fibrous thickening of the endothelial lining of the vessels to prevent further vessel enlargement and ultimately eliminate the lesion from the cerebral circulation. Improved microsurgical techniques have significantly reduced morbidity and mortality rates, and these procedures are becoming the treatment of choice in many medical centers.

Managing Impaired Swallowing

Planning: Expected Outcomes.

The patient with a stroke is expected to avoid aspiration and have adequate nutrition to promote health and prevent complications, including major weight loss.

Interventions.

Aspiration is a frequent complication for patients with dysphagia (difficulty swallowing) (Hughes, 2011). Many of these aspirations are "silent" and are not recognized until pulmonary complications occur.

Nursing Safety Priority QSEN

Action Alert

The best practice for all *suspected* and *diagnosed* stroke patients is to maintain a NPO status until their swallowing ability is assessed. Before the patient is given any liquids, food, or medication, he or she must be screened for the ability to swallow. Follow agency guidelines for screening or use an evidence-based bedside swallowing screening tool to determine if dysphagia is present. If dysphagia is present, develop a plan of care to prevent aspiration and support nutrition.

Observe the patient for facial drooping, drooling, impaired voluntary cough, hoarseness, incomplete mouth closure, or cranial nerve palsies. Next check the gag and cough reflexes. If the patient does not pass this swallowing screen, collaborate with the speech-language pathologist (SLP) to conduct a bedside swallowing evaluation. He or she may recommend a modified barium swallow (video fluoroscopy) to identify specific structures that are impaired during swallowing. *Ensure that the patient remains completely NPO status until the SLP determines that the patient can tolerate liquids or foods without aspirating.* Based on the

complete swallowing evaluation, the SLP makes recommendations for feeding for the staff to follow. Remind all unlicensed assistive personnel (UAP) and the family about the need to follow these precautions exactly as they are written.

Some patients can swallow without difficulty but are at risk for aspiration because they are easily distracted and impulsive. These patients require a distraction-free environment with minimal disruption from television, visitors, or environmental noise. Observe for indications of fatigue, because it can significantly interfere with the patient's desire and ability to eat.

Studies indicate that as many as 50% of patients are malnourished at 2 to 3 weeks after a severe stroke. To avoid this complication, collaborate with the dietitian to provide an accurate, comprehensive nutritional assessment on admission and throughout the hospital stay (Perry et al., 2013). Implement nutritional interventions, such as an early gastrostomy or oral nutrition, by at least the third or fourth hospital day to prevent weight loss, an altered immune status, increased length of stay, and increased mortality (Hughes, 2011).

For patients who can tolerate oral foods and liquids, follow the SLP's recommendations for thickened liquids, head positioning, and patient teaching to prevent aspiration. Teach UAP and family members how to follow these instructions, and have them readily available for reference.

NCLEX Examination Challenge

Physiological Integrity

A client with a confirmed acute ischemic stroke is comatose but breathing spontaneously. The client has an advance directive requesting limited resuscitation and is not a candidate for fibrinolytic therapy. What is the nurse's priority action on admission?

A Ask for palliative care consultation to assist with end-of-life decision making.

B Consult with the speech-language pathologist about alternative strategies for communication.

C Evaluate swallowing ability with an institution-specific, evidence-based protocol.

D Assess vital signs and determine if the advance directives need to be communicated to the health care provider.

Improving Mobility and Promoting Self-Care

Planning: Expected Outcomes.

The patient with a stroke is expected to ambulate and provide self-care independently, with or without one or more assistive-adaptive devices.

Interventions.

Patients who have had a stroke often have flaccid or spastic paralysis. It is not unusual for the patient to eventually have a flaccid arm and spastic leg on the affected side because the affected leg often regains function more quickly than the arm. Patients begin rehabilitation as soon as possible to regain function and prevent complications of immobility, such as pneumonia, atelectasis, and pressure ulcers.

Nursing Safety Priority QSEN

Action Alert

Be sure to support the affected flaccid arm of the stroke patient, and teach UAP to avoid pulling on it. Position the arm on a pillow while the patient is sitting to prevent it from hanging freely, which could cause shoulder subluxation. The physical or occupational therapist provides a sling-like device to support the arm during ambulation.

Another major complication of impaired mobility is the development of venous thromboembolism (VTE), especially deep vein thrombosis (DVT) that can lead to a pulmonary embolism (PE). This risk is highest in older patients and those with a severe stroke. Per The Joint Commission's Core Measures for VTE, provide care to prevent this complication by applying intermittent sequential pneumatic devices, changing the patient's position frequently, and ambulating the patient if possible. Report any indications of DVT to the health care provider, and document assessments in the patient's record. Chapter 36 discusses VTE prevention in detail.

The rehabilitation therapists evaluate the patient's ability to perform mobility skills, basic ADLs, and household tasks that will be performed at home. After a thorough evaluation, collaborate with them to develop a plan of care to promote patient independence, with or without assistive or adaptive devices. Therapy begins in the hospital setting and continues after discharge in most cases. Chapter 6 describes interventions for rehabilitation, including improving mobility and promoting self-care.

Promoting Effective Communication

Planning: Expected Outcomes.

The patient with a stroke is expected to receive, interpret, and express spoken, written, and nonverbal messages, if possible. However, some patients may need to develop strategies for alternative methods of communication, such as pictures or nonverbal language.

Interventions.

Language or speech problems are usually the result of a stroke involving the dominant hemisphere. The left cerebral hemisphere is the speech center in most patients. Speech and language problems may be the result of aphasia or dysarthria. Whereas aphasia is caused by cerebral hemisphere damage, **dysarthria** (slurred speech) is due to a loss of motor function to the tongue or to the muscles of speech, causing facial weakness and slurred speech. Involvement of the speech-language pathologist (SLP) as early as possible in the hospitalization greatly increases the patient's chances for optimal recovery. Remind patients to practice their exercises for dysarthria to strengthen their facial and oral muscles.

Aphasia can be classified in a number of ways. Most commonly, it is classified as expressive, receptive, or mixed (Table 45-4). **Expressive (Broca's, or motor) aphasia** is the result of damage in Broca's area of the frontal lobe. It is a motor speech problem in which the patient generally understands what is said but cannot communicate verbally. He or she also has difficulty writing but may be able to write. Rote speech and automatic speech such as responses to a greeting are often intact. The patient is aware of the deficit and may become frustrated and angry. Reassure patients, and remind them to talk slowly.

TABLE 45-4

Types of Aphasia

Expressive (or nonfluent)
• Referred to as *Broca's*, or *motor, aphasia* • Difficulty speaking • Difficulty writing
Receptive
• Referred to as *Wernicke's*, or *sensory, aphasia* • Difficulty understanding spoken words • Difficulty understanding written words • Speech often meaningless • Made-up words
Mixed
• Combination of difficulty understanding words and speech • Difficulty with reading and writing
Global
• Profound speech and language problems • Often no speech or sounds that cannot be understood

Receptive (Wernicke's, or sensory) aphasia is due to injury involving Wernicke's area in the temporoparietal area. The patient cannot understand the spoken and often the written word. Although he or she may be able to talk, the language is often meaningless. Neologisms (made-up words) are common parts of speech.

Usually the patient has some degree of dysfunction in the areas of both expression and reception. This is known as *mixed aphasia*. Reading and writing ability are equally affected. Few patients have just expressive *or* receptive aphasia. In most cases, though, one type is dominant.

To help communicate with the patient with aphasia, use these guiding principles:

- Present one idea or thought in a sentence (e.g., "I am going to help you get into the chair.").
- Use simple one-step commands rather than ask patients to do multiple tasks.
- Speak slowly but not loudly; use cues or gestures as needed.
- Avoid "yes" and "no" questions for patients with expressive aphasia, because they often give automatic responses that may be incorrect.
- Use alternative forms of communication if needed, such as a computer, communication board, or flash cards (often with pictures).

For more specific communication strategies for your patient, collaborate with the SLP.

Promoting Continence

Planning: Expected Outcomes.

The patient with a stroke is expected to control elimination of urine and stool.

Interventions.

The patient may be incontinent of urine and stool because of an altered level of consciousness, impaired innervation to the bladder and rectum, and/or the inability to communicate the need to urinate or defecate. Before beginning a patient education program to correct these problems, the cause must first be established. Typically, the patient who has had a stroke can regain both bowel and bladder control in time. To begin a bladder training program, place the patient on the bedpan or the commode or offer the urinal every 2 hours. Encourage a total fluid intake to maintain dilute urine and a balanced intake and output. A bedside bladder ultrasound is used to check for residual urine after voiding in the early phase of the bladder training program to ensure that the patient is emptying the bladder. Retained urine can lead to a urinary tract infection.

Before establishing a bowel training program, determine the patient's normal time for bowel elimination and any routine that helps promote a stool. This routine is followed, if possible, and the patient is placed on the commode or toilet at the same time as the previous schedule at home. Encourage the patient to drink apple or prune juice and to consume high-fiber foods to help promote bowel elimination. A stool softener (Colace) may be prescribed. Suppositories may also assist in re-establishing a bowel routine. Chapter 6 provides a discussion of bowel and bladder training programs.

If the patient has an indwelling urinary catheter, it should be removed as soon as hourly urine output is no longer essential to therapeutic decisions. The patient with a fever or an older adult who becomes increasingly confused should always be evaluated for a urinary tract infection.

Managing Changes in Sensory Perception

Planning: Expected Outcomes.

The major concern of patients with sensory perception deficits is adapting to neurologic deficits. Therefore the patient with a stroke is expected to adapt to sensory perception changes in vision, proprioception (position sense), and sensation and to be free from injury.

Interventions.

Patients with right hemisphere brain damage typically have difficulty

with visual-perceptual or spatial-perceptual tasks. They have problems with depth and distance perception and with discrimination of right from left or up from down. Because of these problems, they have difficulty performing routine ADLs. Caregivers help the patient adapt to these disabilities by using frequent verbal and tactile cues and by breaking down tasks into discrete steps. Always approach the patient from the unaffected side, which should face the door of the room.

Place objects within the patient's field of vision. A mirror may help visualize more of the environment. If the patient has **diplopia** (double vision), a patch may be placed over the affected eye. Remind the nursing staff to ensure a safe environment by removing clutter from the room.

The patient with a left hemisphere lesion generally has memory deficits and may show significant changes in the ability to carry out simple tasks. To assist with memory problems, re-orient the patient to the month, year, day of the week, and circumstances surrounding hospital admission. Establish a routine or schedule that is as structured, repetitious, and consistent as possible. Provide information in a simple, concise manner. A step-by-step approach is often most effective because the patient can master one step before moving to the next. When possible, ask the family to bring in pictures and other familiar objects.

The patient may be unable to plan and execute tasks in an organized manner. **Apraxia,** or the inability to perform previously learned motor skills or commands, may be present. Typically, the patient with apraxia exhibits a slow, cautious, and hesitant behavior style. The physical therapist (PT) assists the patient in compensating for loss of position sense.

Managing Unilateral Body Neglect

Planning: Expected Outcomes.

The patient with stroke is expected to adjust and use techniques to compensate for unilateral (one-sided) body neglect.

Interventions.

Unilateral neglect, or neglect syndrome, occurs most commonly in patients who have had a right cerebral stroke. However, it can occur in any patient who experiences hemianopsia, in which the vision of one or both eyes is affected. This problem places the patient at additional risk for injury, especially falls, because of an inability to recognize his or her physical impairment or because of a lack of proprioception (position sense).

Teach the patient to touch and use both sides of the body. For example, encourage the patient to wash both the affected and unaffected sides of the body. When dressing, remind the patient to dress the affected side first. If hemianopsia is present, teach the patient to turn his or her head from side to side to expand the visual field. This scanning technique is also useful when the patient is eating or ambulating.

Community-Based Care

The patient with a stroke may be discharged to home, a rehabilitation center, or a skilled nursing facility (SNF), depending on the extent of the disability and the availability of family or caregiver support. Some patients have no significant neurologic dysfunction and are able to return home and live independently or with minimal support. Other patients are able to return home but require ongoing assistance with ADLs and supervision to prevent accidents or injury. The case or care manager coordinates speech/language, physical, and/or occupational therapy services to continue in the home or on an ambulatory care basis. Patients admitted to a rehabilitation unit/facility or SNF require continued or more complex nursing care as well as extensive physical, occupational, recreational, speech-language, or cognitive therapy, which is coordinated by a case manager. The expected outcome for rehabilitation is to maximize the patient's abilities in all aspects of life. Some patients who have strokes have severe brain damage with profound neurologic impairments and require palliative care.

Home Care Management.

Collaborate with the case manager to plan the patient's discharge. Coordinate with rehabilitation therapists to identify needs for assistive or adaptive and safety equipment. The extent of this assessment depends on the patient's disabilities. Teach the patient and family to ensure that the home is free from scatter rugs or other obstacles in the walking pathways. The bathtub and toilet should be equipped with grab bars. Anti-skid patches or strips should be placed in the bathtub to prevent slipping. The PT or OT works with the patient and the family or significant others to obtain all needed assistive devices and home modifications *before* the patient is discharged from the hospital, rehabilitation setting, or SNF. Appointments for ambulatory care speech, physical, and occupational therapy are arranged before discharge for continuing care.

Self-Management Education.

As part of the discharge process, teach the family about depression that may occur within the 3 months after a stroke. The strongest predictors of post-stroke depression (PSD) are a history of depression, severe stroke, and post-stroke physical or cognitive impairment. Patients may not exhibit typical signs of depression because of their cognitive, physical, and emotional impairments. PSD is associated with increased morbidity and mortality, especially in older men.

The three areas that should be included in patient and family education are disease prevention, disease-specific information, and self-management (American Heart Association, 2014). The teaching plan includes lifestyle changes, drug therapy, ambulation/transfer skills, communication skills, safety precautions, nutritional management, activity levels, and self-management skills. Health teaching should focus on tasks that must be performed by the patient and the family after hospital discharge. Provide both written and verbal instruction in all these areas (see the Evidence-Based Practice box). Return demonstrations assist in evaluating the family members' competency in tasks required for the patient's care (Fig. 45-5).

FIG. 45-5 Son adjusting his mother's wheelchair.

Evidence-Based Practice QSEN

What Are the Best Practices for Teaching Patients and Their

Families About Strokes?

Cameron, V. (2013). Best practices for stroke patient and family education in the acute care setting: A literature review. *MEDSURG Nursing, 22*(3), 51-55.

Many patients have strokes and are admitted to the acute care setting. Nurses need to know the most effective methods for educating these patients and their families before they are discharged from the hospital. The researcher conducted an integrative interdisciplinary review of the literature published between 2003 and 2012 to determine the best practices for patient and family education. Three areas of health teaching are needed: stroke prevention, stroke-specific education, and self-management skills. Best practices for these areas include:

- Be flexible and adapt to the health and learning needs of the patient (e.g., aphasia is/is not present).
- Use multiple types of education materials (written, audiovisual, interactive strategies).
- Focus on key points, and be repetitive; as many as five or six repetitions are associated with retention.
- Group meetings may be beneficial to patient understanding, motivation, and quality of life.
- Use reading materials with a low literacy level, large font type, and short (15 minute) learning sessions.
- Identify sources of emotional support, encourage social support, and locate community education groups for caregivers to enhance their well-being.

Level of Evidence: 1

This study provided a systematic review of literature to determine best practices for teaching patients with strokes and their families about the disease and self-management.

Commentary: Implications for Practice and Research

This review did not use statistical analysis to generate recommendations for patient and family education, an approach common to integrative reviews. The strategies are practical and accessible to nurses and health care team members in both hospital and community care settings. Nurses need to consider the specific limitations, health needs, and health literacy of patients with strokes to modify their approach to health teaching as needed.

Teach patients to take their prescribed drugs to prevent another stroke

and control hypertension. Instruct the patient and the family the name of each drug, the dosage, the timing of administration, how to take it, and possible side effects. In collaboration with the PT and OT, teach the patient how to climb stairs safely, if he or she is able; transfer from the bed to a chair; get into and out of a car; and use any aids for mobility. The patient and family members are also taught how to use any equipment needed to increase independence in self-management skills. Provide important information regarding what to do in an emergency and who to call for nonemergency questions.

Families may feel overwhelmed by the continuing demands placed on them. Depending on the location of the lesion, the patient may be anxious, slow, cautious, and hesitant and lack initiative (left hemisphere lesions). As a result of right hemisphere lesions, he or she may be impulsive and seemingly unaware of any deficit. Family members and other caregivers need to spend time away from the patient on a routine basis to continue to provide full-time care without sacrificing their own physical and emotional health. Refer the family to social services or other community resources for further support, counseling, and possible respite care.

Health Care Resources.

Available resources include a variety of publications from the American Heart Association (www.americanheart.org), including *Stroke: A Guide for Families* and *Stroke: Why Do They Behave That Way?* The National Stroke Association (www.stroke.org) also provides publications and videotapes for caregivers and patients. *Recovering After a Stroke: A Patient and Family Guide* is available from the Agency for Healthcare Research and Quality (www.ahrq.gov). Refer the patient and family members or significant others to local stroke support groups.

For patients who require symptom management or end-of-life care, refer the family to palliative care or hospice services. Chapter 7 gives a detailed description of end-of-life care and advance directives.

Evaluation: Outcomes

Evaluate the care of the patient with stroke based on the identified priority patient problems. The expected outcomes are that the patient:

- Maintains blood pressure and blood sugar within a safe, prescribed range
- Performs self-care and mobility activities independently, with or without assistive devices

- Learns to adapt to sensory perception changes
- Adjusts and uses techniques to compensate for one-sided neglect
- Communicates effectively or develops strategies for effective communication
- Has adequate nutrition and avoids aspiration
- Controls elimination of urine and stool

There are eight core measures associated with the care of stroke patients (The Joint Commission, 2014). These core measures form the basis of not only individual patient goals but also system-wide goals of care. As a result, continuous quality improvement efforts are based on these core measures. Certification as a Stroke Center is tied to consistent performance in achieving satisfactory core measures. The core measures may have additional implications in terms of reimbursement in the future. The eight core measures for Ischemic Stroke Care are:

1. Venous thromboembolism (VTE) prophylaxis
2. Discharge with antithrombotic therapy
3. Anticoagulation therapy for atrial fibrillation/flutter
4. Thrombolytic therapy (in the presence of a thrombotic stroke of <4 hours from symptom onset)
5. Antithrombotic therapy is evaluated by end of hospital day (e.g., diagnostic testing for therapeutic range of values following thrombolytic or anticoagulant therapy)
6. Discharged on statin medication
7. Stroke education provided and documented
8. Assessed for rehabilitation

Comprehensive stroke centers are required to collect data for the eight stroke core measures and submit monthly data points every quarter through the Certification Measure Information Process (CMIP). Nurses not only provide direct care to patients with ischemic stroke but also contribute to the peer review process to evaluate and monitor the care provided to patients with ischemic stroke.

Traumatic Brain Injury

Pathophysiology

Traumatic brain injury (TBI) is damage to the brain from an external mechanical force and not caused by neurodegenerative or congenital conditions. TBI can lead to temporary and permanent impairment of cognitive, physical, and psychosocial functions.

Various terms are used to describe the brain injuries that occur when a mechanical force is applied either directly or indirectly to the brain. A force produced by a blow to the head is a *direct* injury, whereas a force applied to another body part with a rebound effect to the brain is an *indirect* injury. The brain responds to these forces by movement within the rigid cranial vault. It may also rebound or rotate on the brainstem, causing diffuse axonal injury (shearing injuries). The brain may be contused (bruised) or lacerated/torn as it moves over the inner surfaces of the cranium, which are irregularly shaped and sharp.

Movement or distortion within the cranial cavity is possible because of multiple factors. The first factor is how the brain is supported by cerebrospinal fluid (CSF) within the cranial cavity. When external force is applied to the head, the brain can be injured by the internal surfaces of the skull and meninges. The second factor is the consistency of brain tissue, which is very fragile and prone to injury. Brain injury occurs from both initial forces on the head and brain and as a result of secondary derangements of physiologic stability.

The type of force and the mechanism of injury contribute to traumatic brain injury. An *acceleration* injury is caused by an external force contacting the head, suddenly placing the head in motion. A *deceleration* injury occurs when the moving head is suddenly stopped or hits a stationary object (Fig. 45-6). These forces may be sufficient to cause the cerebrum to rotate about the brainstem, resulting in shearing, straining, and distortion of the brain tissue, particularly of the axons in the brainstem and cerebellum. Small areas of hemorrhage (contusion, intracranial hemorrhage) may develop around the blood vessels that sustain the impact of these forces (stress), with destruction of adjacent brain tissue. Particularly affected are the basal nuclei and the hypothalamus.

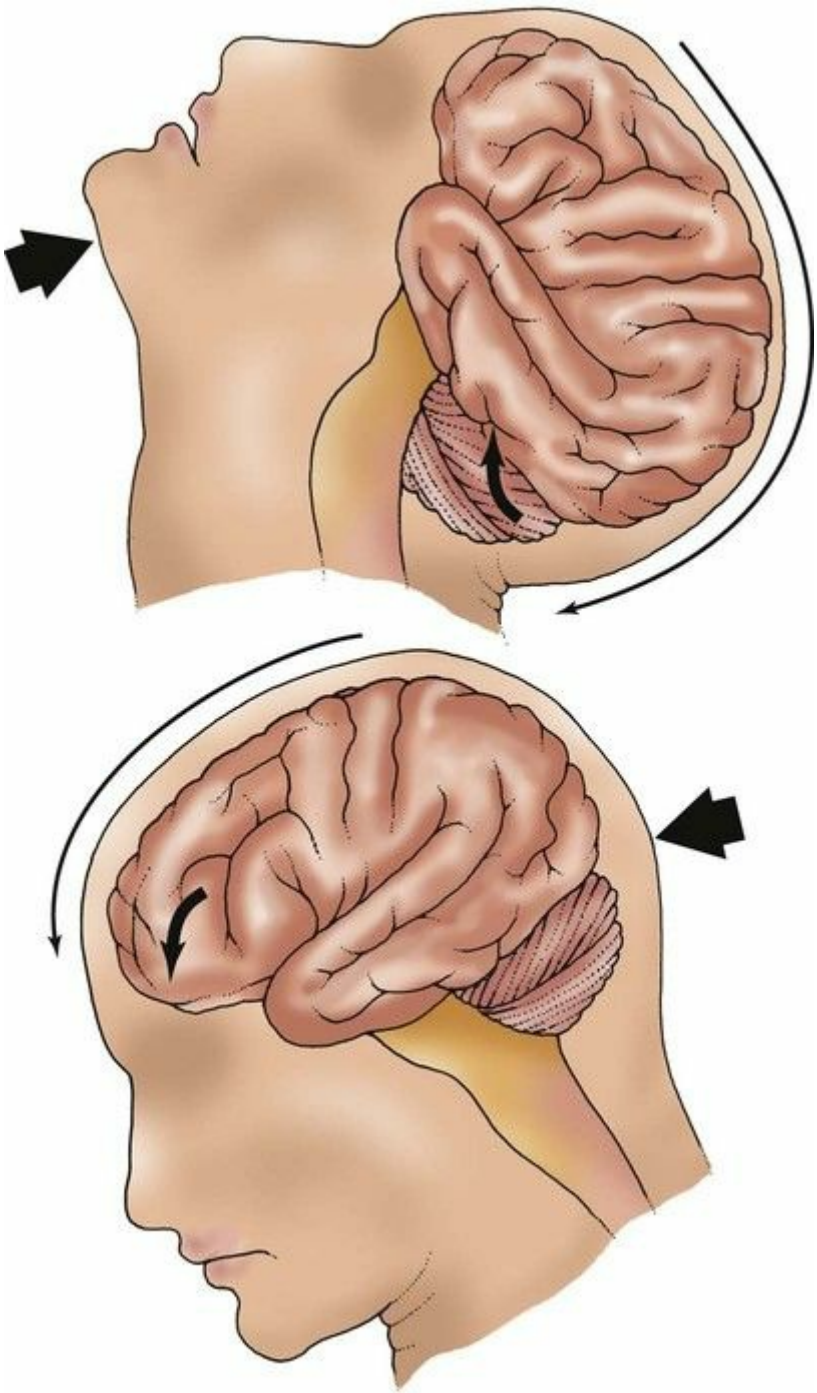

FIG. 45-6 Head movement during acceleration-deceleration injury, which is typically seen in motor vehicle crashes.

Primary Brain Injury

Primary brain damage occurs at the time of injury and results from the physical stress (force) within the tissue caused by blunt force. A primary brain injury may be categorized as focal or diffuse. A *focal* brain injury is confined to a specific area of the brain and causes localized damage that can often be detected with a CT scan or MRI. *Diffuse* injuries are characterized by damage throughout many areas of the brain. They initially may be at a microscopic level and not initially detectable by CT

scan. MRI has greater ability to detect microscopic damage, but these areas may not be imaged until necrosis occurs.

Primary brain injuries are also classed as either open or closed. An **open traumatic brain injury** occurs when the skull is fractured or when it is pierced by a penetrating object. The integrity of the brain and the dura is violated, and there is exposure to environmental contaminants. Damage may occur to the underlying vessels, dural sinus, brain, and cranial nerves. In a **closed traumatic brain injury,** the integrity of the skull is not violated.

Open Versus Closed Traumatic Brain Injury.

The types of skull fractures associated with *open traumatic brain injury* are linear, depressed, open, and comminuted. A *linear fracture* is a simple, clean break in which the impacted area of bone bends inward and the area around it bends outward. Linear fractures are the most common type of skull fracture. In a *depressed fracture,* the bone is pressed inward into the brain tissue to at least the thickness of the skull. In an *open fracture,* the scalp and dura are lacerated, creating a direct opening to the brain tissue. A *comminuted fracture* involves fragmented bone with depression into the brain tissue.

A unique skull fracture is a *basilar fracture.* It occurs at the base of the skull, usually extending into the anterior, middle, or posterior fossa, and can result in cerebrospinal fluid (CSF) leakage from the nose or ears. A CSF leak increases the risk for a central nervous system (CNS) infection. A basilar skull fracture is associated with an increased risk for hemorrhage caused by damage to the internal carotid artery. Basilar skull fractures can also damage cranial nerves (CNs) I, II, VII, and VIII.

Most penetrating injuries to the brain are caused by gunshot wounds (GSWs) and knife injuries. The degree of injury to brain tissue depends on the velocity (speed), mass, shape, and direction of impact. High-velocity injuries produce the greatest damage to brain tissue. As with any open wound, the patient with a penetrating injury is at high risk for infection from the object that pierced the skull and from other environmental contaminants.

Closed traumatic brain injuries are caused by blunt force. The blunt force can be direct or a result of a blast shock wave. These forces can lead to contusions and lacerations of the brain. A **contusion** is a bruising of the brain tissue and is most commonly found at the site of impact (**coup injury**) or in a line opposite the site of impact **(contrecoup injury)** (Fig. 45-7). Contusions and lacerations are most commonly located at the base of the frontal and temporal lobes. A **laceration** causes actual tearing of

the cortical surface vessels, which may lead to secondary hemorrhage and significant cerebral edema and inflammation. This condition is more serious than a contusion.

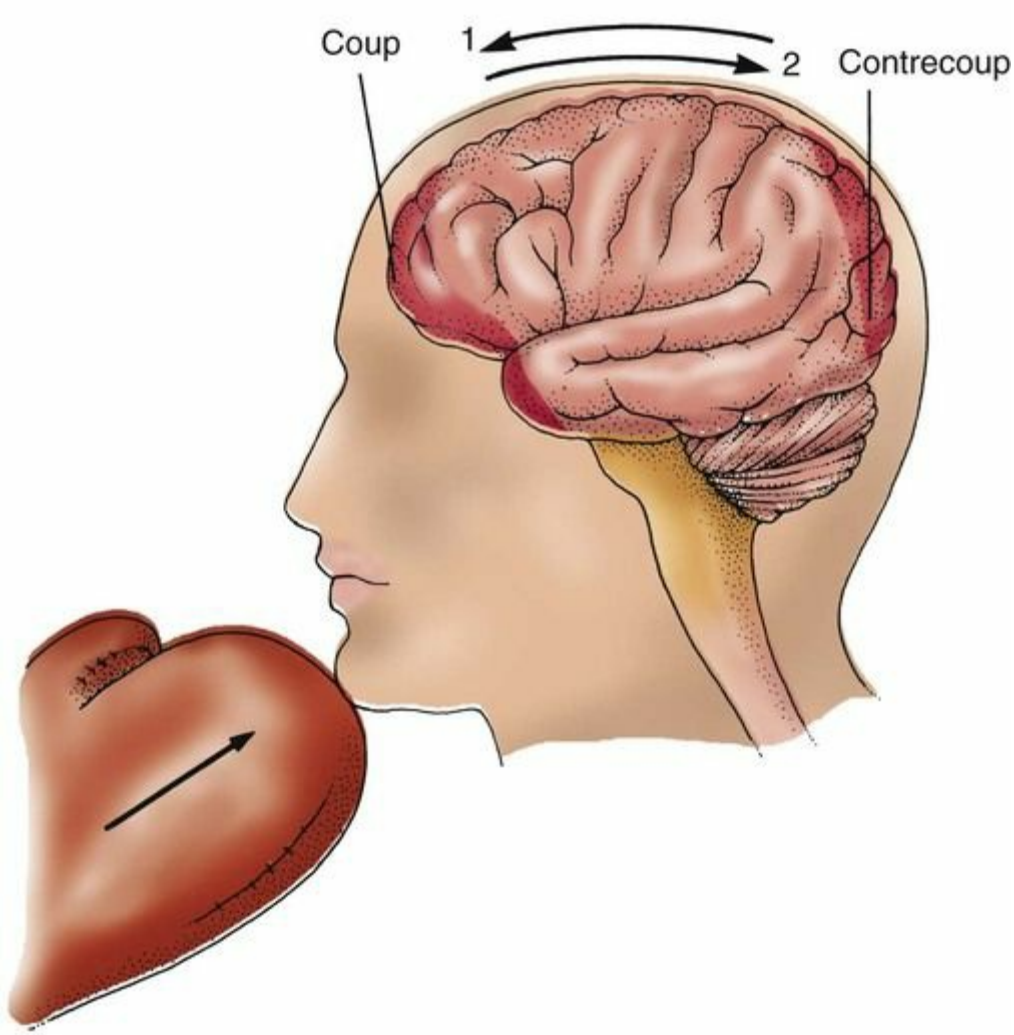

FIG. 45-7 Coup (site of impact) injury to frontal area of brain, and contrecoup injury to frontal and temporal areas of the brain.

When damage to the brain is severe but without local injury such as a contusion or laceration, a closed traumatic brain injury may be diagnosed as diffuse axonal injury or widespread injury to the white matter of the brain. **Diffuse axonal injury (DAI)** is usually related to high-speed acceleration/deceleration, typically seen in motor vehicle crashes. This type of brain injury causes shearing of large nerve fibers and stretching of blood vessels in many areas of the brain. In addition to bleeding, a DAI can trigger a biochemical cascade of toxic substances in the brain during the days following the initial injury. DAI occurs throughout the brain, and the frontal and temporal lobes are particularly

susceptible. Damage may also be found in the corpus callosum, midbrain, cerebellum, and upper brainstem. DAI can also occur in focal but important nerve centers (white matter tracts) causing visual field loss or weakness on one side of the body. Depending on severity, small areas of hemorrhage and changes in the lateral ventricles may be seen with a CT or MRI, but there is no specific or sensitive test to definitively diagnose DAI. The most prominent manifestation of DAI is impaired cognitive function, resulting in disorganization, impaired memory, and varying degrees of inattentiveness. Severe DAI may present with immediate coma, and most survivors require long-term care.

Mild, Moderate, and Severe Traumatic Brain Injury.

TBI is further defined as mild, moderate, or severe. Generally, the determination of severity of TBI is the result of the Glasgow Coma Scale (GCS) score immediately following resuscitation, the presence (or absence) of brain damage imaged by CT or MRI following the trauma, an estimation of the force of the trauma, and symptoms in the injured person.

Mild Traumatic Brain Injury.

The terms *mild traumatic brain injury (MTBI)* and *concussion* are used synonymously (Thompson & Mauk, 2011). MTBI is characterized by a blow to the head, transient confusion or feeling dazed or disoriented, and one or more of these conditions: (1) loss of consciousness for up to 30 minutes, (2) loss of memory for events immediately before or after the accident, and (3) focal neurologic deficit(s) that may or not be transient. Loss of consciousness does not have to occur for a person to be diagnosed with MTBI. With MTBI, there is no evidence of brain damage on a CT or MRI imaging scan. Subsequent to a new MTBI, symptoms can include a wide array of physical and cognitive problems that range from headache and dizziness to changes in behavior listed on Chart 45-7. These symptoms usually resolve within 72 hours. In some cases the symptoms persist and may last days, weeks, or months. For other patients, severe physical and cognitive problems remain despite relatively mild initial symptoms and normal diagnostic test findings. Persistent symptoms following MTBI are also referred to as **post-concussion syndrome.**

Chart 45-7 Key Features

Mild Traumatic Brain Injury

Physical Findings

- Appears dazed or stunned
- Loss of consciousness <30 minutes (unresponsive after injury)
- Headache
- Nausea
- Vomiting
- Balance or gait problems
- Dizziness
- Visual problems
- Fatigue
- Sensitivity to light
- Sensitivity to noise

Cognitive Findings

- Feeling mentally foggy
- Feeling slowed down
- Difficulty concentrating
- Difficulty remembering
- Amnesia about the events around the time of injury

Sleep Disturbances

- Drowsiness
- Sleeping less than usual
- Sleeping more than usual
- Trouble falling asleep

Emotional Changes

- Irritability
- Sadness
- Nervousness
- More "emotional"

The incidence of *MTBI* is difficult to estimate because most cases are not reported. Further, the symptoms and diagnostic terminology (international classification diagnostic [ICD] codes) used for mild traumatic brain injury are not well established in the practice community. For example, some providers use the word *concussion* for a temporary and reversible change in cognition or sensory perception from a blow to the head. A concussion is a MTBI. Regardless of terminology, MTBI accounts for at

least 75% of all traumatic brain injuries in the United States. Estimating incidence and prevalence is also complicated because patients may not seek medical care. Some patients may not perceive any health problem from the injury. Others do not have any health insurance to assist with costs of diagnosis and care or may feel guilty or embarrassed over the circumstances of the injury.

Moderate Traumatic Brain Injury.

A moderate TBI is characterized by a period of loss of consciousness (LOC) for 30 minutes to 6 hours and a GCS score of 9 to 12. Often but not always, focal or diffuse brain injury can be seen with a diagnostic CT or MRI scan. Post-traumatic amnesia (memory loss) may last up to 24 hours. Moderate TBI may occur with either closed or open brain injury. A short acute or critical care stay may be needed for close monitoring and to prevent secondary injury from brain edema, intracranial bleeding, or inadequate cerebral perfusion. Additional secondary injury results from complex inflammatory processes, also known as the *biomolecular cascade* that occurs in the CNS immediately, hours, or days after primary injury (Thompson & Mauk, 2011).

Severe Traumatic Brain Injury.

A severe TBI is defined by a GCS score of 3 to 8 and loss of consciousness for longer than 6 hours. Focal and diffuse damage to the brain, cerebrovascular vessels, and/or ventricles are common. Both open and closed head injuries can cause severe TBI, and injury can be focal or diffuse. When the damage is present in a localized area of the brain, it is usually extensive. CT and MRI scans can capture images of tissue damage quite early in the course of this illness. Patients with severe TBI require management in critical care, including monitoring of hemodynamics, neurologic status, and possibly, intracranial pressure (ICP). Patients with severe TBI are also at high risk for secondary brain injury from cerebral edema, hemorrhage, reduced perfusion, and the biomolecular cascade.

Secondary Injury

Secondary injury to brain injury includes any processes that occur *after* the initial injury and worsen or negatively influence patient outcomes. Secondary injuries result from physiologic, vascular, and biochemical events that are an extension of the primary injury. The most common secondary injuries result from hypotension and hypoxia, intracranial

hypertension, and cerebral edema. Damage to the brain tissue occurs primarily because the delivery of oxygen and glucose to the brain is interrupted.

Hypotension and Hypoxia.

Both hypotension, defined as a mean arterial pressure less than 70 mm Hg, and hypoxemia, defined as a partial pressure of arterial oxygen (Pa_{O_2}) less than 80 mm Hg, restrict the flow of blood to vulnerable brain tissue. Hypotension may be related to shock (Chapter 37) or other states of reduced blood flow to the brain such as clot formation. Hypoxia can be due to respiratory failure, asphyxiation, or loss of airway and impaired ventilation (Chapter 32). These problems may occur as a direct result of moderate to severe brain injury or secondary to systemic injuries and comorbidities. Low blood flow and hypoxemia contribute to cerebral edema, creating a cycle of deteriorating perfusion and hypoxic damage. Patients with hypoxic damage related to moderate or severe brain injury face a poor prognosis and typically experience memory impairment and reduced cognitive function.

Increased Intracranial Pressure.

The cranial contents include brain tissue, blood, and cerebrospinal fluid (CSF). These components are encased in the relatively rigid skull. Within this space, there is little room for any of the components to expand or increase in volume. A normal level of ICP is 10 to 15 mm Hg. Periodic increases in pressure occur with straining during defecation, coughing, or sneezing but do not harm the uninjured brain.

As a result of brain injury, the increase in the volume of one component must be compensated for by a decrease in the volume of one of the other components. As a first response to an increase in the volume of any of these components, the CSF is shunted or displaced from the cranial compartment to the spinal subarachnoid space or the rate of CSF absorption is increased. An additional response, if needed, is a decrease in cerebral blood volume by movement of cerebral venous blood into the sinuses. As long as the brain can compensate for the increase in volume and remain compliant, increases in ICP are minimal.

Increased ICP is the leading cause of death from head trauma in patients who reach the hospital alive. It occurs when compliance no longer takes place and the brain cannot accommodate further volume changes. As ICP increases, cerebral perfusion decreases, leading to brain tissue ischemia and edema. If edema remains untreated, the brain may herniate

downward toward the brainstem or laterally from a unilateral lesion within one cerebral hemisphere, causing irreversible brain damage and possibly death **(brain herniation syndromes).**

Three types of edema may contribute to increased ICP: vasogenic edema, cytotoxic edema, and interstitial edema. *Vasogenic edema* is caused by an abnormal permeability of the walls of the cerebral vessels, which allows protein-rich plasma infiltrate to leak into the extracellular space of the brain. The fluid collects primarily in the white matter. *Cytotoxic edema* may occur as a result of a hypoxic insult, which causes a disturbance in cellular metabolism and active ion transport. The brain is quickly depleted of available oxygen, glucose, and glycogen and converts to anaerobic metabolism. Derangements in cell membrane function result in cell edema, cell dysfunction, and cell death. Cytotoxic edema may lead to vasogenic edema and a further increase in ICP. *Interstitial edema* occurs with fluid accumulation between the cells of the brain. Interstitial edema is *associated with* elevated blood pressure or increased CSF pressure. Interstitial edema develops rapidly in the perivascular and periventricular white space and can be controlled through measures to reduce blood pressure or decrease CSF pressures.

Besides providing oxygen to decrease ischemic injury, sustaining mean arterial pressure or systolic blood pressure within a therapeutic range, and draining cerebral spinal fluid, the staff nurse manages increased intracranial pressure with attention to balancing fluid intake and output and promoting normal serum electrolyte values. When intracranial pressure monitoring is used, a desired outcome of therapy includes maintaining **cerebral perfusion pressure (CPP).** The CPP is the pressure gradient over which the brain is perfused. CPP is determined by subtracting the mean ICP from the mean arterial pressure. *Maintenance of a CPP above 70 mm Hg is generally accepted as an expected outcome of therapy.* ICP monitoring also includes evaluating the shape and quality of the ICP waveform to determine whether compliance is compromised as manifested by an abnormal ICP waveform. Some specialized units also monitor jugular venous oxygenation saturation to evaluate the amount of hemoglobin saturated by oxygen as it drains from the cranium. A value that falls outside the range of 55% to 70% indicates inadequate delivery of oxygen to brain tissue.

Hemorrhage.

Hemorrhage, which causes a brain hematoma (collection of blood) or clot, may occur as part of the primary injury and begin at the moment of impact. It may also arise later from vessel damage. Classically, bleeding is

caused by vascular damage from the shearing force of the trauma or direct physical damage from skull fractures or penetrating injury. *All hematomas are potentially life threatening because they act as space-occupying lesions and are surrounded by edema.* Three major types of hemorrhage after TBI are epidural, subdural, and intracerebral hemorrhage. Subarachnoid hemorrhage may also occur.

An **epidural hematoma** results from arterial bleeding into the space between the dura and the inner skull (Fig. 45-8). It is often caused by a fracture of the temporal bone, which houses the middle meningeal artery. Patients with epidural hematomas have "lucid intervals" that last for minutes during which time the patient is awake and talking. This follows a momentary unconsciousness that occurs within minutes of the injury.

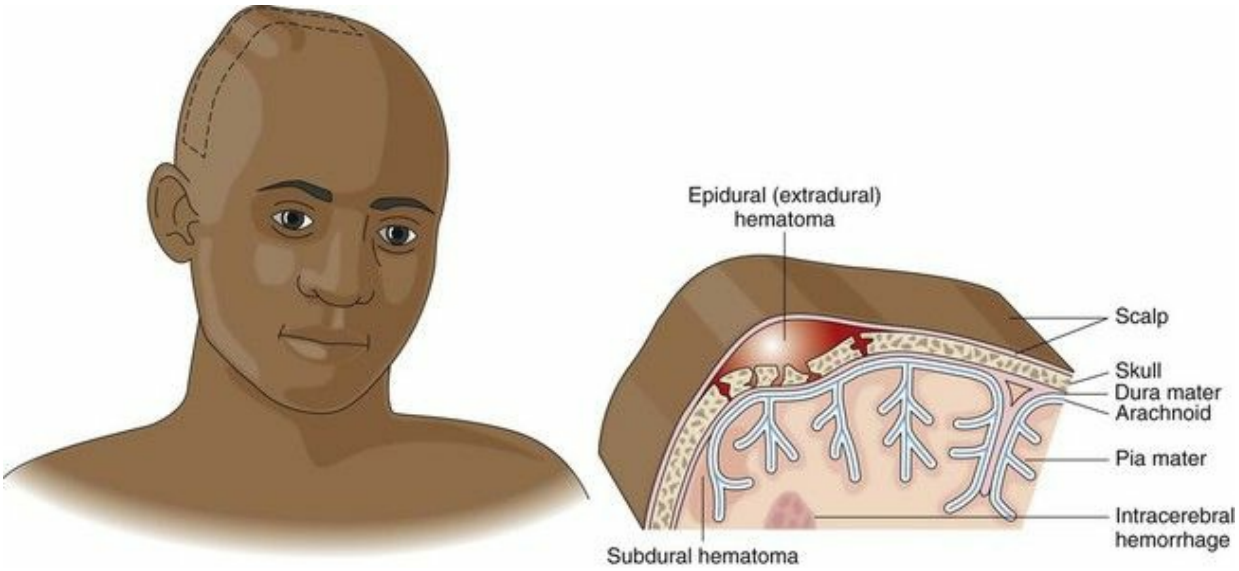

FIG. 45-8 Epidural hematoma (outside the dura mater of the brain), subdural hematoma (under the dura mater), and intracerebral hemorrhage (within the brain tissue).

Nursing Safety Priority QSEN

Critical Rescue

After the initial interval, symptoms of neurologic impairment from hemorrhage can progress very quickly with potentially life-threatening ICP elevation and irreversible structural damage to brain tissue. Monitor the patient suspected of epidural bleeding frequently (every 5-10 minutes) for changes in neurologic status. The patient can become quickly and increasingly symptomatic. *A loss of consciousness from an epidural or subdural hematoma is a neurosurgical emergency!* Notify the

health care provider or Rapid Response Team immediately if these changes occur. Carefully document your assessments.

A **subdural hematoma (SDH)** results from venous bleeding into the space beneath the dura and above the arachnoid (see Fig. 45-8). It occurs most often from a tearing of the bridging veins within the cerebral hemispheres or from a laceration of brain tissue. *Bleeding from this injury occurs more slowly than from an epidural hematoma.* SDHs are subdivided into acute, subacute, and chronic. An acute SDH presents within 48 hours after impact; the subacute SDH, between 48 hours and 2 weeks; and the chronic SDH, from 2 weeks to several months after injury. SDHs have the highest mortality rate because they often are unrecognized until the patient presents with severe neurologic compromise.

Traumatic **intracerebral hemorrhage** (ICH) is the accumulation of blood within the brain tissue caused by the tearing of small arteries and veins in the subcortical white matter (see Fig. 45-8). It often acts as a space-occupying lesion (like a tumor) and may be potentially devastating, depending on its location. ICH may also produce significant brain edema and ICP elevations. A traumatic brainstem hemorrhage occurs as a result of a blow to the back of the head, fractures, or torsion injuries to the brainstem. Brainstem injuries have a very poor prognosis.

Hydrocephalus.

Hydrocephalus is an abnormal increase in CSF volume. It may be caused by impaired reabsorption of CSF at the arachnoid villi (from subarachnoid hemorrhage or meningitis), called a **communicating hydrocephalus.** It may also be caused by interference or blockage with CSF outflow from the ventricular system (from cerebral edema, tumor, or debris). The ventricles may dilate from the relative increase in CSF volume. Ultimately, if not treated, this increase may lead to increased ICP.

Brain Herniation.

In the presence of increased ICP, the brain tissue may shift and herniate downward. Of the several types of herniation syndromes (Fig. 45-9), uncal herniation is one of the most clinically significant because it is life threatening. It is caused by a shift of one or both areas of the temporal lobe, known as the **uncus.** This shift creates pressure on the third cranial nerve. Late findings include dilated and nonreactive pupils, ptosis (drooping eyelids), and a rapidly deteriorating level of consciousness. Central herniation is caused by a downward shift of the brainstem and the diencephalon from a supratentorial lesion. It is clinically manifested

by Cheyne-Stokes respirations, pinpoint and nonreactive pupils, and potential hemodynamic instability. All herniation syndromes are potentially life threatening, and the physician must be notified immediately when they are suspected.

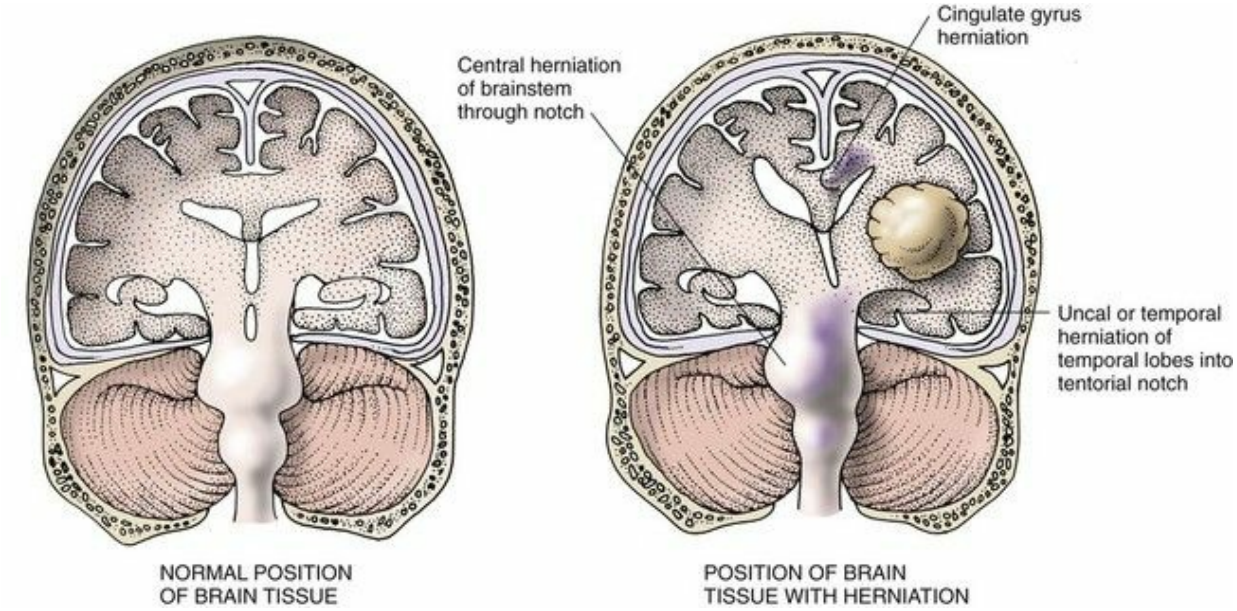

FIG. 45-9 Herniation syndromes.

Etiology

The most common causes of TBI in the United States are falls and motor vehicle crashes, followed by colliding with a stationary or moving object (CDC, 2013a). Alcohol and drugs are significant contributing factors to the causes of TBI. The United States is seeing increasing numbers of survivors of brain injury from wartime blast injuries. Summer and spring months, evenings, nights, and weekends are associated with the greatest number of injuries. Young males are more likely than young females to have a TBI. Men tend to play more sports, take more risks when driving, and consume larger amounts of alcohol than women. Falls are the most common cause of TBI in older adults.

Incidence and Prevalence

Annually, at least 1.4 million people sustain a TBI in the United States. Of these, about 50,000 die, 235,000 are hospitalized, and 1.1 million are treated and released from an emergency department (CDC, 2013a).

Health Promotion and Maintenance

Nurses can educate the public on ways to decrease the incidence of TBI by using safe driving practices such as not driving while impaired and wearing seat belts. Teach people at risk about how alcohol and illicit drug use affect driving ability. Promote the use of helmets for skateboarding and bicycle and motorcycle riding. Help prevent falls by providing a safe environment, especially for older adults. People need to be aware of environmental factors that may increase the likelihood of falls such as inadequate lighting and loose rugs. When possible, install safety equipment in bathtubs and showers. Evaluate balance and coordination as part of a falls prevention strategy inside the hospital and at home.

❖ Patient-Centered Collaborative Care

◆ Assessment

History.

Obtaining an accurate history from a patient who has sustained a TBI may be difficult because of either the seriousness of the injury or the presence of **amnesia** (loss of memory). It is not unusual for the patient to experience amnesia for events before or after the injury. The patient with a serious brain injury may be unconscious or in a confused and combative state. If the patient cannot provide information, the history can be obtained from first responders or witnesses to the injury. Always ask when, where, and how the injury occurred. Did the patient lose consciousness; if so, for how long? Has there been a change in the level of consciousness (LOC)? If trauma is related to drug or alcohol consumption, it may be difficult to differentiate neurologic changes from head trauma from those produced by intoxication.

Determine whether the patient had fluctuating consciousness or seizure activity and whether there is a history of a seizure disorder. Obtain precise information about the circumstances of falls, particularly in the older patient (Chart 45-8). Other pertinent information includes hand dominance, any diseases of or injuries to the eyes, and any allergies to drugs or food. Inquire about a history of alcohol or drug use and abuse because these substances may interfere with the neurologic baseline assessment. Consider whether the patient is a victim of violence if he or she lives in residential care. The Joint Commission and the Centers for Medicare and Medicaid Services require that all patients be screened for abuse and neglect when they are admitted to any type of health care facility.

Chart 45-8 Nursing Focus on the Older Adult

Traumatic Brain Injury

- Brain injury is the fifth leading cause of death in older adults.
- The 65- to 75-year age-group has second highest incidence of brain injury of all age-groups.
- Falls and motor vehicle crashes are the most common causes of brain injury.
- Factors that contribute to high mortality are:
  - Falls causing subdural hematomas (closed head injuries), especially chronic subdural hematomas
  - Poorly tolerated systemic stress, which is increased by admission to a high-stimuli environment
  - Medical complications, such as hypotension, hypertension, and cardiac problems
  - Decreased protective mechanisms, which make patients susceptible to infections (especially pneumonia)
  - Decreased immunologic competence, which is further diminished by brain injury

Physical Assessment/Clinical Manifestations.

No two brain injuries are alike. The patient with a TBI may have a variety of manifestations depending on the severity of injury and the resulting increase in intracranial pressure (ICP) (see Chart 45-6). Assess for signs of increased ICP, hypotension, hypoxemia (decreased blood level of oxygen), or **hypercarbia** ($Paco_2$ >40-45 mm Hg or increased partial pressure of carbon dioxide in arterial blood). Hypercarbia can cause cerebral vasodilation and contribute to elevated ICP. Determination of hypercarbia in an intubated patient can be done with an end-tidal carbon dioxide ($EtCO_2$) monitor. The early detection of changes in the patient's neurologic status enables the health care team to prevent or treat potentially life-threatening complications. Subtle changes in blood pressure, consciousness, and pupillary reaction to light can be very informative about neurologic deterioration.

Airway and Breathing Pattern Assessment.

The first priority is the assessment of the patient's ABCs—airway, breathing, and circulation. Because TBI is occasionally associated with cervical spinal cord injuries, all patients with head trauma are treated as though they have cord injury until radiography proves otherwise. *Older adults are*

especially prone to cervical injuries at the first or second vertebral level, a life-threatening problem. Assess for indicators of spinal cord injury, such as loss of motor function (mobility) and sensory perception, tenderness along the spine, and abnormal head tilt.

Nursing Safety Priority QSEN

Critical Rescue

The upper cervical spinal nerves innervate the diaphragm to control breathing. Monitor TBI patients for respiratory problems and diaphragmatic breathing, as well as diminished or absent reflexes in the airway (cough and gag). Hypoxia and hypercapnia are best detected through arterial oxygen levels (partial pressure of arterial oxygen [PaO_2]), oxygen saturation (Spo_2), and end-tidal volume carbon dioxide measurement ($EtCO_2$). Observe chest wall movement and listen to breath sounds. Report any sign of respiratory problems immediately to the physician!

Injuries to the brainstem may cause a change in the patient's breathing pattern, such as Cheyne-Stokes respirations, central neurogenic hyperventilation, and/or apnea. In the unconscious patient, an artificial airway provides protection from aspiration as well as a route for oxygenation. Mechanical ventilation may be needed to support inadequate respiratory effort.

Spine Precautions.

Patients with blunt trauma to the head or neck are typically transported from the scene of the injury to the hospital with a rigid cervical collar and a long spine board. The goal is to prevent new and secondary spine injury if there is unstable vertebrae or ligament damage. Spine precautions require placing the patient supine and aligning the spinal column in a neutral position so there is no rotation, flexion, or extension. The long spine board is removed as soon as possible upon arrival to the emergency department (ED) or intensive care unit (ICU); some EDs require this to be done within 20 minutes of arrival. The rigid cervical collar is maintained until definitive diagnostic studies to rule out cervical spine injury are completed (see Chapter 43). Skin breakdown and pressure ulcer formation are concerns when either the spine board or rigid collar are used.

Once the spine board is removed, spinal precautions are maintained

until the provider indicates it is safe to bend or rotate the cervical, thoracic, and lumbar spine. Spinal precautions include: (1) bedrest; (2) no neck flexion with a pillow or roll; (3) no thoracic or lumbar flexion with head of bed elevation/bed controls (reverse Trendelenburg is acceptable); (4) manual control of the cervical spine anytime the rigid collar is removed; and (5) using a "log roll" procedure to reposition the patient. Log roll allows for maintaining the neutral anatomic alignment of the entire vertebral column while turning or moving the patient. A patient with known or suspected spine injury requires preplanning and the assistance of three or more qualified people to move the patient. One person is assigned to maintain manual control of the cervical spine, and one person is positioned on each side of the torso to turn the patient while preventing segmental rotation, flexion, extension, and/or lateral bending of the chest or abdomen during transfer of the patient. A fourth person may be assigned to check skin integrity and/or change linens and position padding. Neurologic function must be assessed after each position change.

A rigid cervical collar is used to maintain cervical spine ("c-spine") precautions as well as cervical spine immobilization with a confirmed cervical injury. If the collar is ill-fitting or soiled, it may be changed according to hospital guidelines while a second qualified person maintains c-spine immobilization.

Spine clearance is a clinical decision made by the health care provider, often in collaboration with the radiologist. Spine clearance includes determining the absence of acute bony, ligamentous, and neurologic abnormalities of the cervical spine based on history, physical examination, and/or negative radiologic studies.

Vital Signs Assessment.

The mechanisms of autoregulation are often impaired as the result of a TBI. The more serious the injury, the more severe is the impact on *autoregulation* or the ability of cerebral vasculature to modify systemic pressure such that blood flow to the brain is sufficient. Monitor the patient's blood pressure and pulse. The patient may have hypotension or hypertension. **Cushing's triad,** a classic but late sign of increased ICP, is manifested by severe hypertension, a widened pulse pressure (increasing difference between systolic and diastolic values), and bradycardia. This triad of cardiovascular changes usually indicates imminent death.

Hypotension and tachycardia suggest hypovolemic shock. A decrease in blood volume may lead to decreased CPP and secondary brain ischemia and injury. Hypovolemic shock is usually due to bleeding

outside the cranial vault such as traumatic injuries to the abdomen or chest. Cardiac dysrhythmias may result from chest trauma, bruising of the heart, or interference with the autonomic nervous system from primary or secondary injuries to the brain or spinal cord. Chapter 43 describes acute spinal cord injury manifestations and management.

Neurologic Assessment.

Many hospitals use the Glasgow Coma Scale to document neurologic status (see Fig. 42-10). A change of 2 points is considered clinically important; urgent notification of the provider is advised if the change is a 2-point deterioration of GCS values.

The most important variable to assess with any brain injury is LOC! A decrease or change in LOC is typically the first sign of deterioration in neurologic status. A decrease in arousal or increased sleepiness should result in an increased aggressiveness and/or frequency in assessment. *Early* indicators of a change in LOC include behavior changes (e.g., restlessness, irritability) and disorientation, which are often subtle in nature.

Use a bright light to assess pupillary size and reaction to light. Facial trauma may swell eyelids, making this assessment difficult. Consider whether drugs that affect pupillary dilation and constriction, such as anticholinergics or adrenergics, have been used recently. Cycloplegics (eye drops to dilate the pupil) are used by ophthalmologists to evaluate eye and orbit injuries; these drugs also alter pupillary response to light.

Nursing Safety Priority QSEN

Critical Rescue

Check pupils of TBI patients for size and reaction to light, particularly if the patient is unable to follow directions to assess changes in level of consciousness. Report and document any changes in pupil size, shape, and reactivity to the health care provider immediately because they could indicate an increase in ICP.

Pupillary changes or eye signs differ depending on which areas of the brain are damaged. *Pinpoint and nonresponsive pupils are indicative of brainstem dysfunction at the level of the pons*. Of particular importance is the **ovoid pupil,** which is regarded as the midstage between a normal-size pupil and a dilated pupil. In some agencies, a portable automated pupillometer is used to measure pupil size and reaction rather than

manual examination.

Asymmetric (uneven) pupils, loss of light reaction, or unilateral or bilateral dilated pupils are treated as herniation of the brain from increased ICP until proven differently. *Pupils that are fixed (nonreactive) and dilated are a poor prognostic sign. Patients with this problem are sometimes referred to as having "blown" pupils.*

Check gross vision if the patient's condition permits. Have the patient read any printed material (e.g., your name tag) or count the number of fingers that you hold within the patient's visual field. Loss of vision is usually caused by either direct injury to the eye or injury to the occipital lobe. Visual loss may be temporary or permanent.

If the patient can participate, the health care provider or neurosurgical nurse tests *cranial nerves* (CNs) III, IV, and VI by asking the patient to following the sketch of an "H" in the visual field. Extraocular movements may be diminished because of injury or increased ICP. Damage to the optic chiasm or optic tract may cause visual-field deficits or **diplopia** (double vision). In the unconscious patient, additional oculocephalic and oculovestibular tests are performed to test the integrity of the brainstem and of CNs III, VI, and VII.

Monitor for additional late signs of increased ICP. These manifestations include severe headache, nausea, vomiting (often projectile), and seizures. The provider may evaluate for papilledema (seen by ophthalmoscopic examination). **Papilledema,** *also known as a* **choked disc,** *is edema and hyperemia (increased blood flow) of the optic disc. It is always a sign of increased ICP.* Headache and seizures are a response to the injury and may or may not be associated with increased ICP. Always remember that the patient with a brain injury is at risk for potentially devastating ICP elevations during the first hours after the event and that this risk decreases over the course of 1 to 3 days.

Assess for bilateral *motor* responses. The patient's motor loss or dysfunction usually appears contralateral (opposite side) to the site of the lesion, similar to a stroke. For example, a left-sided hemiparesis reflects an injury to the right cerebral hemisphere. Deterioration in motor function or the development of abnormal posturing **(decerebrate** or **decorticate posturing)** or flaccidity is another indicator of progressive brain injury (see Fig. 41-11 in Chapter 41). These changes are due to dysfunction within the pyramidal (motor) tracts of the spinal cord. Assess for brainstem or cerebellar injury, which may cause **ataxia** (loss of balance), decreased or increased muscle tone, and weakness. Remember that absence of motor function may also be an indicator of a spinal cord injury.

Carefully observe the patient's ears and nose for any signs of cerebrospinal fluid (CSF) leaks that result from a basilar skull fracture. Suspicious ear or nose fluid can be analyzed by the laboratory for glucose and electrolyte content. CSF placed on a white absorbent paper or linen can be distinguished from other fluids by the "halo" sign, a clear or yellowish ring surrounding a spot of blood. Although other body fluids can be used, a halo sign is most reliable when blood is in the center of the absorbent material since tears and saliva can also cause a clear ring in some conditions.

Palpate the patient's head gently to detect the presence of fractures or hematomas. Look for areas of ecchymosis (bruising), tender areas of the scalp, and lacerations. *Battle sign* or mastoid ecchymosis is bruising behind the ears and lower jaw indicating a fracture of the middle cranial fossa of the skull. *Raccoon's eyes* are purplish discoloration around eyes that can follow fracture of the skull's base. When CT scans are used with head and brain injury, these fractures are often visualized before bruising appears.

NCLEX Examination Challenge

Safe and Effective Care Environment

An alert and oriented person is admitted to the emergency department with a GCS of 10, indicating a moderate brain injury. Which assessment finding will the nurse report immediately to the health care provider?

A Photophobia accompanied by headache
B New onset of dizziness when lying quietly in bed
C A brisk pupillary reaction to light
D New difficulty in responsiveness or sudden drowsiness

Psychosocial Assessment.

Patients with mild brain injury may still have symptoms of disability 1 year or longer after injury, but long-term effects are not common. Patients with moderate to severe TBI may have varying degrees of psychosocial changes that persist for a lifetime. Personality changes manifested by temper outbursts, depression, risk-taking behavior, and denial of disability can occur. The patient may become talkative and develop a very outgoing personality. Memory, especially recent or short-term memory, is often affected. The patient may report difficulties in concentrating or the ability to learn new information and may have

problems with insight and planning. Aggressive behavior, agitation, and sleep disorders may interfere with the ability to return to work or school. The ability to communicate and understand the spoken and written language may be altered. Changes in mobility and sensory perception may necessitate rehabilitation or use of assistive devices. All these changes in health status may lead to difficulties within the family structure and with social and work-related interactions. Behavioral interventions are used by cognitive and brain injury rehabilitation specialists to help both the patient and family members develop adaptive strategies.

Assess family dynamics, particularly if the patient is discharged to the family's care directly from the acute care hospital. The family or significant others must also cope with changes in the patient's physical appearance and cognitive abilities. Family members may feel guilty or angry about not being able to prevent the injury or blame the patient for the personal choices that contributed to the event. The family or significant others may feel overwhelmed by the complexity of care required and the long recovery period. Help both the family and the patient identify coping strategies to deal with the role changes caused by the injury.

Laboratory Assessment.

There are no established serum tests to diagnose a primary brain injury. Detection of the protein *S-100B* in serum is showing some promise as an indicator of brain injury (Defazio et al., 2013; Müller et al., 2011). Several laboratory tests are used to guide interventions and to prevent secondary brain insult. The health care provider requests arterial blood gases, complete blood count (CBC), serum glucose, osmolarity, and electrolyte levels. These tests are performed to monitor hemodynamic status, identify electrolyte imbalance, determine oxygen-carrying capacity, and detect infection. Electrolyte imbalances, hypoxia, hypovolemia, and reduced blood pressure from infection or shock can contribute to secondary injury, as well as increase the risk for seizures. A toxicology screen and an electrocardiogram (ECG) are often requested.

Imaging Assessment.

The health care provider immediately requests CT of the brain to identify the extent and scope of injury. This diagnostic test can identify the presence of an injury that requires surgical intervention, such as an epidural or subdural hematoma. *Radiography* and *CT scanning* of the cervical spine and the skull are done to rule out fractures and dislocations. An *MRI* may be done to detect subtle changes in brain

tissue and show more specific detail of the brain injury. MRI is particularly useful in the diagnosis of diffuse axonal injury, but it is not recommended for patients with ICP monitoring devices.

Other Diagnostic Assessment.

As the patient's condition stabilizes, the physician may request other diagnostic tests to identify the extent of injury to the brain. For example, the integrity of the cerebral vessels is measured through the use of ultrasonography. *Evoked potentials* (electroencephalogram recordings with sensory stimuli) provide information on cerebral function and may be useful in predicting the patient's outcome.

Interventions

The patient with a *severe* TBI is admitted to the critical care unit or a trauma center. Patients with *moderate* TBI are admitted to either the general nursing unit or the critical care unit, where they are closely observed for at least 24 hours. Those with *mild* TBI may be sent home from the emergency department with instructions for home-based observation and primary care provider follow-up.

Nonsurgical Management.

As with any critically injured patient, priority is given to maintaining a patent airway, breathing, and circulation. Specific nursing interventions for the patient with a TBI are directed toward preventing or detecting secondary brain injury or the conditions that contribute to secondary brain injury such as increased ICP, promoting fluid and electrolyte balance, and monitoring the effects of treatments and drug therapy. Providing health teaching and emotional support for the patient and family are vital parts of the plan of care.

Preventing and Detecting Secondary Brain Injury.

Take and record the patient's *vital signs* every 1 to 2 hours or more often based on patient acuity. The health care provider may prescribe IV fluids or drug therapy to prevent severe hypertension or hypotension. Dysrhythmias and nonspecific ST-segment or T-wave changes may occur, possibly in response to stimulation of the autonomic nervous system or an increase in the level of circulating catecholamines such as epinephrine. Document and report cardiac dysrhythmias, hypotension, and hypertension to the health care provider. Obtain the target range for blood pressure and heart rate from the health care provider.

The patient with a brain injury may develop a fever as a result of systemic trauma, blood in the cranium, or a generalized inflammatory response to brain injury. Fever as a consequence of infection may develop later in the course of the disease. A third cause of fever is a central fever caused by hypothalamic damage. It is manifested by an absence of sweating and no diurnal (night and day) variation. This type of fever is high and lasts several days to weeks. In addition, it responds better to cooling (e.g., cool air hypothermia, sponge bath) than to the administration of antipyretic drugs such as acetaminophen (Tylenol, Ace-Tabs ✤). *Fever from any cause is associated with higher morbidity and mortality rates.*

Therapeutic hypothermia may be started regardless of the presence of fever. The purpose of **therapeutic hypothermia** is to rapidly cool the patient to a core temperature of 89.6° and 93.2° F (32° to 34° C) for 24 to 48 hours after the primary injury. Rewarming to a normal core temperature requires specialized knowledge and skill because rapid fluid and electrolyte shifts can cause cardiac dysrhythmias and changes to systemic and cerebral pressures. The rationale for therapeutic hypothermia is to reduce brain metabolism and prevent the cascade of molecular and biochemical events that contribute to secondary brain injury in moderate to severe TBI.

Arterial blood gas (ABG), oxygen saturation (Spo_2), and end-tidal carbon dioxide ($EtCO_2$) values are all used to evaluate respiratory status and guide mechanical ventilation therapy. *Hyperventilation* for the intubated patient during the first 24 hours after brain injury is usually avoided because it may produce ischemia by causing cerebral vasoconstriction. The result is a decrease in cerebral blood volume. In acute elevations of ICP or neurologic deterioration, however, brief periods of hyperventilation may be used. After the first 24 hours, when a patient is mechanically ventilated and intracranial hypertension persists, the health care provider may adjust mechanical ventilation settings to reduce arterial carbon dioxide. Other interventions are used first, including diversion of CSF and manipulation of fluid intake and output. When mechanical ventilation adjustments are used, the goal is to maintain the partial pressure of arterial carbon dioxide ($Paco_2$) at 35 to 38 mm Hg. *Carbon dioxide is a very potent vasodilator that can contribute to increases in ICP.*

Prevent intermittent and sustained hypoxemia. Monitor peripheral oxygen saturation continuously in moderate to severe TBI. Hypoxemia damages brain tissue and contributes to cerebral vasodilation and

increased ICP. Arterial oxygen levels (Pa_{O_2}) are maintained between 80 and 100 mm Hg to prevent secondary injury. If the patient is intubated, provide 100% oxygen before each pass of the endotracheal suction catheter. Avoid overly aggressive hyperventilation with endotracheal suctioning because of the potential for hypocarbia. Cerebral ischemia caused by even transiently decreased oxygen and either high or low carbon dioxide levels contributes to secondary brain injury. Lidocaine given IV or endotracheally may be used to suppress the cough reflex; coughing increases ICP.

Patients with moderate or severe brain injury are at risk for losing airway patency. Absence of a cough and/or gag reflex, pooled oral and nasal secretions in the pharynx, and inability to position oneself to facilitate pulmonary secretion removal all contribute to the need to manage the airway in the non-intubated brain-injured adult. Pulmonary secretions may be thick because of the diuretics or fluid intake restriction that may be used to prevent cerebral edema. Collaborate with the respiratory therapist to provide humidified air and chest physiotherapy as needed based on patient assessment. If the patient has an ICP monitor present, pay close attention to the ICP response and moderate or stop suctioning, chest vibration, or repositioning when ICP increases.

Nursing Safety Priority QSEN

Action Alert

Position the TBI patient to avoid extreme flexion or extension of the neck and to maintain the head in the midline, neutral position. Log roll the patient during turning to avoid extreme hip flexion, and keep the head of the bed elevated at least 30 degrees or as recommended by the health care provider.

Generally, HOB elevation in patients with TBI is elevated at 30 to 45 degrees to prevent aspiration. However, if increasing head elevation significantly lowers systemic blood pressure, the patient does not benefit from drainage of venous blood or CSF out of the skull from this position. If hypotension accompanies an elevated backrest position, the patient may be harmed. Adjust head elevation to sustain CPP >70 mm Hg when possible. Avoid sudden vertical changes of the head of the bed in the older patient because the dura is tightly adhered to the skull and may pull away from the brain, leading to a subdural hematoma.

Patients with *severe* TBI often die. As the physiologic deterioration

begins, keep in mind that the patient may be a potential organ donor. *Before* brain death is declared, contact the local organ procurement organization. Determine if the patient consented to be an organ donor. This information is typically on a driver's license or other state-issued card or advance directive. The patient's wishes should be followed unless he or she has a medical condition that prevents organ donation. The organ donor agency representative or physician discusses the possibility of organ donation with the family. Some families may not agree with the patient's decision, which can cause an ethical dilemma. Many health care agencies have an ethics specialist of committee members who can help with these situations.

Determining Brain Death.

In 2010, the American Academy of Neurology guidelines for determining brain death were updated. Four prerequisites must be met to establish a brain death diagnosis (Wijdicks et al., 2010):

- Coma of known cause as established by history, clinical examination, laboratory testing, and neuroimaging
- Normal or near-normal core body temperature (higher than 96.8º F (36° C)
- Normal systolic blood pressure (higher than or equal to 100 mm Hg)
- At least one neurologic examination (some states and health care systems require two)

No consensus has been reached on who is qualified to perform head-to-toe brain death neurologic examinations, but neurologists and critical care intensivists typically do them. Neuroimaging tests are not required to confirm brain death but are desirable. Examples of tests that may be done include cerebral angiography, bedside electroencephalography (EEG), and cerebral computed tomographic angiography (CTA).

Drug Therapy.

Mannitol (Osmitrol), an osmotic diuretic, is used to treat cerebral edema by pulling water out of the extracellular space of the edematous brain tissue. It is most effective when given in boluses rather than as a continuous infusion. Furosemide (Lasix), a loop diuretic, is often used as adjunctive therapy to reduce the incidence of rebound from mannitol. It also enhances the therapeutic action of mannitol, reduces edema and blood volume, decreases sodium uptake by the brain, and decreases the production of CSF at the choroid plexus. *Glucocorticoids* (dexamethasone [Decadron, Dexasone] and methylprednisolone sodium succinate [Solu-

Medrol, Medrol]) have no benefit in the management of increased ICP caused by brain injury or infarction.

Administer *mannitol* through a filter in the IV tubing or, if given by IV push, draw it up through a filtered needle to eliminate microscopic crystals. For the patient receiving either osmotic or loop diuretics, monitor for intake and output, severe dehydration, and indications of acute renal failure, weakness, edema, and changes in urine output. Serum electrolyte and osmolarity levels are measured every 6 hours. Mannitol is used to obtain a serum osmolarity of 310 to 320 mOsm/L, depending on physician preference and the desired outcome of therapy. Insert an indwelling urinary catheter to maintain strict measurement of output. Check the patient's serum and urine osmolarity daily.

Sedative agents like dexmedetomidine (Precedex, Dexdor) or propofol (Diprivan) can be used as continuous IV infusions to manage agitation and ventilatory asynchrony. They have a short duration of action and can be stopped for a daily neurologic examination. However, when a patient requires sedation for management of ICP hypertension, stopping these drugs is not advised until periods of ICP elevation are infrequent and not sustained.

Opioids such as morphine sulfate or fentanyl may be used with ventilated patients to decrease agitation and control restlessness if the agitation is caused by pain. Fentanyl has fewer effects on blood pressure and heart rate than morphine and may therefore be a safer agent to manage pain. These agents may be reversed with naloxone (Narcan), but opioid reversal should be avoided if at all possible to reduce risk for withdrawal and rebound pain and agitation.

Antiepileptic drugs, such as phenytoin (Dilantin), to prevent seizures are not recommended routinely. However, they may be given as an option to prevent early-onset seizure activity that may occur with some types of specific brain injury. Acetaminophen (Tylenol, Ace-Tabs) and aspirin (acetylsalicylic acid [ASA], Ancasal) are given to patients who are febrile (temperature greater than 101° F [38.3° C]) to reduce fever.

Inducing Barbiturate Coma.

Barbiturate coma (coma induced by barbiturates) has been used for intracranial hypertension (increased ICP) that cannot be controlled by other means. Either pentobarbital sodium (Nembutal, Novopentobarb) or thiopentone is the drug of choice. These drugs decrease the metabolic demands of the brain and cerebral blood flow, stabilize cell membranes, decrease the formation of vasogenic edema, and produce a more uniform blood supply. The health care provider adjusts the dosage

to maintain complete unresponsiveness. As a consequence, it is difficult to recognize subtle or obvious neurologic changes. The patient requires mechanical ventilation, sophisticated hemodynamic monitoring, and ICP monitoring. Complications of barbiturate coma include decreased GI motility, cardiac dysrhythmias from hypokalemia, hypotension, and fluctuations in body temperature.

Maintaining Fluid and Electrolyte Management.

The patient with TBI is at risk for diabetes insipidus (DI) and the syndrome of inappropriate antidiuretic hormone (SIADH) because the pituitary gland may be injured or compressed from cerebral edema (see Chapter 62). In the patient with multiple trauma, fluid overload can occur and cerebral edema can worsen from the rapid administration of IV fluids or plasma expanders. Fluid management is titrated to optimize volume resuscitation but minimize brain swelling and ICP elevation. ICP is also influenced by the response to diuretic therapy and laboratory values. Monitor serum and urine osmolarity and electrolytes at least daily when IV fluids and diuretics are used for management of the TBI patient.

Managing Nutritional Status.

The patient with a brain injury may have changes in these areas:

- Coma or impaired ability to feed oneself
- Dysphagia, including swallowing difficulties or pocketing food and being unaware of the presence of food within the oral cavity
- Sense of smell
- Sense of taste

As a result, he or she is at risk for acute or chronic nutritional deficits that may interfere with the healing process. Weigh the patient daily to assess fluid and nutritional intake. Collaborate with the dietitian to determine whether caloric needs are being met.

A small-lumen nasogastric or nasoduodenal tube or a percutaneous endoscopic gastrostomy (PEG) tube can be used to provide enteral nutrition. Parenteral nutrition can be used if the patient is unable to meet caloric or protein intake goals because of GI dysfunction, which is common during acute care and immediately following trauma. Communicate with the health care provider before a nasogastric tube is placed. Do not insert anything into nasal passages in the presence of a cribriform plate fracture since this type of fracture can allow passage of the tube into the brain.

For the patient who can take food and fluids by mouth, ensure that mealtime is a pleasant experience. Position the patient to maximize

swallowing ability. The speech-language pathologist (SLP) identifies strategies to prevent food from accumulating in the cheek of the affected side. In general, patients who have swallowing problems can tolerate or swallow soft or semisoft foods and liquids (mechanical soft or dental diet, junior baby foods, custards, scrambled eggs) better than thin liquids (water, juice, milk). Powdered thickener (e.g., Thick-It) may be added to increase liquid consistency to aid in swallowing effort. Commercial dietary supplements (e.g., Ensure) may be needed to meet the patient's caloric and protein requirements. Collaborate with the dietitian and SLP to create a nutritional plan appropriate for the patient with dysphagia.

Managing Sensory Perception, Cognitive, and Behavioral Changes.

If a large lesion of the parietal lobe is present, the patient may experience a loss of sensation for pain, temperature, touch, and proprioception (position sense), which prevents an appropriate response to environmental stimuli. A hazard-free environment is necessary to prevent injury (e.g., from burns if the patient's coffee is too hot). In collaboration with the rehabilitation therapist, integrate a sensory stimulation program into the comatose or stuporous patient's routine care activities. Sensory stimulation is done to facilitate a meaningful response to the environment. Present visual, auditory, or tactile stimuli one at a time, and explain the purpose and the type of stimulus presented. For example, show a picture of the patient's mother and say, "This is a picture of your mother." The picture is shown several times, and the same words are used to describe the picture. If auditory tapes or DVDs are used, they should be no longer than 10 to 15 minutes. If the stimulus is presented for a longer period, it simply becomes "white" noise, or meaningless background noise.

Patients with a mild brain injury may be disoriented and have a short-term memory loss. Always introduce yourself before any interaction. Keep explanations of procedures and activities short and simple, and give them immediately before and throughout patient care. To the extent possible, maintain a sleep-wake cycle with scheduled rest periods. Orient the patient to time (day, month, and year) and place, and explain the reason for the hospitalization. Reassure the patient that he or she is safe. Ask the family to bring in familiar objects, such as pictures. Provide orientation cues within the environment, such as a large clock with numbers or a single-date calendar.

An overwhelming majority of brain injury survivors have altered cognition. Cognitive impairments interfere with the brain-injured patient's

ability to function effectively in school, at work, and in his or her personal life. *Cognitive rehabilitation* is a way of helping brain-injured patients regain function in areas that are essential for a return to independence and a reasonable quality of life. However, these services are not widely available or accessible.

The patient may be at risk for seizure activity. Keep the bed in low position, and have oxygen and suction available at the bedside. For patients who exhibit poor judgment or who dislodge therapeutic lines, consider the use of hand mittens. Be sure to follow the agency's policy for caring for patients in restraints, if needed. Provide opportunities for toileting. Encourage self-care to promote function at discharge.

Surgical Management.

The physician may elect to insert an intracranial pressure (ICP) monitoring device to evaluate the patient's ICP more closely (Table 45-5). All devices are inserted through a *burr hole* (also known as a *keyhole craniotomy*). Strict sterile technique is observed during placement of ICP monitoring devices, and the site is maintained subsequently with attention to sterile technique. Each device is connected to an electronic transducer and a bedside monitor that displays pressure waves and provides a digital value of the pressure. *Be sure to provide ongoing head-to-toe assessments even though the patient's ICP is being invasively monitored!*

TABLE 45-5

Advantages and Disadvantages of Intracranial Pressure Monitoring Devices

MONITORING DEVICE	ADVANTAGES	DISADVANTAGES
Intraventricular catheter (IVC)	Allows accurate measurement of intracranial pressure (ICP) Allows drainage or sampling of cerebrospinal fluid (CSF) Allows instillation of contrast media Provides reliable evaluation of cerebral compliance	Provides additional site for potential infection Most invasive method for monitoring ICP Must be balanced and recalibrated frequently Catheter can become occluded by blood or tissue Insertion can be difficult with small or collapsed ventricles CSF leakage can occur around insertion site
Subarachnoid bolt or screw	Lower infection rates than with IVC Quickly and easily placed Can be used with small or collapsed ventricles Does not penetrate brain parenchyma	Tendency for dampened waveform Less accurate at high ICP May become occluded by blood or tissue Must be balanced and recalibrated frequently (i.e., every 4 hours and whenever patient is repositioned) Baseline drift Does not provide for CSF sampling
Subdural/epidural catheter or sensor	Least invasive Decreased risk for infection Easily and quickly placed	Increasing baseline drift over time; therefore accuracy and reliability are questionable Does not provide for CSF sampling or drainage
Fiberoptic transducer-tipped catheter	Can be placed in subdural or subarachnoid space, in ventricle, or into brain tissue Easily transported Requires calibrating only once (during insertion) Baseline drift to 1 mm Hg/day Decreased risk for infection Less waveform artifact No need to adjust transducer to patient's position Easy to insert	Does not provide for CSF sampling or drainage Cannot be recalibrated after placement Probe needs periodic replacement Fragile fiberoptic cable easily damaged and broken

In extreme cases in which the patient's ICP cannot be controlled, the physician may elect to perform a **decompressive craniectomy** (removal of a section of the skull) or craniotomy (skull opening followed by immediate skull closure) to remove ischemic brain tissue or the tips of the temporal lobes. The removal of a portion of the skull and/or nonvital brain tissue allows additional space for edema without increasing ICP. Following a craniectomy, information about side-lying restrictions may be placed in the plan of care and repeated in a sign at the head of bed; patients do not lie on the side from with the skull fragment was removed. The patient must wear protective gear (bike or football helmet) when out of bed because an injury to the head where the skull fragment is missing will cause significant brain injury. The skull fragment can be frozen and re-implanted as late as 3 years after removal; re-implantation is planned as the patient becomes ambulatory.

A craniotomy without brain tissue removal may be performed to remove an epidural or subdural clot (hematoma). Care of the patient with a craniotomy is discussed on p. 960 under Postoperative Care in the Brain Tumors section.

Community-Based Care

The patient with a *mild* brain injury recovers at home after discharge from the emergency department (ED) or hospital (Chart 45-9). The patient with a *severe* brain injury requires long-term case management and ongoing rehabilitation after hospitalization. A number of specialized brain injury rehabilitation facilities are available in the United States and Canada. Communicate the patient's plan of care, including drug therapy (use best practices for drug reconciliation and transitions in care), to the receiving nurse or provider during each transition in care.

Chart 45-9 Patient and Family Education: Preparing for Self-Management

Mild Brain Injury

- Initial neurologic assessment occurs hourly until the patient returns to baseline. The frequency of ongoing assessment for mild traumatic brain injury (MTBI) is not established.
- For a headache, give acetaminophen (Tylenol) every 4 hours as needed.
- Avoid giving the person sedatives, sleeping pills, or alcoholic beverages for at least 24 hours unless the physician instructs otherwise.
- Do not allow the person to engage in strenuous activity for at least 48

hours.
- While assessment of balance is a component of advanced nursing or medical practice, the caregiver should be aware that balance disturbances cause safety concerns and he or she should provide for monitored or assisted movement.
- If any of these symptoms occur, take the person back to the emergency department immediately:
  - Severe headache
  - Persistent or severe nausea or vomiting
  - Blurred vision
  - Drainage from the ear or nose
  - Weakness
  - Slurred speech
  - Progressive sleepiness
  - Worsening headache
  - Unequal pupil size
- Keep follow-up appointments with the health care provider.

Home Care Management.

The major desired outcome for rehabilitation after brain injury is to maximize the patient's ability to return to his or her highest level of functioning. Activities such as occupational therapy (OT), physical therapy (PT), and speech-language therapy may continue in the home after discharge from the hospital or rehabilitation facility. Adaptation of the home environment to accommodate the patient safely may be needed. For example, smoke and fire alarms must function properly because the patient with a brain injury often loses the sense of smell. Home evaluations and referrals to outside agencies are completed before discharge.

Self-Management Education.

Collaborate with the case manager (CM) to provide the patient and family with both written and verbal instructions for discharge. The teaching plan includes a review of seizure safety at home and strategies to adapt to sensory dysfunction. Discuss issues related to personality or behavior problems that may arise and how to cope with them. Explain the purpose, dosage, schedule, and route of administration of drug therapy. Teach the family to encourage the patient to participate in activities as tolerated. Demonstrations and return demonstrations of care activities help family members become more skillful. Stress the

importance of regular follow-up visits with therapists and other health care providers.

Patients with personality and behavior problems respond best to a structured and consistent environment. Instruct the family to develop a home routine that provides structure, repetition, and consistency. Remind the family about the importance of reinforcing positive behaviors rather than negative behaviors.

Nursing Safety Priority QSEN

Action Alert

Teach the patient who has sustained a *mild* brain injury, sometimes called a *concussion,* that symptoms that disturb sleep, enjoyment of daily activities, work performance, mood, memory, and ability to learn new material and cause changes in personality require follow-up care. Provide the patient and family with education materials that will alert them to symptoms and management options. A good source of written instructions is *Heads Up: What to Expect After a Concussion—Patient Discharge Instruction Sheet and Getting Better (after concussion)* from the Centers for Disease Control and Prevention (CDC, 2013a).

Most patients with *moderate to severe* TBI are discharged with varied physical and cognitive disabilities. Changes in personality and behavior are very common. The family must learn to cope with the patient's increased fatigue, irritability, temper outbursts, depression, and memory problems. These patients often require constant supervision at home, and families may feel socially isolated. Teach the family about the importance of regular respite care, either in a structured day-care respite program for the patient or through relief provided by a friend or neighbor. Family members, particularly the primary caregiver, may become depressed and have feelings of loneliness. In addition, they may feel angry with the patient because of the physical, financial, and emotional responsibilities that his or her care has placed on them. To help the family cope with these problems, suggest that they join and actively participate in a local brain injury support group.

Health Care Resources.

Collaborate with the CM to refer families and patients to local chapters of the Brain Injury Association of America (BIAA) (www.biausa.org) and the National Brain Injury Foundation (www.nbif.org) for information and

support. The BIAA has a number of helpful publications on preventing and living with TBI. Other resources include religious, spiritual, and cultural leaders.

Brain Tumors

Brain tumors can arise anywhere within the brain structures and are named according to the cell or tissue where they are located; however, cerebral tumors are the most common. *Primary* tumors originate within the CNS and rarely metastasize (spread) outside this area. *Secondary* brain tumors result from metastasis from other areas of the body, such as the lung, breast, kidney, and GI tract.

Pathophysiology

Complications of Cerebral Tumors

Regardless of location, the tumor expands and invades, infiltrates, compresses, and displaces normal brain tissue. This leads to one or more of these complications:

- Cerebral edema/brain tissue inflammation
- Increased intracranial pressure (ICP)
- Neurologic deficits
- Hydrocephalus
- Pituitary dysfunction

Cerebral edema (vasogenic edema) results from changes in capillary endothelial tissue permeability that allows plasma to seep into the extracellular spaces. This leads to *increased ICP* and, depending on the location of the tumor, brain herniation syndromes. A variety of *neurologic deficits* result from edema, infiltration, distortion, and compression of surrounding brain tissue. The cerebral blood vessels may become compressed because of edema and increased ICP. This compression leads to ischemia (decreased blood flow) of the area supplied by the vessel. In addition, the tumor may enter the walls of the vessel, causing it to rupture and hemorrhage into the tumor bed or other brain tissue. Some patients who have brain tumors have seizure activity from interference with the brain's normal electrical activity.

Increased ICP may also result from *hydrocephalus* (increased cerebrospinal fluid [CSF]) related to obstruction of the flow of CSF or displacement of the lateral ventricles by the expanding lesion. Typically, a tumor obstructs the aqueduct of Sylvius or one of the ventricles or pushes into the subarachnoid space.

Pituitary dysfunction may occur as the tumor compresses the pituitary gland and causes the syndrome of inappropriate antidiuretic hormone (SIADH) or diabetes insipidus (DI). These disorders result in severe fluid and electrolyte imbalances and can be life threatening. (See

Chapters 42 and 62 for a complete description.)

Classification of Tumors

Brain tumors are usually classified as benign, malignant (cancerous), or metastatic (Table 45-6). They may or may not be treated, depending on their location. Benign (noncancerous) tumors are generally associated with a favorable outcome. Malignant or metastatic tumors require more aggressive intervention including surgery, radiation, and/or chemotherapy.

TABLE 45-6

Classification of Brain Tumors

Benign	Malignant
• Acoustic neuroma (schwannoma) • Choroid plexus papilloma • Meningioma • Pituitary adenoma • Astrocytoma • Grade 1 (may undergo changes and become malignant) • Chondroma • Craniopharyngioma • Hemangioblastoma	• Astrocytoma (a *glioblastoma multiforme* is a Grade 4 astrocytoma) • Oligodendroglioma • Ependymoma • Medulloblastoma • Chondrosarcoma • Glioma • Lymphoma

A second classification system is based on location. **Supratentorial** tumors are located within the cerebral hemispheres. Located beneath the tentorium (fold of dura mater) is the **infratentorial** area—the area of the brainstem structures and cerebellum.

A third classification system depends on the cellular or anatomic origins of the tumor. The nervous system is composed of two types of cells: (1) neurons, which are responsible for nerve impulse conduction; and (2) neuroglial cells, which provide support, nourishment, and protection for neurons. Four specific types of neuroglial cells are astrocytes, oligodendroglia, ependymal cells, and microglia. When classifying gliomas according to this system, tumors are named by their cell type. For example, an astrocytoma is a tumor of astrocytes. Gliomas are *malignant* tumors.

Meningiomas, the most common *benign* tumors, arise from the coverings of the brain (the meninges). This tumor is capsular, globular, and well outlined and causes compression and displacement of nearby brain tissue. Although complete removal of the tumor is possible, it tends to recur.

Pituitary tumors that occur in the anterior lobe account for up to one fourth of brain tumors and may cause endocrine dysfunction. The most

common type of pituitary tumor is the adenoma. These tumors are *benign* and often occur in young and middle-aged adults. The presenting symptoms include visual disturbances and hypopituitary signs, such as loss of body hair, diabetes insipidus (DI), infertility, visual field defects, and headaches.

Acoustic neuromas arise from the sheath of Schwann cells in the peripheral portion of cranial nerve VIII. They are also referred to as *cerebellar pontine angle (CPA) tumors* to describe their anatomic location. Acoustic neuromas compress brain tissue and tend to surround nearby cranial nerves (VII, V, IX, X), making surgical removal difficult without causing permanent cranial nerve dysfunction. Women are twice as likely as men to have acoustic neuromas. Common symptoms include hearing loss, **tinnitus** (ringing in the ears), and dizziness or vertigo.

Metastatic, or secondary, tumors account for many brain tumors. Cancer cells from the lung, breast, colon, pancreas, and kidney can travel to the brain via the blood and the lymphatic system. Multiple metastatic lesions are fairly common.

Brain tumors are also grouped by grade, which refers to the microscopic tissue evaluated by the histologist:

- Grade I: The tissue is benign; the cells look nearly like normal brain cells, and they grow slowly.
- Grade II: The tissue is malignant; the cells look less like normal cells than do the cells in a Grade I.
- Grade III: The malignant tissue has cells that look very different from normal cells; the abnormal cells are actively growing (anaplastic).
- Grade IV: The malignant tissue has cells that look most abnormal and tend to grow quickly.

Etiology and Genetic Risk

The exact cause of brain tumors is unknown. Several areas under investigation include genetic mutations and a variety of environmental factors. The use of cellular phones has been investigated as a cause of brain tumors, but findings are not confirmed. Brain tumors account for a small percentage of all cancer deaths. Primary brain tumors are relatively uncommon; many more patients have metastatic lesions (Cahill & Armstrong, 2011). Malignant brain tumors are seen primarily in patients 40 to 70 years of age, and the survival rate is low compared with that of other cancers.

❖ Patient-Centered Collaborative Care

Assessment

When possible, obtain a history from both the patient and the family, including current signs and symptoms. A complete neurologic assessment is needed to establish baseline data and to determine the nature and extent of neurologic deficits.

The clinical manifestations of brain tumors vary with the site of the tumor (Chart 45-10). In general, assess for these symptoms of a brain tumor:

Chart 45-10 Key Features

Common Brain Tumors

Cerebral Tumors

- Headache (most common feature)
- Vomiting unrelated to food intake
- Changes in visual acuity and visual fields; diplopia (visual changes caused by papilledema)
- Hemiparesis or hemiplegia
- Hypokinesia (decreased motor ability)
- Hyperesthesia, paresthesia, decreased tactile discrimination
- Seizures
- Aphasia
- Changes in personality or behavior

Brainstem Tumors

- Hearing loss (acoustic neuroma)
- Facial pain and weakness
- Dysphagia, decreased gag reflex
- Nystagmus
- Hoarseness
- Ataxia and dysarthria (cerebellar tumors)

- Headaches that are usually more severe on awakening in the morning
- Nausea and vomiting
- Visual symptoms
- Seizures or convulsions
- Facial numbness or tingling
- Loss of balance or dizziness
- Weakness or paralysis in one part or one side of the body
- Difficulty thinking, speaking, or articulating

- Changes in mentation or personality
- **Papilledema** (swelling of the optic disc) indicating increased ICP

Neurologic deficits result from the destruction, distortion, or compression of brain tissue. *Supratentorial (cerebral)* tumors usually result in paralysis, seizures, memory loss, cognitive impairment, language impairment, or vision problems. *Infratentorial* tumors produce ataxia, autonomic nervous system dysfunction, vomiting, drooling, hearing loss, and vision impairment. As the tumor grows, ICP increases and the symptoms become progressively more severe.

Diagnosis is based on the history, neurologic assessment, clinical examination, and results of neurodiagnostic testing. Noninvasive diagnostic studies such as *CT, MRI,* and *skull films* are conducted first. These tests identify the size, location, and extent of the tumor. The MRI may be used for initial diagnostic evaluation and is a more sensitive diagnostic study, whereas the CT is often used for follow-up during the course of illness.

Cerebral angiography is usually not indicated to diagnose a brain tumor but may be used to provide additional information about blood supply to the tumor. *Electroencephalography (EEG), lumbar puncture (LP), brain scan,* and *positron emission tomography (PET)* may be indicated to provide further information about the size, location, and characteristics of the tumor. *To prevent brain herniation, LP should not be performed if the patient is exhibiting signs of ICP elevation.* Laboratory tests may also be requested to evaluate endocrine function, renal status, and electrolyte balance.

Interventions

Interventions depend on the type, size, and location of the tumor. For example, a small benign tumor may be periodically monitored through CT and MRI scanning to assess its growth. Malignant tumors may be managed by chemotherapy, radiation, and/or surgery.

Nonsurgical Management.

The desired outcomes of treatment of brain tumors are to decrease tumor size, improve quality of life, and improve survival time. The type of treatment selected depends on the tumor size and location, patient symptoms and general condition, and whether the tumor has recurred. In addition to traditional interventions, a number of experimental treatment modalities are being investigated. These include blood-brain barrier disruption, recombinant DNA, monoclonal antibodies, new chemotherapeutic drugs, and immunotherapy. Traditional *radiation*

therapy may be used alone, after surgery, or in combination with chemotherapy and surgery. Chapter 22 discusses radiation treatment for patients with cancer.

Drug Therapy.

The health care provider may prescribe a variety of drugs to treat the tumor, manage the patient's symptoms, and prevent complications. *Chemotherapy* may be given alone, in combination with radiation and surgery, and with tumor progression. Although these drugs may control tumor growth or decrease tumor burden, the benefit does not last. Chemotherapy usually involves more than one agent that may be given orally, IV, intra-arterially, and/or intrathecally through an Ommaya reservoir placed in a cranial ventricle. In electrochemotherapy, electric voltage carries agents into the tumor. When given systemically, the drug must be lipid-soluble to cross the blood-brain barrier.

Commonly used oral drugs are lomustine (CCNU), temozolomide (Temodar), procarbazine (Matulane), and methotrexate (MTX). Vincristine (Oncovin) may be given IV in combination with other drugs. Monitor for side effects of these drugs, which are similar to those of any chemotherapeutic drug. Chapter 22 describes general nursing implications for care of a patient receiving chemotherapy.

Direct drug delivery to the tumor is an emerging practice. Disk-shaped drug (Gliadel) wafers may be placed directly into the cavity created during surgical tumor removal (interstitial chemotherapy). The major drug in the wafer is carmustine (BCNU). This therapy is usually given for newly diagnosed high-grade malignant gliomas, but recurrent tumors may also be treated with this method. Other drugs used are molecularly targeted. Examples include erlotinib (Tarceva), gefitinib (Iressa), and bevacizumab (Avastin) (Lilley et al., 2014).

Analgesics, such as codeine and acetaminophen (Tylenol, Ace-Tabs ), are given for headache. Dexamethasone (Decadron) is usually given to control cerebral edema. Phenytoin (Dilantin) or other antiepileptic drugs may be given to prevent or treat seizure activity. Proton pump inhibitors are given to decrease gastric acid secretion and prevent the development of stress ulcers.

Stereotactic Radiosurgery.

Stereotactic radiosurgery (SRS) is an alternative to traditional surgery. Several techniques are used, including the modified linear accelerator (LINAC) using accelerated x-rays, a particle accelerator using beams of protons (cyclotron), and isotope seeds implanted in the tumor

(brachytherapy).

The gamma knife is an SRS procedure that uses a single high dose of ionized radiation to focus multiple beams of gamma radiation produced by the radioisotope *cobalt-60* to destroy intracranial lesions selectively without damaging surrounding healthy tissue (Fig. 45-10). Combining neurodiagnostic imaging tools—including MRI, CT, magnetic resonance angiography (MRA), and angiography—with the gamma knife allows for precise localization of deep-seated or anatomically difficult lesions. Treatment usually takes less than an hour, and patients require only overnight hospitalization. Advantages of this technique include its:

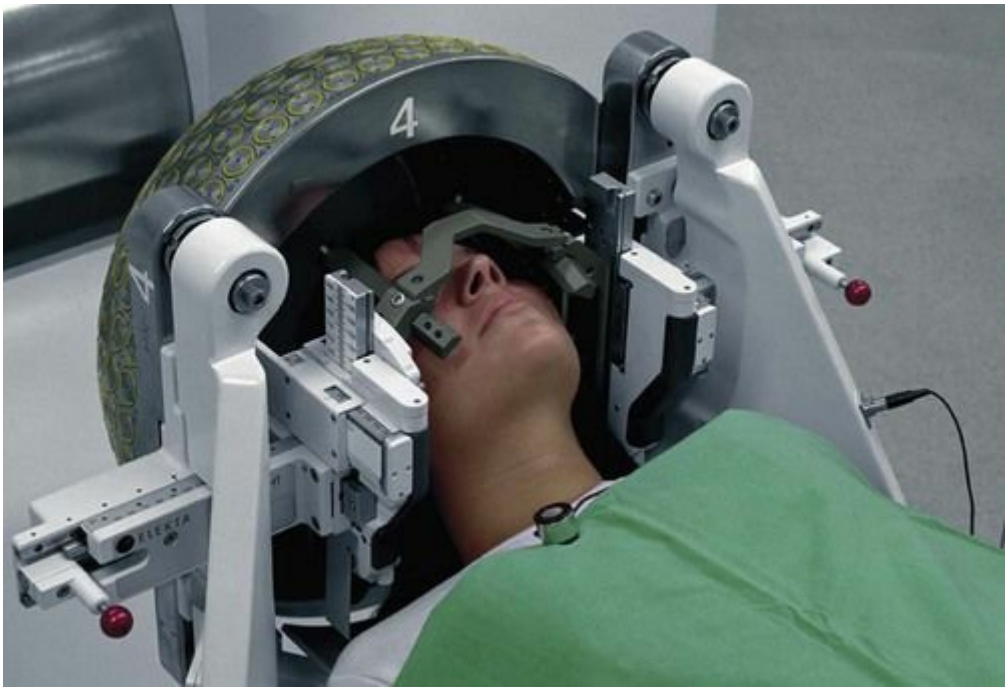

FIG. 45-10 A gamma knife treatment. The treatment beams are widely dispersed over the surface of the head to prevent damage to healthy brain tissue. The beams are intense only at the point of target.

- Noninvasive nature
- Lower risk when compared with traditional craniotomy
- Surgical precision
- Decreased cost
- Decreased morbidity
- Deceased length of hospital stay
- Rapid recovery time

A disadvantage is that the device requires an uncomfortable rigid head frame. In another system, called the *CyberKnife*, no frame is needed. A third stereotactic system is the Novalis system. This radiosurgery system

utilizes a small computer-controlled micro Multi Leaf Collimator (mMLC) that can produce many complicated shapes with a wide range of tumor area. Both procedures are used primarily for brain tumors or arteriovenous malformations (AVMs) that are in a difficult location and therefore not removable by craniotomy. These procedures may also be used with patients who decline conventional surgery, for patients whose age and physical condition do not allow general anesthesia, as an adjunct to radiation therapy, and for recurrent or residual AVM or tumors after embolization or craniotomy.

Surgical Management.

A **craniotomy** (incision into the cranium) may be performed to remove the tumor, to improve symptoms related to the lesion, or to decrease the tumor size (debulk). The challenge for the neurosurgeon is to remove the tumor as completely as possible without damaging normal tissue. Complete removal is possible with some benign tumors, which results in a "surgical cure." Postoperatively, the patient may be admitted to the critical care unit or neurosurgical unit for frequent observation.

Preoperative Care.

The patient having a craniotomy is typically very anxious about having his or her head opened and the brain exposed. Concerns are centered on the possibility of increased neurologic deficits after the surgery and the patient's self-image when part or all of the head is shaved. Provide reassurance that the surgeon will spare vital parts of the brain while removing or decreasing the size of the tumor. Teach the patient and family about what to expect immediately after surgery and throughout the recovery period. Some patients require short-term or long-term rehabilitation.

Check that the patient has not had alcohol, tobacco, anticoagulants, or NSAIDs for at least 5 days before surgery. Some neurosurgeons require a week or longer. Be sure that the patient has been NPO status for at least 8 hours. Other preoperative care is similar to that for any patient having surgery, as described in Chapter 14.

Operative Procedures.

Surgery is performed under local or general anesthesia or sedation. Small tumors that are easily located may be removed by *minimally invasive surgery (MIS).* For example, the trans-nasal approach using endoscopy can be performed for pituitary tumors. The patient has a short hospital stay and few complications after surgery. Stereotactic surgery using a

rigid head frame can be done for tumors that are easily reached. This procedure requires only burr holes and local anesthesia because the brain has no sensory neurons for pain. Laser surgery can also be done.

For a *craniotomy,* the surgeon makes an incision along or behind the hairline after placing the patient's head in a skull fixation device. Several burr holes are drilled into the skull, and a saw is used to remove a piece of bone (bone flap) to expose the tumor area. The flap is stored carefully until the end of the procedure. The tumor is located using imaging technology and removed or debulked. After the tumor removal, the bone flap is replaced and held by small screws or bolts. A drain or monitoring device may be inserted. The surgeon creates a soft dressing "cap" over the top of the head to keep the surgical area clean.

Postoperative Care.

The focus of postoperative care is to monitor the patient to detect changes in status and to prevent or minimize complications, especially increased intracranial pressure (ICP).

Nursing Safety Priority QSEN

Action Alert

Assess neurologic and vital signs every 15 to 30 minutes for the first 4 to 6 hours after a craniotomy and then every hour. If the patient is stable for 24 hours, the frequency of these checks may be decreased to every 2 to 4 hours, depending on the agency's policy or the patient's condition. *Report immediately and document new neurologic deficits, particularly a decreased level of consciousness (LOC), motor weakness or paralysis, aphasia (speech and/or language problems), decreased sensation, and reduced pupil reaction to light!* Personality changes such as agitation, aggression, or passivity can also indicate worsening neurologic status.

Managing the Patient.

Periorbital (around the eye) edema and ecchymosis of one or both eyes are not unusual and are treated with cold compresses to decrease swelling. Irrigate the affected eye with warm saline solution or artificial tears to improve patient comfort. The patient in the critical care unit has routine cardiac monitoring because dysrhythmias may occur as a result of brain–autonomic nervous system–cardiac interactions or fluid and electrolyte imbalance.

Regardless of setting, ensure recording of the patient's intake and

output for the first 24 hours. Anticipate fluid restriction to 1500 mL daily if there is pituitary involvement in either the tumor or surgical site. Reposition the patient, but do not turn him or her onto the operative site. Delegate or provide repositioning and deep breathing every 2 hours. To prevent the development of VTE, maintain intermittent sequential pneumatic devices until the patient ambulates.

For patients who have undergone *supratentorial* surgery, elevate the head of the bed 30 degrees or as tolerated to promote venous drainage from the head. *Position the patient to avoid extreme hip or neck flexion and maintain the head in a midline, neutral position to prevent increased ICP.* Turn the patient side to side or supine to prevent pressure ulcers and prevent pneumonia.

Keep the patient with an *infratentorial* (brainstem) craniotomy flat and positioned side-lying, alternating sides every 2 hours, for 24 to 48 hours. This position prevents pressure on the neck-area incision site. It also prevents pressure on the internal tumor excision site from higher cerebral structures. Make sure that the patient remains NPO status for 24 hours, because edema around the medulla and lower cranial nerves may cause vomiting and aspiration.

Check the head dressing every 1 to 2 hours for signs of drainage. Mark the area of drainage once during each shift for baseline comparison, although this practice varies by health care agency. A small or moderate amount of drainage is expected. Some patients may have a Hemovac, Jackson-Pratt, or other surgical drain in place for 24 hours after surgery. Measure the drainage every 8 hours, and record the amount and color. A typical amount of drainage is 30 to 50 mL every 8 hours. Follow the manufacturer's and neurosurgeon's instructions to maintain suction within the drain.

Nursing Safety Priority QSEN

Critical Rescue

After craniotomy, monitor the patient's dressing for excessive amounts of drainage. Report a saturated head dressing or drainage greater than 50 mL/8 hrs immediately to the surgeon! Observe for manifestations of hypovolemic shock, and position the patient flat to maintain blood pressure if needed.

The usual laboratory studies monitored postoperatively include complete blood count (CBC), serum electrolyte levels and osmolarity, and

coagulation studies. The patient's hematocrit and hemoglobin concentration may be abnormally low from blood loss during surgery or elevated if the blood was replaced. Hyponatremia (low serum sodium) may occur as a result of fluid volume overload, syndrome of inappropriate antidiuretic hormone (SIADH), or steroid administration.

Hypokalemia (low serum potassium) may cause cardiac irritability. Weakness, a change in LOC, and confusion are symptoms of hyponatremia and hypokalemia. Hypernatremia may be caused by meningitis, dehydration, or diabetes insipidus (DI). It is manifested by muscle weakness, restlessness, extreme thirst, and dry mouth. Additional signs of dehydration such as decreased urinary output, thick lung secretions, and hypotension may be present. *Untreated hypernatremia can lead to seizure activity. DI should be considered if the patient voids large amounts of very dilute urine with an increasing serum osmolarity and electrolyte concentration.*

Often the patient is mechanically ventilated for the first 24 to 48 hours after surgery to help manage the airway and maintain optimal oxygen levels. If the patient is awake or attempting to breathe at a rate other than that set on the ventilator, drugs such as dexmedetomidine (Precedex) or propofol (Diprivan) and fentanyl are given to treat pain and anxiety, as well as to promote rest and comfort. Suction the patient as needed. *Remember to hyperoxygenate the patient carefully before, during, and after suctioning!*

Drugs routinely given postoperatively include antiepileptic drugs, histamine blockers or proton pump inhibitors for stress ulcer prophylaxis, and glucocorticoids, such as dexamethasone (Decadron) to reduce intracranial edema. Give acetaminophen for fever or mild pain. Some surgeons may prescribe antibiotics to prevent infection.

NCLEX Examination Challenge

Physiological Integrity

A client returns from the postanesthesia care unit (PACU) after a craniotomy for removal of a left parietal lobe tumor. How will the nurse position the client after surgery?

A Flex the client's knees to decrease intra-abdominal pressure and cerebral hypertension.

B Keep the client on the left side to prevent surgical site bleeding or cerebrospinal fluid leakage.

C Elevate the client's head to at least 30 degrees to promote cerebral

venous drainage.

D Hyperextend the client's neck to maintain the airway and prevent aspiration regardless of supine or side-lying positioning.

Preventing and Managing Postoperative Complications.

Postoperative complications are listed in Table 45-7. The major complications of supratentorial surgery are increased ICP from cerebral edema or hydrocephalus and hemorrhage.

TABLE 45-7

Postoperative Complications of Craniotomy

- Increased intracranial pressure (ICP)
- Hematomas
  - Subdural hematoma
  - Epidural hematoma
- Subarachnoid hemorrhage
- Hypovolemic shock
- Hydrocephalus
- Respiratory complications
  - Atelectasis
  - Hypoxia
  - Pneumonia
  - Neurogenic pulmonary edema

- Wound infection
- Meningitis
- Fluid and electrolyte imbalances
  - Dehydration
  - Hyponatremia
  - Hypernatremia
- Seizures
- Cerebrospinal fluid (CSF) leak
- Cerebral edema

Symptoms of *increased ICP* include severe headache, deteriorating LOC, restlessness, irritability, and dilated or pinpoint pupils that are slow to react or nonreactive to light. Treatment of increased ICP is the same as that described on p. 948 under Interventions in the Traumatic Brain Injury section.

Hydrocephalus (increased CSF in the brain) is caused by obstruction of the normal CSF pathway from edema, an expanding lesion such as a hematoma, or blood in the subarachnoid space. Rapidly progressive hydrocephalus produces the classic symptoms of increased ICP. Slowly progressive hydrocephalus is manifested by headache, decreased LOC, irritability, blurred vision, and urinary incontinence. An intraventricular catheter (ventriculostomy) may be placed to drain CSF during surgery or emergently postoperatively for rapidly deteriorating neurologic function. If long-term treatment is required for chronic hydrocephalus, a surgical shunt is inserted to drain CSF to another area of the body. A major

complication of the shunting procedure is a subdural hematoma from the tearing of bridging veins. An external lumbar drain may also be used temporarily. Additional information about shunts may be found in neuroscience nursing textbooks.

Subdural and epidural *hematomas and intracranial hemorrhage* are manifested by severe headache, a rapid decrease in LOC, progressive neurologic deficits, and herniation syndromes (brain tissue shifting, often downward). Bleeding into the posterior fossa may lead to sudden cardiovascular and respiratory arrest. Treatment of a hematoma requires surgical removal. An intracranial hemorrhage is treated with aggressive medical management (e.g., osmotic diuretics, ICP monitoring, CPP management).

Respiratory complications include atelectasis, pneumonia, and neurogenic pulmonary edema. Prevent atelectasis and pneumonia by turning the patient frequently and encouraging him or her to take frequent deep breaths to expand the lungs each hour. Humidified air and incentive spirometry are also useful techniques. Other treatment modalities include endotracheal or oral tracheal suctioning and chest physiotherapy. However, these measures may cause an increase in ICP. Although not common, *neurogenic pulmonary edema* is a life-threatening complication of traumatic brain injury (TBI), brain tumors, and brain surgery. Its symptoms are the same as those of acute pulmonary edema, but there are no associated cardiac problems. In spite of aggressive treatment, most patients with neurogenic pulmonary edema do not survive.

Wound infections occur more often in older and debilitated patients and in patients with a history of diabetes, long-term steroid use, obesity, and previous infections. The patient may contribute to the problem by rubbing or scratching the wound. If infection is present, the wound appears reddened and puffy. It may begin to separate, is sensitive to touch, and feels warm. The patient may or may not be febrile. Treatment is based on the degree and extent of the infection. A localized infection may be treated by cleaning it with an antiseptic and applying a topical antibiotic. For more severe infections, systemic antibiotic administration is needed. If the underlying bone is involved, it may need to be removed.

Meningitis is an inflammation of the meninges and may occur as a result of surgery or wound infection, a cerebrospinal fluid (CSF) leak, or contamination during surgery. (See the Meningitis section in Chapter 42 for a more complete explanation of this condition.)

Complications related to *fluid and electrolyte imbalance* include DI, SIADH, and cerebral salt wasting (CSW). DI is seen most often after

supratentorial surgery, especially procedures involving the pituitary gland or hypothalamus. Failure of the posterior pituitary gland to release antidiuretic hormone (ADH) leads to failure of the renal tubules to reabsorb water. The patient's urine output increases dramatically (it may be up to 10 L/day), and the urine specific gravity drops to below 1.005. Urine osmolarity decreases, whereas serum osmolarity increases. The patient may become dehydrated and hypovolemic shock may develop rapidly if this condition is left untreated. Fluid therapy to replace urinary losses and prevent dehydration may be accomplished by having the patient increase oral intake or use IV fluids. Hormonal replacement may also be necessary, especially if fluid loss is greater than 6 L/24 hr. Aqueous vasopressin is short-acting, lasting only 6 to 8 hours. Desmopressin acetate (DDAVP) may be administered for long-term replacement therapy.

Syndrome of inappropriate antidiuretic hormone (SIADH) occurs when the posterior pituitary gland releases too much ADH, causing water retention. The urine output decreases dramatically, with a urine output of less than 20 mL/hr. Sodium concentration in the urine is normal or elevated, whereas the serum sodium level falls. Other indications of SIADH are loss of thirst, weight gain, irritability, muscle weakness, and decreased LOC. SIADH is treated by fluid restriction, which is usually sufficient to correct the hyponatremia. Conivaptan (Vaprisol) and tolvaptan are vasopressin receptor antagonists used to increase water diuresis without serum electrolyte loss and may be useful in hypervolemic hyponatremic conditions. Slow, controlled IV infusion of hypertonic sodium may be needed for severe hyponatremia (<118 mEq/L).

Cerebral salt wasting (CSW) is thought to result from the influence of atrial natriuretic factor (ANF). ANF cells are located in the hypothalamus and the right atrium and regulate fluid volume. CSW is believed to be the primary cause of hyponatremia in the neurosurgical population. It is characterized by hyponatremia, decreased serum osmolarity, and decreased blood volume. Serum vasopressin and ANF levels can differentiate CSW and SIADH. CSW is treated with the replacement of sodium and isotonic fluid volume.

Patients with complications related to fluid and electrolyte imbalance undergo strict measurement of their intake and output. Be sure that an accurate weight measurement is taken every day at the same time with the same scale. Carefully assess for indications of fluid overload or dehydration during treatment. Serum electrolyte levels and osmolarity are measured daily (or more often if clinically indicated).

Community-Based Care

The patient with a brain tumor is managed at home if possible. Maintaining a reasonable quality of life is an important outcome for recovery and rehabilitation. Unless the patient has a significant degree of disability, no special preparation for home care is needed. Patients with hemiparesis need assistance to ensure that their home is accessible according to their method of mobility (e.g., cane, walker, and wheelchair). The environment should be made safe to prevent falls. For example, teach caregivers to remove scatter rugs and to place grab bars in the bathroom.

Information about the selection of rehabilitation or chronic care facility, if needed, can be obtained from the case manager (CM) or discharge planner. The selected facility should have experience in providing care for neurologically impaired patients. A psychologist should be available to provide input in the evaluation of the cognitive disabilities that the patient may have.

It is very important that the patient and family fully understand the importance of any recommended follow-up health care appointments. The discharge summary should state the name of the person who has been given the follow-up information.

Health teaching includes drug therapy and who to call if adverse drug events occur. Remind the patient to avoid taking any over-the-counter drugs unless approved by the health care provider.

Teach the patient to maintain a program of regular physical exercise within the limits of any disabilities. Referral to the dietitian may be needed to ensure adequate caloric intake for the patient receiving radiation or chemotherapy.

Seizures are a potential complication that can occur at any time for as long as 1 year or more after surgery. Provide the patient and the family with information about seizure precautions and what to do if a seizure occurs.

Refer the patient and the family or significant others to the American Brain Tumor Association (www.abta.org) or the National Brain Tumor Foundation (www.braintumor.org). The American Cancer Society (www.cancer.org) is also an appropriate community resource for patients with malignant tumors. Home care agencies are available to provide both the physical and rehabilitative care that the patient may need at home. Hospice services and palliative care may be needed if he or she is terminally ill. (See Chapter 7 for additional information about end-of-life care.) Brain tumor support groups may also be a valuable asset to the

patient and family.

Brain Abscess

A **brain abscess** is a purulent infection of the brain in which pus forms in the extradural, subdural, or intracerebral area of the brain. The causative organisms are usually bacteria that invade the brain directly or indirectly. Cerebral abscesses may be a complication of meningitis.

Pathophysiology

In general, organisms from the ear, sinus, or mastoid area enter the brain by traveling along the wall of the cerebral veins, and therefore they may spread to any area of the brain. The typical source is a lung infection, although it is common not to find the source of infection. Bacteria may travel from a nearby infected area such as an ear infection or a sinus infection or enter the body with a bullet, knife wound, or neurosurgery. At times, the organisms (especially those from the ear) destroy the bone, form a tract, and enter the brain directly. A portion of an abscess from a distant organ, such as the heart or tonsils, may break off and enter the systemic circulation. These septic emboli contain organisms that may become lodged in a cerebral vessel and produce a localized infection. Penetrating trauma, open head injuries, and neurosurgical procedures provide a potential means for the direct entry of an organism into the brain.

The organisms cause a local infection, and acute inflammation surrounds the involved area. Within a few days, necrosis of the tissue takes place, pus forms, and the tissue liquefies. This process is followed by the development of cerebral edema from localized vascular congestion and tissue swelling in response to inflammation. During the next few weeks, the area becomes encapsulated. The abscess usually occurs deep within the cerebral hemisphere and involves the white matter of the brain. In a few cases, it spreads through the brain tissue to the subarachnoid space and ventricular system. The organism varies with the source of the abscess. Streptococci are the most common organisms and are often found with other anaerobes such as *Bacteroides.* Enterobacteriaceae such as *Escherichia coli* and proteus organisms may also be combined with streptococcus. Yeast and fungi also cause cerebral abscess formation, particularly in patients who are immunosuppressed. *Toxoplasma gondii* is one of the most commonly seen central nervous system (CNS) opportunistic infections in the acquired immune deficiency syndrome (AIDS) population.

Most brain abscesses occur in the frontal and temporal lobes. A few affected patients have more than one abscess. Mortality rates vary up to

more than one half of patients with abscesses. Those that occur in immunosuppressed patients are associated with a higher mortality rate.

Patient-Centered Collaborative Care

Assessment

Physical Assessment/Clinical Manifestations.

The clinical manifestations of a brain abscess begin slowly and are similar to some of the manifestations of meningitis. The patient may have headache, fever, and neurologic deficits or nonspecific signs and symptoms (Chart 45-11). Perform ongoing neurologic assessments. The patient may be mildly lethargic or somewhat confused. The pupillary response to light is normal in the early stages. As increased intracranial pressure (ICP) progresses, the pupils may become sluggish, unequal, dilated, and nonresponsive to light. The patient's level of consciousness (LOC) declines to a state in which he or she loses the ability to interact with the environment. Airway and respiratory function may also be altered.

Chart 45-11 Key Features

Brain Abscess

- Headache
- Fever
- Pain
- Motor deficits, such as hemiplegia
- Ataxia
- Sensory impairment (varies)
- Aphasia
- Seizure activity
- Visual field changes (e.g., decreased peripheral vision, nystagmus)
- *If severe,* signs of increased intracranial pressure (ICP), such as decreased level of consciousness (LOC), severe headache, bradycardia, widened pulse pressure

Examination of the patient's visual fields often reveals a **temporal field blindness** (decrease in peripheral vision laterally). If the abscess affects the cerebral hemispheres, nystagmus (involuntary eye movements) may be evident. Motor examination reveals a generalized weakness. More significant motor problems, such as hemiplegia, may be apparent in the

presence of a frontal lobe abscess. An ataxic gait is seen with a cerebellar abscess. Sensory impairment varies, although the patient often exhibits no sensory perception deficits. The patient may have varying degrees of aphasia (impaired communication ability) if he or she has a frontal or temporal lobe abscess. Seizure activity may occur because of irritation of the cortical tissue. Late in the disease process, more severe symptoms of increased ICP occur and include severe headache, decreased LOC (possibly coma), a widened pulse pressure, bradycardia, and irregular respirations. The patient with AIDS often presents with systemic infection, CNS involvement, and lymphoma.

Some patients may have atypical presentations, including older adults (age-related compromise in immune function), those receiving steroid therapy or immune-modulating drugs, and patients with later stages of human immune deficiency virus (HIV) infection (immune system compromise). In the earlier stages, the inflammatory response is responsible for much of the clinical presentation, particularly if cerebral abscess formation results from meningitis. The risk is that the patient may progress to severe abscess formation before the onset of "classic" manifestations.

Diagnostic Assessment.

The white blood cell (WBC) count and erythrocyte sedimentation rate (ESR) are usually elevated, indicating the presence of infection. If the abscess is encapsulated, the WBC count may be normal. Obtain specimens for aerobic and, when possible, anaerobic cultures of the blood, ear, nose, and throat to determine the primary source of infection.

The health care provider requests a CT scan to determine the presence of cerebritis, hydrocephalus, or a midline shift. MRI is also useful in detecting the presence of an abscess early in the course of the disease. An EEG can localize the lesion in most cases and shows high-voltage, slow-wave activity; electro-cerebral silence may be noted in the area of the abscess. Radiography of the sinuses and the mastoid is often indicated. A lumbar puncture may be performed if meningitis is also suspected and the patient does not have ICP elevation. A needle biopsy is performed to identify the cause of the infection.

Interventions

Drug therapy is recommended if the patient has several abscesses, a small abscess (less than 2 cm), an abscess deep in the brain, an abscess and meningitis, a shunt for hydrocephalus (in some cases the shunt may

need to be removed temporarily or replaced) or *Toxoplasma gondii* infection in a person with HIV. Drug therapy is prescribed by the physician to treat the abscess. Antibiotic dosing may be maximized to ensure adequate CNS penetration. Antibiotics are particularly useful in the early stages (cerebritis) of abscess formation. A combination of antibiotics is used, particularly if the infection resulted from septic emboli. Antiepileptic drugs such as phenytoin (Dilantin) may be used to prevent seizures. The drug regimen is strictly followed to maintain therapeutic blood levels. Give analgesics to treat headache.

The physician may surgically drain an encapsulated abscess via a burr hole to reduce the mass effect of the lesion. In certain cases, a craniotomy may be performed to remove the abscess. The decision to perform surgery is based on the patient's general condition, the stage of abscess development, and the site of the abscess. Provide routine preoperative and postoperative care for the patient undergoing a craniotomy, as discussed in this chapter under Surgical Management in the Brain Tumors section.

The patient with a brain abscess is discharged to home if few or no neurologic deficits are present. Patients with severe dysfunction are usually transferred to long-term care or a rehabilitation facility. Some patients have permanent neurologic deficits.

Acquired Hypoxic-Anoxic Brain Injury

Acquired hypoxic-anoxic brain injury is brain damage caused by a reduced or absent supply of oxygen. Common causes include cardiac arrest, asphyxiation from a suicide attempt (i.e., hanging), near-drowning, drug use and overdose, accidental electrocution, and severe asthma. Neurons in the brain experience ischemia, injury, and cell death within 4 minutes of a reduced oxygen supply to the brain. The reduction of oxygen can be a primary event such as asphyxiation or a secondary event such as loss of airway during a drug overdose or decreased cerebral perfusion from increased intracranial pressure (Smania et al., 2013). Generally hypoxic-anoxic brain injury is global with decreases in cognition, mobility, and sensation that occur with the event and persist in an unpredictable manner following resuscitation. An MRI provides the most sensitive diagnostic test for determining hypoxic-anoxic brain injury (Muttikkal & Wintermark, 2013).

Initial interventions are generally supportive with a focus on airway, breathing, and circulation to restore the oxygen. Therapeutic hypothermia, described earlier in this chapter on p. 953, is useful when anoxia is related to a witnessed cardiac arrest. Frequent neurologic assessment is undertaken to detect and prevent secondary injury as discussed with severe traumatic brain injury in this chapter. It is not uncommon for patients to experience increased intracranial pressure from cerebral edema in the days following the initial anoxic event. Increased intracranial pressure and cerebral edema are managed similarly to severe traumatic brain injury. Because it is difficult to predict whether brain function will be restored and the course of recovery, patients and family often require emotional support to deal with uncertainty. Early physical and specialized neurocognitive rehabilitation can promote functional outcomes following this type of brain injury.

Nursing Concepts and Clinical Judgment Review

What might you NOTICE if the patient is experiencing changes in cerebral perfusion, mobility, sensory perception, and cognition as a result of severe acute neurologic health problems affecting the brain?

- Decreased level of consciousness (LOC)
- Inability to communicate (aphasia)
- Impaired swallowing (dysphagia)
- Weakness or paralysis of one side of the body (hemiparesis or hemiplegia)

- Alteration in gait
- Inability to perform ADLs
- Report of nausea and vomiting
- Report of impaired visual acuity or fields
- Ptosis (eyelid drooping)
- Unilateral body neglect
- Report of decreased peripheral sensation
- Inability to make appropriate judgments; confusion
- Impaired memory
- Report of severe headache

What should you INTERPRET and how should you RESPOND to a patient experiencing impaired perfusion, mobility, sensory perception, and cognition as a result of severe neurologic health problems affecting the brain?

Perform and interpret physical assessment, including:

- Assess airway, breathing, and circulation status.
- Assess neurologic status, especially LOC and mental state.
- Take vital signs, and establish blood pressure goals.
- Assess neurologic status with particular attention to level of consciousness and cognition.
- Assess functional status.
- Assess for swallowing and nutrition status.

Respond by:

- Notifying health care provider or Rapid Response Team of changes in the Glasgow Coma Scale value of 2 or more points, a reduction in level of consciousness or pupil reactivity to light, hypertension, hypotension, widened pulse pressure, dysrhythmias, fever, and hypoxemia (low Spo_2) urgently
- Ensuring an adequate airway
- Giving oxygen if Spo_2 <92%
- Establishing IV access
- Communicating and collaborating with health care team members efficiently to meet patient's needs
- Assisting with ADLs and mobility as needed
- Providing a safe environment to prevent harm from altered sensory perception

On what should you REFLECT?

- Evaluate the effectiveness and timeliness of health care team

responses, including your own.
- Determine strategies to efficiently monitor neurologic status.
- Monitor for indications of secondary brain insult as the patient is treated.
- Plan health teaching for the patient and family.
- Initiate actions to provide emotional and spiritual support for the patient and family.
- Consider whether the patient preferences and values been incorporated into care.

Get Ready for the NCLEX® Examination!

Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- When caring for a patient with a stroke or traumatic brain injury (TBI), assess airway, breathing, and circulation status first and implement interventions to maintain them.
- Collaborate with the interdisciplinary team members including physicians, physical therapists, respiratory therapists, occupational therapists, social workers, and dietitians to ensured shared priorities in care. **Teamwork and Collaboration** QSEN
- Develop electronic care pathways and document patient progress using interdisciplinary patient-centered plans for care based on patient values for the patient recovering from neurologic critical illness. **Informatics** QSEN

Health Promotion and Maintenance

- Identify risk factors for new or recurrent stroke and teach patients and families about modifiable risk factors for stroke as listed in Chart 45-2. **Evidence-Based Practice** QSEN
- Prevent secondary brain injury by protecting the airway, promoting an appropriate range of blood pressure and mean arterial pressure, maintaining fluid and electrolyte balance, promptly treating fever, avoiding sustained hypoglycemia and hyperglycemia, addressing hypoxia and hypercarbia, positioning the patient appropriately, and managing intracranial hypertension with prescribed interventions.
- Teach patients and families about community organizations, such as the National Stroke Association and the Brain Injury Association of America.

Psychosocial Integrity

- Assess the emotional reactions of families to a TBI, stroke, or brain cancer diagnosis, and help them cope by providing information and including them in planning for care. **Patient-Centered Care** QSEN

Physiological Integrity

- Perform a comprehensive, rapid, or focal neurologic assessment at

regular intervals to identify changes in status. **Evidence-Based Practice** QSEN

- Recall that decreased level of consciousness is the most sensitive indicator of adverse outcome or complication from stroke, TBI, brain tumor, or craniotomy.
- Recall the differences between a transient ischemic attack and a brain attack (stroke) as described in Table 45-1 and Chart 45-1.
- Monitor patients with critical neurologic health problems for manifestations of increasing intracranial pressure (ICP) as described in Chart 45-6.
- Assess the patient's ability to swallow before providing oral intake if a stroke is suspected or diagnosed. **Safety** QSEN
- Assess patients with strokes for sensory perception changes such as unilateral neglect and impaired vision; help patients adapt to these changes, such as turning their head from side to side to see the entire meal tray. **Patient-Centered Care** QSEN
- Provide alternate means of communication when expressive and/or receptive aphasia is present in patients who have had a stroke or brain injury in consultation with the speech-language expert. **Teamwork and Collaboration** QSEN
- Monitor the patient on fibrinolytic therapy or anticoagulants for bleeding and abnormal coagulation studies. Best practices for fibrinolytic therapy administration are listed in Chart 45-5. **Safety** QSEN
- Teach patients with mild traumatic brain injury and their families to monitor for neurologic changes as listed in Charts 45-7 and 45-9.
- Assess for manifestations of brain tumors as listed in Chart 45-10.
- Recognize that the desired outcome for the patient with a brain tumor is to remove it if possible. Other methods may be used to decrease its size, including chemotherapy and radiation.
- Administer antibiotic therapy to provide the most effective management of patients with brain abscess.

UNIT XI

Problems of Sensory Perception: Management of Patients with Problems of the Sensory System

OUTLINE

CHAPTER 46

Assessment of the Eye and Vision

M. Linda Workman

PRIORITY CONCEPTS

- Sensory Perception

Learning Outcomes

Safe and Effective Care Environment

1. Prevent injury or infection of the eye to preserve visual sensory perception.

Health Promotion and Maintenance

2. Teach all people about eye health and the use of eye protection equipment and strategies.

Psychosocial Integrity

3. Reduce the psychological impact for the patient and family regarding the assessment and testing of the eyes and vision.

Physiological Integrity

4. Use knowledge of anatomy, physiology, pathophysiology, and psychomotor skills when assessing the eye and vision.
5. Perform a focused assessment of visual sensory perception, incorporating information about genetic risk and age-related changes affecting the eye and vision.

http://evolve.elsevier.com/Iggy/

The eye and the brain work together to allow visual sensory perception. Many people consider vision to be the most important sensory perception. It is used to assess surroundings, allow independence, warn of danger, appreciate beauty, work, play, and interact with others.

Vision begins with the eye, where light is changed into nerve impulses. These impulses are sent to the brain, where images are fully perceived (McCance et al., 2014). Many systemic conditions, as well as eye problems, change vision temporarily or permanently. Changes in the eye and vision can provide information about the patient's general health status and problems that might occur in self-care.

Anatomy and Physiology Review

Structure

The eyeball, a round, ball-shaped organ, is located in the front part of the eye orbit. The **orbit** is the bony socket of the skull that surrounds and protects the eye along with the attached muscles, nerves, vessels, and tear-producing glands.

Layers of the Eyeball

The eye has three layers (Fig. 46-1). The external layer is the **sclera** (the "white" of the eye) and the transparent cornea on the front of the eye.

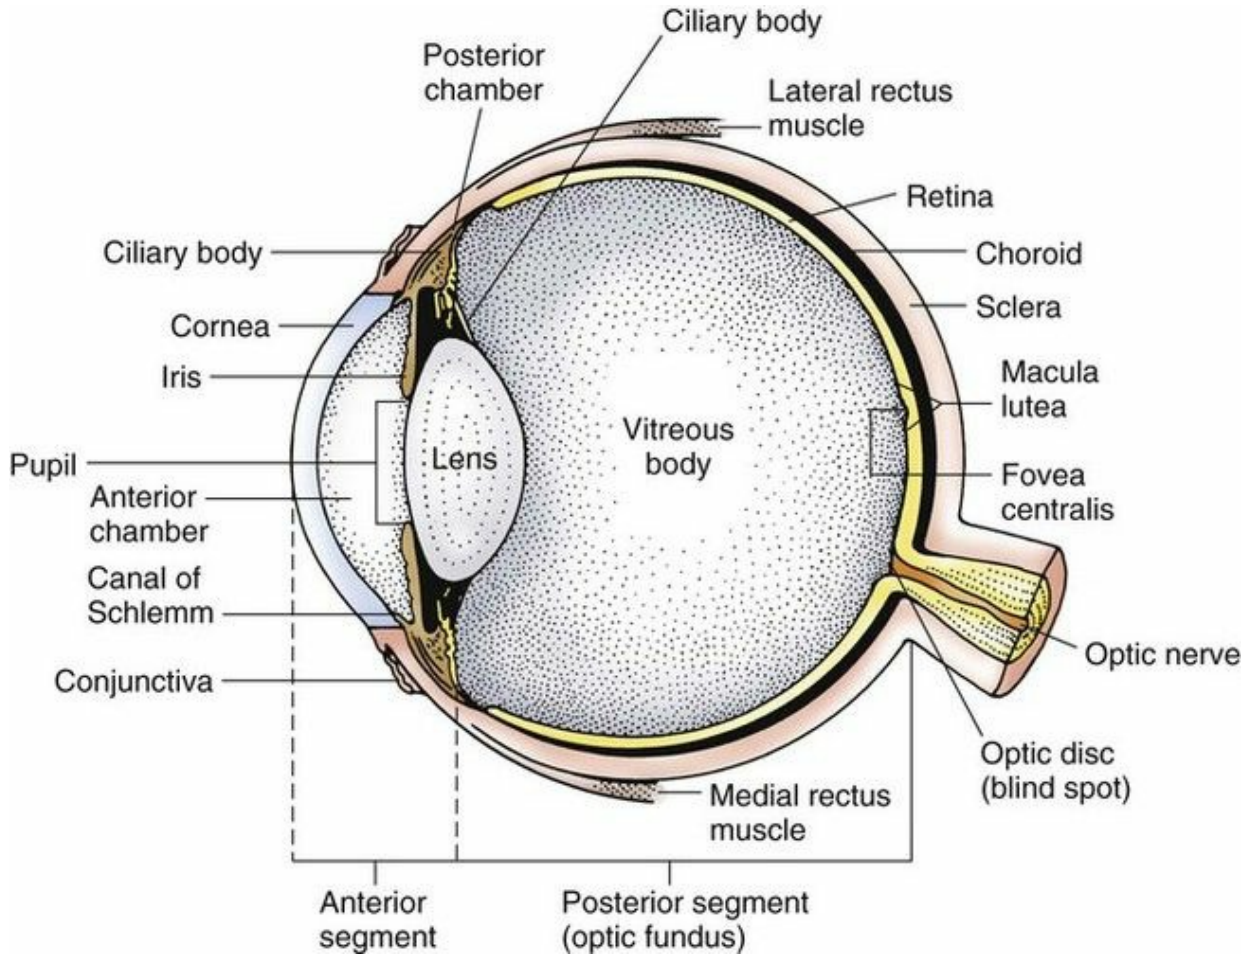

FIG. 46-1 Anatomic features of the eye.

The middle layer, or **uvea,** is heavily pigmented and consists of the choroid, the ciliary body, and the iris. The choroid, a dark brown membrane between the sclera and the retina, lines most of the sclera. It has many blood vessels that supply nutrients to the retina.

The ciliary body connects the choroid with the iris and secretes aqueous humor. The **iris** is the colored portion of the external eye; its

center opening is the **pupil**. The muscles of the iris contract and relax to control pupil size and the amount of light entering the eye.

The innermost layer is the **retina,** a thin, delicate structure made up of sensory photoreceptors that begin the transmission of impulses to the optic nerve (McCance et al., 2014). The retina contains blood vessels and two types of photoreceptors called *rods* and *cones.* The rods work at low light levels and provide peripheral vision. The cones are active at bright light levels and provide color and central vision.

The **optic fundus** is the area at the inside back of the eye that can be seen with an ophthalmoscope. This area contains the **optic disc**—a pink or white depressed area where the nerve fibers that synapse with the photoreceptors join together to form the optic nerve and exit the eyeball. The optic disc contains only nerve fibers and no photoreceptor cells. To one side of the optic disc is a small, yellowish pink area called the *macula lutea.* The center of the macula is the *fovea centralis,* where vision is most acute.

Refractive Structures and Media

Light waves pass through the cornea, aqueous humor, lens, and vitreous humor on the way to the retina. Each structure bends *(refracts)* the light waves to focus images on the retina. Together, these structures are the eye's *refracting media.*

The **cornea** is the clear layer that forms the external bump on the front of the eye (see Fig. 46-1). The **aqueous humor** is a clear, watery fluid that fills the anterior and posterior chambers of the eye. This fluid is continually produced by the ciliary processes and passes from the posterior chamber, through the pupil, and into the anterior chamber. This fluid drains through the canal of Schlemm into the blood to maintain a balanced intraocular pressure (IOP), the pressure within the eye (Fig. 46-2).

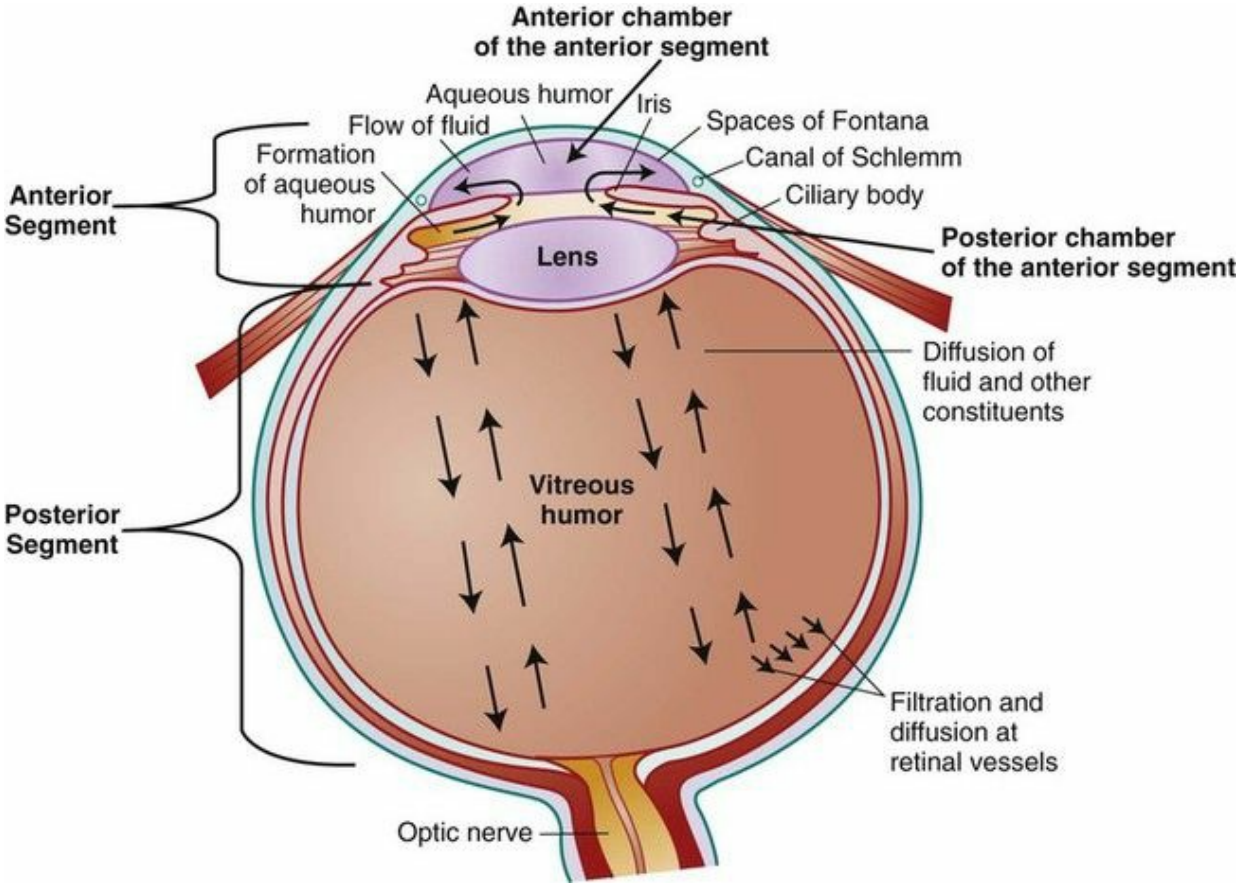

FIG. 46-2 Flow of aqueous humor.

The **lens** is a circular, convex structure that lies behind the iris and in front of the vitreous body. It is transparent and bends the light rays entering through the pupil to focus properly on the retina. The curve of the lens changes to focus on near or distant objects. A *cataract* is a lens that has lost its transparency.

The **vitreous body** is a clear, thick gel that fills the large vitreous chamber (the space between the lens and the retina). This gel transmits light and maintains eye shape.

The eye is a hollow organ and must be kept in the shape of a ball for vision to occur. To maintain this shape, the vitreous humor gel in the posterior segment and the aqueous humor in the anterior segment must be present in set amounts that apply pressure inside the eye to keep it inflated. This pressure is the **intraocular pressure** or **IOP**. IOP has to be just right. If the pressure is too low, the eyeball is soft and collapses, preventing light from getting to the photoreceptors on the retina in the back of the eye. If the pressure becomes too high, the extra pressure compresses capillaries in the eye as well as nerve fibers. Pressure on retinal blood vessels prevents blood from flowing through them; therefore the photoreceptors and nerve fibers become hypoxic. Compression of the fine nerve fibers prevents intracellular fluid flow,

which also reduces nourishment to the distal portions of these thin nerve fibers. The increased pressure and resulting hypoxia of photoreceptors and their synapsing nerve fibers is a condition called *glaucoma.* Continued hypoxia in the retina results in photoreceptor necrosis and death and permanent nerve fiber damage. When extensive photoreceptor and nerve fiber loss occur, vision is lost and the person is permanently blind.

External Structures

The eyelids are thin, movable skinfolds that protect the eyes and keep the cornea moist. The upper lid is larger than the lower one. The **canthus** is the place where the two eyelids meet at the corner of the eye.

The **conjunctivae** are the mucous membranes of the eye. The palpebral conjunctiva is a thick membrane with many blood vessels that lines the under surface of each eyelid. The thin, transparent bulbar conjunctiva covers the entire front of the eye.

Tears are produced by a small **lacrimal gland**, which is located in the upper outer part of each orbit (Fig. 46-3). Tears flow across the front of the eye, toward the nose, and into the inner canthus. They drain through the **punctum** (an opening at the nasal side of the lid edges) into the lacrimal duct and sac and then into the nose through the nasolacrimal duct.

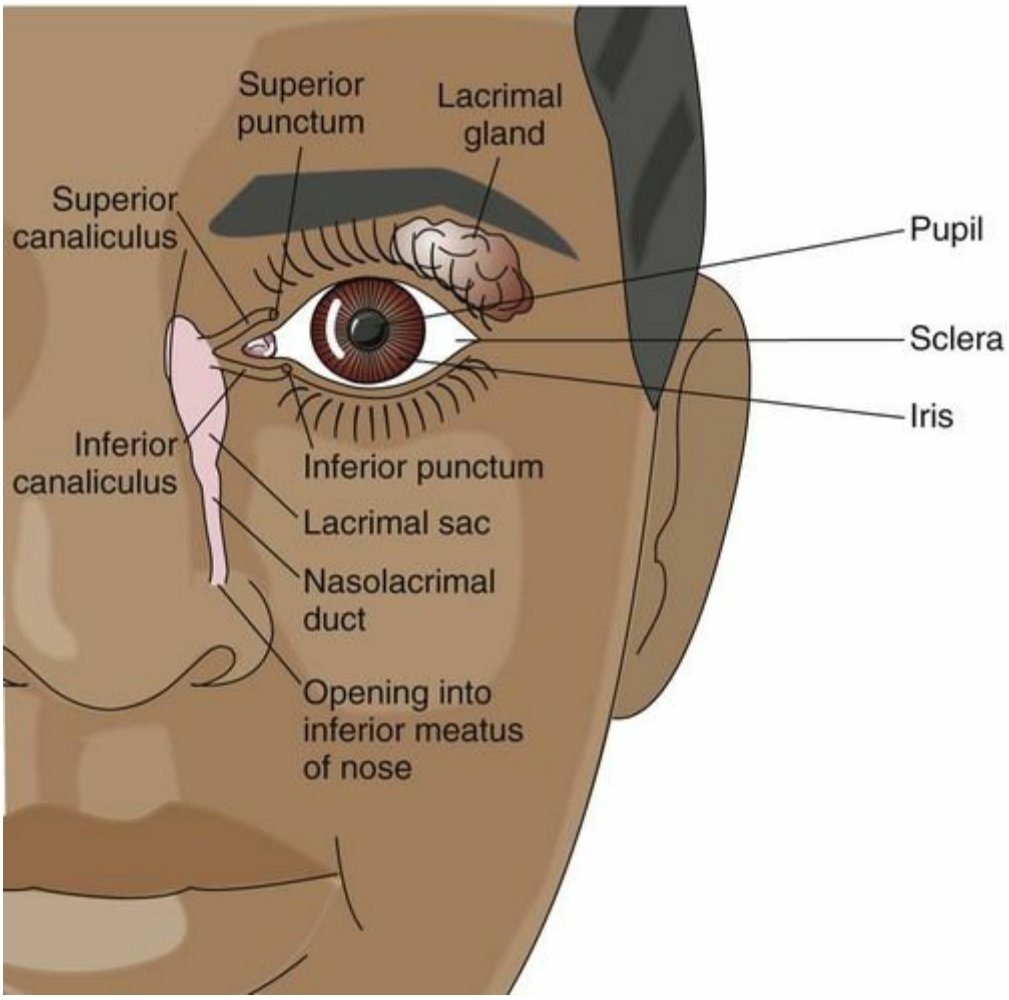

FIG. 46-3 Front view of the eye and adjacent structures.

Muscles, Nerves, and Blood Vessels

Six voluntary muscles rotate the eye and coordinate eye movements (Fig. 46-4 and Table 46-1). Coordinated eye movements ensure that both eyes receive an image at the same time so only a single image is seen.

TABLE 46-1
Functions of Ocular Muscles

Superior Rectus Muscle
• Together with the lateral rectus, this muscle moves the eye diagonally upward toward the side of the head. • Together with the medial rectus, this muscle moves the eye diagonally upward toward the middle of the head.
Lateral Rectus Muscle
• Together with the medial rectus, this muscle holds the eye straight. • Contracting alone, this muscle turns the eye toward the side of the head.
Medial Rectus Muscle
• Contracting alone, this muscle turns the eye toward the nose.
Inferior Rectus Muscle
• Together with the lateral rectus, this muscle moves the eye diagonally downward toward the side of the head. • Together with the medial rectus, this muscle moves the eye diagonally downward toward the middle of the head.
Superior Oblique Muscle
• Contracting alone, this muscle pulls the eye downward.
Inferior Oblique Muscle
• Contracting alone, this muscle pulls the eye upward.

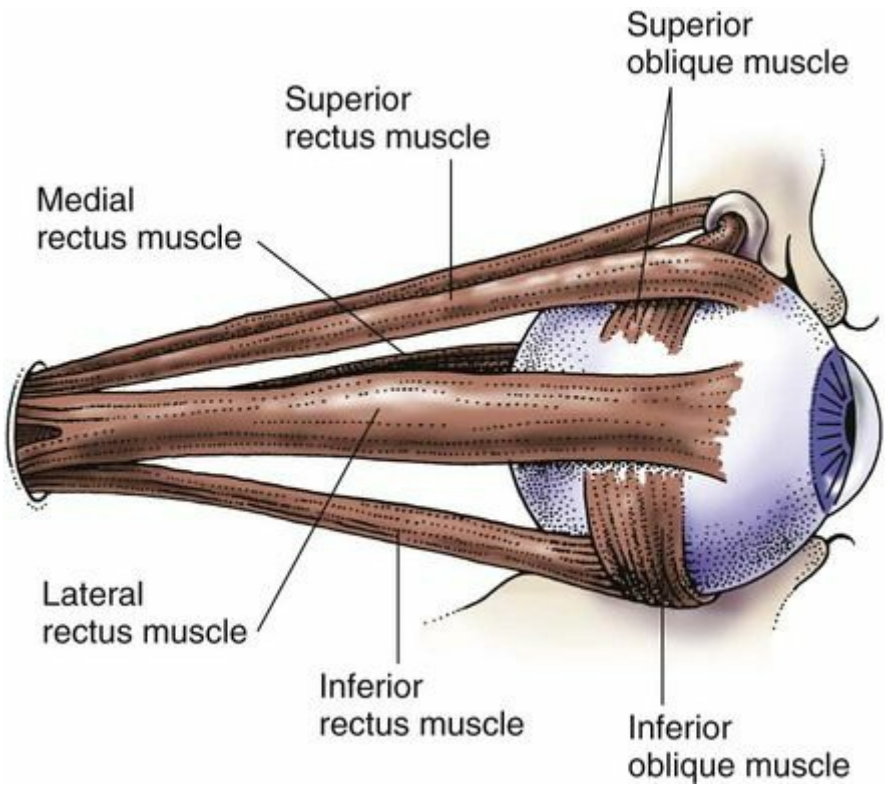

FIG. 46-4 The extraocular muscles.

The muscles around the eye are innervated by cranial nerves (CNs) III (oculomotor), IV (trochlear), and VI (abducens). The **optic nerve** (CN II) is the nerve of sight, connecting the optic disc to the brain. The trigeminal nerve (CN V) stimulates the blink reflex when the cornea is

touched. The facial nerve (CN VII) innervates the lacrimal glands and muscles for lid closure.

The ophthalmic artery brings oxygenated blood to the eye and the orbit. It branches to supply blood to the retina. The ciliary arteries supply the sclera, choroid, ciliary body, and iris.

Function

The four eye functions that provide clear images and vision are refraction, pupillary constriction, accommodation, and convergence.

Refraction bends light rays from the outside into the eye through curved surfaces and refractive media and finally to the retina. Each surface and media bend (refract) light differently to focus an image on the retina. **Emmetropia** is the perfect refraction of the eye in which light rays from a distant source are focused into a sharp image on the retina. Fig. 46-5 shows the normal refraction of light within the eye. Images fall on the retina inverted and reversed left to right. For example, an object in the lower nasal visual field strikes the upper outer area of the retina.

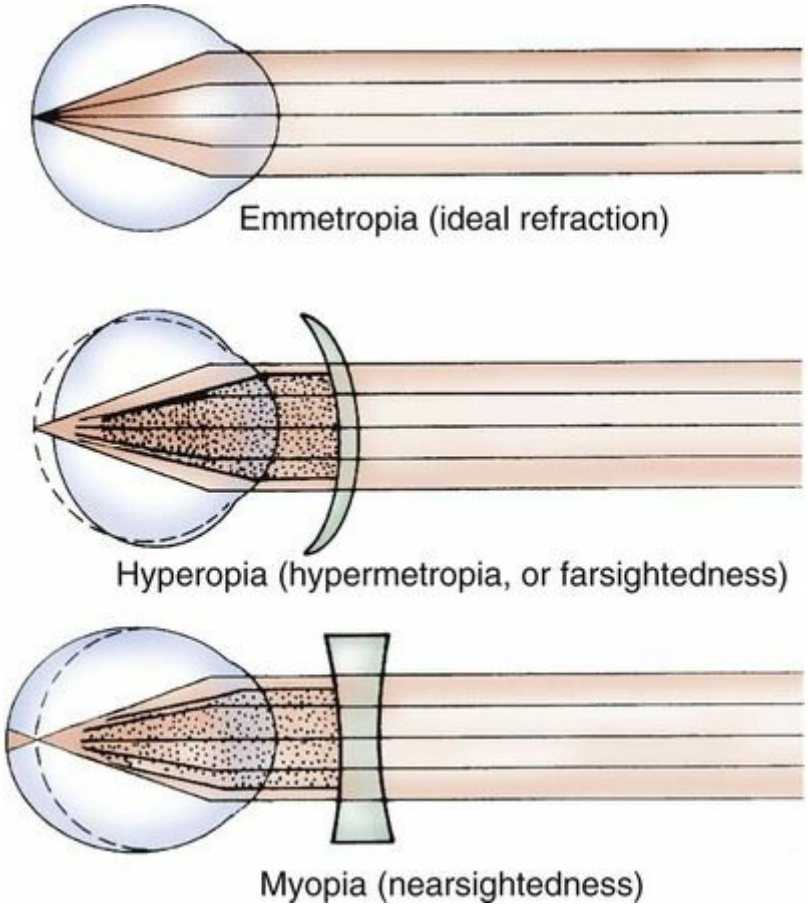

FIG. 46-5 Refraction and correction in emmetropia, hyperopia, and myopia.

Errors of refraction are common. **Hyperopia** (farsightedness) occurs when the eye does not refract light enough. As a result, images actually converge behind the retina (see Fig. 46-5). With hyperopia, distant vision is normal but near vision is poor. It is corrected with a convex lens in eyeglasses or contact lenses.

Myopia (nearsightedness) occurs when the eye overbends the light and images converge in front of the retina (see Fig. 46-5). Near vision is normal, but distance vision is poor. Myopia is corrected with a biconcave lens in eyeglasses or contact lenses.

Astigmatism is a refractive error caused by unevenly curved surfaces on or in the eye, especially of the cornea. These uneven surfaces distort vision.

Pupillary constriction and dilation control the amount of light that enters the eye. If the level of light to one or both eyes is increased, both pupils constrict (become smaller). The amount of constriction depends on how much light is available and how well the retina can adapt to light changes. Pupillary constriction is called **miosis**, and pupillary dilation is called **mydriasis** (Fig. 46-6). Drugs can alter pupillary constriction.

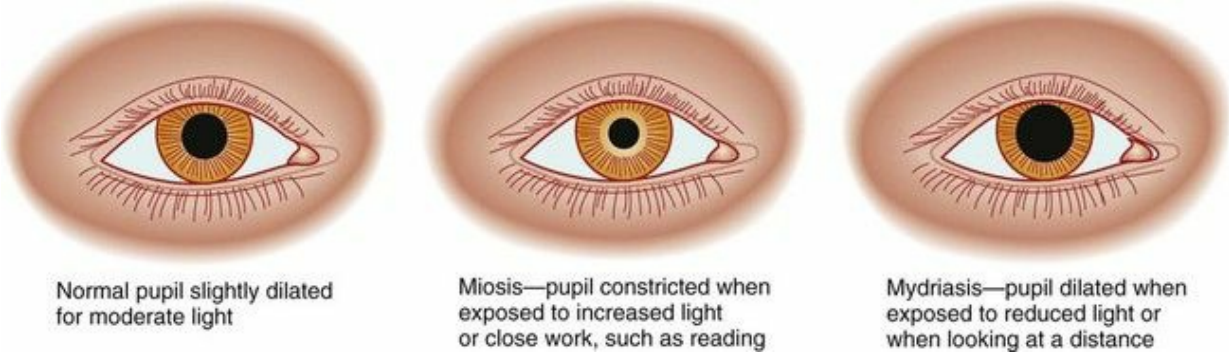

FIG. 46-6 Miosis and mydriasis.

Accommodation allows the healthy eye to focus images sharply on the retina whether the image is close to the eye or distant. The process of maintaining a clear visual image when the gaze is shifted from a distant to a near object is known as **accommodation**. The healthy eye can adjust its focus by changing the curve of the lens.

Convergence is the ability to turn both eyes inward toward the nose at the same time. This action helps ensure that only a single image of close objects is seen.

Eye Changes Associated with Aging

Changes inside the eye cause visual acuity to decrease with age (Touhy &

Jett, 2014). Age-related changes of the nervous system and in the eye support structures also reduce visual function (Chart 46-1).

Chart 46-1 Nursing Focus on the Older Adult

Changes in the Eye and Vision Related to Aging

STRUCTURE/FUNCTION	CHANGE	IMPLICATION
Appearance	Eyes appear "sunken."	Do not use eye appearance as an indicator for hydration status.
	Arcus senilis forms.	Reassure patient that this change does not affect vision.
	Sclera yellows or appears blue.	Do not use sclera to assess for jaundice.
Cornea	Cornea flattens, which blurs vision.	Encourage older adults to have regular eye examinations and wear prescribed corrective lenses for best vision.
Ocular muscles	Muscle strength is reduced, making it more difficult to maintain an upward gaze or maintain a single image.	Reassure patient that this is a normal happening and to re-focus gaze frequently to maintain a single image.
Lens	Elasticity is lost, increasing the near point of vision (making the near point of best vision farther away).	Encourage patient to wear corrective lenses for reading.
	Lens hardens, compacts, and forms a cataract.	Stress the importance of yearly vision checks and monitoring.
Iris and Pupil	Decrease in ability to dilate results in small pupil size and poor adaptation to darkness.	Teach about the need for good lighting to avoid tripping and bumping into objects.
Color vision	Discrimination among greens, blues, and violets decreases.	The patient may not be able to use color-indicator monitors of health status.
Tears	Tear production is reduced, resulting in dry eyes, discomfort, and increased risk for corneal damage or eye infections.	Teach about the use of saline eyedrops to reduce dryness. Teach patient to increase humidity in the home.

Structural changes occur with aging, including decreased eye muscle tone that reduces the ability to keep the gaze focused on a single object. The lower eyelid may relax and fall away from the eye *(ectropion)*, leading to dry eye manifestations.

Arcus senilis, an opaque, bluish white ring within the outer edge of the cornea, is caused by fat deposits (see Fig. 24-4 in Chapter 24). This change does not affect vision.

The clarity and shape of the cornea change with age. The cornea flattens, and the curve of its surface becomes irregular. This change causes or worsens astigmatism and blurs vision.

Fatty deposits cause the sclera to develop a yellowish tinge. A bluish color may be seen as the sclera thins. With age, the iris has less ability to dilate, which leads to difficulty in adapting to dark environments. Older adults may need additional light for reading and other "close up" work and to avoid tripping over objects.

Functional changes also occur with aging. The lens yellows with aging, reducing the ability to transmit and focus light. The lens hardens, shrinks, and loses elasticity, which reduces accommodation. The **near point of vision** (the closest distance at which the eye can see an object clearly) increases. Near objects, especially reading material, must be placed farther from the eye to be seen clearly **(presbyopia)**. The **far point** (farthest point at which an object can be distinguished) decreases.

Together these changes narrow the visual field of an older adult.

General color perception decreases, especially for green, blue, and violet. More light is needed to stimulate the visual receptors. Intraocular pressure (IOP) is slightly higher in older adults.

Health Promotion and Maintenance

Vision is important for function and quality of life. Many vision and eye problems can be avoided, and others can be corrected or managed if discovered early. Teach all people about eye protection methods, adequate nutrition, and the importance of regular eye examinations.

The risks for cataract formation and for cancer of the eye (ocular melanoma) increase with exposure to ultraviolet (UV) light. Teach people to protect the eyes by using sunglasses that filter UV light whenever they are outdoors, at tanning salons, and when work involves UV exposure.

Vision can be affected by injury. Eye injury also increases the risk for both cataract formation and glaucoma. Urge all people to wear eye and head protection when working with particulate matter, fluid or blood spatter, high temperatures, or sparks. Protection also should be worn during participation in sports, such as baseball, or any activity that increases the risk for the eye being hit by objects in motion. Teach people to avoid rubbing the eyes to avoid trauma to outer eye surfaces.

Eye infections can lead to vision loss. Although the eye surface is not sterile, the sclera and cornea have no separate blood supply and thus are at risk for infection. Teach everyone to wash their hands before touching the eye or eyelid. Teach people who use eyedrops about the proper technique to use these drugs (Chart 46-2), which includes not touching the eye with the bottle tip, and to not share eyedrops with others. If an eye has a discharge, teach the patient to use a separate eyedrop bottle for this eye and to wash the unaffected eye before washing the affected eye.

Chart 46-2 Patient and Family Education: Preparing for Self-Management

Using Eyedrops

- Check the eyedrop name, strength, expiration date, color, and clarity.
- If both eyes are to receive the same drug and one eye is infected, use two separate bottles and label each bottle with “right” or “left” for the correct eye.
- Wash your hands.
- Remove the cap from the bottle.

- Tilt your head backward, open your eyes, and look up at the ceiling.
- Using your nondominant hand, gently pull the lower lid down against your cheek, forming a small pocket.
- Hold the eyedrop bottle (with the cap off) like a pencil, with the tip pointing down, with your dominant hand.
- Rest the wrist holding the bottle against your mouth or upper lip.
- Without touching any part of the eye or lid with the tip of the bottle, gently squeeze the bottle and release the prescribed number of drops into the pocket of your lower lid.
- Release the lower lid and gently close your eye without squeezing the lids.
- Gently press and hold the corner of the eye nearest the nose to close off the punctum and prevent the drug from being absorbed systemically.
- Gently blot away any excess drug or tears with a tissue.
- Keep the eye closed for about 1 minute.
- Place the cap back on the bottle, and store it as prescribed.
- Wash your hands again.

Other health problems, especially diabetes and hypertension, can seriously affect visual sensory perception. Teach patients with these health problems about the importance of controlling blood glucose levels and managing blood pressure to reduce the risk for vision loss. Yearly evaluation by an ophthalmologist is needed to slow or prevent eye complications.

Teach all people who have a refractive error to have an eye examination yearly. Young adults without vision problems may need an eye examination only every 3 to 5 years. Adults older than 40 years should have an eye examination yearly that includes assessment of intraocular pressure and visual fields, because the risk for both glaucoma and cataract formation increases with age.

Nursing Safety Priority QSEN

Action Alert

Teach people to see a health care provider *immediately* when an eye injury occurs or an eye infection is suspected.

NCLEX Examination Challenge

Health Promotion and Maintenance

For which client does the nurse recommend annual evaluation by an ophthalmologist?
A 35-year-old man with asthma
B 21-year-old man with psoriasis
C 24-year-old woman with diabetes
D 38-year-old woman who has lost 50 pounds

Assessment Methods

Patient History

Collect information to determine whether problems with the eye or vision have an impact on ADLs or other daily functions. *Age* is an important factor to consider when assessing visual sensory perception and eye structure. The incidence of glaucoma and cataract formation increases with aging. Presbyopia commonly begins in the 40s.

Gender may be important. Retinal detachments occur more often in men, and dry eye syndromes occur more often in women.

Occupation and leisure activities can affect visual sensory perception. Ask about how the eye is used at work. In occupations such as computer programming, constant exposure to monitors may lead to eyestrain. Machine operators are at risk for eye injury because of the high speeds at which particles can be thrown at the eye. Chronic exposure to infrared or ultraviolet light may cause photophobia and cataract formation. Teach the patient about the use of eye protection during work.

Ask whether the patient wears eye protection when participating in sports. A blow to the head near the eye, such as with a baseball, can damage external structures, the eye, the connections with the brain, or the area of the brain where vision is perceived.

Systemic health problems can affect vision. Check whether the patient has any condition listed in Table 46-2. Ask about past accidents, injuries, surgeries, or blows to the head that may have led to the present problem. Specifically ask about previous laser surgeries.

TABLE 46-2

Systemic Conditions and Common Drugs Affecting the Eye and Vision

SYSTEMIC CONDITIONS AND DISORDERS	DRUGS
Diabetes mellitus	Antihistamines
Hypertension	Decongestants
Lupus erythematosus	Antibiotics
Sarcoidosis	Opioids
Thyroid problems	Anticholinergics
Acquired immune deficiency syndrome	Cholinergic agonists
Cardiac disease	Adrenergic agonists
Multiple sclerosis	Adrenergic antagonists (beta blockers)
Pregnancy	Oral contraceptives
	Chemotherapy agents
	Corticosteroids

Drugs can affect vision and the eye (see Table 46-2). Ask about the use of any prescription or over-the-counter drugs, especially decongestants

and antihistamines, which tend to dry the eye and may increase intraocular pressure. Document the name, strength, dose, and scheduling for all drugs the patient uses. Ocular effects from drugs include itching, foreign body sensation, redness, tearing, **photophobia** (sensitivity to light), and the development of cataracts or glaucoma.

Nutrition History

Some eye problems are caused by or made worse with vitamin deficiencies. Ask the patient about food choices. For example, vitamin A deficiency can cause eye dryness, keratomalacia, and blindness. Some nutrients and antioxidants, such as lutein and beta carotene, help maintain retinal function. A diet rich in fruit and red, orange, and dark green vegetables is important to eye health. Teach all people to eat about 10 servings of these foods daily.

Family History and Genetic Risk

Ask about a family history of eye problems because some conditions have a familial tendency and some genetic problems lead to visual impairment. When a patient tells you that other relatives, especially first-degree relatives (parents, siblings, and children), have eye problems, document the gender of the affected person, the relationship to the patient, the exact nature of the problem, and the age that the problem was first noted.

Current Health Problems

Ask the patient about the onset of visual changes. Did the change occur rapidly or slowly? Determine whether the manifestations are present to the same degree in both eyes. Ask these questions if eye injury or trauma is involved:

- How long ago did the injury occur?
- What was the patient doing when it happened?
- If a foreign body was involved, what was its source?
- Was any first aid administered at the scene? If so, what actions were taken?

Nursing Safety Priority QSEN

Critical Rescue

Notify the ophthalmologist immediately for any patient who has a

sudden or persistent loss of visual sensory perception within the past 48 hours, eye trauma, a foreign body in the eye, or sudden ocular pain.

Physical Assessment

Inspection

Look for head tilting, squinting, or other actions that indicate the patient is trying to attain clear vision. For example, patients with double vision may cock the head to the side to focus the two images into one or they may close one eye to see clearly.

Assess for symmetry in the appearance of the eyes. Check the eyes to determine whether they are equal distance from the nose, are the same size, and have the same degree of prominence. Assess the eyes for their placement in the orbits and for symmetry of movement. **Exophthalmos** (*proptosis*) is protrusion of the eye. **Enophthalmos** is the sunken appearance of the eye.

Examine the eyebrows and eyelashes for hair distribution, and determine the direction of the eyelashes. Eyelashes normally point outward and away from the eyelid. Assess the eyelids for **ptosis** (drooping), redness, lesions, or swelling. The lids normally close completely, with the lid edges touching. When the eyes are open, the upper lid covers a small portion of the iris. The edge of the lower lid lies at the iris. No sclera should be visible between the eyelid and the iris.

Scleral and corneal assessment require a penlight. Examine the sclera for color; it is usually white. A yellow color may indicate jaundice or systemic problems. In dark-skinned people, the normal sclera may appear yellow and small, pigmented dots may be visible (Jarvis, 2016).

The cornea is best seen by directing a light at it from the side. The cornea should be transparent, smooth, shiny, and bright. Any cloudy areas or specks may indicate injury.

Assess the blink reflex by bringing a fist quickly toward the patient's face. Patients with vision will blink.

Pupillary assessment involves examining each pupil separately and comparing the results. The pupils are usually round and of equal size. About 5% of people normally have a noticeable difference in the size of their pupils, which is known as **anisocoria** (Jarvis, 2016). Pupil size varies in people exposed to the same amount of light. Pupils are smaller in older adults. People with myopia have larger pupils. People with hyperopia have smaller pupils. The normal pupil diameter is between 3 and 5 mm. Smaller pupils reduce vision in low light conditions.

Observe pupils for response to light. Increasing light causes constriction, whereas decreasing light causes dilation. Constriction of both pupils is the normal response to direct light and to accommodation. Assess pupillary reaction to light by asking the patient to look straight ahead while you quickly bring the beam of a penlight in from the side and direct it at the right pupil. Constriction of the right pupil is a direct response to shining the penlight into that eye. Constriction of the left pupil when light is shined at the right pupil is known as a **consensual response**. Assess the responses for each eye. (You may see the abbreviation "PERRLA" in a patient's medical record, which stands for **p**upils **e**qual, **r**ound, **r**eactive to **l**ight, and **a**ccommodative.)

Evaluate each pupil for speed of reaction. The pupil should immediately constrict when a light is directed at it—a *brisk* response. If the pupil takes more than 1 second to constrict, the response is *sluggish*. Pupils that fail to react are *nonreactive* or *fixed.* Compare the reactivity speed of right and left pupils, and document any difference.

Assess for accommodation by holding your finger about 18 cm from the patient's nose and move it toward the nose. The patient's eyes normally converge during this movement, and the pupils constrict equally.

Vision Testing

Visual sensory perception is measured by first testing each eye separately and then testing both eyes together. Patients who wear corrective lenses are tested both without and with their lenses.

Visual acuity tests measure both distance and near vision. The Snellen eye chart measures distance vision. This chart has letters, numbers, pictures, or a single letter presented in various positions. The chart with one letter in different positions is used for patients who cannot read, who do not speak the language used at the facility, or who cannot speak but do have adequate cognition. Have the patient stand or sit 20 feet from the chart, cover one eye, and use the other eye to read the line that appears most clear. If the patient can do this accurately, ask him or her to read the next lower line. Repeat this sequence to the last line on which the patient can correctly identify most characters. Repeat the procedure with the other eye. Record findings as a comparison between what the patient can read at 20 feet and the distance that a person with normal vision can read the same line. For example, *20/50* means that the patient sees at 20 feet from the chart what a healthy eye sees at 50 feet.

For patients who cannot see the 20/400 character, assess visual acuity

by holding fingers in front of their eyes and asking them to count the number of fingers. Acuity is recorded as "count fingers vision at 5 feet," or the farthest distance at which fingers are counted correctly.

Patients who cannot count fingers are tested for hand motion (HM) acuity. Stand about 2 to 3 feet in front of the patient. Ask him or her to cover the eye not being tested. Direct a light onto your hand from behind the patient. Demonstrate the three possible directions in which the hand can move during the test (stationary, left-right, or up-down). Move your hand slowly (1 second per motion), and ask the patient, "What is my hand doing now?" Repeat this procedure 5 times. Visual acuity is recorded as HM at the farthest distance at which most of the hand motions are identified correctly.

If the patient cannot detect hand motion, assess light perception (LP). Ask the patient first to cover the left eye. In a darkened room, direct the beam of a penlight at the patient's right eye from a distance of 2 to 3 feet for 1 to 2 seconds. Instruct the patient to say "on" when the beam of light is perceived and "off" when it is no longer detected. If the patient identifies the presence or absence of light 3 times correctly, acuity is documented as LP.

Near vision is tested for patients who have difficulty reading without using glasses or other means of vision correction. Use a small, handheld miniature eye chart called a *Rosenbaum Pocket Vision Screener* or a *Jaeger card.* Ask the patient to hold the card 14 inches away from his or her eyes and read the characters. Test each eye separately and then together. Document the lowest line on which the patient can identify more than half the characters.

Visual field testing determines the degree of peripheral vision. It can be performed with a computerized machine or with a "confrontation test" for a rapid check of peripheral vision. Perimetry is a computerized test. During this test, the patient is asked to look straight ahead into a viewer and then indicate, by pressing a control button, when a moving light enters the peripheral vision. This process maps the person's peripheral vision and any deficits.

During the confrontation test, sit facing the patient and ask him or her to look directly into your eyes while you look into the patient's eyes. Cover your right eye and have the patient cover his or her left eye so that you both have the same visual field. Then move a finger or an object from a nonvisible area into the patient's line of vision. The patient with normal peripheral vision notices the object at about the same time you do. Repeat this examination by covering your left eye and the patient covering his or her right eye. Document any areas in which you can see

but the patient cannot.

Extraocular muscle function is assessed using the corneal light reflex and the six cardinal positions of gaze. These tests assess smoothness of eye movements and the function of cranial nerves III, IV, and VI.

The corneal light reflex determines alignment of the eyes. After asking the patient to stare straight ahead, shine a penlight at both corneas from a distance of 12 to 15 inches. The bright dot of light reflected from the shiny surface of the cornea should be in a symmetric position (e.g., at the 1 o'clock position in the right eye and at the 11 o'clock position in the left eye). An asymmetric reflex indicates a deviating eye and possible muscle weakness.

Use the six cardinal positions of gaze to assess muscle function (Fig. 46-7). The eye will not turn to a particular position if the muscle is weak or if the controlling nerve is affected. Ask the patient to hold his or her head still and to move only the eyes to follow a small object. Move the object to the patient's right (lateral), upward and right (temporal), down and right, left (lateral), upward and left (temporal), and down and left (see Fig. 46-7). While the patient moves the eyes to these positions, note whether both eyes move in a parallel manner and any deviation of movement. **Nystagmus**, an involuntary and rapid twitching of the eyeball, is a normal finding for the far lateral gaze. It may also be caused by abnormal nerve function or problems with the inner ear.

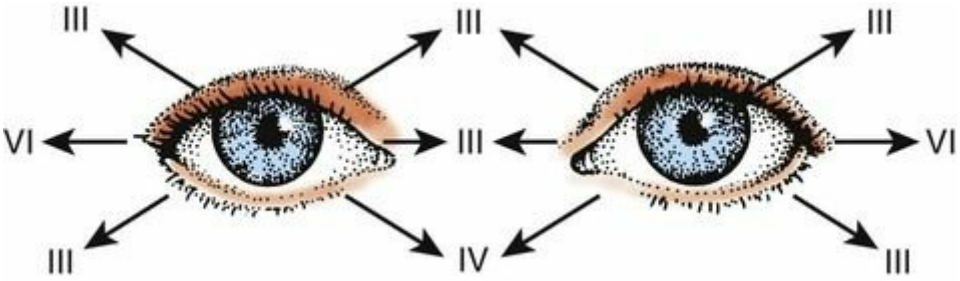

FIG. 46-7 Checking extraocular movements in the six cardinal positions indicates the functioning of cranial nerves III, IV, and VI.

Color vision is usually tested using the *Ishihara chart,* which shows numbers composed of dots of one color within a circle of dots of a different color (Fig. 46-8). Test each eye separately by asking the patient what numbers he or she sees on the chart. Reading the numbers correctly indicates normal color vision.

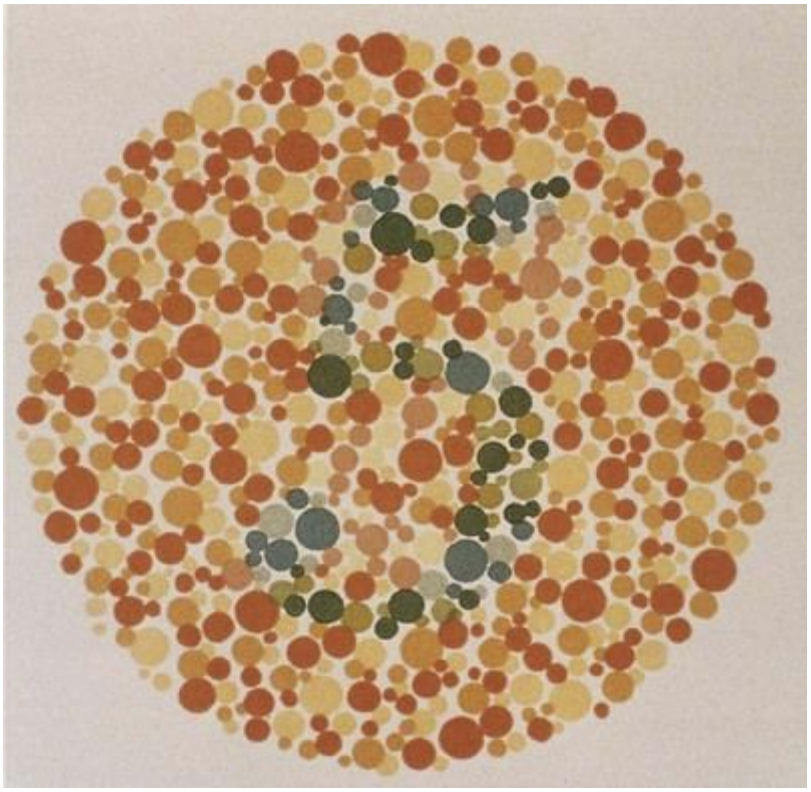

FIG. 46-8 An Ishihara chart for testing color vision.

Psychosocial Assessment

A patient with changes in visual sensory perception may be anxious about possible vision loss. Patients with severe visual defects may be unable to perform ADLs. Dependency from reduced vision can affect self-esteem. Ask the patient how he or she feels about the vision changes, and assess coping techniques. Assess the family to determine available support. Provide information about local resources and services for reduced vision.

Diagnostic Assessment

Laboratory Assessment

Cultures of corneal or conjunctival swabs and scrapings help diagnose infections. Obtain a sample of the exudate for culture before antibiotics or topical anesthetics are instilled. Take swabs from the conjunctivae and any ulcerated or inflamed areas.

Imaging Assessment

CT is useful for assessing the eyes, the bony structures around the eyes, and the extraocular muscles. It can also detect tumors in the orbital space. Contrast dye is used unless trauma is suspected. Tell the patient

that this test is not painful but does require being in a confined space and keeping the head still.

MRI is often used to examine the orbits and the optic nerves and to evaluate ocular tumors. MRI cannot be used to evaluate injuries involving metal in the eyes. *Metal in the eye is an absolute contraindication for MRI.*

Radioisotope scanning is used to locate tumors and lesions. This test requires that the patient sign an informed consent. The patient receives a tracer dose of the radioactive isotope, either orally or by injection, and must then lie still. The scanner measures the radioactivity emitted by the radioactive atoms concentrated in the area being studied. Sedation may be used for patients who are anxious. No special follow-up care is required.

Ultrasonography is used to examine the orbit and eye with high-frequency sound waves. This noninvasive test helps diagnose trauma, intraorbital tumors, proptosis, and choroidal or retinal detachments. It is also used to determine the length of the eye and any gross outline changes in the eye and the orbit in patients with cloudy corneas or lenses that reduce direct examination of the fundus.

Inform the patient that this test is painless because the test is performed either with the eyes closed or, when the eyes must remain open, anesthetic eyedrops are instilled first. He or she sits upright with the chin in the chin rest. The probe is touched against the patient's anesthetized cornea, and sound waves are bounced through the eye. The sound waves create a reflective pattern on a computer screen that can be examined for abnormalities. No special follow-up care is needed. Remind the patient not to rub or touch the eye until the anesthetic agent has worn off.

Other Diagnostic Assessment

Many tests are used to examine specific eye structures when patients have specific risks, manifestations, or exposures. These tests are performed only by physicians, optometrists, or advanced practice nurses.

Slit-lamp examination magnifies the anterior eye structures (Fig. 46-9). The patient leans on a chin rest to stabilize the head. A narrow beam (slit) of light is aimed so that only a segment of the eye is brightly lighted. The examiner can then locate the position of any abnormality in the cornea, lens, or anterior vitreous humor.

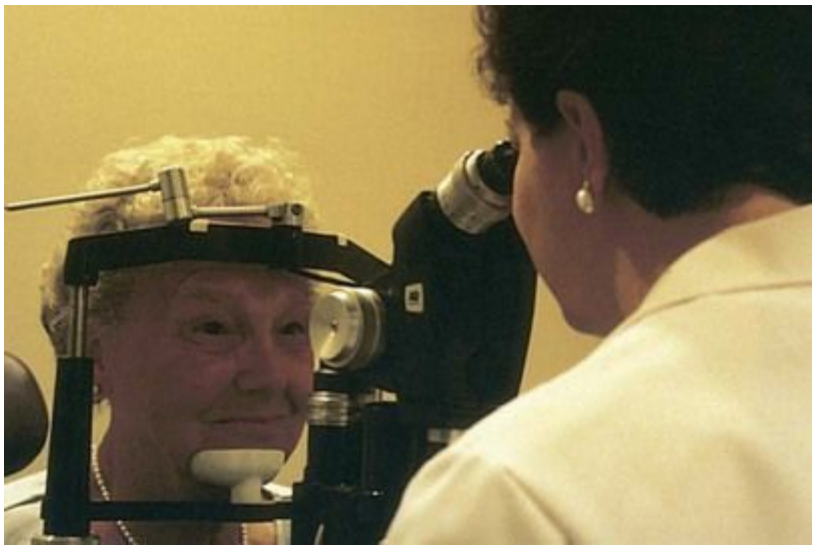

FIG. 46-9 Slit-lamp ocular examination.

Corneal staining consists of placing fluorescein or other topical dye into the conjunctival sac. The dye outlines irregularities of the corneal surface that are not easily visible. This test is used for corneal trauma, problems caused by a contact lens, or the presence of foreign bodies, abrasions, ulcers, or other corneal disorders.

This procedure is noninvasive and is performed under aseptic conditions. The dye is applied topically to the eye, and the eye is then viewed through a blue filter. Nonintact areas of the cornea stain a bright green color.

Tonometry measures intraocular pressure (IOP) using a tonometer. This instrument applies pressure to the outside of the eye until it equals the pressure inside the eye. Normal IOP readings have always been considered to range from 10 to 21 mm Hg; however, this number is not absolute and must be considered along with corneal thickness. The thickness of the cornea affects how much pressure must be applied before indentation occurs. For example, a person with a thicker cornea will have a higher tonometer reading that may falsely indicate increased IOP. A person with a thinner-than-normal cornea may have a low tonometer reading even when higher IOP is present.

About 5% of patients with healthy eyes have a slightly higher pressure. Tonometer readings are indicated for all patients older than 40 years. Adults with a family history of glaucoma should have their IOP measured once or twice a year. The most common method to measure IOP by an ophthalmologist is the Goldman's applanation tonometer used with a slit lamp (Fig. 46-10). This method involves direct eye contact. Another instrument, the Tono-Pen (Fig. 46-11), is designed for use by patients in the home to measure IOP daily.

FIG. 46-10 Use of Goldman's applanation tonometer and a slit lamp to measure intraocular pressure (IOP).

FIG. 46-11 The Tono-Pen.

Intraocular pressure varies throughout the day and may peak at any time of the day. Therefore always document the time of IOP measurement, and teach patients who are measuring IOP at home to perform the measurement at the same time or times each day.

Ophthalmoscopy allows viewing of the eye's external and interior structures with an instrument called an *ophthalmoscope.* This examination can be performed by any nurse but usually is performed by a physician,

advanced practice nurse, or physician assistant. It is easiest to examine the fundus when the room is dark, because the pupil dilates. Stand on the same side as the eye being examined. Tell the patient to look straight ahead at an object on the wall behind you. Hold the ophthalmoscope firmly against your face, and align it so that your eye sees through the sight hole (Fig. 46-12).

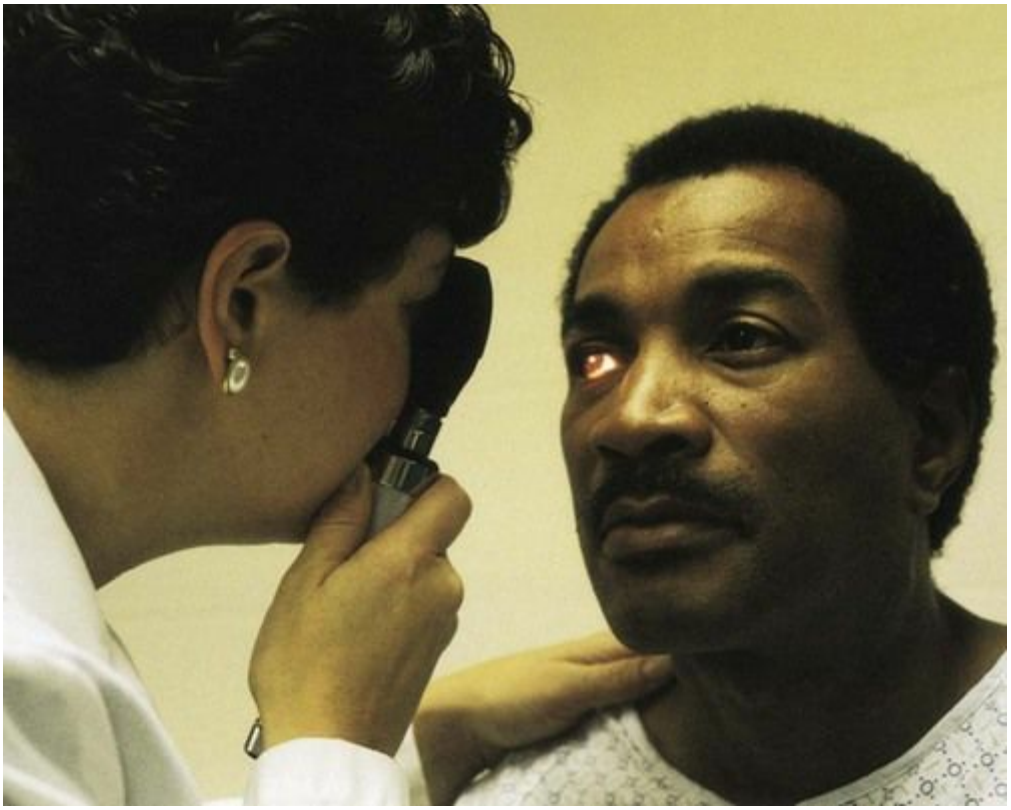

FIG. 46-12 Proper technique for direct ophthalmoscopic visualization of the retina.

When using the ophthalmoscope, move toward the patient's eye from about 12 to 15 inches away and to the side of his or her line of vision. As you direct the ophthalmoscope at the pupil, a red glare **(red reflex)** should be seen in the pupil as a reflection of the light on the retina. An absent red reflex may indicate a lens opacity or cloudiness of the vitreous. Move toward the patient's pupil while following the red reflex. The retina should then be visible through the ophthalmoscope. Examine the optic disc, optic vessels, fundus, and macula. Table 46-3 lists the features that can be observed in each structure.

TABLE 46-3

Structures Assessed By Direct Ophthalmoscopy

Red Reflex
• Presence or absence
Optic Disc
• Color • Margins (sharp or blurred) • Cup size • Presence of rings or crescents
Optic Blood Vessels
• Size • Color • Kinks or tangles • Light reflection • Narrowing • Nicking at arteriovenous crossings
Fundus
• Color • Tears or holes • Lesions • Bleeding
Macula
• Presence of blood vessels • Color • Lesions • Bleeding

The use of an ophthalmoscope may make a confused patient or one who does not understand the language more anxious. When working with a patient who does not speak the language used at the facility, use an interpreter, when possible, to ensure the patient's understanding and cooperation with the examination.

Nursing Safety Priority QSEN

Action Alert

Avoid using an ophthalmoscope with a confused patient.

Fluorescein angiography, which is performed by a physician or advanced practice nurse, provides a detailed image of eye circulation. Digital pictures are taken in rapid succession after the dye is given IV. This test helps assess problems of retinal circulation (e.g., diabetic retinopathy, retinal hemorrhage, and macular degeneration) or diagnose intraocular tumors.

Explain the procedure to the patient, and instill mydriatic eyedrops (cause pupil dilation) 1 hour before the test. Chart 46-3 lists the best practice for correct eyedrop instillation. Check that the informed consent

has been signed by the patient. Warn that the dye may cause the skin to appear yellow for several hours after the test. The stain is eliminated through the urine, which turns green.

Chart 46-3 Best Practice for Patient Safety & Quality Care QSEN

Instillation of Eyedrops

- Check the name, strength, expiration date, color, and clarity of the eyedrops to be instilled.
- Check to see whether only one eye is to have the drug or if both eyes are to receive the drug.
- If both eyes are to receive the same drug and one eye is infected, use two separate bottles and carefully label each bottle with "right" or "left" for the correct eye.
- Wash your hands.
- Put on gloves if secretions are present in or around the eye.
- Explain the procedure to the patient.
- Have the patient sit in a chair, and you stand behind the patient.
- Ask the patient to tilt the head backward, with the back of the head resting against your body and looking up at the ceiling.
- Gently pull the lower lid down against the patient's cheek, forming a small pocket.
- Hold the eyedrop bottle (with the cap off) like a pencil, with the tip pointing down.
- Rest the wrist holding the bottle against the patient's check.
- Without touching any part of the eye or lid with the tip of the bottle, gently squeeze the bottle and release the prescribed number of drops into the pocket you have made with the patient's lower lid.
- Gently release the lower lid.
- Tell the patient to close the eye gently (without squeezing the lids tightly).
- Gently press and hold the corner of the eye nearest the nose to close off the punctum and prevent the drug from being absorbed systemically.
- Without pressing on the lid, gently blot away any excess drug or tears with a tissue.
- Remove your gloves, and place the cap back on the bottle.
- Ask the patient to keep the eye closed for about 1 minute.
- Wash your hands again.

Encourage patients to drink fluids to help eliminate the dye. Remind them that any staining of the skin will disappear in a few hours. Instruct the patient to wear dark glasses and avoid direct sunlight until pupil dilation returns to normal, because the bright light will cause eye pain.

Electroretinography graphs the retina's response to light stimulation. This test is helpful in detecting and evaluating blood vessel changes from disease or drugs. The graph is obtained by placing an electrode on an anesthetized cornea. Lights at varying speeds and intensities are flashed, and the neural response is graphed. The measurement from the cornea is identical to the response that would be obtained if electrodes were placed directly on the retina.

Gonioscopy is a test performed when a high IOP is found and determines whether open-angle or closed-angle glaucoma is present. It uses a special lens that eliminates the corneal curve, is painless, and allows visualization of the angle where the iris meets the cornea.

Laser imaging of the retina and optic nerve creates a three-dimensional view of the back of the eye. It is often used for those people with ocular hypertension or who are at risk for glaucoma from other problems. This computerized examination assesses the thickness and contours of the optic nerve and retina for changes that indicate damage as a result of high IOP. It can be used serially for a person at risk for glaucoma to detect early changes and indicate when intervention is needed.

Clinical Judgment Challenge

Patient-Centered Care; Safety QSEN

The patient is a 56-year-old woman whose primary care provider has referred her to an ophthalmologist because she is having manifestations of glaucoma. She has never been evaluated by an ophthalmologist, even though she has used reading glasses for about 10 years. She seems very anxious and tells you that she cannot stand to have her eyes touched directly. She also tells you that her mother developed an eye infection and lost the vision in that eye after she had her intraocular pressure tested by an instrument with small feet that scratched her eye.

1. Will this patient's eyes be “touched” during a typical assessment of intraocular pressure?
2. What will you tell her about this procedure?
3. What assurance can you give her that she will not develop an infection from this evaluation?
4. Should you relay this patient's concerns to the ophthalmologist? Why

or why not?

Nursing Concepts and Clinical Judgment Review

What might you NOTICE in a patient with adequate visual sensory perception?

Physical assessment:

- Eyes are symmetric on the face on a line just about even with the tops of the ears.
- Eyes are clear with no drainage or open areas.
- Patient does not squint or tilt the head.
- Patient does not close one eye to read or see at a distance.
- Patient startles when a sudden move is made at the face.
- Patient blinks 5 to 10 times per minute.
- Pupils are the same size in each eye.
- Both pupils constrict when a light is shined at only one eye.
- Patient comments on the presence of art or unusual visual objects in the immediate environment.
- Patient walks without hesitation into a room without bumping into objects in his or her path.

Psychological assessment:

- Patient is oriented and not confused.
- Patient makes eye contact when speaking.

Safe and Effective Care Environment

- Wash your hands before moving a patient's eyelids or instilling drugs into the eye. **Safety** QSEN
- If a patient has discharge from one eye, examine the eye without the discharge first. **Safety** QSEN
- Wear gloves when examining an eye with drainage. **Safety** QSEN
- Avoid using an ophthalmoscope on a confused patient. **Safety** QSEN

Health Promotion and Maintenance

- Teach patients not to rub their eyes. **Patient-Centered Care** QSEN
- Identify patients at risk for eye injury as a result of work environment or leisure activities. **Patient-Centered Care** QSEN
- Urge all patients to wear eye protection when they are performing yard work, working in a woodshop or metal shop, using chemicals, or are in any environment in which drops or particulate matter is airborne. **Safety** QSEN
- Teach everyone to wear sunglasses outdoors in bright sunlight. **Patient-Centered Care** QSEN

Psychosocial Integrity

- Provide opportunities for the patient and family to express their concerns about a possible change in visual sensory perception. **Patient-Centered Care** QSEN
- Explain all diagnostic procedures, restrictions, and follow-up care to the patient scheduled for tests. **Patient-Centered Care** QSEN

Physiological Integrity

- Ask the patient about vision problems in any other members of the family, because some vision problems have a genetic component. **Patient-Centered Care** QSEN
- Test the vision of both eyes immediately of any person who experiences an eye injury or any sudden change in vision. **Patient-Centered Care** QSEN

CHAPTER 47

Care of Patients with Eye and Vision Problems

M. Linda Workman

PRIORITY CONCEPTS

- Sensory Perception
- Infection

Learning Outcomes

Safe and Effective Care Environment

1. Protect the patient with eye and vision problems from injury or infection.
2. Ensure that all members of the health care team are aware of a patient's visual limitations and need for assistance.

Health Promotion and Maintenance

3. Teach people when annual eye examinations with measurement of intraocular pressure are important to receive.
4. Teach patients and family members how to correctly instill ophthalmic drops and ointment into the eye.
5. Teach patients with glaucoma the relationship between increased intraocular pressure (IOP) and their eye problems.
6. Teach the patient with reduced visual sensory perception and family how to alter the home environment for patient safety.

Psychosocial Integrity

7. Reduce the psychological impact for the patient and family experiencing a potential change in visual sensory perception.
8. Work with other members of the health care team to ensure that the values, preferences, and expressed needs of patients with reduced

visual sensory perception are respected.

Physiological Integrity

9. Prioritize care and educational needs for the patient after cataract surgery with lens replacement.
10. Prioritize care and educational needs for patients with primary open-angle glaucoma.
11. Collaborate with other health care professionals to help patients and families experiencing reduced visual sensory perception achieve their desired health outcomes.
12. Coordinate interventions for the patient with reduced visual sensory perception in the community.

 http://evolve.elsevier.com/Iggy/

Many factors and problems can affect visual sensory perception. Problems may have a gradual onset, such as the most common form of glaucoma or cataracts, whereas others may have a sudden onset. Any temporary or permanent change in visual sensory perception requires the patient to make some changes in function or lifestyle.

Eyelid Disorders

The eyelid is composed of skin and small muscles to protect the eye surface and spread tears. Vision is affected by problems that change the structure, function, or position of the eyelid.

Entropion and Ectropion

An **entropion** is the turning inward of the eyelid causing the lashes to rub against the eye. It can be caused by eyelid muscle spasms or by scarring and deformity of the eyelid after trauma and is seen more often among older adults because of age-related loss of tissue support.

The patient reports "feeling something in my eye." Pain and tears may also be present. The conjunctiva is red, and corneal abrasion may result from constant irritation.

Surgery corrects eyelid position by either tightening the orbicular muscles and moving the eyelid to a normal position or by preventing inward rotation of the eyelid. After surgery, the eye is covered with a patch and the patient is discharged.

Demonstrate instillation of eyedrops, and evaluate the patient's ability to instill the drops. Teach the patient how to clean the suture line with a cotton swab and the prescribed solution. A small amount of antibiotic ointment may be applied (Fig. 47-1). Chart 47-1 describes how to apply ophthalmic ointment. Chart 47-2 lists common drugs for eye inflammation and infection.

Chart 47-1 Best Practice for Patient Safety & Quality Care QSEN

Instillation of Ophthalmic Ointment

- Check the name, strength, and expiration date of the ointment to be instilled. Be sure it is an ophthalmic (eye) preparation and not a general topical ointment.
- Check whether only one eye or both eyes are to receive the drug.
- If both eyes are to receive the same drug and one eye is infected, use two separate tubes and carefully label each tube with "right" or "left" for the correct eye.
- Wash your hands and put on gloves.
- Explain the procedure to the patient.
- Ask the patient to tilt the head backward and look up at the ceiling.
- Gently pull the lower lid down against the patient's cheek, forming a

small pocket.
- Hold the tube (with the cap off) like a pencil, with the tip down.
- Rest the wrist holding the tube against the patient's cheek.
- Without touching any part of the eye or lid with the tip of the tube, gently squeeze the tube and release a small thin strip of ointment into the pocket of the lower lid. Start at the nose side of the pocket, and move toward the outer edge of the pocket.
- Gently release the lower lid.
- Tell the patient to close the eye without squeezing the lid.
- While the eye is closed, gently wipe away excess ointment.
- Remind the patient that vision in that eye will be blurred and to not drive or operate heavy machinery until the ointment is removed.
- Remove your gloves, and place the cap back on the tube.
- Ask the patient to keep the eye closed for about 1 minute.
- Wash your hands again.
- To remove ointment, wear gloves if drainage is present.
- Then ask the patient to close the eye; wipe the closed lids with a clean tissue from the corner of the eye nearest the nose outward. If you are wiping the same eye twice, use a different area of the tissue or use a new one.

Chart 47-2 Common Examples of Drug Therapy

Eye Inflammation and Infection

DRUG	NURSING INTERVENTIONS*†	RATIONALES
Topical Anesthetics		
Proparacaine HCl, or proxymetacaine (AK-Taine, Alcaine, Ocu-Caine, Ophthetic) Tetracaine HCl, cocaine HCl (Pontocaine)	Remind the patient not to rub or touch the eye while it is anesthetized.	Touching may injure the eye.
	Patch the eye if the patient leaves the facility before the anesthetic wears off.	The use of a patch prevents injury, such as corneal abrasion.
	Instruct the patient not to use discolored solution.	Discoloration is a sign of altered drug composition.
	Teach the patient to store the bottle tightly closed.	Air may cause drug contamination and oxidation.
Topical Steroids		
Prednisolone acetate (Ocu-Pred, Ophtho-Tate)	Tell the patient to shake the bottle vigorously before use.	Drug is a suspension; shaking is required to distribute the drug evenly in the solution.
Prednisolone phosphate (Inflamase) Dexamethasone (Dexair, Dexotic, Maxidex) Betamethasone (Betnesol) Fluorometholone (Fluor-Op, Liquifilm)	Teach the patient to check for corneal ulceration (pain, reduced vision, secretions).	Steroid use predisposes the patient to local infection.
	Warn the patient not to share eyedrops with others.	Disease transmission is possible when sharing eyedrops.
Anti-Infective Agents		
Gentamicin (Genoptic, Gentak Alcomicin)	Teach the patient the importance of using the drug exactly as prescribed, even if he or she needs to use it hourly.	Bacterial and fungal eye infections worsen rapidly and can lead to blindness if not treated adequately.
Tobramycin (Tobrex) Ciprofloxacin (Ciloxan) Erythromycin (Ilotycin) Chlortetracycline (Aureomycin) Sulfisoxazole (Gantrisin) Ofloxacin (Ocuflox) Levofloxacin (Quixin) Bacitracin; Polymyxin B (Polysporin, Polytracin ophthalmic, AK-Poly-Bac)	Teach the patient how to clean exudate from the eyes before using drops.	Cleansing decreases the risk for contaminating the drug and increases contact of the conjunctiva with the drug.
	Reinforce the importance of completing the prescribed drug regimen.	Adherence is critical to maintain a therapeutic level of drug.
Antibiotic-Steroid Combinations		
Tobramycin with dexamethasone (TobraDex) Neomycin sulfate with polymyxin B sulfate and dexamethasone (Maxitrol)	This is the same as for the general anti-infective agents alone and for the steroids alone.	This is the same as for the general anti-infective agents alone and for the steroids alone.
Topical Antiviral Agents		
Trifluridine (Viroptic) Vidarabine (Vira-A)	Teach the patient to refrigerate the drug and protect it from light.	Drug stability is affected by warm temperatures and light.
	Teach the patient to assess for itching lids and burning eyes.	Sensitivity to these drugs is common.
Antifungal Agents		
Amphotericin B Natamycin (Natacyn)	Teach the patient to assess for itching lids and burning eyes.	Sensitivity to these drugs is common.
Nonsteroidal Anti-Inflammatory Agents		
Flurbiprofen (Ocufen) Diclofenac (Voltaren) Bromfenac (Xibrom) Ketorolac (Acular)	Teach the patient to check for bleeding in the eye.	These drugs disrupt platelet aggregation.
	Teach the patient not to wear soft contact lenses during therapy with these drugs.	These drugs interact with contact lens materials and increase the risk for infection.

*When instilling eyedrops, teach patients to use nasal punctal occlusion to reduce the risk for systemic absorption and side effects.

†When more than one topical ophthalmic drug is prescribed, teach patients to separate the instillation of each drug by 5-10 minutes (or package recommendations).

FIG. 47-1 Application of ophthalmic ointment.

Nursing Safety Priority QSEN

Drug Alert

Check the route of administration for ophthalmic drugs. Most are administered by the eye instillation route, not the oral route. Administering these drugs orally can cause systemic side effects in addition to not having a therapeutic effect on the eye.

An **ectropion** is the turning outward and sagging of the eyelid caused by muscle relaxation or weakness, which often occurs with aging. This lid position reduces the washing action of tears, leading to corneal drying and ulceration.

Patients often have constant tears and a sagging lower eyelid. Surgery can restore lid alignment. After surgery, the eye is covered with a patch and the patient is discharged. Nursing care is the same as for an entropion.

Hordeolum

A **hordeolum**, or *stye*, is infection of the eyelid sweat glands (external hordeolum) or of the eyelid sebaceous gland (internal hordeolum). A red, swollen, painful area occurs on the skin surface side of the eyelid. The most common causative organisms are *Staphylococcus aureus*, *Staphylococcus epidermidis*, and *Streptococcus*. Visual sensory perception is not

affected.

Management includes applying warm compresses 4 times a day and an antibacterial ointment. When the lesion opens, the purulent material drains and the pain subsides.

Nursing interventions include instructing the patient how to apply compresses to the eye (Chart 47-3) and how to instill antibiotic ointment (see Chart 47-1). Remind the patient to remove the ointment from the eyes before driving or operating machinery.

Chart 47-3 Patient and Family Education: Preparing for Self-Management

Application of an Ocular Compress

- Wash your hands.
- Fold a clean washcloth into fourths.
- Soak the washcloth with running tap water that is warm to your inner wrist. (If cool compresses are needed, follow the same steps using cold running tap water.)
- Place the cloth over your closed eye.
- Keep the cloth in place with light pressure until the cloth cools (or warms, if cool compresses are prescribed).
- Refold the washcloth so that a different "fourth" will be held against the eye.
- Resoak the cloth with running tap water.
- Repeat applications 3 times for as many times each day as prescribed by your health care provider.

Chalazion

A **chalazion** is an inflammation of a sebaceous gland in the eyelid. It begins with redness and tenderness, followed by a gradual *painless* swelling. Later, redness and tenderness are not present. Most chalazia protrude on the inside of the eyelid. The patient has eye fatigue, light sensitivity, and excessive tears.

Management includes applying warm compresses 4 times a day, followed by instillation of ophthalmic antibiotic ointment. If the chalazion is large enough to affect vision or is cosmetically displeasing, it may be removed surgically. Instruct the patient to immediately report increasing redness, purulent drainage, or reduced vision to the ophthalmologist.

Keratoconjunctivitis Sicca

The lacrimal system moistens the eye surface with tears and removes tears from the eye. Problems arise from reduced tear production, infection, or inflammation in the lacrimal system.

Keratoconjunctivitis sicca, or dry eye syndrome, results from changes in tear production, tear composition, or tear distribution. Drugs (e.g., antihistamines, beta-adrenergic blocking agents, anticholinergic drugs) also can reduce tear production. Diseases associated with dry eye syndrome include rheumatoid arthritis, leukemia, sarcoidosis, and Sjögren's syndrome. Radiation or chemical burns to the eye also decrease tear production. Injury to cranial nerve VII inhibits tears. Eye dryness may follow vision-enhancing surgery.

The patient has a foreign body sensation in the eye, burning and itching eyes, and *photophobia* (sensitivity to light). The corneal light reflex is dulled. Tears contain mucus strands.

Management depends on symptom severity. Cyclosporine (Restasis) eyedrops may be prescribed to increase tear production. Artificial tears (HypoTears, Refresh) also can be used to reduce daytime dryness. A lubricating ointment (Lacri-Lube SOP, Refresh P.M.) is used at night. If the dry eye syndrome is caused by an abnormal eyelid position, surgery may be needed.

Conjunctival Disorders

The conjunctiva is a thin mucous membrane that covers and protects the eye. Because of its location, the conjunctiva is subject to trauma and infection.

Conjunctivitis

Conjunctivitis is an inflammation with or without infection of the conjunctiva. Inflammation occurs from exposure to allergens or irritants. Infectious conjunctivitis occurs with bacterial or viral infection and is easily transmitted from person to person.

Allergic conjunctivitis manifestations are edema, a sensation of burning, a "bloodshot" eye appearance, excessive tears, and itching (Watkinson, 2013). Management includes vasoconstrictor and corticosteroid eyedrops (see Chart 47-2). Instruct patients to avoid using makeup near the eye until all manifestations are gone.

Bacterial conjunctivitis, or "pink eye," is most often caused by *S. aureus*. Manifestations are blood vessel dilation, edema, tears, and discharge. The discharge is watery at first and then becomes thicker, with shreds of mucus.

Cultures of the drainage may be obtained to identify the organism. Ophthalmic antibiotics are prescribed to eliminate the infection. Nursing interventions focus on preventing infection spread to the other eye or to other people. Remind the patient to wash his or her hands after touching the eye and before using eyedrops. Warn him or her not to touch the unaffected eye without first washing the hands and to avoid sharing washcloths and towels with others. Instruct patients to discard eye makeup and applicators used at the time the infection developed. Contact lenses worn during the infection need to be discarded to avoid reinfection.

Trachoma

Trachoma is a chronic conjunctivitis caused by *Chlamydia trachomatis.* It scars the conjunctiva and is a common cause of preventable blindness worldwide. The incidence is highest in warm, moist climates where sanitation is poor.

At first the disease resembles bacterial conjunctivitis with manifestations of tears, photophobia, and eyelid edema. Follicles form on the upper eyelid conjunctiva. As the disease progresses, the eyelid scars and turns inward, causing the eyelashes to damage the cornea.

Antibiotic therapy is used when the organism is identified. The most

effective antibiotic is oral azithromycin (Zithromax). The infection also can be eliminated early in the disease with a 4-week course of tetracycline eye ointment. Nursing interventions focus on infection control. Patient teaching is the same as for conjunctivitis.

Nursing Safety Priority QSEN

Action Alert

Teach patients who are prescribed oral antibiotics or antibiotic ointments to complete the entire course of antibiotics. Stopping antibiotic therapy too soon promotes infection recurrence and development of antibiotic-resistant bacteria.

Corneal Disorders

For a sharp retinal image, the cornea must be transparent and intact. Corneal problems may be caused by irritation or infection (keratitis) with ulceration of the corneal surface, degeneration of the cornea (keratoconus), or deposits in the cornea. All corneal problems reduce visual sensory perception, and some can lead to blindness.

Corneal Abrasion, Ulceration, and Infection

❖ Pathophysiology

A **corneal abrasion** is a scrape or scratch injury of the cornea. This painful condition can be caused by a small foreign body, trauma, or contact lens use (Corneal Abrasion, 2013). Other problems contributing to corneal injury are malnutrition, dry eye syndromes, and some cancer therapies. The abrasion allows organisms to enter, leading to corneal infection. Bacterial, protozoal, and fungal infections can lead to **corneal ulceration**, which is a deeper injury. *This problem is an emergency because the cornea has no separate blood supply and infections that can permanently impair vision develop rapidly.* Use of homemade contact lens solutions and the use of large-volume solution containers that can easily become contaminated have led to a sharp rise in the incidence of corneal ulcers infected with *Pseudomonas aeruginosa* and fungi.

❖ Patient-Centered Collaborative Care

The patient with a corneal disorder has pain, reduced vision, photophobia, and eye secretions. Cloudy or purulent fluid may be present on the eyelids or lashes. Wear gloves when examining the eye.

The cornea looks hazy or cloudy with a patchy area of ulceration. When fluorescein stain is used, the patchy areas appear green. Microbial culture and corneal scrapings are used to determine the causative organism. Anti-infective therapy is started before the organism is identified because of the high risk for vision loss. For culture, obtain swabs from the ulcer and its edges. For corneal scrapings, the cornea is anesthetized with a topical agent and a physician or advanced practice nurse removes samples from the ulcer center and edge.

Antibiotics, antifungals, and antivirals are prescribed to eliminate the organisms. A broad-spectrum antibiotic is prescribed first and may be changed when culture results are known. Steroids may be used with antibiotics to reduce the eye inflammation. Drugs can be given topically as eyedrops, injected subconjunctivally, or injected IV. Chart 46-3 in

Chapter 46 lists best practices for instilling eyedrops. The nursing priorities are to begin the drug therapy, to ensure patient understanding of the drug therapy regimen, and to prevent infection spread.

Often the anti-infective therapy involves instilling eyedrops *every hour* for the first 24 hours. Teach the patient or family member how to instill the eyedrops correctly. (See Chart 46-2 in Chapter 46.)

If the eye infection occurs only in one eye, teach the patient not to use the drug in the unaffected eye. Instruct him or her to wash hands after touching the affected eye and before touching or doing anything to the healthy eye. If both eyes are infected, separate bottles of drugs are needed for each eye. Teach the patient to clearly label the bottles "right eye" and "left eye" and not to switch the drugs from eye to eye. Also teach him or her to completely care for one eye, then wash the hands, and using the drugs designated for the other eye, care for that eye. Remind the patient not to wear contact lenses during the entire time that these drugs are being used because the eye is more vulnerable to infection or injury and because the drugs can cloud or damage the contact lenses.

Nursing Safety Priority QSEN

Action Alert

Stress the importance of applying the drug as often as prescribed, even at night. Stopping the infection at this stage can save the vision in the infected eye. Instruct the patient to make and keep all follow-up appointments; usually the patient is seen again in 24 hours or less.

Drug therapy may continue for 3 or more weeks to ensure eradication of the infection. Warn patients to avoid using makeup around the eye until the infection has cleared (Corneal Abrasion, 2013). Instruct patients to discard all open containers of contact lens solutions and bottles of eyedrops because these may be contaminated. Patients should not wear contact lenses for weeks to months until the infection is gone and the ulcer is healed.

Keratoconus and Corneal Opacities

Pathophysiology

The cornea can permanently lose it shape, become scarred or cloudy, or become thinner, reducing useful visual sensory perception. **Keratoconus**, the degeneration of the corneal tissue resulting in abnormal corneal shape,

can occur with trauma or may be an inherited disorder (Fig. 47-2). Inadequately treated corneal infection and severe trauma can scar the cornea and lead to severe visual impairment that can be improved only by surgical interventions.

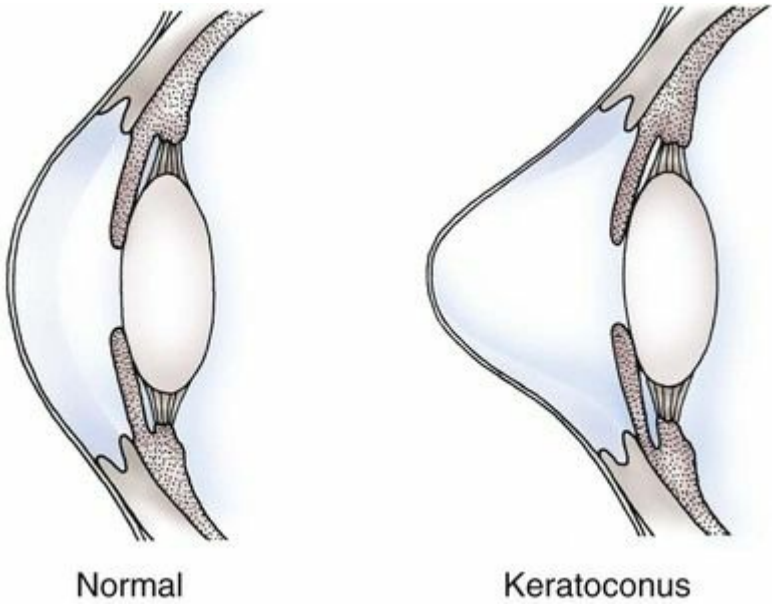

FIG. 47-2 Profile of a normal cornea and one with keratoconus.

Patient-Centered Collaborative Care

For a misshaped cornea that is still clear, surgical management involves a corneal ring implant that adjusts the shape of the cornea. With this procedure, the shape of the cornea is changed by placing a flexible ring in the outer edges of the cornea (outside of the optical zone).

The procedure is performed under local anesthesia. Improvement to best vision is immediate. Removal, replacement, or adjustment of ring tightness can enhance refraction, especially when the patient's vision changes further as a result of aging. Because the ring is placed outside of the optical zone, the risk for corneal clouding or scarring is low.

Surgery to improve clarity for a permanent corneal disorder that obscures vision is a **keratoplasty** (corneal transplant), in which the diseased corneal tissue is removed and replaced with tissue from a human donor cornea. This process improves vision by removing corneal deformities and replacing them with healthy corneal tissue.

Preoperative care may be short, with little time for teaching because transplantation is performed when the donor cornea becomes available. Examine the eyes for manifestations of infection, and report any redness,

drainage, or edema to the ophthalmologist. Instill prescribed antibiotic eyedrops and obtain IV access before surgery.

Operative procedures are *keratoplasties* and are usually performed with local anesthesia in an ambulatory surgical setting. The transplant may involve the entire depth of corneal tissue (penetrating keratoplasty) or only certain layers of the corneal tissue (lamellar keratoplasty). The nerves around the eye are anesthetized so that the patient cannot move the eye or see out of the eye. The center 7 to 8 mm of the diseased cornea is removed with an instrument that works like a cookie cutter (Fig. 47-3). The same instrument is used to cut the tissue graft from the donor cornea so that the graft will be a perfect fit. The donor cornea is sutured into place on the eye. The procedure takes about an hour, and the patient is discharged to home within 1 to 2 hours.

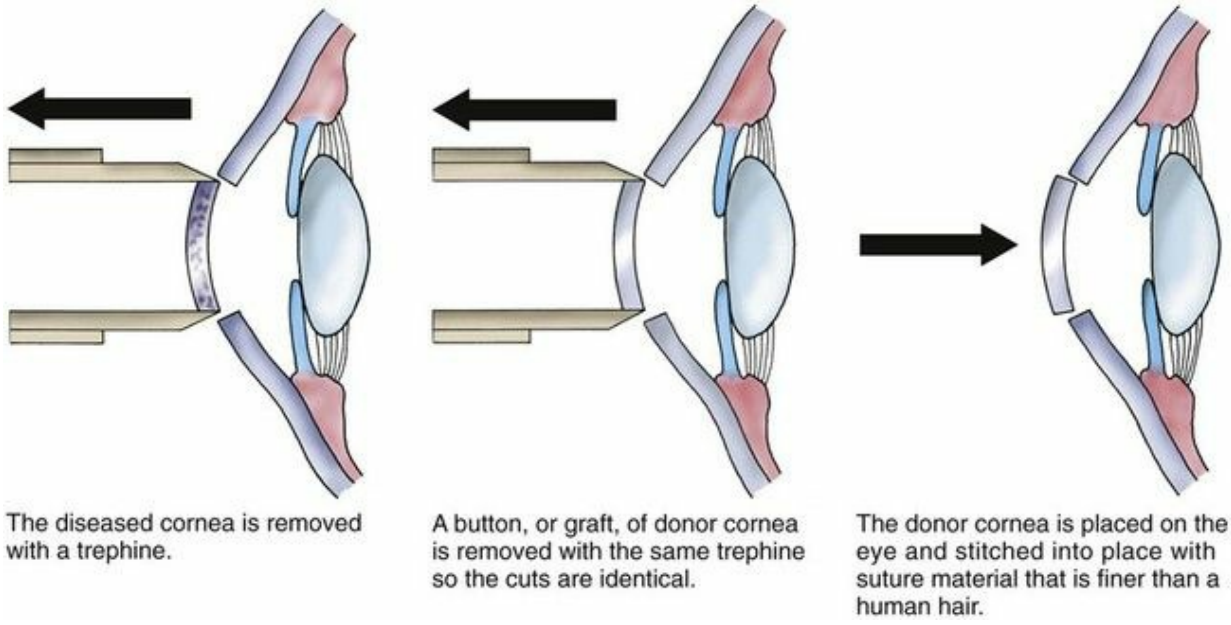

FIG. 47-3 The steps involved in corneal transplantation (penetrating keratoplasty).

Postoperative care involves extensive patient teaching. Local antibiotics are injected or instilled. Usually the eye is covered with a pressure patch and a protective shield until the patient returns to the surgeon.

Instruct the patient to lie on the nonoperative side to reduce intraocular pressure (IOP). If a patch is to be used for more than a day, teach the patient or family member how to apply it. Instruct the patient to wear the shield at night for the first month after surgery and whenever he or she is around small children or pets. Instruct him or her *not* to use an ice pack on the eye. Complications after surgery include bleeding, wound leakage, infection, and graft rejection. Teach the patient how to

instill eyedrops. Teach him or her to examine the eye (or have a family member do the examination) daily for the presence of infection or graft rejection. Stress that the presence of purulent discharge, a continuous leak of clear fluid from around the graft site (not tears), or excessive bleeding needs to be reported immediately to the surgeon. Other complications include decreased vision, increased reddening of the eye, pain, increased sensitivity to light, and the presence of light flashes or "floaters" in the field of vision. Teach the patient to report any of these manifestations to the surgeon if they develop after the first 48 hours and persist for more than 6 hours.

The eye should be protected from any activity that can increase the pressure on, around, or inside the eye. Teach the patient to avoid jogging, running, dancing, and any other activity that promotes rapid or jerky head motions for several weeks after surgery. Other activities that may raise intraocular pressure (IOP) and should be avoided are listed in Table 47-1.

TABLE 47-1

Activities That Increase Intraocular Pressure

• Bending from the waist • Lifting objects weighing more than 10 lbs • Sneezing, coughing • Blowing the nose • Straining to have a bowel movement
• Vomiting • Having sexual intercourse • Keeping the head in a dependent position • Wearing tight shirt collars

Graft rejection can occur and starts as inflammation in the cornea near the graft edge that moves toward the center. Vision is reduced, and the cornea becomes cloudy. Topical corticosteroids and other immunosuppressants are used to stop the rejection process. If rejection continues, the graft becomes opaque and blood vessels branch into the opaque tissue.

Eye donation is a common procedure and needed for corneal transplantation. If a deceased patient is a known eye donor, follow these recommended steps:

- Raise the head of the bed 30 degrees.
- Instill prescribed antibiotic eyedrops.
- Close the eyes, and apply a *small* ice pack.

Cataract

Pathophysiology

The lens is a transparent, elastic structure suspended behind the iris that focuses images onto the retina. A **cataract** is a lens opacity that distorts the image (Fig. 47-4). With aging, the lens gradually loses water and increases in density (Touhy & Jett, 2014). Lens density increases with drying and compression of older lens fibers and production of new fibers and lens crystals. With time, as lens density increases and transparency is lost, visual sensory perception is greatly reduced. Both eyes may have cataracts, but the rate of progression in each eye is different.

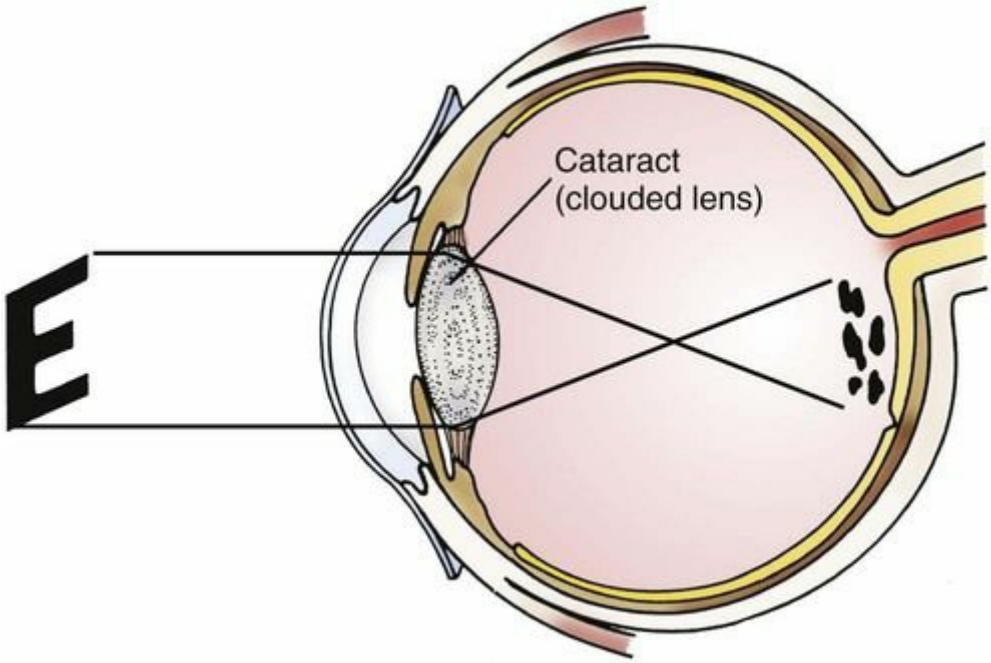

FIG. 47-4 The visual impairment produced by the presence of a cataract.

Etiology and Genetic Risk

Cataracts may be present at birth or develop at any time. They may be age-related or caused by trauma or exposure to toxic agents. They also occur with other diseases and eye disorders (Table 47-2).

TABLE 47-2

Common Causes of Cataracts

Age-Related Cataracts
• Lens water loss and fiber compaction
Traumatic Cataracts
• Blunt injury to eye or head • Penetrating eye injury • Intraocular foreign bodies • Radiation exposure, therapy
Toxic Cataracts
• Corticosteroids • Phenothiazine derivatives • Miotic agents
Associated Cataracts
• Diabetes mellitus • Hypoparathyroidism • Down syndrome • Chronic sunlight exposure
Complicated Cataracts
• Retinitis pigmentosa • Glaucoma • Retinal detachment

Incidence and Prevalence

About 25 to 27 million people in North America have cataracts (National Eye Institute, 2012). The age-related cataract is the most common type. Some degree of cataract formation is expected in all people older than 70 years.

Health Promotion and Maintenance

Although most cases of cataracts in North America are age-related, the onset of cataract formation occurs earlier with heavy sun exposure or exposure to other sources of ultraviolet (UV) light. Teach people to reduce the risk for cataract by wearing sunglasses that limit exposure to UV light whenever they are outdoors in the daytime. Cataracts also may result from direct eye injury. Urge all people to wear eye and head protection during sports, such as baseball, or any activity that increases the risk for the eye being hit.

❖ Patient-Centered Collaborative Care

◆ Assessment

History.

Age is important because cataracts are most prevalent in the older adult. Ask about these predisposing factors:

- Recent or past trauma to the eye
- Exposure to radioactive materials, x-rays, or UV light
- Systemic disease (e.g., diabetes mellitus, hypoparathyroidism)
- Prolonged use of corticosteroids, chlorpromazine, beta blockers, or miotic drugs
- Intraocular disease (e.g., recurrent uveitis)
- Family history of cataracts

Ask the patient to describe his or her vision. For example, you might say "Tell me what you can see well and what you have difficulty seeing."

Physical Assessment/Clinical Manifestations.

Early manifestations of cataracts are slightly blurred vision and decreased color perception. At first the patient may think his or her glasses or contact lenses are smudged. As lens cloudiness continues, blurred and double vision occur and the patient may have difficulty with ADLs. Without surgical intervention, visual impairment progresses to blindness. *No pain or eye redness is associated with age-related cataract formation.*

Visual sensory perception is tested using an eye chart and brightness acuity testing (see Chapter 46). Examine the lens with an ophthalmoscope, and describe any observed densities by size, shape, and location. As the cataract matures, the opacity makes it difficult to see the retina and the red reflex may be absent. When this occurs, the pupil is bluish white (Fig. 47-5).

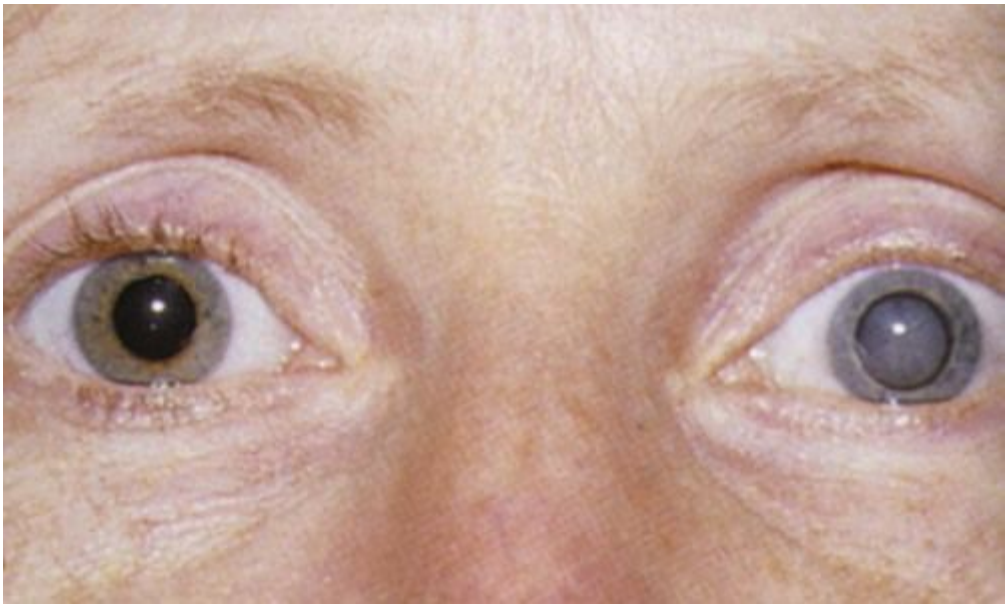

FIG. 47-5 The appearance of an eye with a mature cataract.

Psychosocial Assessment.

Loss of vision is gradual, and the patient may not be aware of it until reading or driving is affected. The patient often has anxiety about loss of independence. Encourage the patient and family to express concerns about reduced vision.

◆ Planning and Implementation

The priority problem for the patient with cataracts is reduced visual sensory perception, which is a safety risk. Patients often live with reduced vision for years before the cataract is removed. Interventions for safety and independence before surgery are on pp. 993-994 in Patient-Centered Collaborative Care in the Reduced Visual Sensory Perception section.

Improving Vision

Planning: Expected Outcomes.

The patient with cataracts is expected to recognize when ADLs cannot be performed safely and independently and then is expected to have cataract surgery. This procedure is covered by Medicare for patients who are 65 years or older.

Interventions.

Surgery is the only "cure" for cataracts and should be performed as soon as possible after vision is reduced to the extent that ADLs are affected.

Preoperative Care.

The ophthalmologist provides the patient with accurate information so that he or she can make informed decisions about treatment and obtains informed consent. Reinforce this information, and teach about the nature of cataracts, their progression, and their treatment.

Assess how the reduced vision affects ADLs, especially dressing, eating, and ambulating. Stress that care after surgery requires the instillation of different types of eyedrops several times a day for 2 to 4 weeks. Careful assessment of eye appearance is also needed. If the patient is unable to perform these tasks, help him or her make arrangements for this care.

Ask whether the patient takes any drugs that affect blood clotting, such as aspirin, warfarin (Coumadin), clopidogrel (Plavix), and dabigatran (Pradaxa). Communicate this information to the surgeon because, for some patients, these drugs may need to be discontinued before cataract surgery.

A series of ophthalmic drugs are instilled just before surgery to dilate the pupils and cause vasoconstriction. Other eyedrops are instilled to induce paralysis to prevent lens movement. When the patient is in the surgical area, a local anesthetic is injected into the muscle cone behind the eye for anesthesia and eye paralysis.

Operative Procedures.

The lens is extracted by *phacoemulsification* (Fig. 47-6), in which a probe is inserted through the capsule and high-frequency sound waves break the lens into small pieces, which are then removed by suction. The replacement intraocular lens (IOL) is placed inside the capsule to be positioned so that light rays are focused in the retina. The IOL is a small, clear, plastic lens. Different types are available, and one is selected by the surgeon and patient to allow correction of a specific refractive error. Some patients have distant vision restored to 20/20 and may need glasses only for reading or close work. Some replacement lenses have multiple focal planes and may correct vision to the extent that glasses or contact lenses may not be needed.

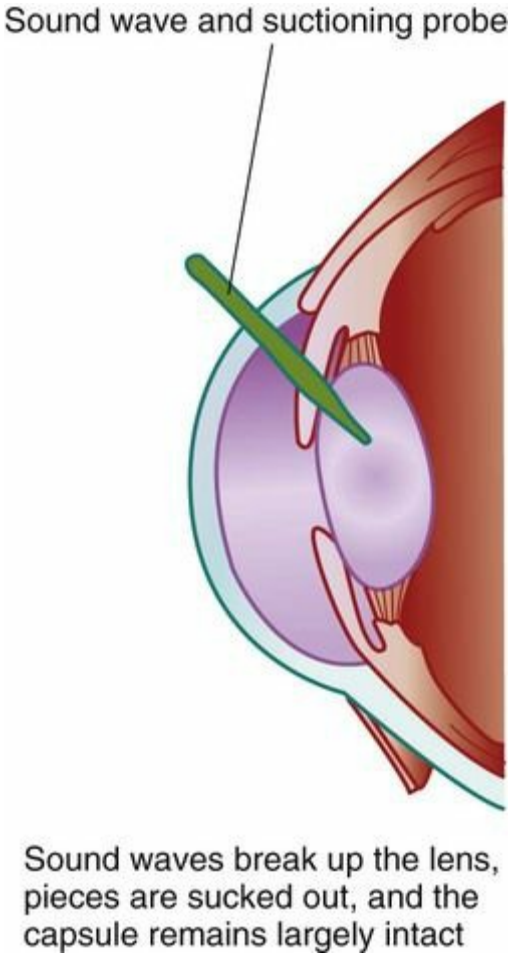

FIG. 47-6 Cataract removal by phacoemulsification.

Postoperative Care.

Immediately after surgery, antibiotic and steroid ointments are instilled. The patient usually is discharged within an hour after surgery. Instruct him or her to wear dark glasses outdoors or in brightly lit environments until the pupil responds to light. Teach the patient and family members how to instill the prescribed eyedrops. (See Chart 46-2 in Chapter 46.) Work with them in creating a written schedule for the timing and the order of eyedrops administration. Stress the importance of keeping all follow-up appointments.

Remind the patient that mild eye itching is normal, as is a "bloodshot appearance." The eyelid may be slightly swollen. However, significant swelling or bruising is abnormal. Cool compresses may be beneficial. Discomfort at the site is controlled with acetaminophen (Abenol, Tylenol) or acetaminophen with oxycodone (Endocet, Percocet, Tylox). Aspirin is avoided because of its effects on blood clotting.

Pain early after surgery may indicate increased intraocular pressure (IOP) or hemorrhage. Instruct patients to contact the surgeon if pain occurs with nausea or vomiting.

To prevent increases in IOP, teach the patient and family about activity restrictions. Activities that can cause a sudden rise in IOP are listed in Table 47-1.

Infection is a potential and serious complication. Teach the patient and family to observe for increasing eye redness, a decrease in vision, or an increase in tears and photophobia. Creamy white, dry, crusty drainage on the eyelids and lashes is normal. However, yellow or green drainage indicates infection and must be reported.

Patients experience a dramatic improvement in vision within a day of surgery. Remind them that final best vision will not occur until 4 to 6 weeks after surgery.

Nursing Safety Priority QSEN

Action Alert

Instruct the patient who has had cataract surgery to immediately report any reduction of vision after surgery in the eye that had the cataract removed.

Community-Based Care

The patient is usually discharged within an hour after cataract surgery. Nursing interventions focus on helping the patient and family plan the eyedrop schedule and daily home eye examination.

Home Care Management.

If the patient has difficulty instilling eyedrops, a supportive neighbor, friend, or family member can be taught the procedure. Adaptive equipment that positions the bottle of eyedrops directly over the eye can also be purchased (Fig. 47-7).

FIG. 47-7 The Ableware automatic eyedrop guide for self-administering eyedrops.

Self-Management Education.

The best outcome of cataract removal requires close adherence to the eyedrop regimen after surgery. Providing the patient or family with accurate information and demonstration of needed skills are nursing priorities. Before discharge, review these indications of complications after cataract surgery with the patient and family:

- Sharp, sudden pain in the eye
- Bleeding or increased discharge
- Green or yellow, thick drainage
- Lid swelling
- Reappearance of a bloodshot sclera after the initial appearance has cleared
- Decreased vision
- Flashes of light or floating shapes

Remind the patient to avoid activities that might increase IOP (see Table 47-1). Some patients are prescribed to wear a light eye patch at night to prevent accidental rubbing. Instruct the patient to avoid getting water in the eye for 3 to 7 days after surgery.

Teach the patient about activity restrictions. Cooking and light housekeeping are permitted, but vacuuming should be avoided for

several weeks because of the forward flexion involved and the rapid, jerky movements required. Advise him or her to refrain from driving until vision is not blurry. Chart 47-4 lists items to cover in the focused assessment of a patient at home after cataract surgery.

Chart 47-4 Focused Assessment

The Patient After Cataract Surgery

Assess the eye and vision:
- Visual acuity in both eyes using a handheld eye chart
- Visual fields of both eyes
- Compare operative eye with nonoperative eye for presence or absence of:
  - Redness
  - Tearing
  - Drainage

Ask the patient about:
- Pain in or around the operative eye
- Any change in vision (decreased or improved) in the operative eye
- Whether any of these has been noticed in the operative eye:
  - Dark spots
  - Increase in the number of floaters
  - Bright flashes of light

Assess the home environment for:
- Safety hazards (especially tripping and falling hazards)
- Level of room lighting

Assess patient adherence with and understanding of treatment and limitations, such as:
- Manifestations to report
- Drug regimen
- Activity restrictions
- Ability to perform ADLs

Health Care Resources.

If the patient lives alone and has no support, arrange for a home care nurse to assess him or her and the home situation. If the patient is unable to instill eyedrops independently, a friend, neighbor, or family member can be taught this technique.

◆ Evaluation: Outcomes

Evaluate the care of the patient with cataracts on the basis of improving visual sensory perception. The expected outcomes include that the patient after cataract surgery will:

- Have improved visual sensory perception
- Recognize manifestations of complications

Specific indicators for these outcomes are listed under the Planning and Implementation section (see earlier).

NCLEX Examination Challenge

Health Promotion and Maintenance

The client who had cataract surgery with a lens implant 1 week ago remarks to the home care nurse that after his daughter left to go to her home in another state yesterday, he combined all of his prescribed eyedrops together in one container so he had fewer drops to administer. What is the nurse's best response?

A "This is not a good idea because not all of the drugs are on the same schedule."

B "That is a good idea; just remember to not touch the dropper to your eye when giving yourself the drops."

C "Call your surgeon immediately and get new prescriptions because together these drugs can lower your blood pressure."

D "Call your surgeon immediately and get new prescriptions to use one at a time because these drugs cannot be mixed together."

Glaucoma

Pathophysiology

Glaucoma is a group of eye disorders resulting in increased IOP (intraocular pressure). As described in Chapter 46, the eye is a hollow organ. For proper eye function, the gel in the posterior segment (vitreous humor) and the fluid in the anterior segment (aqueous humor) must be present in set amounts that apply pressure inside the eye to keep it ball-shaped.

In adults the volume of the vitreous humor does not change. The aqueous humor, however, is continuously made from blood plasma by the ciliary bodies located behind the iris and just in front of the lens (see Fig. 46-2 in Chapter 46). The fluid flows through the pupil into the bulging area in front of the iris. At the outer edges of the iris beneath the cornea, blood vessels collect fluid and return it to the blood. Usually about 1 mL of aqueous humor is always present, but it is continuously made and reabsorbed at a rate of about 5 mL daily. *A normal IOP requires a balance between production and outflow of aqueous humor (McCance et al., 2014). If the IOP becomes too high, the extra pressure compresses retinal blood vessels and photoreceptors and their synapsing nerve fibers. This compression results in poorly oxygenated photoreceptors and nerve fibers. These sensitive nerve tissues become ischemic and die. When too many have died, vision is lost permanently.* Tissue damage starts in the periphery and moves inward toward the fovea centralis. Untreated, glaucoma can lead to complete loss of visual sensory perception. Glaucoma is usually painless, and the patient may be unaware of gradual vision reduction.

There are several causes and types of glaucoma (Table 47-3), classified as primary, secondary, or associated. The most common type is primary glaucoma.

TABLE 47-3

Common Causes of Glaucoma

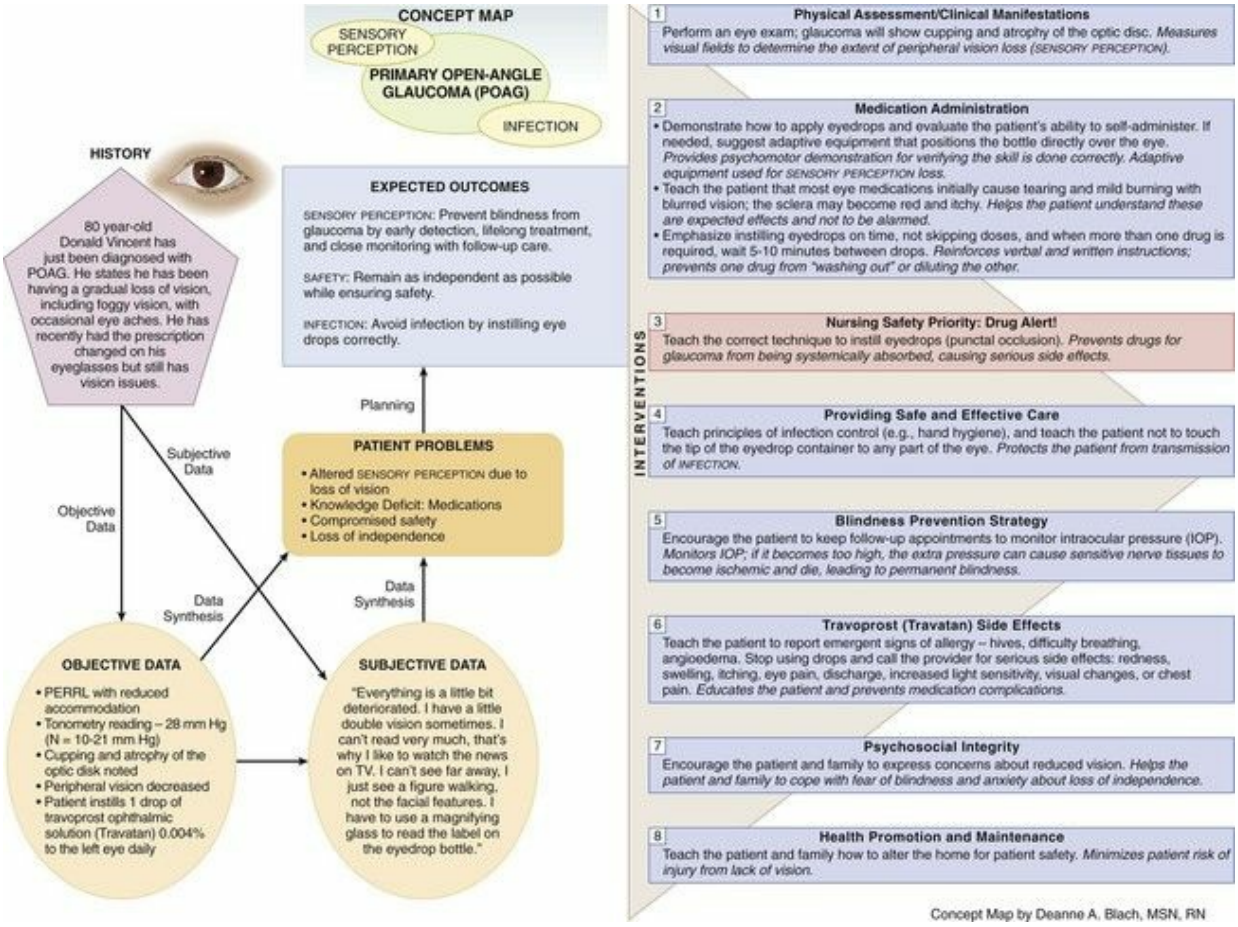
Primary Glaucoma
• Aging • Heredity • Central retinal vein occlusion
Associated Glaucoma
• Diabetes mellitus • Hypertension • Severe myopia • Retinal detachment
Secondary Glaucoma
• Uveitis • Iritis • Neovascular disorders • Trauma • Ocular tumors • Degenerative disease • Eye surgery

Primary open-angle glaucoma (POAG), the most common form of primary glaucoma, usually affects both eyes and has no manifestations in the early stages. Outflow of aqueous humor through the chamber angle is reduced. Because the fluid cannot leave the eye at the same rate it is produced, IOP gradually increases. **Primary angle-closure glaucoma** (PACG or *acute glaucoma*) has a sudden onset and is an emergency. The problem is a forward displacement of the iris, which presses against the cornea and closes the chamber angle, suddenly preventing outflow of aqueous humor.

Glaucoma is a common cause of blindness in North America. It is usually age-related, occurring in about 3.5 million people in North America (National Eye Institute, 2012).

Patient-Centered Collaborative Care

Primary open-angle glaucoma (POAG) develops slowly, with gradual loss of visual fields that may go unnoticed because central vision at first is unaffected. At times, vision is foggy and the patient has mild eye aching or headaches. Late manifestations occur after irreversible damage to optic nerve function and include seeing halos around lights, losing peripheral vision, and having decreased visual sensory perception that does not improve with eyeglasses. The Concept Map on p. 986 addresses collaborative care issues for patients with glaucoma.



Assessment

Physical Assessment/Clinical Manifestations.

Ophthalmoscopic examination shows cupping and atrophy of the optic disc. It becomes wider and deeper and turns white or gray. In POAG the visual fields first show a small loss of peripheral vision that gradually progresses to a larger loss.

Manifestations of acute angle-closure glaucoma include a sudden, severe pain around the eyes that radiates over the face. Headache or brow pain, nausea, and vomiting may occur. Other manifestations include seeing colored halos around lights and sudden blurred vision with decreased light perception. The sclera may appear reddened and the cornea foggy. Ophthalmoscopic examination reveals a shallow anterior chamber, cloudy aqueous humor, and a moderately dilated, nonreactive pupil.

Diagnostic Assessment.

An elevated intraocular pressure (IOP) is measured by tonometry. In open-angle glaucoma, the tonometry reading is between 22 and 32 mm Hg (normal is 10 to 21 mm Hg). In angle-closure glaucoma, the

tonometry reading may be 30 mm Hg or higher. Visual field testing by perimetry is performed, as is visualization by gonioscopy to determine whether the angle is open or closed. Usually the optic nerve is imaged to determine to what degree nerve damage is present. All of these diagnostic assessment techniques are described in Chapter 46.

Interventions

Nonsurgical Management.

Loss of visual sensory perception from glaucoma can be prevented by early detection, lifelong treatment, and close monitoring. Use of ophthalmic drugs that reduce ocular pressure delays or prevents damage. Chart 47-5 lists ways to assist the patient with reduced vision to remain as independent as possible.

Chart 47-5 Nursing Focus on the Older Adult

Promote Independent Living in Patients with Impaired Vision

Drugs

- Having a neighbor, relative, friend, or visiting nurse visit once a week to measure the proper drugs for each day may be helpful.
  - If the patient is to take drugs more than once each day, it is helpful to use a container of a different shape (with a lid) each time. For example, if the patient is to take drugs at 9 am, 1 pm, and 9 pm, the 9 am drugs would be placed in a round container, the 1 pm drugs in a square container, and the 9 pm drugs in a triangular container.
  - It is helpful to place each day's drug containers in a separate box with raised letters on the side of the box spelling out the day.
- "Talking clocks" are available for the patient with low vision.
- Some drug boxes have alarms that can be set for different times.

Communication

- Telephones with large, raised block numbers may be helpful. The best models are those with black numbers on a white phone or white numbers on a black phone.
- Telephones that have a programmable automatic dialing feature ("speed dial") are very helpful. Programmed numbers should include those for the fire department, police, relatives, friends, neighbors, and 911.

Safety

- It is best to leave furniture the way the patient wants it and not move it.
- Throw rugs are best eliminated.
- Appliance cords should be short and kept out of walkways.
- Lounge-style chairs with built-in footrests are preferable to footstools.
- Nonbreakable dishes, cups, and glasses are preferable to breakable ones.
- Cleansers and other toxic agents should be labeled with large, raised letters.
- Hook-and-loop (Velcro) strips at hand level may help mark the locations of switches and electrical outlets.

Food Preparation

- Meals on Wheels is a service that many older adults find helpful. This service brings meals at mealtime, cooked and ready to eat. The cost of this service varies, depending on the patient's ability to pay.
- Many grocery stores offer a “shop by telephone” service. The patient can either complete a computer booklet indicating types, amounts, and brands of items desired, or the store will complete this booklet over the telephone by asking the patient specific information. The store then delivers groceries to the patient's door (many stores also offer a “put away” service) and charges the patient's bank card.
- A microwave oven is a safer means of cooking than a standard stove, although many older patients are afraid of microwave ovens. If the patient has and will use a microwave oven, others can prepare meals ahead of time, label them, and freeze them for later use. Also, many microwavable complete frozen dinners that comply with a variety of dietary restrictions are available.
- Friends or relatives may be able to help with food preparation. Often relatives do not know what to give an older person for birthdays or other gift-giving occasions. One suggestion is a homemade prepackaged frozen dinner that the patient enjoys.

Personal Care

- Handgrips should be installed in bathrooms.
- The tub floor should have a nonskid surface.
- Male patients should use an electric shaver rather than a razor.
- Choosing a hairstyle that is becoming but easy to care for (avoiding parts) helps in independent living.
- Home hair care services may be available.

Diversional Activity

- Some patients can read large-print books, newspapers, and magazines (available through local libraries and vision services).
- Books, magazines, and some newspapers are available on audiotapes or discs.
- Patients experienced in knitting or crocheting may be able to create items fashioned from straight pieces, such as afghans.
- Card games, dominoes, and some board games that are available in large, high-contrast print may be helpful for patients with low vision.

Drug therapy for glaucoma works to reduce IOP in several ways. Eyedrop drugs can reduce the production, increase the absorption of aqueous humor, or constrict the pupil so that the ciliary muscle is contracted, allowing better circulation of the aqueous humor to the site of absorption. *These drugs do not improve lost vision but prevent more damage by decreasing IOP.* The prostaglandins agonists drugs reduce IOP by dilating blood vessels in the trabecular mesh, which then collects and drains aqueous humor at a faster rate. The adrenergic agonists and beta-adrenergic blockers reduce IOP by limiting the production of aqueous humor and by dilating the pupil, which improves the flow of the fluid to its absorption site. Cholinergic agonists reduce IOP by limiting the production of aqueous humor and by making more room between the iris and the lens, which improves fluid outflow. Carbonic anhydrase inhibitors directly and strongly inhibit production of aqueous humor. They do not affect the flow or the absorption of the fluid. Most eyedrops cause tearing, mild burning, blurred vision, and a reddened sclera for a few minutes after instilling the drug. Specific nursing interventions are listed in Chart 47-6.

Chart 47-6 Common Examples of Drug Therapy (Eyedrops)

Glaucoma

CATEGORY/DRUG	NURSING IMPLICATIONS	RATIONALES
Prostaglandins Agonists		
Bimatoprost (Lumigan) Latanoprost (Xalatan) Tafluprost (Zioptan) Travoprost (Travatan) Unoprostone (Rescula)	Teach the patient to check the cornea for abrasions or trauma.	Drugs should not be used when the cornea is not intact.
	Remind the patient that, over time, the eye color darkens and eyelashes elongate in the eye receiving the drug.	Knowing the side effects in advance reassures the patient that their presence is expected and normal.
	If only one eye is to be treated, teach the patient *not* to place drops in the other eye to try to make the eye colors similar.	Using the drug in an eye with normal IOP can cause a *lower*-than-normal IOP, which reduces vision.
	Warn the patient that using more drops than prescribed reduces drug effectiveness.	Drug action is based on blocking receptors, which can increase in number when the drug is overused.
Adrenergic Agonists		
Apraclonidine (Iopidine) Brimonidine tartrate (Alphagan) Dipivefrin hydrochloride (Propine)	Ask whether the patient is taking any antidepressants from the MAO inhibitor class, such as phenelzine (Nardil) or tranylcypromine (Parnate).	These enzyme inhibitors increase blood pressure as do the adrenergic agonists. When taken together, the patient may experience hypertensive crisis.
	Teach the patient to wear dark glasses outdoors and also indoors when lighting is bright.	The pupil dilates (mydriasis) and remains dilated, even when there is plenty of light, causing discomfort.
	Teach the patient not to use the eyedrops with contact lenses in place and to wait 15 minutes after using the drug to put in the lenses.	These drugs are absorbed by the contact lens, which can become discolored or cloudy.
Beta-Adrenergic Blockers		
Betaxolol hydrochloride (Betoptic) Carteolol (Cartrol, Ocupress) Levobunolol (Betagan) Timolol (Betimol, Istalol, Timoptic) Timoptic GFS (gel-forming solution) (Timoptic-XE, Timolol-GFS)	Ask whether the patient has moderate to severe asthma or COPD.	If these drugs are absorbed systemically, they constrict pulmonary smooth muscle and narrow airways.
	Warn diabetic patients to check their blood glucose levels more often when taking these drugs.	These drugs induce hypoglycemia and also mask the hypoglycemic symptoms.
	Teach patients who also take oral beta blockers to check their pulse at least twice per day and to notify the health care provider if the pulse is consistently below 58 beats per minute.	These drugs potentiate the effects of systemic beta blockers and can cause an unsafe drop in heart rate and blood pressure.
Cholinergic Agonists		
Carbachol (Carboptic, Isopto Carbachol, Miostat) Echothiophate (Phospholine Iodide) Pilocarpine (Adsorbocarpine, Akarpine, Isopto Carpine, Ocu-Carpine, Ocusert, Piloptic, Pilostat)	Teach the patient not to use more eyedrops than are prescribed and to report increased salivation or drooling to the health care provider.	These drugs are readily absorbed by conjunctival mucous membranes and can cause systemic side effects of headache, flushing, increased saliva, and sweating.
	Teach the patient to use good light when reading and to take care in darker rooms.	The pupil of the eye will not open more to let in more light, and it may be harder to see objects in dim light. This problem can increase the risk for falls.
Carbonic Anhydrase Inhibitors		
Brinzolamide (Azopt) Dorzolamide (Trusopt)	Ask whether the patient has an allergy to sulfonamide antibacterial drugs.	Drugs are similar to the sulfonamides, and if a patient is allergic to the sulfonamides, an allergy is likely with these drugs, even as eyedrops.
	Teach the patient to shake the drug before applying.	Drug separates on standing.
	Teach the patient not to use the eyedrops with contact lenses in place and to wait 15 minutes after using the drug to put in the lenses.	These drugs are absorbed by the contact lens, which can become discolored or cloudy.
Combination Drugs		
Brimonidine tartrate and timolol maleate (Combigan) Latanoprost and timolol (Xalcom)	Same as for each drug alone.	Same as for each drug alone.

COPD, Chronic obstructive pulmonary disease; *IOP*, intraocular pressure; *MAO*, monamine oxidase.

The priority nursing intervention for the patient on drug therapy for glaucoma is teaching. The benefit of drug therapy occurs only when the drugs are used on the prescribed schedule, usually every 12 hours. Teach patients the importance of instilling the drops on time and not skipping doses. When more than one drug is prescribed, teach him or her to wait 5 to 10 minutes between drug instillations to prevent one drug from "washing out" or diluting another drug. Stress the need for good handwashing, keeping the eyedrop container tip clean, and avoiding touching the tip to any part of the eye. Also teach the technique of punctal occlusion (placing pressure on the corner of the eye near the nose) immediately after eyedrop instillation to prevent systemic absorption of the drug (Fig. 47-8).

FIG. 47-8 Applying punctal occlusion to prevent systemic absorption of eyedrops.

Nursing Safety Priority QSEN

Drug Alert

Most eyedrops used for glaucoma therapy can be absorbed systemically and cause systemic problems. It is critical to teach punctal occlusion to patients using eyedrops for glaucoma therapy.

Systemic osmotic drugs may be given for angle-closure glaucoma to rapidly reduce IOP. These agents include oral glycerin and IV mannitol (Osmitrol).

Surgical Management.

Surgery is used when drugs for open-angle glaucoma are not effective at controlling IOP. Two common procedures are laser trabeculoplasty and trabeculectomy. A *laser trabeculoplasty* burns the trabecular meshwork, scarring it and causing the meshwork fibers to tighten. Tight fibers increase the size of the spaces between the fibers, improving outflow of aqueous humor and reducing IOP. *Trabeculectomy* is a surgical procedure that creates a new channel for fluid outflow. Both are ambulatory surgery procedures.

If glaucoma fails to respond to common approaches, an implanted shunt procedure may be used. A small tube or filament is connected to a flat plate that is positioned on the outside of the eye in the eye orbit. (The

plate is not visible on the front part of the eye.) The open part of the fine tube is placed into the front chamber of the eye. The fluid then drains through or around the tube into the area around the flat plate where it collects and is reabsorbed into the bloodstream. Potential complications of glaucoma surgery include choroidal hemorrhage and choroidal detachment.

NCLEX Examination Challenge

Safe and Effective Care Environment

Which assessment is most important for the nurse to perform before instilling travoprost (Travatan) into the client's eye?
A Measuring the client's blood pressure
B Measuring the client's intraocular pressure
C Checking the cornea for abrasions or open areas
D Assessing heart rate and rhythm for 1 full minute

Retinal Disorders

Macular Degeneration

Pathophysiology

Macular degeneration is the deterioration of the macula (the area of central vision) and can be age-related or exudative. Age-related macular degeneration (AMD) has two types. The most common type is *dry* AMD, caused by gradual blockage of retinal capillaries, allowing retinal cells in the macula to become ischemic and necrotic. Central vision declines, and patients describe mild blurring and distortion at first. Eventually the person loses all central vision. About 2.5 million older adults in the United States and Canada have dry AMD (National Eye Institute, 2012). This loss of visual sensory perception affects independence, well-being, and quality of life. It is often the reason an older adult leaves his or her independent living environment and moves into an assisted-living facility (Touhy & Jett, 2014).

Dry AMD is more common and progresses at a faster rate among smokers than among nonsmokers. Other risk factors include hypertension, female gender, short stature, family history, and a long-term diet poor in carotene and vitamin E.

Another cause of AMD is the growth of new blood vessels in the macula, which have thin walls and leak blood and fluid (*wet* AMD). Exudative macular degeneration is also a type of wet macular degeneration but can occur at any age. The condition can occur in only one eye or in both eyes. The person with dry AMD can also develop exudative macular degeneration. Patients with exudative degeneration have a sudden decrease in vision after a detachment of pigment epithelium in the macula. Newly formed blood vessels invade this injured area and cause fluid and blood to collect under the macula (like a blister), with scar formation and visual distortion.

Patient-Centered Collaborative Care

Dry AMD has no cure. Management is focused on slowing the progression of the vision loss and helping the patient maximize remaining vision (Kerr, 2013). The risk for dry AMD can be reduced by increasing long-term dietary intake of antioxidants, vitamin B_{12}, and the carotenoids *lutein* and *zeaxanthin*. The same dietary therapy slows the progression of dry AMD.

Central vision loss reduces the ability to read, write, recognize safety hazards, and drive. Suggest alternatives (e.g., large-print books, public

transportation) and referrals to community resources that provide adaptive equipment. See pp. 992-994 of Patient-Centered Collaborative Care in the Reduced Visual Sensory Perception section for discussion of patient care needs.

Management of patients with exudative or wet AMD is geared toward slowing the process and identifying further changes in visual perception. Fluid and blood may resorb in some patients. Laser therapy to seal the leaking blood vessels can limit the extent of the damage. Ocular injections with the vascular endothelial growth factor inhibitors (VEGFIs), such as bevacizumab (Avastin) or ranibizumab (Lucentis), can improve vision for the patient with wet AMD.

NCLEX Examination Challenge

Health Promotion and Maintenance

Which precaution is most important for the nurse to teach a 62-year-old client newly diagnosed with early-stage dry age-related macular degeneration?

A Quit smoking
B Quit drinking alcoholic beverages
C Eat more dark green, red, and yellow vegetables
D Wear dark glasses whenever he or she is outside or in bright interior lighting environments

Retinal Holes, Tears, and Detachments

Pathophysiology

A **retinal hole** is a break in the retina. These holes can be caused by trauma or can occur with aging. A **retinal tear** is a more jagged and irregularly shaped break in the retina. It can result from traction on the retina. A **retinal detachment** is the separation of the retina from the epithelium. Detachments are classified by the type and cause of their development.

Patient-Centered Collaborative Care

The onset of a retinal detachment is usually sudden and painless. Patients may suddenly see bright flashes of light (**photopsia**) or floating dark spots in the affected eye. During the initial phase of the detachment or if the detachment is partial, the patient may describe the sensation of a curtain being pulled over part of the visual field. The visual field loss

corresponds to the area of detachment.

On ophthalmoscopic examination, detachments are seen as gray bulges or folds in the retina. Sometimes a hole or tear may be seen at the edge of the detachment.

If a retinal hole or tear is discovered before it causes a detachment, the defect may be closed or sealed. Closure prevents fluid from collecting under the retina and reduces the risk for a detachment. Treatment involves creating a scar that will bind the retina and choroid together around the break. Common methods to create the scar are with laser photocoagulation or with a freezing probe (cryopexy).

Spontaneous reattachment of a totally detached retina is rare. Surgical repair is needed to place the retina in contact with the underlying structures. A common repair procedure is scleral buckling.

Preoperative Care

The patient is usually anxious and fearful about a possible permanent loss of vision. *Nursing priorities include providing information and reassurance to allay fears.*

Instruct the patient to restrict activity and head movement before surgery to prevent further tearing or detachment. An eye patch is placed over the affected eye to reduce eye movement. Topical drugs are given before surgery to inhibit pupil constriction and accommodation.

Operative Procedures

The surgery is performed with the patient under general anesthesia. In scleral buckling, the ophthalmologist repairs wrinkles or folds in the retina and indents the eye surface to relieve the tugging pressure on the retina. The indentation or "buckling" is performed by placing a small piece of silicone against the outside of the sclera and holding it in place with an encircling band. This device keeps the retina in contact with the choroid for reattachment. Any fluid under the retina is drained.

A gas or silicone oil placed inside the eye can be used to promote retinal reattachment. These agents float up and against the retina to hold it in place until healing occurs.

Postoperative Care

After surgery an eye patch and shield usually are applied. Monitor the patient's vital signs, and check the eye patch and shield for any drainage.

Activity after surgery varies. If gas or oil has been placed in the eye, teach the patient to keep his or her head in the position prescribed by the surgeon to promote reattachment. Teach the patient to report any sudden

increase in pain or pain occurring with nausea to the surgeon immediately. Remind the patient to avoid activities that increase intraocular pressure (IOP) (see Table 47-1).

Instruct the patient to avoid reading, writing, and close work, such as sewing, in the first week after surgery because these activities cause rapid eye movements and detachment. Teach him or her the manifestations of infection and detachment (sudden reduced visual acuity, eye pain, pupil that **does not constrict** in response to light) and to notify the surgeon immediately if these manifestations occur.

Clinical Judgment Challenge

Safety; Patient-Centered Care QSEN

The patient is a 68-year-old retired college professor who was recently widowed. He lives alone with a cat. His main leisurely activities are reading, using the computer, and listening to classical music. While hiking with a friend, he pulled himself along a rope bridge, assuming a variety of positions. At the far end of the bridge, he stood up and noticed that the vision in his right eye was greatly reduced to the extent that he could see only the bottom half of the visual field. His friend insisted that the patient go immediately to the emergency department. Once there, a large partial retinal detachment is diagnosed. It is treated within the hour with laser therapy and the injection of a gas to the affected eye. He is permitted to go home and instructed to sit upright with his head bent slightly downward for the next 24 hours and then to return to the ophthalmology office. He tells you that he really likes wine and sometimes drinks as much as two bottles in an evening.

1. Should he drive himself home? Why or why not?
2. Is drinking permitted at this time? Why or why not?
3. What will you tell him about a sleeping position?
4. What suggestions and precautions do you have for him about caring for the cat?
5. Which of the leisure-time activities can he perform this evening and which ones should he avoid? Provide a rationale for your choices.

Retinitis Pigmentosa

Several types of retinal disorders can cause progressive degeneration of the retina and lead to loss of visual sensory perception. Retinitis pigmentosa (RP) is a condition in which retinal nerve cells degenerate and the pigmented cells of the retina grow and move into the sensory areas of the

retina, causing further degeneration.

Genetic/Genomic Considerations

Patient-Centered Care QSEN

Different forms of retinitis pigmentosa can be inherited as an autosomal dominant (AD) trait, an autosomal recessive (AR) trait, or an X-linked recessive trait (Online Mendelian Inheritance in Man [OMIM], 2014). Mutations in more than 20 genes have been identified as being responsible for retinitis pigmentosa, and gene testing for more than 800 mutations of the AR and AD forms of the problem is commercially available.

The earliest manifestation of RP is night blindness, often occurring in childhood. Over time, decreased acuity progresses to total blindness. Examination of the retina shows heavy pigmentation in a lacy pattern. Cataracts may accompany this disorder.

No current therapy is effective in preventing the degenerative process. Management strategies focus on protecting active retinal cells and slowing the progression of disease. Teach patients with RP to avoid drugs that are known to adversely affect retinal cells, such as isotretinoin (Accutane) and drugs for erectile dysfunction (e.g., sildenafil [Viagra]). Also remind them to wear eyeglasses that provide ultraviolet protection. The ingestion of 15,000 international units of vitamin A daily is recommended to slow the progression of the disorder, as is the daily ingestion of docosahexaenoic acid (DHA), an omega-3 fatty acid and antioxidant. Additional supplements that may slow the progression of RP include beta carotene, lutein, and zeaxanthin. When macular edema is present, oral acetazolamide (Diamox) can reduce the edema. Cataract surgery and lens replacement is recommended when cataracts further reduce vision. Other treatments under investigation include retinal transplantation, stem cell therapy, and gene therapy (Foundation Fighting Blindness, 2012).

Refractive Errors

Pathophysiology

The ability of the eye to focus images on the retina depends on the length of the eye from front to back and the refractive power of the lens system. **Refraction** is the bending of light rays. Problems in either eye length or refraction can result in refractive errors.

Myopia is nearsightedness, in which the eye over-refracts the light and the bent images fall in front of, not on, the retina. **Hyperopia**, also called *hypermetropia*, is farsightedness, in which refraction is too weak, causing images to be focused behind the retina. **Presbyopia** is the age-related problem in which the lens loses its elasticity and is less able to change shape to focus the eye for close work. As a result, images fall behind the retina. This problem usually begins in people in their 30s and 40s. **Astigmatism** occurs when the curve of the cornea is uneven. Because light rays are not refracted equally in all directions, the image does not focus on the retina.

Patient-Centered Collaborative Care

Refractive errors are diagnosed through a process known as **refraction**. The patient is asked to view an eye chart while lenses of different strengths are systematically placed in front of the eye. With each lens strength, he or she is asked whether the lenses sharpen or worsen vision. The strength of the lens needed to focus the image on the retina is expressed in measurements called *diopters*.

Nonsurgical Management

Refractive errors are corrected with eyeglass lenses or contact lenses that focus light rays on the retina (see Fig. 46-5 in Chapter 46). Hyperopic vision is corrected with a convex lens that moves the image forward. Myopic vision is corrected with a biconcave lens to move the image back to the retina.

Surgical Management

Surgery can correct some refractive errors and enhance vision. The most common vision-enhancing surgery is laser in-situ keratomileusis (LASIK). This procedure can correct nearsightedness, farsightedness, and astigmatism. The superficial layers of the cornea are lifted temporarily as a flap, and powerful laser pulses reshape the deeper corneal layers. After reshaping is complete, the corneal flap is placed

back into its original position.

Usually both eyes are treated at the same time, which is convenient for the patient, although this practice has some risks. Many patients have improved vision within an hour after surgery, and complete healing to best vision takes up to 4 weeks. The outer corneal layer is not damaged, and pain is minimal.

Complications of LASIK include infection, corneal clouding, chronic dry eyes, and refractive errors. Some patients have developed blurred vision, halos around lights, and other refractive errors months to years after this surgery as a result of excessive laser-thinning of the cornea. The cornea then becomes unstable and does not refract appropriately.

Another procedure, corneal ring placement, can enhance vision for nearsightedness, although this procedure is usually performed for keratoconus. For more information about the procedure, see surgical intervention for keratoconus on pp. 981-982.

Trauma

Trauma to the eye or orbital area can result from almost any activity. Care varies depending on the area of the eye affected and whether the globe of the eye has been penetrated.

Foreign Bodies

Eyelashes, dust, dirt, and airborne particles can come in contact with the conjunctiva or cornea and irritate or abrade the surface. If nothing is seen on the cornea or conjunctiva, the eyelid is everted to examine the conjunctivae. The patient usually has a feeling of something being in the eye and may have blurred vision. Pain occurs if the corneal surface is injured. Tearing and photophobia may be present.

Visual sensory perception is assessed before treatment. The eye is examined with fluorescein, followed by irrigation with normal saline (0.9%) to gently remove the particles. Best practices for ocular irrigation are listed in Chart 47-7.

Chart 47-7 Best Practice for Patient Safety & Quality Care QSEN

Ocular Irrigation

1. Assemble equipment:
   - Normal saline IV (1000-mL bag)
   - Macrodrip IV tubing
   - IV pole
   - Eyelid speculum
   - Topical anesthetic (proparacaine hydrochloride)
   - Gloves
   - Collection receptacle (emesis basin works well)
   - Towels
   - pH paper
2. Quickly obtain a history from the patient while flushing the tubing with normal saline:
   - Nature and time of the injury
   - Type of irritant or chemical (if known)
   - Type of first aid administered at the scene
   - Any allergies to the "caine" family of medications
3. Evaluate the patient's visual acuity *before* treatment:
   - Ask the patient to read your name tag with the affected eye while

covering the good eye.
- Ask the patient to "count fingers" with the affected eye while covering the good eye.

4. Put on gloves.
5. Place a strip of pH paper in the cul-de-sac of the patient's affected eye to test the pH of the agent splashed into the eye and to know when it has been washed out.
6. Instill proparacaine hydrochloride eyedrops as prescribed.
7. Place the patient in a supine position with the head turned slightly toward the affected eye.
8. Have the patient hold the affected eye open, or position an eyelid speculum.
9. Direct the flow of normal saline across the affected eye from the nasal corner of the eye toward the outer corner of the eye.
10. Assess the patient's comfort during the procedure.
11. If both eyes are affected, irrigate them simultaneously using separate personnel and equipment.

If an eye patch is applied after the foreign body is removed, tell the patient how long the patch must be left in place. Follow-up with the ophthalmologist is needed.

Lacerations

Lacerations are caused by sharp objects and projectiles. The injury occurs most commonly to the eyelids and cornea, although any part of the eye can be lacerated.

The patient should receive medical attention as soon as possible. Initially the eye is closed and a small ice pack is applied to decrease bleeding. Minor lacerations of the eyelid can be sutured in an emergency department, an urgent care center, or an ophthalmologist's office. A microscope is needed in the operating room if the patient has a laceration that involves the eyelid margin, affects the lacrimal system, involves a large area, or has jagged edges.

Corneal lacerations are an emergency because eye contents may prolapse through the laceration. Manifestations include severe eye pain, photophobia, tearing, decreased vision, and inability to open the eyelid. If the laceration is the result of a penetrating injury, an object may be seen protruding from the eye.

Nursing Safety Priority QSEN

Action Alert

An object protruding from the eye is removed only by an ophthalmologist because it may be holding the eye structures in place. Improper removal can cause structures to prolapse out of the eye.

Antibiotics are given to reduce the risk for infection. Depending on the depth of the laceration, scarring may develop. If the scar alters vision, a corneal transplant may be needed later. If the eye contents have prolapsed through the laceration or if the injury is severe, **enucleation** (surgical eye removal) may be indicated.

Penetrating Injuries

A penetrating eye injury often leads to permanent loss of visual sensory perception. Glass, high-speed metal or wood particles, BB pellets, and bullets are common causes of penetrating injuries. The particles can enter the eye and lodge in or behind the eyeball.

The patient has eye pain and reports "I suddenly felt something hit my eye." A wound may be visible. Depending on where the object enters and rests within the eye, vision may be affected.

X-rays and CT scans of the orbit are usually performed. *MRI is contraindicated because the procedure may move any metal-containing projectile and cause more injury.*

Surgery is usually needed to remove the foreign object, and sometimes vitreal removal is needed. IV antibiotics are started before surgery, and a tetanus booster is given if necessary.

Ocular Melanoma

Pathophysiology

Melanoma is the most common malignant eye tumor in adults (American Cancer Society, 2014). This tumor occurs most often in the uveal tract among people in their 30s and 40s and is associated with exposure to ultraviolet (UV) light. Because of its rich blood supply, a melanoma can spread by extension through the sclera or invasion into nearby tissue and the brain.

Patient-Centered Collaborative Care

Manifestations of melanoma may not be readily apparent; the tumor may be discovered during a routine examination. Blurred vision may occur if the macular area is invaded. Vision is reduced if the tumor grows inward toward the center of the eye and alters the visual pathway. Increased intraocular pressure (IOP) can result if the tumor obstructs flow of aqueous humor. Iris color changes when the tumor infiltrates the iris. Sudden loss of a visual field may result from tumor invasion that causes retinal detachment.

Diagnostic tests for a melanoma depend on the size and tumor growth rate. Ultrasonography or MRI is performed to determine the tumor's location and size. Treatment depends on the tumor's size and growth rate, as well as the condition of the other eye. Small iris lesions are monitored until growth is observed. Tumors of the choroid are treated by surgical enucleation or by radiation therapy with a radioactive plaque.

Enucleation (surgical removal of the entire eyeball) is the most common surgery for ocular melanoma and is performed under general anesthesia. After the eye is removed, a ball implant is inserted as a base for the socket prosthesis, which is fitted about 1 month after surgery.

Radiation therapy is an "eye-sparing" procedure that can reduce the size and thickness of melanomas and sometimes eliminates the tumor completely. The radioactive plaque—a round, flat disk about the size of a dime and containing a radioactive material—is sutured to the sclera overlying the tumor site. The length of time the plaque remains sutured to the sclera depends on the size of the tumor and the dose of radiation to be delivered (usually 3 to 6 days).

Complications of radiation therapy include vascular changes, retinopathy, glaucoma, necrosis of the sclera, and cataract formation. Vitreous hemorrhage may develop as the tumor becomes smaller and pulls or breaks blood vessels.

While the plaque is in place, an eye patch may or may not be used. Cycloplegic eyedrops and an antibiotic-steroid combination are given. Teach the patient how to instill eyedrops.

Reduced Visual Sensory Perception

Pathophysiology

Different forms of reduced visual sensory perception may affect color, light, image, eye movement, and acuity. Reduced vision may be temporary, such as when cataracts obscure vision but surgery has not yet been performed. Patients are legally blind if their best visual acuity with corrective lenses is 20/200 or less in the better eye or if the visual field is 20 degrees or less.

Blindness can occur in one or both eyes. When one eye is affected, the field of vision is narrowed and depth perception is impaired.

Patient-Centered Collaborative Care

Priorities for nursing involve safety and teaching the patient with reduced visual sensory perception some techniques to make better use of existing vision. Moving the head slightly up and down can enhance a three-dimensional effect. When shaking hands or pouring water, the patient can line up the object and move toward it. He or she should choose a position that favors the eye with better vision. For example, people with vision in the right eye should position people and items on their right.

Nursing interventions for the patient with reduced sight focus on communication, safety, ambulation, self-care, and support. Chart 47-8 lists ways to help patients with reduced vision to function as independently as possible.

Chart 47-8 Best Practice for Patient Safety & Quality Care QSEN

Care of the Patient with Reduced Vision

- Always knock or announce your entrance into the patient's room or area and introduce yourself.
- Ensure that all members of the health care team also use this courtesy of announcement and introduction.
- Ensure that the patient's reduced vision is noted in the medical record, is communicated to all staff, is marked on the call board, and is identified on the door of the patient's room.
- Determine to what degree the patient can see anything.
- Orient the patient to the environment, counting steps with him or her

to the bathroom.
- Assist the patient in placing objects on the bedside table or in the bed and around the bed and room, and do not move them without the patient's permission.
- Remove all objects and clutter between the patient's bed and the bathroom.
- Ask the patient what type of assistance he or she prefers for grooming, toileting, eating, and ambulating, and communicate these preferences with the staff.
- Describe food placement on a plate in terms of a clock face.
- Open milk cartons; open salt, pepper, and condiment packages; and remove lids from cups and bowls.
- Unless the patient also has a hearing problem, use a normal tone of voice when speaking.
- When walking with the patient, offer him or her your arm and walk a step ahead.

Communication is important in helping the patient remain independent and connected to the world. Many adaptive devices are available to help the person with reduced vision maintain independence. Many cities have auditory traffic signals so that people with reduced vision can know when it is safe to cross a street. Curbs in these areas may have high-contrast color paint to let the person know when to step up or down. Libraries have large-print books and books on disc. "Talking" clocks, watches, and timers are available. Playing cards, games, restaurant menus, calendars, and instruction booklets are available in large print sizes using bold black print, sans-serif fonts, and white or yellow backgrounds (Russo & Bowden, 2013). Computer keyboards with high contrast and larger letters on the keys are available, as are large screens. Direct the patient with reduced vision to the local resources to obtain adaptive items and to learn how to use them (Warren, 2013).

Safety is a major issue for the person with reduced vision. For most patients, home is the place where they feel most safe because they are familiar with room and item location. For example, they may have counted the number of footsteps needed to move from one area to another. Stress to family members not to change item locations without input from the patient. Teach family members with vision to make these home adaptations to increase the patient's independence and safety:
- Using tape and a heavy black marker, mark the 350-degree temperature setting on the oven and mark the 70-degree temperature setting on the heating or cooling thermostat.

- Paint or mark light switches in a deep color that contrasts with the surrounding wall.
- Label canned goods with large, bold, black letters on white tape.
- Teach the patient to feel for the crease in paper milk cartons that indicates the place to open the spout.
- Differentiate different drugs by altering the shape of a bottle. Rubber bands can be wound around a bottle to change its texture. Raised symbols can be glued to caps to make identification easier.

The patient with reduced visual sensory perception is most at risk for safety problems in an unfamiliar or changing environment. When he or she must be hospitalized, promote safety and independence by orienting him or her to the new environment.

Many people with reduced vision had sight at some time and have background knowledge regarding size and shape that can be used when providing information. When talking with a person who has limited vision, use a normal tone of voice unless he or she also has a hearing problem.

First orient the patient to the immediate environment, including the size of the room. Use one object in the room, such as a chair or hospital bed, as the focal point for the description. Guide the person to the focal point, and orient him or her to the environment from that point. For example, you might say "To the left of the bed is a chair." Then describe all other objects in relation to the focal point. Go with the patient to the bathroom so that he or she can learn this location. Highlight the location of the toilet, sink, and toilet paper. Use specific descriptors, and avoid gestures or vague language (Warren, 2013). For example, say "the wall to the right of the door" instead of "over there."

Nursing Safety Priority QSEN

Action Alert

Never leave the patient with reduced vision in the center of an unfamiliar room.

Patients with reduced vision prefer to establish the location of important objects, such as the call light, water pitcher, and clock. Once their location has been fixed, do not move these items without the patient's consent. Do not move the location of chairs, stools, and wastebaskets without consulting the patient.

At mealtime, set up food on the tray using clock placement. For

example, “There is sliced ham at the 6 o'clock position; peas are located at the 3 o'clock position; to the right of the plate is coffee; salt and pepper are next to the coffee.”

Ambulation with a patient who has reduced vision is best when he or she holds your arm at the elbow. Keep the arm close to your body so that the patient can detect your direction of movement. Alert him or her when obstacles are in the path ahead.

Patients may use a cane to detect obstacles, such as furniture, walls, or curbs. The cane is held several inches off the floor and sweeps the ground where the foot will be placed next. The laser cane sends out signals to help detect obstacles.

Self-care and the ability to control the environment are important. Knock on the door before entering the hospital room or any other environment of a patient with reduced vision. State your name and the reason for visiting when entering the room. Coordinate with other members of the health care team to ensure this etiquette is used consistently. Mark the door to the room to indicate it is occupied by a person with reduced visual sensory perception.

Support is needed, especially when the reduced vision occurs suddenly and may be permanent. The reactions are similar to the reaction to loss of a body part. Allow the newly blind person a period of grieving for the “dead” (nonseeing) eye. He or she may feel hopeless and angry. The ability to cope may begin within days, but some patients mourn for months or years.

Patients benefit from the honest support that you can provide. They need to hear that it is normal to mourn, to cry, and to feel the loss. Help them move toward acceptance by encouraging the mastery of one task at a time and by providing positive reinforcement for each success.

NCLEX Examination Challenge

Safe and Effective Care Environment

Which action by a nurse is most likely to increase accurate communication with a client who has low vision?

A Speaking slowly and loudly
B Enhancing the talk using hand gestures
C Being very specific with descriptions and directions
D Marking the door of the client's room to indicate his or her vision status

What might you NOTICE if the patient is experiencing reduced visual sensory perception?

Assessment:

- Patient squints or tilts the head when viewing objects or print at a distance.
- Patient closes one eye to read or see at a distance.
- Patient moves reading materials either very close to his or her face or as far away from the face as he or she can reach.
- Patient may not startle when a sudden move is made at the face.
- Pupils are unequal and may not react to light.
- Eyes do not focus on a distant object and track it as it is moved closer to the face.
- Red reflex may be absent or present in only one eye.
- Patient does not make eye contact and turns head toward sounds rather than sights.
- Patient walks with hesitation into a room or bumps into objects in his or her path.
- Patient may seem confused about time and place.

What should you INTERPRET and how should you RESPOND to a patient experiencing reduced visual sensory perception?

Interpret by:

- Assessing visual acuity with an eye chart, counting fingers, hand motion, or light perception
- Asking the patient to describe the objects in the room and their colors
- Asking the patient what he or she can see well and what is more difficult to see

Respond by:

- Orienting the patient to the immediate surroundings
- Offering your arm for the patient to hold when he or she is moving to a different location
- Not leaving the patient alone in the center of a strange room
- Asking him or her what assistance is needed for independent activity
- Assessing the immediate environment for safety hazards and removing the hazard

On what should you REFLECT?

- Consider what environmental changes could make the unit safer or more manageable for a person with reduced vision.

Get Ready for the NCLEX® Examination!

Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Use aseptic technique when performing an eye examination or instilling drugs into the eye. **Safety** QSEN
- Apply the principles of infection control when caring for a patient with an eye infection. **Safety** QSEN
- Avoid performing an ophthalmoscopic examination on a confused patient. **Safety** QSEN
- Orient the patient with reduced vision to his or her immediate surroundings, including how to call for help and where the bathroom is located. **Safety** QSEN
- Identify the room of a patient with reduced vision. **Safety** QSEN
- Never administer a topical ophthalmic liquid or ointment by the oral route. **Safety** QSEN

Health Promotion and Maintenance

- Identify people at risk for visual sensory perception problems as a result of work environment or leisure activities, and teach them specific ways to protect the eyes. **Patient-Centered Care** QSEN
- Encourage all patients to wear eye protection when they are performing yard work, are working in a woodshop or metal shop, are using chemicals, or are in any environment in which drops or particulate matter is airborne.
- Encourage all adult patients older than 40 years and those with chronic disorders that affect the eye and vision to have an eye examination with measurement of intraocular pressure every year. **Patient-Centered Care** QSEN
- Encourage everyone to use polarizing sunglasses whenever outdoors in the daytime. **Patient-Centered Care** QSEN
- Teach all patients to wash their hands before and after touching the eyes. **Patient-Centered Care** QSEN
- Teach family members who have good vision to make the adaptations for the patient's home listed on p. 993 to increase the patient's independence and safety. **Patient-Centered Care** QSEN

Psychosocial Integrity

- Teach patients and family members about what to expect during procedures to correct visual sensory perception and eye problems.
- Provide opportunities for the patient and family to express concerns about a change in visual sensory perception.
- Refer the patient with reduced visual sensory perception to local services, resources, and support groups for the blind and those with low vision. **Patient-Centered Care** QSEN
- Teach the patient with reduced visual sensory perception techniques for performing ADLs and self-care independently. **Patient-Centered Care** QSEN
- Use a normal tone of voice to talk with a patient who has a vision problem and normal hearing.
- Knock on the door before entering the room of a patient with reduced visual sensory perception and introduce yourself. **Patient-Centered Care** QSEN

Physiological Integrity

- Ask the patient about vision problems in any other members of the family, because many vision problems have a genetic component. **Evidence-Based Practice** QSEN
- Teach patients the proper techniques for self-instillation of eyedrops and eye ointment. **Safety** QSEN
- Stress the importance of completing an antibiotic regimen for an eye infection. **Evidence-Based Practice** QSEN
- When instilling more than one type of eyedrop into the same eye, wait 5 to 10 minutes (or as directed by the manufacturer) between instillations. **Evidence-Based Practice** QSEN
- Teach patients who are at risk for increased intraocular pressure (IOP) what activities to avoid (see Table 47-1). **Patient-Centered Care** QSEN
- Teach patients with an infection of the eye or eyelid not to rub the eye (to avoid infecting the other eye). **Evidence-Based Practice** QSEN
- Instruct the patient who has cataract surgery to report immediately any reduction in vision after initial improvement in vision in the eye that had cataract surgery. **Patient-Centered Care** QSEN
- Stress the importance of using antiglaucoma eyedrop agents exactly as prescribed to prevent IOP from increasing and to prevent complications of glaucoma drug therapy. **Patient-Centered Care** QSEN
- Never attempt to remove any object protruding from the eye. **Safety** QSEN

- Use and teach punctal occlusion technique when administering antiglaucoma eyedrops. **Safety** QSEN
- Work with the physician, occupational therapist, social worker, and other health care professionals to increase the patient's independence and safety within the home and the community. **Teamwork and Collaboration** QSEN

CHAPTER 48

Assessment and Care of Patients with Ear and Hearing Problems

M. Linda Workman

PRIORITY CONCEPTS

- Sensory Perception

Learning Outcomes

Safe and Effective Care Environment

1. Protect the patient with ear and hearing problems from injury and infection.

Health Promotion and Maintenance

2. Teach all people how to protect the ear and hearing.
3. Teach patients who need them how to use hearing assistive devices.

Psychosocial Integrity

4. Reduce the psychological impact for the patient and family experiencing a potential change in auditory sensory perception.
5. Work with other members of the health care team to ensure that the values, preferences, and expressed needs of the patient with reduced auditory sensory perception are respected.

Physiological Integrity

6. Perform a focused assessment of the ear and auditory sensory perception, incorporating information about anatomy and physiology, genetic risk, environmental risk, and age-related changes affecting the ear and hearing.

7. Use laboratory data and clinical manifestations to evaluate and prioritize the nursing care needs for the patient with a problem of the ear or hearing.
8. Prioritize the nursing care and educational needs of the patient with Ménière's disease.
9. Prioritize nursing care and educational needs for the patient after ear surgery.
10. Collaborate with other health care professionals to help patients and families experiencing reduced auditory sensory perception achieve desired health outcomes.

http://evolve.elsevier.com/Iggy/

Together, the ear and the brain allow auditory sensory perception. Hearing is one of the five senses important for cognition and communicating with others. It is used to assess surroundings, allow independence, warn of danger, appreciate music, work, play, and interact with other people.

Ear and hearing problems are common among adults of all ages. Assessment of the ear and hearing is an important skill for nurses in any care environment. Many ear and hearing problems develop over long periods and may be affected by drugs or systemic health problems. Auditory sensory perception problems reduce the ability to fully communicate with the world and can lead to confusion, mistrust, and social isolation.

Anatomy and Physiology Review

Structure

The ear has three divisions: the external ear, the middle ear, and the inner ear. Each part is important to hearing.

External Ear

The external ear develops in the embryo at the same time as the kidneys and urinary tract. Thus any person with a defect of the external ear should be examined for possible problems of the kidney and urinary systems.

The *pinna* is the part of the external ear that is composed of cartilage covered by skin and attached to the head at about a 10-degree angle at the level of the eyes. The external ear extends from the pinna through the external ear canal to the *tympanic membrane* (eardrum) (Fig. 48-1). The external ear includes the *mastoid process,* which is the bony ridge located over the temporal bone behind the pinna. The ear canal is slightly S-shaped and lined with cerumen-producing glands, oil glands, and hair follicles. Cerumen (ear "wax") helps protect and lubricate the ear canal. The distance from the opening of the ear canal to the eardrum in an adult is 1 to $1\frac{1}{2}$ inches (2.5 to 3.75 cm).

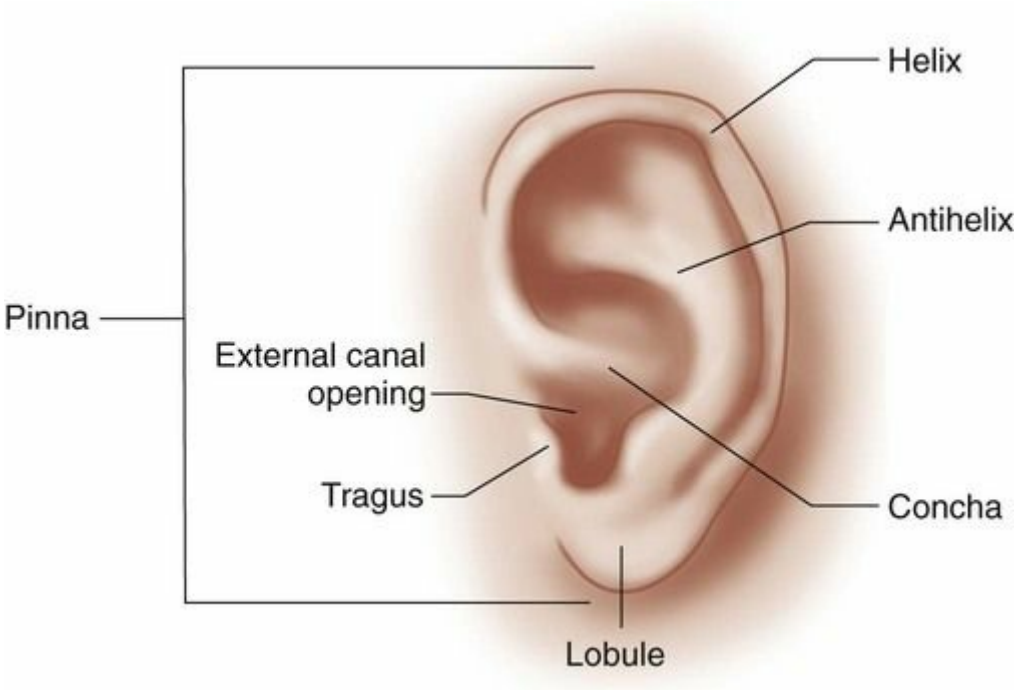


FIG. 48-1 Anatomic features of the external ear.

Middle Ear

The eardrum separates the external ear and the middle ear. The middle ear consists of a compartment called the *epitympanum*. Located in the epitympanum are the top opening of the eustachian tube and three small bones known as the *bony ossicles,* which are the *malleus* (hammer), the *incus* (anvil), and the *stapes* (stirrup) (Fig. 48-2). The bony ossicles are joined loosely, thereby moving with vibrations created when sound waves hit the eardrum.

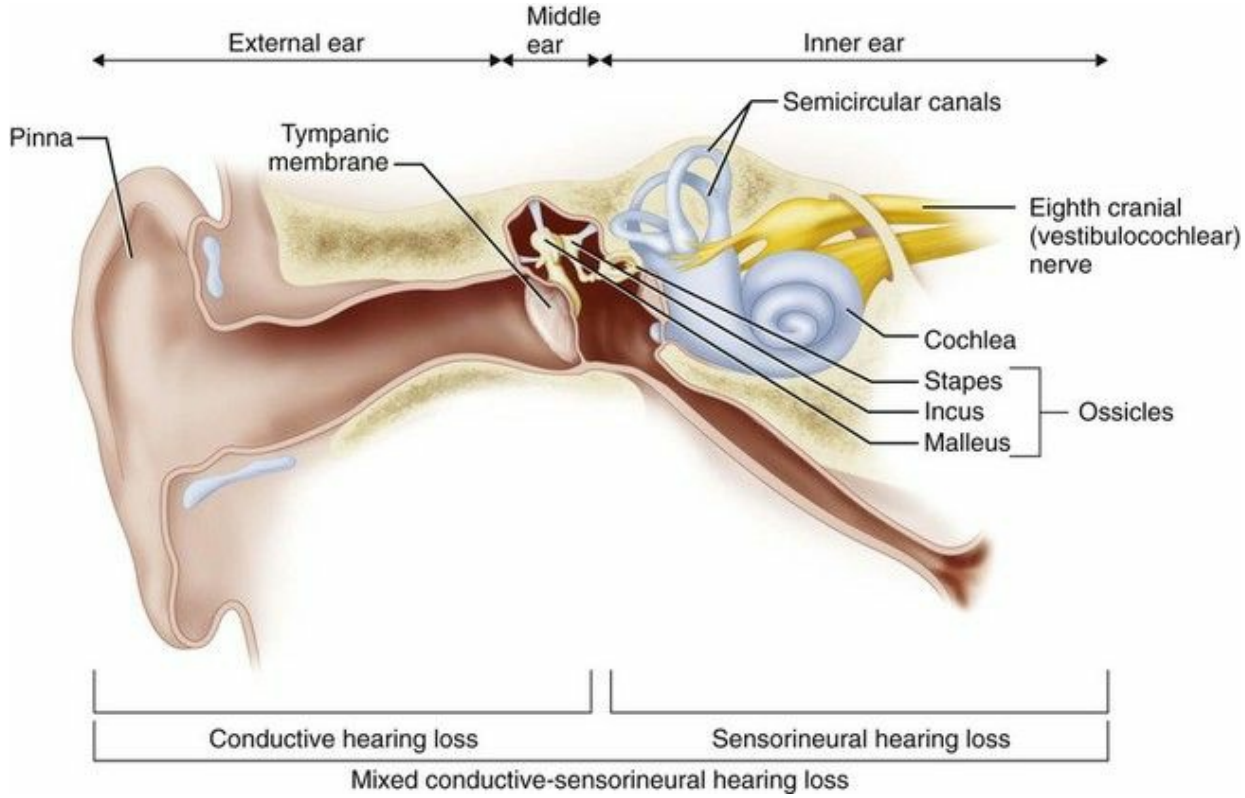

FIG. 48-2 Anatomic features of the middle and inner ear and areas involved in the three types of hearing loss.

The eardrum is a thick sheet of tissue; is transparent, opaque, or pearly gray; and moves when air is injected into the external canal. The landmarks on the eardrum include the *annulus,* the *pars flaccida,* and the *pars tensa*. These correspond to the parts of the malleus that can be seen through the transparent eardrum. The eardrum is attached to the first bony ossicle, the malleus, at the umbo (Fig. 48-3). The umbo is seen through the eardrum membrane as a white dot and is one end of the long process of the malleus. The pars flaccida is that portion of the eardrum above the short process of the malleus. The pars tensa is that portion surrounding the long process of the malleus.

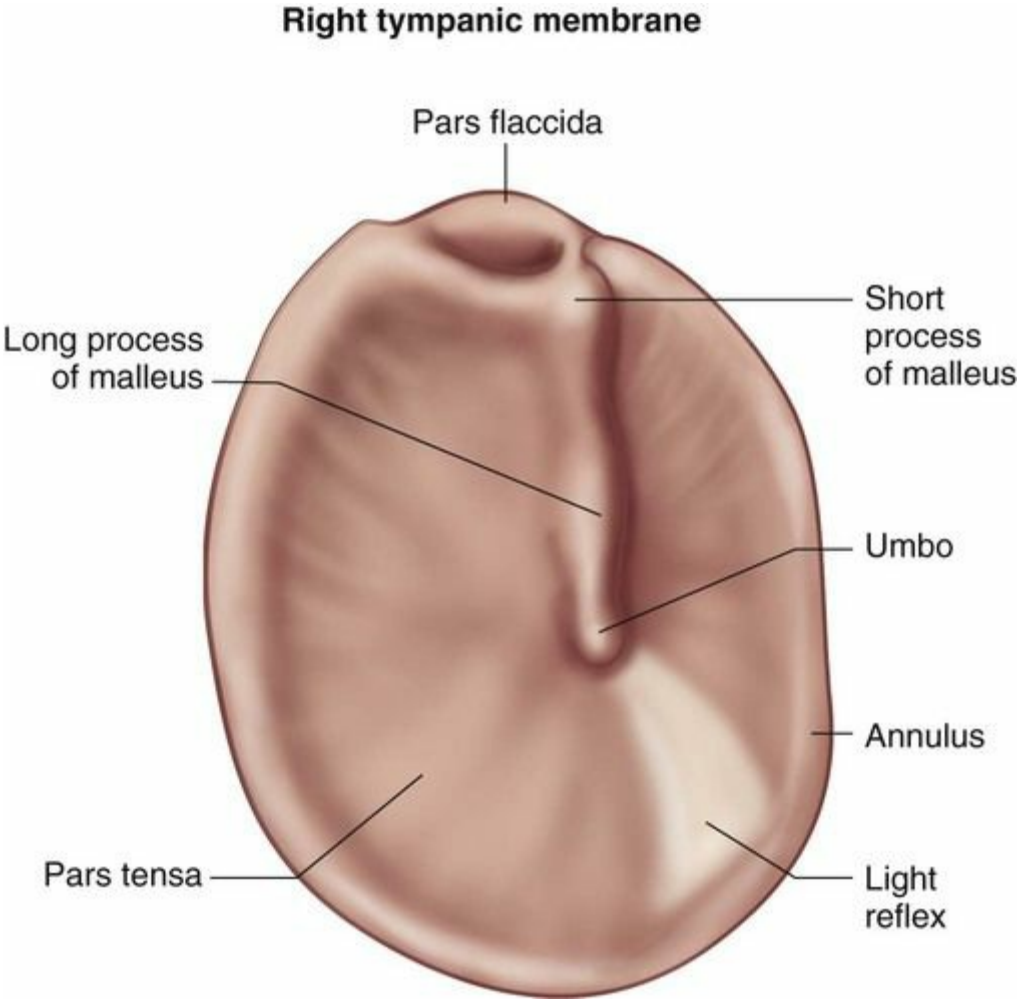

FIG. 48-3 Landmarks on the tympanic membrane.

The middle ear is separated from the inner ear by the round window and the oval window. The eustachian tube begins at the floor of the middle ear and extends to the throat. The tube opening in the throat is surrounded by adenoid lymphatic tissue (Fig. 48-4). The eustachian tube allows the pressure on both sides of the eardrum to equalize. Secretions from the middle ear drain through the tube into the throat.

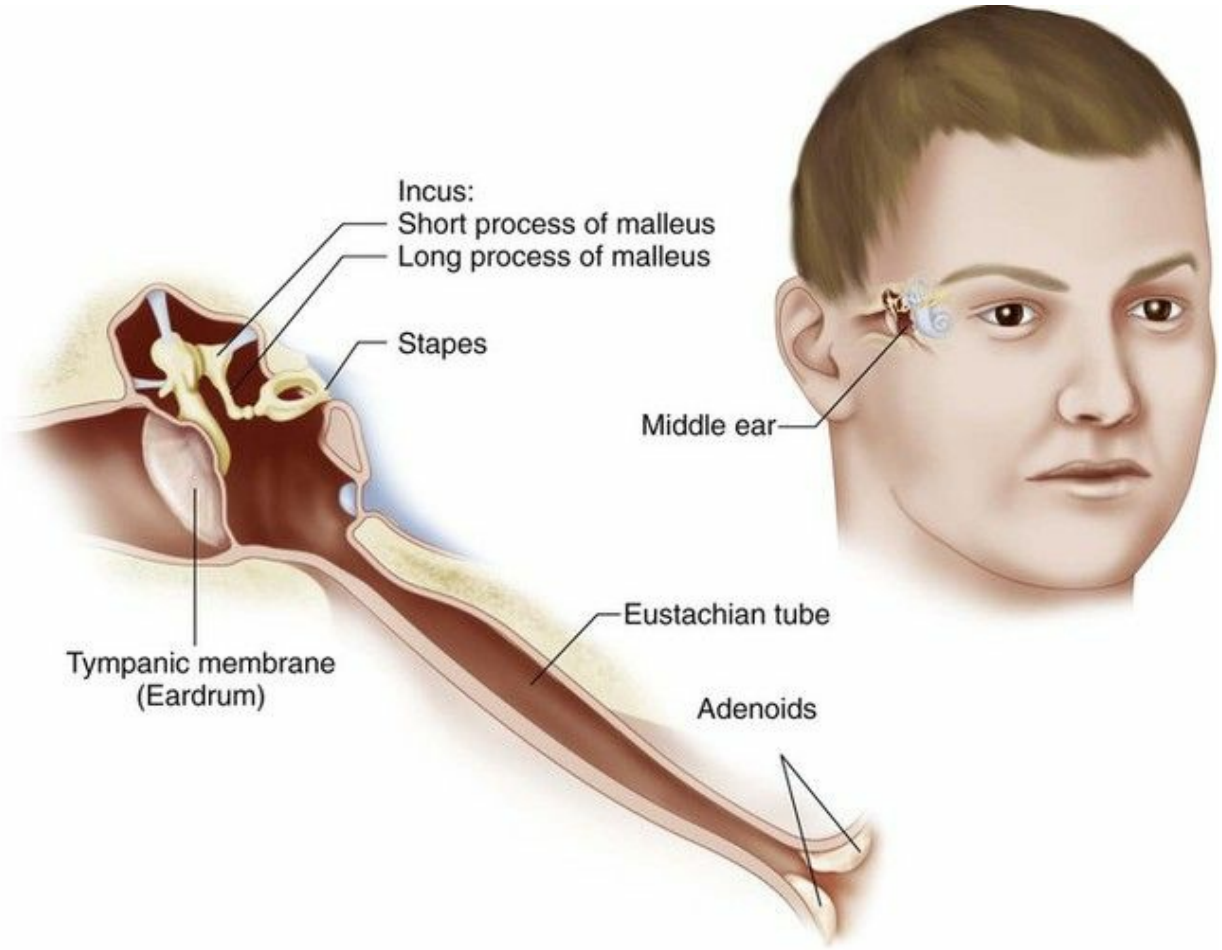

FIG. 48-4 Anatomic features and attached structures of the middle ear.

Inner Ear

The inner ear is on the other side of the oval window and contains the semicircular canals, the cochlea, the vestibule, and the distal end of the eighth cranial nerve (see Fig. 48-2). The *semicircular canals* are tubes made of cartilage and contain fluid and hair cells. These canals are connected to the sensory nerve fibers of the vestibular portion of the eighth cranial nerve. The fluid and hair cells within the canals help maintain the sense of balance.

The *cochlea,* the spiral organ of hearing, is divided into the scala tympani, the scala media, and the scala vestibuli. The scala media is filled with *endolymph,* and the scala tympani and scala vestibuli are filled with *perilymph*. These fluids protect the cochlea and the semicircular canals by allowing these structures to "float" in the fluids and be cushioned against abrupt head movements.

The *organ of Corti* is the receptor of hearing located on the membrane of the cochlea. The cochlear hair cells detect vibration from sound and stimulate the eighth cranial nerve.

The *vestibule* is a small, oval-shaped, bony chamber between the semicircular canals and the cochlea. It contains the utricle and the saccule, organs that are important for balance.

Function

Auditory sensory perception is the main function of the ear and occurs when sound is delivered through the air to the external ear canal. The sound waves strike the movable eardrum, creating vibrations. The eardrum is connected to the first bony ossicle, which allows the sound wave vibrations to be transferred from the eardrum to the malleus, the incus, and the stapes. From the stapes, the vibrations are transmitted to the cochlea. Receptors at the cochlea transduce (change) the vibrations into action potentials. The action potentials are conducted to the brain as nerve impulses by the cochlear portion of the eighth cranial (auditory) nerve. The nerve impulses are processed and interpreted as sound by the brain in the auditory cortex of the temporal lobe.

Ear and Hearing Changes Associated with Aging

Ear and hearing changes related to aging are listed in Chart 48-1, along with implications for care of older patients who have these changes. Some of the ear changes are harmless, and others may pose threats to the hearing ability of older adults.

Chart 48-1 Nursing Focus on the Older Adult

Age-Related Changes in the Ear and Hearing

EAR OR HEARING CHANGE	NURSING ADAPTATIONS AND ACTIONS
Pinna becomes elongated because of loss of subcutaneous tissues and decreased elasticity.	Reassure the patient that this is normal. When positioning a patient on the side, do not "fold" the ear under the head.
Hair in the canal becomes coarser and longer, especially in men.	Reassure the patient that this is normal. More frequent ear irrigation may be needed to prevent cerumen clumping.
Cerumen is drier and impacts more easily, reducing hearing function.	Teach the patient to irrigate the ear canal weekly or whenever he or she notices a change in hearing.
Tympanic membrane loses elasticity and may appear dull and retracted.	Do not use this finding as the only indication of otitis media.
Hearing acuity decreases (in some people).	Assess hearing with the voice test or the watch test. If a deficit is present, refer the patient to a specialist to determine hearing loss and appropriate intervention. Do not assume all older adults have a hearing loss!!
The ability to hear high-frequency sounds is lost first. Older adults may have particular problems hearing the *f, s, sh,* and *ph* sounds.	Provide a quiet environment when speaking (close the door to the hallway), and face the patient. If the patient wears glasses, be sure he or she is using them to enhance speech understanding. Speak slowly and in a deeper voice, and emphasize beginning word sounds. Some patients with a hearing loss that is not corrected may benefit from wearing a stethoscope while listening to you speak.

All older adults should be screened for hearing acuity, starting by asking "Do you have a hearing problem now?" Family members may

have noticed behaviors that suggest changes in a patient's hearing.

Assessment Methods

Patient History

Hearing assessment begins while observing the patient listening to and answering questions (Jarvis, 2016). The patient's posture and responses can provide information about hearing acuity. For example, posture changes, such as tilting the head to one side or leaning forward when listening to another person speak, may indicate the presence of a hearing problem. Other indicators of hearing difficulty include frequently asking the speaker to repeat statements or frequently saying "What?" or "Huh?" Notice whether the patient responds to whispered questions and startles when an unexpected sound occurs in the environment. Also assess whether the patient's responses match the question asked. For example, when you ask the patient "How old are you?" does the patient respond with an age or does he or she say "No, I don't have a cold."

During the interview, sit in adequate light and face the patient to allow him or her to see you speak. Use short, simple language the patient is comfortable with rather than long medical terms. Obtain data on demographics, personal and family history, socioeconomic status, current health problems, and the use of remedies for ear problems.

The patient's gender is important. Some hearing disorders, such as otosclerosis, are more common in women. Other disorders, such as Ménière's disease, are more common in men. Age is also an important factor in hearing loss.

Personal history includes past or current manifestations of ear pain, ear discharge, **vertigo** (spinning sensation), **tinnitus** (ringing), decreased hearing, and difficulty understanding people when they talk. Ask the patient about:

- Ear trauma or surgery
- Past ear infections
- Excessive cerumen
- Ear itch
- Any invasive instruments routinely used to clean the ear (e.g., Q-tip, match, bobby pin, key)
- Type and pattern of ear hygiene
- Exposure to loud noise or music
- Air travel (especially in unpressurized aircraft)
- Swimming habits and the use of ear protection when swimming
- History of health problems that can decrease the blood supply to the ear such as heart disease, hypertension, or diabetes

- History of vitiligo (a pigment disorder that may include a loss of melanin-containing cells in the inner ear, resulting in hearing loss)
- History of smoking
- History of vitamin B_{12} and folate deficiency

If the patient uses foreign objects to clean the ear canal, explain the danger in using these objects. They can scrape the skin of the canal, push cerumen up against the eardrum, and even puncture the eardrum. If the patient says that cerumen buildup is a problem, teach him or her to use an ear irrigation syringe and proper solutions to remove it. Chart 48-2 describes techniques to teach patients how to remove cerumen safely.

Chart 48-2 Patient and Family Education: Preparing for Self-Management

Self–Ear Irrigation for Cerumen Removal

- *Do not attempt to remove earwax or irrigate the ears if you have ear tubes or if you have blood, pus, or other drainage from the ear.*
- Use an ear syringe designed for the purpose of wax removal (available at most drugstores).
- The safest type of ear syringe to use is one that has a right-angle or "elbow" in the tip.
- Irrigating your ears in the shower is an easy method.
- Always use tap water that feels just barely warm to you. Water that is warmer or colder can make you feel dizzy and nauseated.
- If your earwax is thick and sticky, you may need to place a few warm commercial eardrops that soften earwax (or baby oil or mineral oil) into the ear an hour or so before you irrigate the ear.
- Fill the syringe with the lukewarm tap water.
- If you are using a syringe with an elbow tip, place only the last part of the tip into your ear and aim it toward the roof of your ear canal.
- If you are using a straight-tipped syringe, insert the tip only about ½ to ¾ inch into your ear canal, aiming toward the roof of the canal.
- Hold your head at a 30-degree angle to the side you are irrigating.
- Use one hand to hold the syringe and the other to push the plunger or squeeze the bulb.
- Apply gentle but firm continuous pressure, allowing the water to flow against the top of the canal.
- *Do not use blasts or bursts of sudden pressure.*
- The ear canal should fill, and water will begin to flow out, bringing

earwax and debris with it.
- If a dental water-pressure irrigator is used, put it on the lowest possible setting.
- This process should not be painful! If pain occurs, decrease the pressure. If pain persists, stop the irrigation.
- Continue the irrigation until at least a cup of solution has washed into and out from your ear canal. (You may have to refill the syringe.)
- Tilting your head at a 90-degree angle to the side should allow most, if not all, of the water to drain out of your ear.
- Repeat the procedure on the other ear.
- If you feel that water is still in the canal, hold a hair dryer on a low setting near the ear.
- Irrigate your ears weekly to monthly, depending on how fast your earwax collects.

Nursing Safety Priority QSEN

Action Alert

Teach patients the safe way to clean their ears, stressing that nothing smaller than his or her own fingertip should be inserted into the canal.

If the patient uses a hearing aid, assess whether hearing is improved with its use. Obtain the date of the last hearing test, the type of test given, and the results. Ask about problems that may impair auditory sensory perception such as allergies, upper respiratory infections, hypothyroidism, atherosclerosis, head trauma, and recent head, facial, or dental surgery. A thorough drug history is important because many drugs are **ototoxic** (damaging to the ear), especially many antibiotics, some diuretics, NSAIDs, and many chemotherapy agents. Use a drug handbook to determine whether any of the patient's prescribed drugs are known to affect auditory sensory perception.

Ask about the patient's occupation and hobbies that involve exposure to loud noise or music. Assess whether protective ear devices are used. Also ask whether any devices are consistently inserted into the ear, such as ear plugs or earpiece headsets, and for how long each day they are used. Use this opportunity to teach the patient about protecting the ears from loud noises by wearing protective ear devices, such as over-the-ear headsets or foam ear inserts, when persistent loud noises are in the environment. Also suggest the use of earplugs when engaging in water sports to prevent ear infections.

Family History and Genetic Risk

Family history, as well as personal history, is important in determining genetic risk for hearing loss. Although most hearing loss as a result of a genetic mutation is seen in childhood, some genetic problems can lead to progressive hearing loss in adults. For example, most people with Down syndrome develop hearing loss as adults. People with osteogenesis imperfecta have bilateral and progressive hearing loss by their 30s.

Genetic/Genomic Considerations

Patient-Centered Care QSEN

Mutations in several different genes are associated with hearing loss. One type of hearing loss among adults has a genetic basis with a mutation in gene *GJB2* (Online Mendelian Inheritance in Man [OMIM], 2014). This mutation causes poor production of the protein *connexin-26*, which has a role in the function of cochlear hair cells. Other genetic variations in some of the genes for drug-metabolizing enzymes (cytochrome p450) family) slow the metabolism and excretion of drugs, including ototoxic drugs. This allows ototoxic drugs to remain in the body longer, thus increasing the risk for hearing loss.

Ask the patient:

- Who in your family has hearing problems?
- Are the hearing problems present in men and women equally, or are they present more in one gender?
- At what age was hearing loss diagnosed in your relative(s)?
- Are both ears affected?

Current Health Problems

Assess current ear-related problems by asking about any ear "trouble," ear pain, or discharge, including earwax. Ask about a change in hearing, such as **hyperacusis** (the intolerance for sound levels that do not bother other people), or **tinnitus** (ringing in the ears). If a change in hearing is reported, ask whether one or both ears are involved and if the change was sudden or gradual. Also ask about problems with dizziness, sensations of being "off-balance," or vertigo.

Physical Assessment

Begin the examination by having the patient sit or lie down. Remove any hearing aids before the examination. After the examination, inspect the

hearing aid for cracks, debris, and a proper fit. A complete ear examination is usually performed by a physician, advanced practice nurse, or physician assistant. The brief assessment of the ear and hearing usually performed by a medical-surgical nurse is described next.

External Ear and Mastoid Assessment

Inspect the entire external ear for shape, location of attachment to the head, and condition of all visible ear structures. The normal pinna has no skin tags or deformity. It should be attached to the side of the head at a posterior angle of 10 degrees or less. The normal external canal is dry, clean, free from lesions, and not reddened.

Abnormalities of the pinna include swelling, nodules, and lesions (Jarvis, 2016). In chronic gout, collections of uric acid crystals result in hard, irregular, painless nodules called *tophi* on the pinna. Other nodules on the pinna might also be from basal cell carcinoma or rheumatoid arthritis. Small, crusted, ulcerated, or indurated lesions on the pinna that fail to heal could be squamous cell carcinoma.

Inspect the mastoid process for redness and swelling. To assess for tenderness, gently tap with one finger over the mastoid process, compress the tragus with one finger, and gently move the pinna forward and backward. Any tenderness suggests an inflammation in either the external ear or the mastoid.

Assess for and record these problems:

- Furuncles
- Large amounts of cerumen
- Scaliness
- Redness
- Swelling of the ear
- Drainage and its character

Otoscopic Assessment

The purpose of a brief otoscopic examination is to assess the patency of the external canal, identify lesions or excessive cerumen in the canal, and assess whether the tympanic membrane (eardrum) is intact or inflamed (Jarvis, 2016). An instrument called an **otoscope** is used to examine the ear. Many types are available. It consists of a light, a handle, a magnifying lens, and a pressure bulb for injecting air into the external canal to test mobility of the eardrum (Fig. 48-5). Specula of various diameters attach to the head of the otoscope. Select the largest speculum that most comfortably fits the patient's external canal.

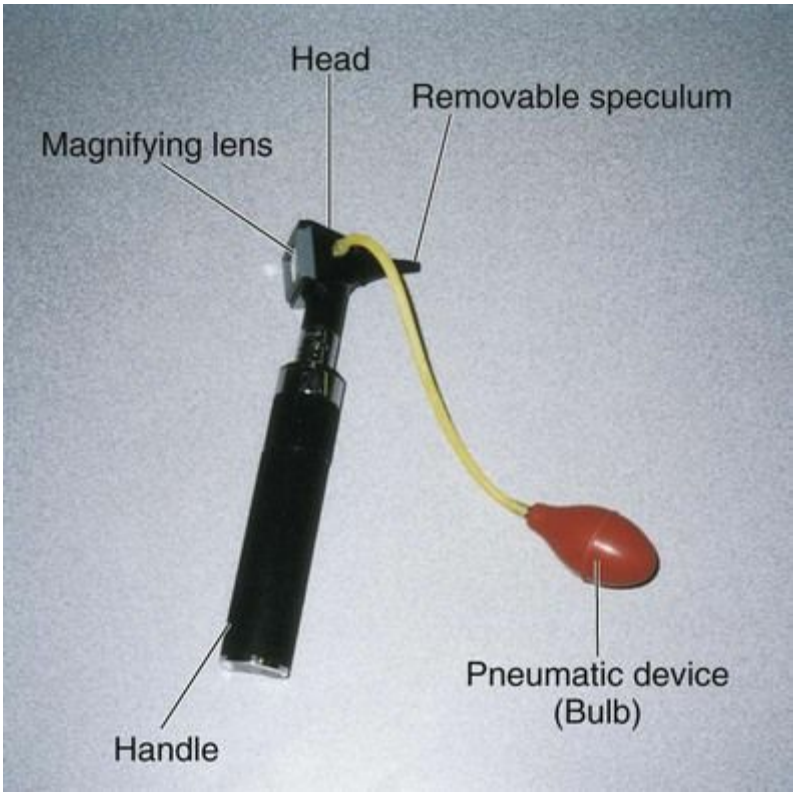

FIG. 48-5 Functional components of an otoscope.

Nursing Safety Priority QSEN

Action Alert

Do not use an otoscope to examine the ears of any patient who is unable to hold his or her head still during the examination or who is confused.

If the patient has pain during the external ear examination, cautiously attempt an otoscopic examination. The speculum will cause extreme pain if it comes in contact with inflamed tissue in the external canal.

Tilt the patient's head slightly away, and hold the otoscope upside down, like a large pen (Fig. 48-6). This position permits your hand to lie against the patient's head for support. If the patient moves, both your hand and the otoscope also move, preventing damage to the canal or eardrum. Hold the otoscope in your dominant hand, and gently pull the pinna up and back with your other hand to straighten the canal. View the ear canal while you slowly insert the speculum. Use caution to avoid causing pain by touching the speculum on the walls of the canal.

FIG. 48-6 Proper technique for an otoscopic examination.

Nursing Safety Priority QSEN

Action Alert

Observe the ear canal through the otoscope as you insert the speculum into the external canal to avoid the risk for perforating the eardrum.

After the otoscope is comfortably in the external canal, assess for lesions and the amount, consistency, and color of cerumen and hair. The normal external canal is skin-colored, intact, and without lesions. It contains various amounts of soft cerumen and small, fine hairs.

Assess the eardrum for intactness and color. *The normal eardrum is always intact.* The eardrum is shiny, transparent or opaque, pearly gray, and without lesions. Redness is seen in otitis media. Reflection of the otoscope's light from the normal eardrum is the **light reflex**, and it appears as a clearly outlined triangle of light. On the right eardrum, the light reflex appears in the right lower quadrant. On the left eardrum, the light reflex appears in the left lower quadrant. The light reflex is termed **diffuse** when the light reflex is spotty or multiple because of a changed eardrum shape.

Cultural Considerations

Patient-Centered Care QSEN

Cerumen is generally moist and tan or brown in white people and black people. It is dry and light brown to gray in Asians and American Indians. The color of the lining of the external ear canal varies with the patient's skin tone. Variations should not be mistaken for indications of problems. Patients with more moist earwax form cerumen impactions more easily than patients with drier, flaky earwax and require more frequent ear irrigations.

General Hearing Assessment

Several rapid and simple tests for acuity of auditory sensory perception can be performed at the patient's bedside. Although these tests do not determine the true extent or type of hearing loss, they can indicate a patient's functional hearing ability.

The *voice test* for hearing is conducted by asking the patient to block one external ear canal while standing 1 to 2 feet (30 to 60 cm) away. Quietly whisper a statement, and then ask the patient to repeat it. Test each ear separately. If the patient does not respond correctly, use a louder whisper. If you suspect the patient is lip-reading, use your hand to block the view of your mouth or stand behind him or her while whispering. More complex hearing tests, performed by audiologists, physicians, advanced practice nurses, specialty nurses, and physician assistants, can determine the type and extent of hearing loss.

Sound is transmitted by air conduction and bone conduction. Air conduction of sound is normally more sensitive than bone conduction. If auditory sensory perception is decreased, the hearing loss is categorized as:

- **Conductive hearing loss**, resulting from obstruction of sound wave transmission such as a foreign body in the external canal, a retracted or bulging tympanic membrane, or fused bony ossicles.
- **Sensorineural hearing loss**, resulting from a defect in the cochlea, the eighth cranial nerve, or the brain. Exposure to loud noise or music causes this type of hearing loss by damaging the cochlear hair.
- **Mixed conductive-sensorineural hearing loss**, resulting from both conductive and sensorineural hearing loss.

Audioscopy testing involves the use of a handheld device to generate tones of varying intensities to test hearing. Auditory sensory perception can be measured at a 40-decibel (dB) intensity at frequencies of 500, 1000, 2000, and 4000 cycles per second (cps), or hertz (Hz).

Tuning fork tests for hearing are the Weber and Rinne tests. These tests are useful, although limited, in distinguishing between conductive and

sensorineural hearing losses. The frequency range of the tuning fork used for these tests corresponds to that of normal speech.

The Weber tuning fork test is performed by placing a vibrating tuning fork on the middle of the patient's head and asking him or her to indicate in which ear the sound is louder. The normal test result is sound heard equally in both ears. The term *lateralization* is used if the sound is louder in one ear. For example, lateralization to the right means that the sound is heard louder in the right ear.

The Rinne tuning fork test compares hearing by air conduction with hearing by bone conduction. Sound is normally heard 2 to 3 times longer by air conduction than by bone conduction. Perform this test by placing the vibrating tuning fork stem on the mastoid process (bone conduction) and asking the patient to indicate when the sound is no longer heard. When the patient no longer hears the sound, bring the fork quickly in front of the pinna (air conduction) without touching the patient. He or she should then indicate when this sound is no longer heard. The patient normally continues to hear the sound 2 to 3 times longer in front of the pinna after not hearing it with the tuning fork touching the mastoid process.

Psychosocial Assessment

The patient may become frustrated and depressed by an inability to hear well. Reduced or lost hearing may lead to social isolation. Be sensitive to the patient, and conduct the interview at a pace appropriate for that person.

Ask about social and work relationships to determine whether the patient is isolated because of hearing problems. Encourage the patient to express feelings related to hearing loss and discuss any changes in ADLs that have been made as a result of a change in hearing. Ask family members whether hearing problems have changed the patient's interactions.

NCLEX Examination Challenge

Safe and Effective Care Environment

With which client does the nurse avoid performing an otoscopic examination?

A 34-year-old woman who is pregnant
B 90-year-old woman who is visually impaired
C 75-year-old man with dizziness and vertigo

D 70-year-old man with advanced Alzheimer's disease

Diagnostic Assessment

Laboratory Assessment

Laboratory tests are helpful only when an external or internal ear infection is suspected. For an external ear infection, the typical causative organisms are known and this infection is managed without obtaining cultures. If the usual antibiotic therapy is not successful at clearing the infection, microbial culture and antibiotic sensitivity tests may be performed.

Imaging Assessment

CT, with or without contrast enhancement, shows the structures of the ear in great detail. CT is especially helpful in diagnosing acoustic tumors.

MRI most accurately reflects soft-tissue changes. Patients with older internal metal vascular clips cannot have MRI. Newer clips are made from titanium and are not a contraindication for MRI.

Specific Auditory Assessment

Audiometry.

Audiometry is the most reliable method of measuring the acuity of auditory sensory perception. It is performed by audiologists, audiology technicians, or nurses with special training. **Frequency** is the highness or lowness of tones (expressed in hertz). The greater the number of vibrations per second, the higher the frequency (pitch) of the sound. The fewer the number of vibrations per second, the lower the frequency (pitch).

Intensity of sound is expressed in decibels (dB). **Threshold** is the lowest level of intensity at which pure tones and speech are heard by a patient about 50% of the time. The lowest intensity at which a young, healthy ear can detect sound about 50% of the time is 0 dB. Sound at 110 dB is so intense (loud) that it is painful for most people with normal hearing. Conversational speech is around 60 dB, and a soft whisper is around 20 dB (Table 48-1). With a hearing loss of 45 to 50 dB, speech cannot be heard without a hearing aid. A person with a hearing loss of 90 dB may not be able to hear speech even with a hearing aid.

TABLE 48-1

Decibel Intensity and Safe Exposure Time for Common Sounds

SOUND	DECIBEL INTENSITY (dB)	SAFE EXPOSURE TIME*
Threshold of hearing	0	
Whispering	20	
Average residence or office	40	
Conversational speech	60	
Car traffic	70	>8 hr
Motorcycle	90	8 hr
Chain saw	100	2 hr
Rock concert, front row	120	3 min
Jet engine	140	Immediate danger
Rocket launching pad	180	Immediate danger

*For every 5-dB increase in intensity, the safe exposure time is cut in half.

Pure tones are generated by an audiometer to determine hearing acuity. The two types of audiometry are pure-tone audiometry and speech audiometry.

Pure-Tone Audiometry.

Pure-tone audiometry generates tones that are presented to the patient at frequencies for hearing speech, music, and other common sounds. The results of pure-tone audiometry are graphed on an audiogram. For some patients, the hearing of one ear is "masked" while the hearing of the other ear is tested.

Pure-tone air-conduction testing determines whether a patient hears normally or has a hearing loss. It tests air-conduction hearing sensitivity (through earphones) at frequencies ranging from 125 to 8000 Hz. The intensities for pure tones generally range from 10 to 110 dB.

The patient sits in a sound-isolated room so that background noise does not interfere with the test. Earphones are placed over his or her ears, and tones of varying frequencies and intensities are delivered through the earphones, testing one ear at a time. The patient presses a button or raises a hand to indicate when he or she hears a tone.

Pure-tone bone-conduction testing determines whether the hearing loss detected by air-conduction testing is due to conductive or sensorineural factors or to a combination of the two. It is used only when air-conduction testing results are abnormal. Testing is similar to air-conduction testing except that a bone-conduction vibrator, placed firmly behind the ear on the mastoid process, is used instead of earphones.

Interpretation of audiometric evaluation determines whether hearing is

within normal limits or shows a hearing impairment and, if present, whether the hearing loss is conductive, sensorineural, or mixed. The type of loss is determined by an experienced clinician who examines the shape of the audiogram after completion of pure-tone air-conduction and bone-conduction audiometry.

Speech Audiometry.

In speech audiometry, the patient's ability to hear spoken words is measured. The speech reception threshold and speech discrimination are assessed.

Speech reception threshold is the minimum loudness at which a patient can repeat simple words. This test determines how intense (or loud) a simple speech stimulus must be before the patient can hear it well enough to repeat it correctly at least 50% of the time. In one common test, lists of two-syllable words called **spondee** are used (i.e., words in which there is equal stress on each syllable, such as *airplane, railroad,* and *cowboy*).

Speech discrimination testing determines the patient's ability to discriminate among similar sounds or among words that contain similar sounds. This test assesses the patient's *understanding* of speech. An auditory sensory perception loss decreases sensitivity to sound and impairs understanding of what is being said.

A standard format contains lists of 25 to 50 *monosyllabic* (one-syllable) words, such as *carve, day, toe,* and *ran,* and phonemically balanced words, and with equal word difficulty between lists. The lists are presented to the patient through earphones at a selected loudness level, generally about 30 to 40 dB above the speech reception threshold, or at the patient's most comfortable listening level. The score indicates the percentage of words repeated correctly.

Tympanometry.

Tympanometry assesses mobility of the eardrum and structures of the middle ear by changing air pressure in the external ear canal. The progression or resolution of serous otitis and otitis media can be accurately monitored with this procedure.

This test is helpful in distinguishing middle ear problems, such as otosclerosis, ossicular disarticulation, otitis media, and perforation of the eardrum. It is also useful for assessing patency of the eustachian tube and for checking recovery of middle ear function after surgery.

Auditory Brainstem-Evoked Response.

Auditory brainstem-evoked response (ABR) assesses hearing in patients who are unable to indicate their recognition of sound stimuli during standard hearing tests. It helps diagnose conductive and sensorineural hearing losses. Electrodes are placed on the scalp during the test. After the test, the patient's hair should be cleansed to remove the electrode gel.

Assessment of Balance

Electronystagmography (ENG) is a test to assess for central and peripheral disease of the vestibular system in the ear by detecting and recording **nystagmus** (involuntary eye movements). This response is accurate because the eyes and ears depend on each other for balance. Electrodes are taped to the skin near the eyes, and one or more procedures (caloric testing, changing gaze position, or changing head position) are performed to stimulate nystagmus. Failure of nystagmus to occur with cerebral stimulation suggests an abnormality in the vestibulocochlear apparatus, the cerebral cortex, the auditory nerve, or the brainstem.

To prepare the patient for ENG:

- Explain the procedure and its purpose. The examiners will be asking the patient to name names or do simple mathematics problems during the test to ensure he or she stays alert.
- Tell the patient to fast for several hours before the test and to avoid caffeine-containing beverages for 24 to 48 hours before the test.
- Tell patients with pacemakers that they should not have the test because pacemaker signals interfere with the sensitivity of ENG.
- Carefully introduce oral fluids after the test to prevent nausea and vomiting.

Caloric testing evaluates the vestibular (inner ear) portion of the auditory nerve. Water or air that is warmer or cooler than body temperature is infused into the ear. A normal response is the onset of vertigo and nystagmus within 20 to 30 seconds. Prepare the patient for caloric testing by:

- Explaining the procedure and its purpose
- Telling the patient to fast for several hours before the test
- Explaining that he or she will be on bedrest after the procedure with careful introduction of oral fluids to prevent nausea and vomiting

Disorders of the Ear and Hearing

Although ear and hearing disorders are often easily managed, early recognition and intervention are necessary to prevent additional damage and to promote a maximum level of wellness. Without proper intervention, auditory sensory perception can be affected.

Conditions Affecting the External Ear

The external ear is subject to outside factors that can cause problems. Disorders include congenital malformation, trauma, and infectious or noninfectious lesions of the pinna, auricle, or auditory canal. Abnormalities of the external ear range from crumpling or falling forward of the pinna to complete absence of the ear canal. Trauma can damage or destroy the auricle and external canal. Surgical reconstruction can re-form the pinna with skin grafts and plastic prostheses. Trauma to the auricle resulting in a hematoma requires the removal of blood via needle aspiration to prevent calcification and hardening, which is often referred to as a *cauliflower* or *boxer's ear.*

Benign cysts or polyps of the auricle or external canal are surgically removed if they block the canal and affect hearing. Cancer cells, usually basal cell carcinoma, can occur on the pinna. Usually treatment consists of simple excision. When the lesion becomes larger, its location near the skull and facial nerve makes treatment more difficult.

External Otitis

Pathophysiology

External otitis is a painful condition caused when irritating or infective agents come into contact with the skin of the external ear. The result is either an allergic response or inflammation with or without infection. Affected skin becomes red, swollen, and tender to touch or movement. Swelling of the ear canal can lead to temporary hearing loss from obstruction. Allergic external otitis is often caused by contact with cosmetics, hair sprays, earphones, earrings, or hearing aids. The most common infectious organisms are *Pseudomonas aeruginosa, Streptococcus, Staphylococcus,* and *Aspergillus.*

External otitis occurs more often in hot, humid environments, especially in the summer, and is known as **swimmer's ear** because it occurs most often in people involved in water sports. Patients who have traumatized their external ear canal with sharp or small objects (e.g.,

hairpins, cotton-tipped applicators) or with headphones also are more susceptible to external otitis.

Necrotizing or *malignant otitis* is the most virulent form of external otitis. Organisms spread beyond the external ear canal into the ear and skull. Death from complications such as meningitis, brain abscess, and destruction of cranial nerve VII is possible.

Patient-Centered Collaborative Care

Manifestations of external otitis range from mild itching to pain with movement of the pinna or tragus, particularly when upward pressure is applied to the external canal. Patients report feeling as if the ear is plugged and hearing is reduced. The temporary hearing loss can be severe when inflammation obstructs the canal and prevents sounds from reaching the eardrum.

Treatment focuses on reducing inflammation, edema, and pain. Nursing priorities include comfort measures, such as applying heat to the ear for 20 minutes 3 times a day. This can be accomplished by using towels warmed with water and then wrapped in a plastic bag or by using a heating pad placed on a low setting. Teach the patient that minimizing head movements reduces pain.

Topical antibiotic and steroid therapies are most effective in decreasing inflammation and pain. Review best practices for instilling eardrops with the patient, as shown in Chart 48-3. Observe the patient self-administer the eardrops to make sure that proper technique is used. Oral or IV antibiotics are used in severe cases, especially when infection spreads to surrounding tissue or area lymph nodes are enlarged.

Chart 48-3 Best Practice for Patient Safety & Quality Care QSEN

Instillation of Eardrops

- Gather the solutions to be administered.
- Check the labels to ensure correct dosage and time.
- Wear gloves to remove and discard any ear packing.
- Wash your hands.
- Perform a gentle otoscopic examination to determine whether the eardrum is intact.
- Irrigate the ear if the eardrum is intact (see Chart 48-4).
- Place the bottle of eardrops (with the top on tightly) in a bowl of warm water for 5 minutes.

- Tilt the patient's head in the opposite direction of the affected ear, and place the drops in the ear.
- With his or her head tilted, ask the patient to gently move the head back and forth 5 times.
- Insert a cotton ball into the opening of the ear canal to act as packing.
- Wash your hands again.

Analgesics, including opioids, may be needed for pain relief during the initial days of treatment. NSAIDs, such as acetylsalicylic acid (aspirin, Entrophen) and ibuprofen (Advil), or acetaminophen (Tylenol, Abenol) may relieve less severe pain.

After the inflammation has subsided, a solution of 50% rubbing alcohol, 25% white vinegar, and 25% distilled water may be dropped into the ear to keep it clean and dry and to prevent recurrence. Teach the patient to use preventive measures for minimizing ear canal moisture, trauma, or exposure to materials that lead to local irritation or contact dermatitis.

Perichondritis

Perichondritis is an infection of the **perichondrium**, a tough, fibrous tissue layer that surrounds the cartilage and shapes the pinna. This tissue supplies blood to the ear cartilage. Infection can be caused by opening an area of pus or localized infection, insect bites, trauma, and cartilage ear piercing. When infection occurs between the perichondrium and the cartilage, blood flow to the cartilage can be reduced, leading to necrosis and pinna deformity. This can occur as a complication of high helical ear piercing and may require removal of necrotic tissue.

The purposes of management are to eliminate the infection and ensure that the perichondrium stays in direct contact with the cartilage. In addition to systemic antibiotic therapy, a wide incision is made and suction drainage is used to remove pus and other fluid.

Cerumen or Foreign Bodies

Pathophysiology

Cerumen (earwax) is the most common cause of an impacted canal. A canal can also become impacted as a result of foreign bodies that can enter or be placed in the external ear canal, such as vegetables, beads, pencil erasers, and insects. Although uncomfortable, cerumen or foreign bodies are rarely emergencies and can be carefully removed by a health

care professional. Cerumen impaction in the older adult is common, and removal of the cerumen from older adults often improves hearing.

Patient-Centered Collaborative Care

Patients with a cerumen impaction or a foreign body in the ear may have a sensation of fullness in the ear, with or without hearing loss, and may have ear pain, itching, dizziness, or bleeding from the ear. The object may be visible with direct inspection.

When the occluding material is cerumen, management options include watchful waiting, manual removal, and the use of ceruminolytic agents followed by either manual irrigation or the use of a low-pressure electronic oral irrigation device. The canal can be irrigated with a mixture of water and hydrogen peroxide at body temperature (Fig. 48-7), following best practices for proper irrigation (Chart 48-4). Removal of a cerumen obstruction by irrigation is a slow process and may take more than one sitting. When it is the cause of hearing loss, cerumen removal may improve hearing. Between 50 and 70 mL of solution is the maximum amount that the patient usually can tolerate at one sitting.

Chart 48-4 Best Practice for Patient Safety & Quality Care QSEN

Ear Irrigation

- Wash your hands.
- Use an otoscope to locate the impaction; ascertain that the eardrum is intact and that the patient does not have otitis media.
- Gather the equipment: basin, irrigation syringe, otoscope, towel.
- Warm tap water (or other prescribed solution) to body temperature.
- Fill a syringe with the warmed irrigating solution.
- Place a towel around the patient's neck.
- Place a basin under the ear to be irrigated.
- Place the tip of the syringe at an angle so that the fluid pushes to one side of and not directly on the impaction (to loosen it without moving it deeper into the canal).
- Apply gentle but firm continuous pressure, allowing the water to flow against the top of the canal.
- Do not use blasts or bursts of sudden pressure.
- If pain occurs, reduce the pressure. If pain persists, stop the irrigation.
- Watch the fluid return for cerumen plug removal.
- Continue to irrigate the ear with about 70 mL of fluid.

- If the cerumen does not drain out, wait 10 minutes and repeat the irrigation procedure.
- Monitor the patient for signs of nausea.
- If the patient becomes nauseated, stop the procedure.
- If the cerumen cannot be removed by irrigation, place mineral oil into the ear 3 times a day for 2 days to soften dry, impacted cerumen, after which irrigation may be repeated.
- After completion of the irrigation, have the patient turn his or her head to the side just irrigated to drain any remaining irrigation fluid.
- Wash your hands.

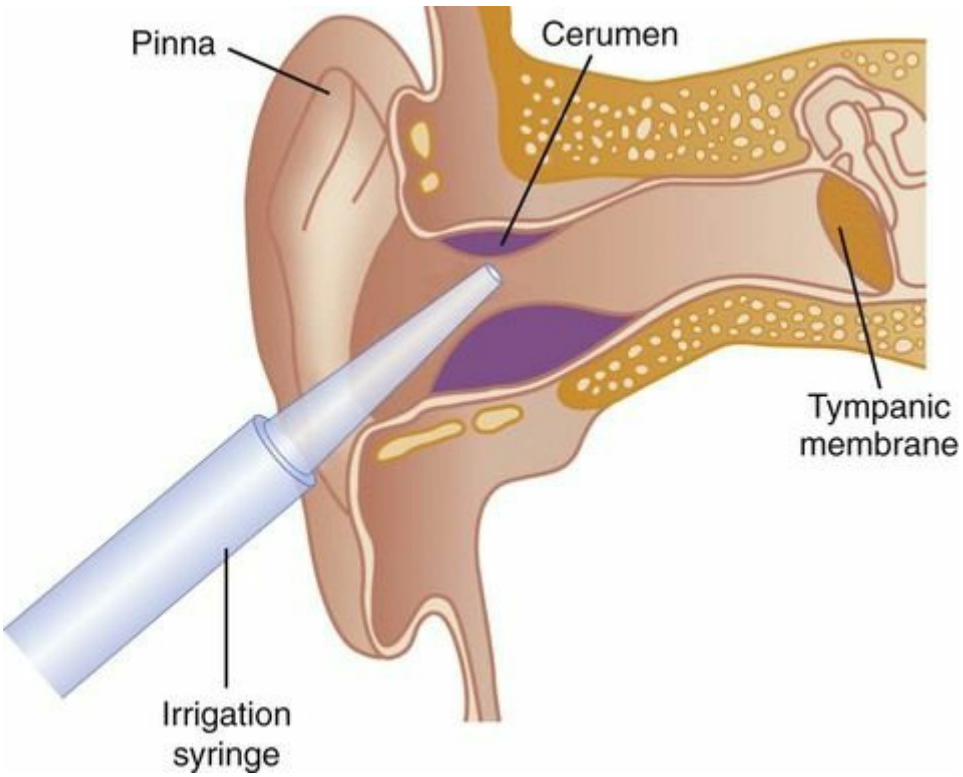

FIG. 48-7 Irrigation of the external canal. Cerumen and debris can be removed from the ear by irrigation with warm water. The stream of water is aimed above or below the impaction to allow back-pressure to push it out rather than further down the canal.

Nursing Safety Priority QSEN

Action Alert

Do not irrigate an ear with an eardrum perforation or otitis media because this may spread the infection to the inner ear. Also, do not irrigate the ear when the foreign object is vegetable matter, because this

material expands when wet, making the impaction worse. For vegetable matter, the object needs to be physically removed by an experienced health care professional.

If the cerumen is thick and dry or cannot be removed easily, use a ceruminolytic product such as Cerumenex to soften the wax before trying to remove it. Another way to soften cerumen is to add 3 drops of glycerin or mineral oil to the ear at bedtime and 3 drops of hydrogen peroxide twice a day for several days. Then the cerumen is more easily removed by irrigation. In some cases, a small curette or cerumen spoon may be used by a health care professional to scoop out the wax. Improper use of the curette can damage the canal or the eardrum.

Discourage the use of cotton swabs and ear candles (hollow tubes coated in wax inserted into the ear and then lighted at the far end) to clean the ears or remove cerumen. Chart 48-2 describes steps to teach patients regarding ear hygiene and self–ear irrigation. Refer to Chart 48-5 for nursing care considerations of older adult patients with cerumen impaction.

Chart 48-5 Nursing Focus on the Older Adult

Cerumen Impaction

- Assess the hearing of all older patients using simple voice tests.
- Perform a gentle otoscopic inspection of the external canal and eardrum of any older patient who has a problem with hearing acuity, especially the patient who wears a hearing aid.
- Use ear irrigation to remove any impacted cerumen.
- Make certain that the irrigating fluid is about 98.6° F (37° C) to reduce the chance for stimulating the vestibular sense.
- Use no more than 5 to 10 mL of irrigating fluid at a time.
- If nausea, vomiting, or dizziness develops, stop the irrigation immediately.
- Teach the patient how to irrigate his or her own ears.
- Obtain a return demonstration of ear irrigation from the patient, observing for specific areas in which the patient may need assistance.
- Encourage the patient to wash the external ears daily using a soapy, wet washcloth over the index finger (best done in the shower or while washing the hair).

Insects are killed before removal unless they can be coaxed out by a

flashlight. A topical anesthetic can be placed in the ear canal for pain relief. Mineral oil or diluted alcohol instilled into the ear can suffocate the insect, which is then removed with ear forceps.

If the patient has local irritation, an antibiotic or steroid ointment may be applied to prevent infection and reduce local irritation. Hearing acuity is tested if hearing loss is not resolved by removal of the object.

Surgical removal of the foreign object may be performed through the ear canal by a health care provider using a wire bent at a 90-degree angle. The wire is looped around the object, and the object is pulled out. Because this procedure is painful, general anesthesia is needed.

Conditions Affecting the Middle Ear

Otitis Media

Pathophysiology

The common forms of otitis media are acute otitis media, chronic otitis media, and serous otitis media. Each type affects the middle ear but has different causes and pathologic changes. If otitis progresses or is untreated, permanent conductive hearing loss may occur.

Acute otitis media and chronic otitis media are similar. An infecting agent in the middle ear causes inflammation of the mucosa, leading to swelling and irritation of the ossicles within the middle ear, followed by purulent inflammatory exudate. Acute disease has a sudden onset and lasts 3 weeks or less. Chronic otitis media often follows repeated acute episodes, has a longer duration, and causes greater middle ear injury. It may be a result of the continuing presence of a biofilm in the middle ear. A *biofilm* is a community of bacteria working together to overcome host defense mechanisms to continue to survive and proliferate (see Chapter 23 for more information about biofilms). Therapy for complications associated with chronic otitis media usually involves surgical intervention.

The eustachian tube and mastoid, connected to the middle ear by a sheet of cells, are also affected by the infection. If the eardrum membrane perforates, the infection can thicken and scar the eardrum and middle ear if left untreated. Necrosis of the ossicles destroys middle ear structures and causes hearing loss.

Patient-Centered Collaborative Care

Assessment

The patient with acute or chronic otitis media has ear pain. Acute otitis media causes more intense pain from increased pressure in the middle ear. Conductive hearing is reduced and distorted as sound wave transmission is obstructed. The patient may notice tinnitus in the form of a low hum or a low-pitched sound. Headaches and systemic manifestations such as malaise, fever, nausea, and vomiting can occur. As the pressure on the middle ear pushes against the inner ear, the patient may have dizziness.

Otoscopic examination findings vary, depending on the stage of the condition. The eardrum is initially retracted, which allows landmarks of the ear to be seen clearly. At this early stage, the patient has only vague ear discomfort. As the condition progresses, the eardrum's blood vessels dilate and appear red (Fig. 48-8). Later, the eardrum becomes red, thickened, and bulging, with loss of landmarks. Decreased eardrum mobility is evident on inspection with a pneumatic otoscope. Pus may be seen behind the membrane.

FIG. 48-8 Otoscopic view of otitis media.

With progression, the eardrum spontaneously perforates and pus or blood drains from the ear (Fig. 48-9). Then the patient notices a marked decrease in pain as the pressure on middle ear structures is relieved. Eardrum perforations often heal if the underlying problem is controlled. Simple central perforation does not interfere with hearing unless the ossicles are damaged or the perforation is large. Repeated perforations with extensive scarring cause hearing loss.

FIG. 48-9 Otoscopic view of a perforated tympanic membrane.

Interventions

Nonsurgical Management.

Management can be as simple as putting the patient in a quiet environment. Bedrest limits head movements that intensify the pain. Application of low heat may help reduce pain.

Systemic antibiotic therapy is prescribed. Teach the patient to complete the antibiotic therapy as prescribed and to not stop taking the drug when manifestations are relieved. Analgesics such as aspirin, ibuprofen (Advil), and acetaminophen (Tylenol, Abenol) relieve pain and reduce fever. For severe pain, opioid analgesics may be prescribed. Antihistamines and decongestants are prescribed to decrease fluid in the middle ear.

Surgical Management.

If pain persists after antibiotic therapy and the eardrum continues to bulge, a **myringotomy** (surgical opening of the eardrum) is performed. This procedure drains middle ear fluids and immediately relieves pain.

The procedure is a small surgical incision, which is often performed in an office or clinic setting, and the incision heals rapidly. Another approach is the removal of fluid from the middle ear with a needle. For relief of pressure caused by serous otitis media and for those patients who have repeated episodes of otitis media, a small **grommet** (polyethylene tube) may be surgically placed through the eardrum to allow continuous drainage of middle ear fluids (Fig. 48-10).

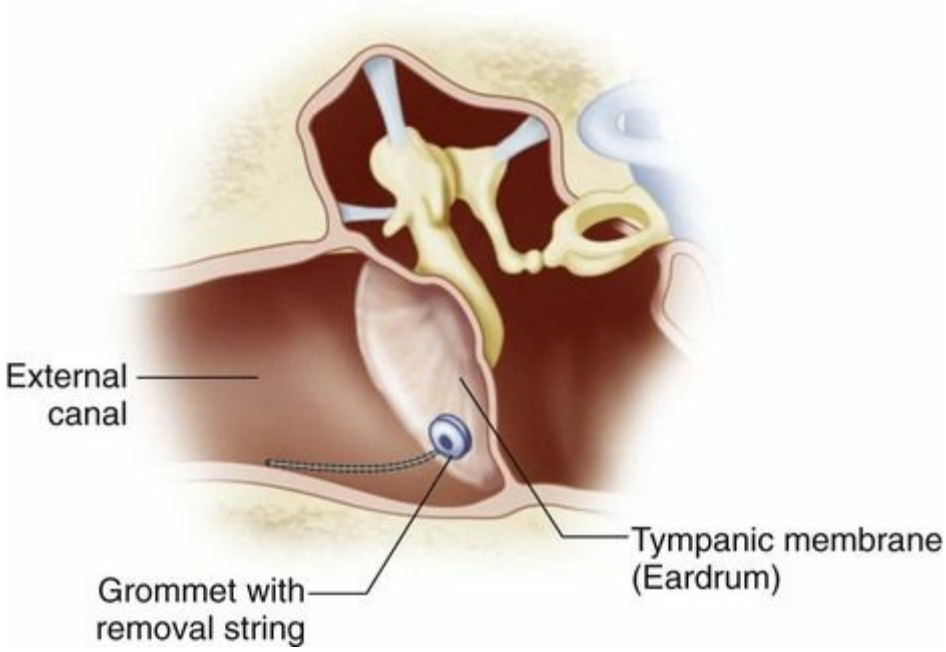

FIG. 48-10 Grommet through the tympanic membrane. A small grommet is placed through the tympanic membrane away from the margins, which allows prolonged drainage of fluids from the middle ear.

Priority care after surgery includes teaching the patient to keep the external ear and canal clean and dry while the incision is healing. Instruct him or her to not wash the hair or shower for several days. Other instructions after surgery are listed in Chart 48-6.

Chart 48-6 Patient and Family Education: Preparing for Self-Management

Recovery from Ear Surgery

- Avoid straining when you have a bowel movement.
- Do not drink through a straw for 2 to 3 weeks.
- Avoid air travel for 2 to 3 weeks.
- Avoid excessive coughing for 2 to 3 weeks.
- Stay away from people with respiratory infections.
- When blowing your nose, blow gently, without blocking either nostril, with your mouth open.
- Avoid getting your head wet, washing your hair, and showering for 1 week.
- Keep your ear dry for 6 weeks by placing a ball of cotton coated with petroleum jelly (e.g., Vaseline) in your ear. Change the cotton ball daily.
- Avoid rapidly moving the head, bouncing, and bending over for 3 weeks.

- Change your ear dressing every 24 hours or as directed.
- Report excessive drainage immediately to your physician.

Mastoiditis

Pathophysiology

The lining of the middle ear is continuous with the lining of the mastoid air cells, which are embedded in the temporal bone. **Mastoiditis** is an infection of the mastoid air cells caused by progressive otitis media. Antibiotic therapy is used to treat the middle ear infection before it progresses to mastoiditis. If mastoiditis is not managed appropriately, it can lead to brain abscess, meningitis, and death.

Patient-Centered Collaborative Care

The manifestations of mastoiditis include swelling behind the ear and pain when moving the ear or the head. Pain is *not* relieved by myringotomy. Cellulitis develops on the skin or external scalp over the mastoid process, pushing the ear sideways and down. The eardrum is red, dull, thick, and immobile. Perforation may or may not be present. Lymph nodes behind the ear are tender and enlarged. Patients may have low-grade fever, malaise, and ear drainage. Hearing loss occurs, and CT scans show fluid in the air cells of the mastoid process.

Interventions focus on halting the infection before it spreads to other structures. IV antibiotics are used but do not easily penetrate the infected bony structure of the mastoid. Cultures of the ear drainage determine which antibiotics should be most effective. Surgical removal of the infected tissue is needed if the infection does not respond to antibiotic therapy within a few days. A simple or modified radical mastoidectomy with tympanoplasty is the most common treatment. All infected tissue must be removed so that the infection does not spread to other structures. A tympanoplasty is then performed to reconstruct the ossicles and the eardrum to restore hearing (see pp. 1012-1013 for care after tympanoplasty.)

Trauma

Trauma and damage may occur to the eardrum and ossicles by infection, by direct damage, or through rapid changes in the middle ear pressure. Objects placed in the external canal exert pressure on the eardrum and cause perforation. If the objects continue through the canal, the ossicles may be damaged. Blunt injury to the skull and ears can also damage or

fracture middle ear structures. Slapping the external ear increases the pressure in the ear canal and can tear the eardrum. Excessive nose blowing and rapid changes of pressure *(barotrauma)* can increase pressure within the middle ear leading to damaged ossicles and a perforated eardrum.

Most eardrum perforations heal within a week or two without treatment. Repeated perforations heal more slowly, with scarring. Depending on the amount of damage to the ossicles, auditory sensory perception may or may not return. Hearing aids can improve hearing in this type of hearing loss. Surgical reconstruction of the ossicles and eardrum through a tympanoplasty or a myringoplasty may also improve hearing. (See later discussion of nursing care on p. 1013 in the Tympanoplasty section.)

Nursing care priorities focus on teaching about trauma prevention. Caution patients to avoid inserting objects into the external canal and to follow the steps in Chart 48-2 for ear hygiene. Stress the importance of using ear protectors when blunt trauma is likely.

Neoplasms

Middle ear tumors are rare, and the most common type is the *glomus jugulare,* a benign vascular lesion. Malignant ear tumors also can occur. The growth of any lesion within the middle ear area disrupts conductive auditory sensory perception, erodes the ossicles, and may affect the inner ear and cranial nerves.

Patients have progressive hearing loss and tinnitus. Infection and pain are rare. Otoscopic examination shows a bulging eardrum or a mass extending to the external ear canal. The blood vessels of the *glomus jugulare* tumor give the mass a reddish color and a visible pulsation.

Diagnosis is made by physical examination, tomography, and angiography. Tumors are removed by surgery, which often destroys hearing in the affected ear. Depending on the extent of the tumor, surgery can performed through the ear canal or may involve opening the cranium to remove the tumor.

Benign tumors are removed because, with continued growth, other structures can be affected, further damaging the facial or trigeminal nerve. When possible, reconstruction of the middle ear structures is performed later to restore conductive hearing.

Conditions Affecting the Inner Ear

Tinnitus

Tinnitus (continuous ringing or noise perception in the ear) is a common ear problem that can occur in one or both ears. Diagnostic testing cannot confirm tinnitus; however, testing is performed to assess hearing and rule out other disorders.

Manifestation range from mild ringing, which can go unnoticed during the day, to a loud roaring in the ear, which can interfere with thinking and attention span. Some patients feel as if the constant ringing could drive them mad. Factors that contribute to tinnitus include age, sclerosis of the ossicles, Ménière's disease, certain drugs (aspirin, NSAIDs, high-ceiling diuretics, quinine, aminoglycoside antibiotics), exposure to loud noise, and other inner ear problems (Ruppert & Fay, 2012).

The problem and its management vary with the underlying cause. When no cause can be found or the disorder is untreatable, therapy focuses on ways to mask the tinnitus with background sound, noisemakers, and music during sleeping hours. Ear mold hearing aids can amplify sounds to drown out the tinnitus during the day. A drug that is helpful to some patients is pramipexole (Mirapex), an antiparkinson drug. The American Tinnitus Association assists patients in coping with tinnitus. Refer patients with tinnitus to local and online support groups to help them cope with this problem.

NCLEX Examination Challenge

Physiological Integrity

The client who has tinnitus is taking these drugs daily: 1 multiple vitamin, losartan (Cozaar) 50 mg, aspirin 650 mg, and diphenhydramine (Benadryl) 25 mg. Which drug alerts the nurse to a possible cause of tinnitus?

A Aspirin
B Losartan
C Multiple vitamin
D Diphenhydramine

Vertigo and Dizziness

Vertigo and dizziness are common manifestations of many ear disorders. **Dizziness** is a disturbed sense of a person's relationship to space. Vertigo is often used interchangeably with dizziness, but the definition and cause are somewhat different. True **vertigo** is a sense of whirling or turning in space.

Because the visual system, the vestibular system, and the

proprioceptive system (muscles and nerve endings) combine to give input to the brain about balance, problems in any of these areas lead to a disturbed sense of balance. Problems that cause vertigo include Ménière's disease, labyrinthitis, acoustic neuromas, motion sickness, and drug or alcohol ingestion.

Manifestations of vertigo include nausea, vomiting, falling, nystagmus, hearing loss, and tinnitus. Until the cause of the vertigo can be identified, each manifestation is treated. Teach patients these strategies to reduce manifestations:

- Restrict head motion and change position slowly
- Take drugs that reduce the vertigo effects, such as over-the counter dimenhydrinate (Dramamine, Gravol) or prescription drugs such as diazepam (Valium, Apo-Diazepam), meclizine (Antivert, Bonamine), and scopolamine (Transderm Scop, Transderm-V)

Labyrinthitis

Labyrinthitis is an infection of the labyrinth, which may occur as a complication of acute or chronic otitis media that spreads to the inner ear. Labyrinthitis also may result from the growth of a **cholesteatoma** (benign overgrowth of squamous cell epithelium) from the middle ear into the semicircular canal. It may follow middle ear or inner ear surgery and may follow a viral upper respiratory infection or mononucleosis.

Manifestations include auditory sensory perception loss, tinnitus, nystagmus to the affected side, and vertigo with nausea and vomiting. Labyrinthitis is usually a self-limiting condition. If it does not resolve with supportive therapy, management includes systemic antibiotics. Teach the patient to complete the antibiotic therapy as prescribed and to not stop taking the drug when manifestations are no longer present because inadequate treatment may lead to meningitis. Advise patients to stay in bed in a darkened room until manifestations are reduced. Antiemetics and antivertiginous drugs, such as dimenhydrinate (Dramamine, Gravol) and meclizine (Antivert, Bonamine), relieve nausea and dizziness.

Ménière's Disease

Pathophysiology

Ménière's disease has three features: tinnitus, one-sided sensorineural auditory sensory perception loss, and vertigo, occurring in attacks that can last for several days (Haynes, 2014). (Some patients have continuous

manifestations of varying intensity rather than intermittent attacks.) Patients are almost totally incapacitated during an attack, and recovery takes hours to days. The pathology of Ménière's disease is an excess of endolymphatic fluid that distorts the entire inner-canal system. This distortion decreases hearing by dilating the cochlear duct, causes vertigo because of damage to the vestibular system, and stimulates tinnitus. At first, hearing loss is reversible, but repeated damage to the cochlea from increased fluid pressure leads to permanent hearing loss.

Patient-Centered Collaborative Care

Assessment

Ménière's disease usually first occurs in people between the ages of 20 and 50 years. It is more common in men and affects about 615,000 people in the United States (Alm, 2012). Severe, debilitating attacks alternate with symptom-free periods. Patients often have certain manifestations before an attack of vertigo, such as headaches, increasing tinnitus, and fullness in the affected ear.

Patients describe the tinnitus as a continuous, low-pitched roar or a humming sound, which worsens just before and during an attack. Hearing loss occurs first with the low-frequency tones but progresses to include all levels and, with repeated attacks, can become permanent. The vertigo with periods of whirling may even cause patients to fall. It is so intense that even while lying down, the patient often holds the bed or ground to keep from falling. Severe vertigo usually lasts 3 to 4 hours, but he or she may feel dizzy long after the attack. Nausea and vomiting are common. Other manifestations include rapid eye movements (**nystagmus**) and severe headaches.

Interventions

Nonsurgical Management.

Teach patients to move the head slowly to prevent worsening of the vertigo. Nutrition and lifestyle changes can reduce the amount of endolymphatic fluid. Encourage patients to stop smoking because of the blood vessel constricting effects.

Nutrition therapy with a hydrops diet may stabilize body fluid levels to prevent excess endolymph accumulation. The basic structure of this diet involves:

- Distributing food and fluid intake evenly throughout the day and from day to day

• Avoiding foods or fluids with a high salt content
• Drinking adequate amounts of fluids daily
• Avoiding caffeine-containing fluids and foods
• Limiting alcohol intake to one serving per day
• Avoiding monosodium glutamate (MSG)

Coordinate with a dietitian for more information about diet therapy for reduction of Ménière's manifestations.

Drug therapy may reduce the vertigo and vomiting and restore normal balance. Mild diuretics are prescribed to decrease endolymph volume, which reduces vertigo, hearing loss, tinnitus, and aural fullness. Nicotinic acid has been found to be useful because of its vasodilatory effect. Antihistamines, such as diphenhydramine hydrochloride (Benadryl, Allerdryl) and dimenhydrinate (Dramamine, Gravol), and antivertiginous drugs, such as meclizine (Antivert, Bonamine), help reduce the severity of or stop an acute attack. Antiemetics, such as chlorpromazine hydrochloride (Thorazine, Novo-Chlorpromazine), droperidol (Inapsine), promethazine (Phenergan), and ondansetron (Zofran), help reduce the nausea and vomiting. Diazepam (Valium, Apo-Diazepam) calms the patient; reduces vertigo, nausea, and vomiting; and allows the patient to rest quietly during an attack. Intratympanic therapy with gentamycin and steroids can prevent manifestations; however, this therapy results in some hearing loss.

Pressure pulse treatments, such as the Meniett device, which use a tympanostomy tube to apply low-pressure micropulses to the inner ear several times daily, have helped reduce episodes in some patients with Ménière's disease (National Institute on Deafness and other Communication Disorders [NIDCD], 2010). This action displaces inner ear fluid and prevents or relieves manifestations.

An experimental technique to control dizziness is in clinical trials. This technique involves the use of an implant placed behind the affected ear that blocks abnormal activity of the eighth cranial nerve (Alm, 2012).

Surgical Management.

When medical therapy is ineffective and the patient's general function is decreased significantly, surgery may be performed. The choice of the surgical procedure depends on the degree of usable hearing, the severity of the spells, and the condition of the opposite ear. The most radical procedure involves resection of the vestibular nerve or total removal of the labyrinth (**labyrinthectomy**), performed through the ear canal. This procedure results in total auditory sensory perception loss on the operative side.

Another procedure performed early in the course of the disease is endolymphatic decompression with drainage and a shunt. The effectiveness of this procedure varies. The endolymphatic sac is drained, and a tube is inserted for continued fluid drainage. Some patients report relief of vertigo with retention of their hearing. Vertigo is present immediately after surgery from movement of the vestibule of the inner ear during surgery. Reassure the patient that the vertigo is a temporary result of the surgical procedure, not the disease.

NCLEX Examination Challenge

Health Promotion and Maintenance

Which lifestyle modification does the nurse suggest to the client with Ménière's disease to reduce the frequency or intensity of acute episodes?
A Quitting cigarette smoking
B Avoiding aspirin-containing drugs
C Reducing the amount of saturated fats in the diet
D Avoiding crowds and people who have upper respiratory infections

Acoustic Neuroma

An **acoustic neuroma** is a benign tumor of cranial nerve VIII that often damages other structures as it grows. Depending on the size and exact location of the tumor, damage to hearing, facial movements, and sensation can occur (McCance et al., 2014). An acoustic neuroma can cause many neurologic manifestations as the tumor enlarges in the brain.

Manifestations begin with tinnitus and progress to gradual sensorineural hearing loss. Later, patients have constant mild to moderate vertigo. As the tumor enlarges, nearby cranial nerves are damaged.

The tumor is diagnosed with CT scanning and MRI. Cerebrospinal fluid assays show increased pressure and protein.

Surgical removal can be performed in a variety of ways. Usually a craniotomy is performed, and usually the remaining hearing is lost. Care is taken to preserve the function of the facial nerve (cranial nerve VII). Care after craniotomy is discussed in Chapter 45. Acoustic neuromas rarely recur after surgical removal.

Hearing Loss

Pathophysiology

Loss of auditory sensory perception is common and may be conductive, sensorineural, or a combination of the two (see Fig. 48-2). Conductive hearing loss occurs when sound waves are blocked from contact with inner ear nerve fibers because of external ear or middle ear disorders. If the inner ear sensory nerve that leads to the brain is damaged, the hearing loss is *sensorineural*. Combined hearing loss is *mixed conductive-sensorineural*.

The differences in conductive and sensorineural hearing loss are listed in Table 48-2. Disorders that cause conductive hearing loss are often corrected with minimal or no permanent damage. Sensorineural hearing loss is often permanent.

TABLE 48-2

Comparison of Features for Conductive and Sensorineural Hearing Loss

CONDUCTIVE HEARING LOSS	SENSORINEURAL HEARING LOSS
Causes	
Cerumen Foreign body Perforation of the tympanic membrane Edema Infection of the external ear or middle ear Tumor Otosclerosis	Prolonged exposure to noise Presbycusis Ototoxic substance Ménière's disease Acoustic neuroma Diabetes mellitus Labyrinthitis Infection Myxedema
Assessment Findings	
Evidence of obstruction with otoscope Abnormality in tympanic membrane Speaking softly Hearing best in a noisy environment Rinne test: air conduction greater than bone conduction Weber test: lateralization to affected ear	Normal appearance of external canal and tympanic membrane Tinnitus common Occasional dizziness Speaking loudly Hearing poorly in loud environment Rinne test: air conduction less than bone conduction Weber test: lateralization to unaffected ear

Etiology and Genetic Risk

Conductive hearing loss can be caused by any inflammation or obstruction of the external or middle ear. Changes in the eardrum such as bulging, retraction, and perforations may damage middle ear structures and lead to conductive hearing loss. Tumors, scar tissue, and overgrowth of soft bony tissue (**otosclerosis**) on the ossicles from previous middle ear surgery also lead to conductive hearing loss.

Sensorineural hearing loss occurs when the inner ear or auditory nerve (cranial nerve VIII) is damaged. Prolonged exposure to loud noise damages the hair cells of the cochlea (NIDCD, 2012). Many drugs are

toxic to the inner ear structures, and their effects on hearing can be transient or permanent, dose related, and affect one or both ears. When ototoxic drugs are given to patients with reduced kidney function, increased ototoxicity can occur because drug elimination is slower, especially among older patients.

Presbycusis is a sensorineural auditory sensory perception loss that occurs with aging (McCance et al., 2014). It is caused by degeneration of cochlear nerve cells, loss of elasticity of the basilar membrane, or a decreased blood supply to the inner ear. Deficiencies of vitamin B_{12} and folic acid increase the risk for presbycusis. Other causes include atherosclerosis, hypertension, infections, fever, Ménière's disease, diabetes, and ear surgery (Touhy & Jett, 2014). Trauma to the ear, head, or brain also contributes to sensorineural hearing loss.

Incidence and Prevalence

Because hearing loss may be gradual and affect only some aspects of hearing, many adults are unaware that their hearing is impaired. The incidence of adult hearing loss in the United States is estimated to be 36 to 46 million, or 17% of the population, and dramatically increases among people in their 70s and 80s (NIDCD, 2014; Oyler, 2012).

Health Promotion and Maintenance

With special care to the ears, hearing can be preserved at maximum levels. Address barriers to the use of hearing protection, exposure to loud music, and other modifiable risk factors that affect hearing. Encourage everyone to have simple hearing testing performed as part of their annual health assessment.

Teach everyone the danger in using objects such as bobby-pins, Q-tips, or toothpicks to clean the ear canal. These can scrape the skin of the canal, push cerumen up against the eardrum, and puncture the eardrum. If cerumen buildup is a problem, teach the person the proper technique to remove it (see Chart 48-2).

Teach all people to use protective ear devices, such as over-the-ear headsets or foam ear inserts, when exposed to persistent loud noises. Suggest using earplugs when engaging in water sports to prevent ear infections, as well as using an over-the-counter product such as Swim-Ear to assist with drying the ears after swimming.

❖ Patient-Centered Collaborative Care

◆ Assessment

History.

Ask patients how long they have noticed a change in hearing and whether the changes were sudden or gradual. Age is important, because some ear and hearing changes occur with aging. Ask about exposures to loud or continuous noises, as well as current or previous use of ototoxic drugs. Also ask about a history of ear infections and whether eardrum perforation occurred. Ask patients about any direct trauma to the ears. Because some types of hearing loss have a genetic basis, ask whether any family members are hearing impaired. When pain occurs with acute-onset hearing loss, ask about recent upper respiratory infection and allergies affecting the nose and sinuses.

The patient with hearing loss from peripheral neuropathy may have other systemic diseases, including human immune deficiency virus (HIV) disease or diabetes. Patients undergoing cancer chemotherapy or interferon therapy are at risk for neuropathic hearing loss.

Physical Assessment/Clinical Manifestations.

Chart 48-7 lists focused assessment techniques for patients with suspected loss of auditory sensory perception. The loss may be sudden or gradual and often affects both ears. The ability to hear high-frequency consonants—especially *s*, *sh*, *f*, *th*, and *ch* sounds—is lost first. Patients may state that they have no problem with hearing but cannot understand specific words and that other people are mumbling. Vertigo and continuous tinnitus may be present.

Chart 48-7 Focused Assessment

The Patient with Suspected Hearing Loss

Assess whether the patient has any of these ear problems:

- Pain
- Feeling of fullness or congestion
- Dizziness or vertigo
- Tinnitus
- Difficulty understanding conversations, especially in a noisy room
- Difficulty hearing sounds
- The need to strain to hear
- The need to turn the head to favor one ear or the need to lean forward to hear

Assess visible ear structures, particularly the external canal and tympanic membrane:

- Position and size of the pinna
- Patency of the external canal; presence of cerumen or foreign bodies, edema, or inflammation
- Condition of the tympanic membrane: intact, edema, fluid, inflammation

Assess functional ability, including:

- Frequency of asking people to repeat statements
- Withdrawal from social interactions or large groups
- Shouting in conversation
- Failing to respond when not looking in the direction of the sound
- Answering questions incorrectly

Tuning fork tests help diagnose hearing loss. With the Weber test, the patient can usually hear sounds well in the ear with a conductive hearing loss because of bone conduction. With the Rinne test, the patient reports that sound transmitted by bone conduction is louder and more sustained than that transmitted by air conduction.

Otoscopic examination is used to assess the ear canal, eardrum, and middle ear structures that can be seen through the eardrum. Findings vary, depending on the cause of the hearing loss. Perform the examination as described earlier on pp. 1000-1001, and document the findings.

Psychosocial Assessment.

For people with a loss of auditory sensory perception, communication can be a struggle and they may isolate themselves because of the difficulty in talking and listening. Social isolation can lead to depression (Spyridakou, 2012). Be sensitive to emotional changes that may be related to reduced hearing and a decline in conversational skills. Encourage the patient and family to express their feelings and concerns about an actual or potential hearing loss.

Laboratory Assessment.

No laboratory test diagnoses hearing loss. However, some laboratory findings can indicate problems that affect hearing. White blood cell counts are assessed in the patient with otitis media.

Imaging Assessment.

Imaging assessment can determine some problems affecting hearing ability. Skull x-rays determine bony involvement in otitis media and the location of otosclerotic lesions. CT and MRI are used to determine soft-

tissue involvement and the presence and location of tumors.

Other Diagnostic Assessment.

Audiometry can help determine whether hearing loss is only conductive or whether it has a sensorineural component. This is important in determining possible causes of the hearing loss and in planning interventions.

◆ Analysis

The priority NANDA-I nursing diagnoses and collaborative problems for the patient with any degree of hearing impairment include:
1. Difficulty hearing related to obstruction, infection, damage to the middle ear, or damage to the auditory nerve
2. Impaired Verbal Communication related to difficulty hearing (NANDA-I)

◆ Planning and Implementation

Increasing Hearing

Planning: Expected Outcomes.

The patient with impaired auditory sensory perception is expected to either have an increase in functional hearing or maintain existing hearing levels. Indicators include:
- No or minimal loss of high-pitch tones
- No or minimal loss of ability to distinguish conversation from background noise
- Turning toward sound
- Identifying discrete sounds

Interventions.

Interventions are expected to identify the problem, halt the pathologic processes, and increase usable hearing. Nursing care priorities focus on teaching the patient about the use of an appropriate assistive device, providing support to the patient and family to maintain or increase communication, and assisting patients to find support services.

Nonsurgical Management.

Interventions include early detection of impaired auditory sensory perception, use of appropriate therapy, and use of assistive devices to augment the patient's usable hearing.

Early detection helps correct the problem causing the hearing loss. Assess for indications of hearing loss, as listed in Chart 48-7.

Drug therapy is focused on correcting the underlying problem or reducing the side effects of problems occurring with hearing loss. Antibiotic therapy is used to manage external otitis and other ear infections. Teach the patient the importance of taking the drug or drugs exactly as prescribed and completing the entire course. Caution him or her to not stop the drug just because manifestations have improved. By treating the infection, antibiotics reduce local edema and improve hearing. When pain is also present, analgesics are used. Many ear disorders induce vertigo and dizziness with nausea and vomiting. Antiemetic, antihistamine, antivertiginous, and benzodiazepine drugs can help reduce these problems.

Assistive devices are useful for patients with permanent hearing loss. Portable amplifiers can be used while watching television to avoid increasing the volume and disturbing others. Telephone amplifiers increase telephone volume, allowing the caller to speak in a normal voice. Flashing lights activated by the ringing telephone or a doorbell alert patients visually. Some patients may have a service dog to alert them to sounds (ringing telephones or doorbells, cries of other people, and potential dangers). Provide information about agencies that can assist the hearing-impaired person.

Small, portable audio amplifiers can assist in communicating with patients with hearing loss who do not use a hearing aid. Using amplifiers or allowing patients to use a stethoscope for listening helps you communicate with anyone who requires additional volume to hear speech.

A hearing aid is a small electronic amplifier that assists patients with conductive hearing loss but is less effective for sensorineural hearing loss. Most common hearing aids are small. Some are attached to a person's glasses and are visible to other people. Another type fits into the ear and is less noticeable. Newer devices fit completely in the canal with only a fine, clear filament visible. The cost of smaller hearing aids varies with size and quality. Some people benefit from classes that explain the best use and care of these devices.

Remind patients that hearing with a hearing aid is different from natural hearing. Teach the patient to start using the hearing aid slowly, at first wearing it only at home and only during part of the day. Listening to television and the radio and reading aloud can help the patient get used to new sounds. A difficult aspect of a hearing aid is the amplification of background noise. The patient must learn to concentrate and filter out

background noises. In a study of hearing aid users, the most desired feature for a hearing aid is its functionality in noisy settings (see the Evidence-Based Practice box).

Evidence-Based Practice QSEN

What Do People with Reduced Hearing Want Most from a Hearing Aid?

Bridges, J., Lataille, A., Buttorff, C., White, S., & Niparko, J. (2012). Consumer preference for hearing aid attributes: A comparison of rating and conjoint analysis methods. *Trends in Amplification, 16*(1), 40-48.

The number of older adults with hearing loss is increasing, although only about one in five hearing-impaired people uses a hearing aid. Several drawbacks from hearing aid use include cost, appearance, and the quality of amplification, particularly the utility of the device in noisy environments. The purpose of this study was to determine what hearing aid factors or attributes are preferred by users. There were 75 subjects with documented hearing loss followed in the ambulatory care setting of a large medical center. With the exception of income, the cohort strongly represented the typical hearing aid user (male, older). This group had a higher-than-typical education level and income level. The study built upon previous studies that identified the seven hearing aid attributes (i.e., performance in quiet settings, comfort, feedback, frequency of battery replacement, purchase price, water and sweat resistance, and performance in noisy settings) that were important in the choice and use of different models of hearing aids.

Subjects were asked to rate these attributes on a Likert-like scale and were asked to perform eight pair-comparison conjoint tasks. In addition to descriptive statistics, data were analyzed using ordinary least squares (OLS) and logit models.

Although all positive attributes (e.g., good performance, lower cost, longer battery life) were considered desirable, the attribute considered by a large margin to be most desirable and most likely to help the person continue usual activities was improved performance in noisy environments. Both methods of measurement and analysis had similar results. This result was confirmed by the subjects indicating that they would be willing to pay $2000 to $4000 more for a hearing aid that had good performance in noisy environments.

Level of Evidence: 3

This quasi-experimental study did not include randomization or a true

control group. However, the identified variables were evidence-based from previous studies and the methods of statistical analysis were appropriate for the research questions posed.

Commentary: Implications for Practice and Research

A limitation to the generalizability of this study is the higher-than-average levels of income and education among the subject population. The results of this study indicated that the attribute of improving hearing in a noisy environment is very important in hearing aid selection, even when the cost of hearing aids with this attribute is considerably greater than for hearing aids that performed less well in this area. These results indicate that people with hearing loss would prefer to maintain all their social and work activities, including those in environments in which noise affects communication. Nurses and other health care professionals may have been underestimating the degree and effect of social isolation experienced by people who have reduced or lost auditory sensory perception. Until technologic advances in hearing aid performance in noisy environments are more affordable, research into the types of social activities that can be satisfying to the person with reduced hearing is needed.

Teach the patient how to care for the hearing aid (Chart 48-8). Hearing aids are delicate devices that should be handled only by people who know how to care for them properly.

Chart 48-8 Patient and Family Education: Preparing for Self-Management

Hearing Aid Care

- Keep the hearing aid dry.
- Clean the ear mold with mild soap and water while avoiding excessive wetting.
- Using a toothpick, clean debris from the hole in the middle of the part that goes into your ear.
- Turn off the hearing aid when not in use.
- Check and replace the battery frequently.
- Keep extra batteries on hand.
- Keep the hearing aid in a safe place.
- Avoid dropping the hearing aid or exposing it to temperature extremes.
- Adjust the volume to the lowest setting that allows you to hear, to

prevent feedback squeaking.
- Avoid using hair spray, cosmetics, oils, or other hair and face products that might come into contact with the receiver.
- If the hearing aid does not work:
  - Change the battery.
  - Check the connection between the ear mold and the receiver.
  - Check the on/off switch.
  - Clean the sound hole.
  - Adjust the volume.
  - Take the hearing aid to an authorized service center for repair.

Cochlear implantation may help patients with sensorineural hearing loss. Although a superficial surgical procedure is needed to implant the device, the procedure does not enter the inner ear and thus is not considered a surgical correction for hearing impairment. A small computer converts sound waves into electronic impulses. Electrodes are placed near the internal ear, with the computer attached to the external ear. The electronic impulses then directly stimulate nerve fibers. Some patients have a 50% return of their hearing with this method (Holmes et al., 2012).

Surgical Management.

Many surgical interventions are available for patients with specific disorders leading to hearing loss.

Tympanoplasty.

Tympanoplasty reconstructs the middle ear to improve conductive hearing loss. The procedures vary from simple reconstruction of the eardrum (**myringoplasty**) to replacement of the ossicles within the middle ear (**ossiculoplasty**).

Preoperative Care.

The patient requires specific instructions before surgery. Systemic antibiotics reduce the risk for infection. Teach the patient to follow other measures to decrease the risks for infection, such as avoiding people with upper respiratory infections, getting adequate rest, eating a balanced diet, and drinking adequate amounts of fluid.

Assure the patient that hearing loss immediately after surgery is normal because of canal packing and that hearing will improve when it is removed. Stress that forceful coughing increases middle ear pressure and must be avoided.

Operative Procedures.

Surgery is performed only when the middle ear is free of infection. If an infection is present, the graft is more likely to become infected and not heal. Surgery of the eardrum and ossicles requires the use of a microscope and is a delicate procedure. Local anesthesia can be used, although general anesthesia is often used to prevent the patient from moving.

The surgeon can repair the eardrum with many materials, including muscle fascia, a skin graft, and venous tissue. If the ossicles are damaged, more extensive surgery is needed for repair or replacement. The ossicles can be reached in several ways—through the ear canal, with an endaural incision, or by an incision behind the ear (Fig. 48-11).

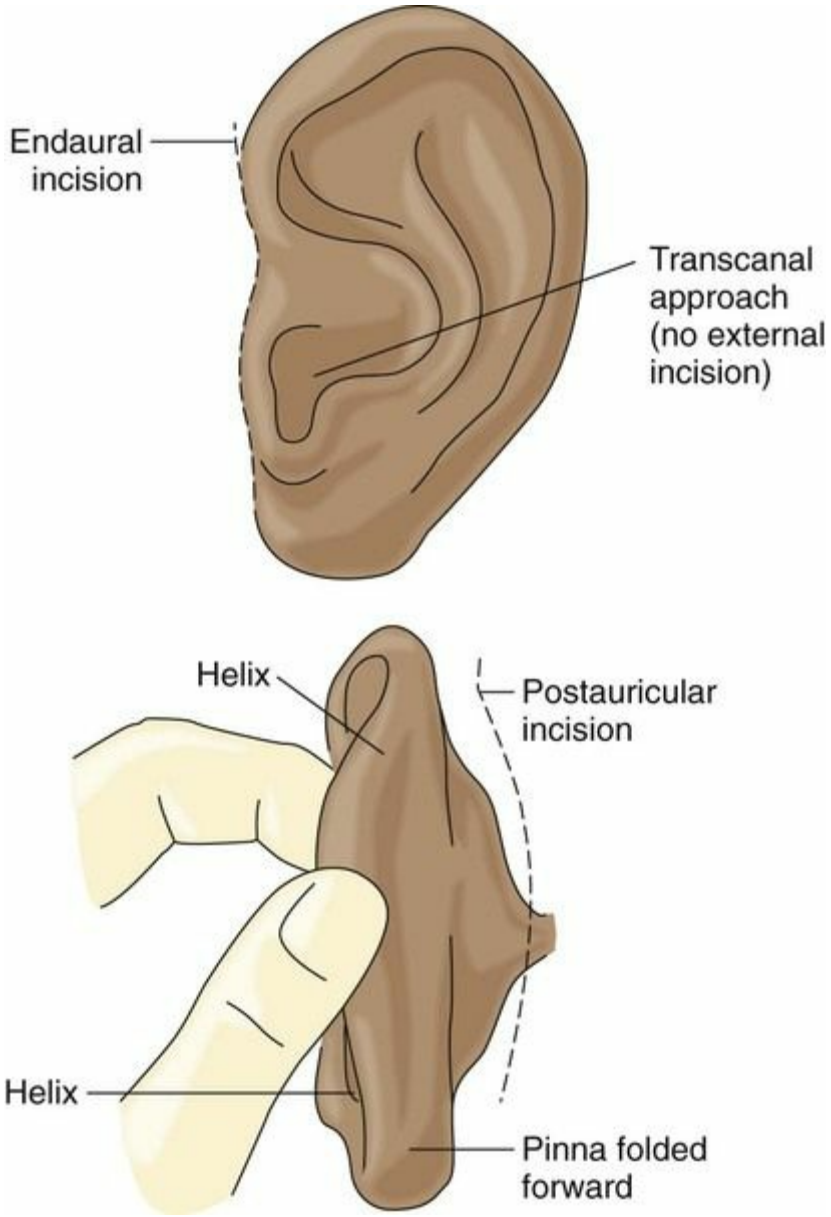

FIG. 48-11 Surgical approaches for repair of the ear and hearing structures.

The surgeon removes diseased tissue and cleans the middle ear cavity. The patient's cartilage or bone, cadaver ossicles, stainless steel wire, or special polymers (Teflon) are used to repair or replace the ossicles.

Postoperative Care.

An antiseptic-soaked gauze, such as iodoform gauze (NU GAUZE), is packed in the ear canal. If a skin incision is used, a dressing is placed over it. Keep the dressing clean and dry, using sterile technique for changes. Keep the patient flat, with the head turned to the side and the operative ear facing up for at least 12 hours after surgery. Give prescribed antibiotics to prevent infection.

Patients often report hearing improvement after removal of the canal packing. Until that time, communicate as with a hearing-impaired

patient, directing conversation to the unaffected ear. Instruct the patient in care and activity restrictions (see Chart 48-6).

Stapedectomy.

A partial or complete stapedectomy with a prosthesis can correct some hearing loss, especially in patients with hearing loss related to otosclerosis. Although hearing usually improves after primary stapes surgery, some patients redevelop conductive hearing loss after surgery and revision surgery is needed.

Preoperative Care.

To prevent infection, the patient must be free from external otitis at surgery. Teach the patient to follow measures that prevent middle ear or external ear infections (Chart 48-9).

Chart 48-9 Patient and Family Education: Preparing for Self-Management

Prevention of Ear Infection or Trauma

- Do not use small objects, such as cotton-tipped applicators, matches, toothpicks, keys, or hairpins, to clean your external ear canal.
- Wash your external ear and canal daily in the shower or while washing your hair.
- Blow your nose gently.
- Do not block one nostril while blowing your nose.
- Sneeze with your mouth open.
- Wear sound protection around loud or continuous noises.
- Avoid or wear head and ear protection during activities with high risk for head or ear trauma, such as wrestling, boxing, motorcycle riding, and skateboarding.
- Keep the volume on head receivers at the lowest setting that allows you to hear.
- Frequently clean objects that come into contact with your ear (e.g., headphones, telephone receivers).
- Avoid environmental conditions with rapid changes in air pressure.

Review with the patient the expected outcomes and possible complications of the surgery. Hearing is initially worse after a stapedectomy. The success rate of this procedure is high. However, there is always a risk for failure that might lead to total deafness on the

affected side. Other possible complications include vertigo, infection, and facial nerve damage.

Operative Procedures.

A stapedectomy is usually performed through the external ear canal with the patient under local anesthesia. After removal of the affected ossicles, a piston-shaped prosthesis is connected between the incus and the footplate (Fig. 48-12). Because the prosthesis vibrates with sound as the stapes did, most patients have restoration of functional hearing.

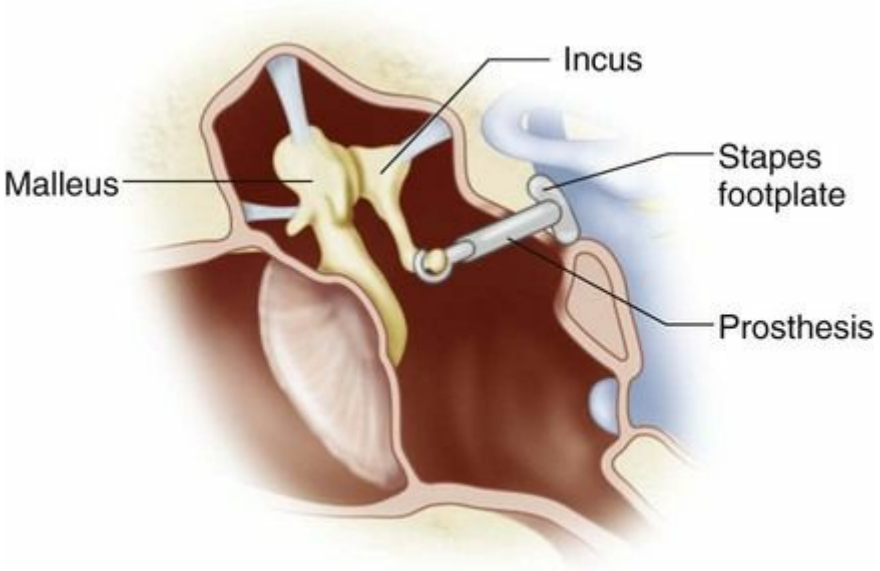

FIG. 48-12 Prosthesis used with stapedectomy. The stapes is removed, leaving the footplate. A metal or plastic prosthesis is connected to the incus and inserted through the hole to act as an artificial stapes.

Postoperative Care.

Remind the patient that improvement in hearing may not occur until 6 weeks after surgery. Drugs for pain help reduce discomfort, and antibiotics are used to prevent infection. Teach the patient about the precautions in Chart 48-6.

The surgical procedure is performed in an area where cranial nerves VII, VIII, and X can be damaged by trauma or by swelling after surgery. *Assess for facial nerve damage or muscle weakness. Indications include an asymmetric appearance or drooping of features on the affected side of the face. Ask the patient about changes in facial perception of touch and in taste.* Vertigo, nausea, and vomiting usually occur after surgery because of the nearness to inner ear structures.

Antivertiginous drugs, such as meclizine (Antivert, Bonamine), and antiemetic drugs, such as droperidol (Inapsine), are given. Take care to prevent falls.

Nursing Safety Priority QSEN

Action Alert

Prevent injury by assisting the patient with ambulation during the first 1 to 2 days after stapedectomy. Keep top bed siderails up, and remind the patient to move the head slowly to avoid vertigo.

Totally Implanted Devices.

Totally implanted devices, such as the Esteem, can improve bilateral moderate to severe sensorineural hearing loss without any visible part (Barbara et al., 2011). These devices have three totally implanted components: a sound processor, a sensor, and a computer. Vibrations of the eardrum and ossicles are picked up by the sensor and converted to electric signals that are processed by the sound processor. The processor is programmed to the patient's specific hearing pathology. The processor filters out some background noise and amplifies the desired sound signal. The signal is transferred to the computer, which then converts the processed signal into vibrations that are transmitted to the inner ear for auditory sensory perception.

Patient criteria for totally implantable devices include:

- Bilateral stable sensorineural hearing loss
- Speech discrimination score of 40% or higher
- Healthy tympanic membrane, eustachian tube, and ossicles of the middle ear
- Large enough ear cavity to fit the device components
- At least 30 days experience with an appropriate hearing aid
- Absence of middle ear, inner ear, or mastoid infection
- Absence of Ménière's disease or recurring vertigo
- Absence of sensitivity to device materials

The devices and the surgery may lead to complications, including temporary facial paralysis, changes in taste sensation, and ongoing or new-onset tinnitus. Unlike cochlear implants, the middle ear is entered and it is considered a surgical procedure. Care before and after surgery is similar to that required with stapedectomy. The cost of the implant and procedure can exceed $30,000 and is not covered by insurance.

Maximizing Communication

Planning: Expected Outcomes.

The patient with reduced auditory sensory perception is expected to become proficient in hearing compensation behaviors to maintain or improve communication. Indicators include that the patient consistently demonstrates these behaviors:

- Uses hearing assistive devices
- Uses sign language, lip-reading, closed captioning, or video description (for television viewing)
- Accurately interprets messages
- Uses nonverbal language
- Exchanges messages accurately with others

Interventions.

Nursing priorities focus on facilitating communication and reducing anxiety.

Use best practices that are listed in Chart 48-10 for communicating with a hearing-impaired patient. Ask the patient what type of communication tools he or she is most comfortable using, and then use that format (Shuler et al., 2013). Do not shout at the patient, because the sound may be projected at a higher frequency, making him or her less able to understand. Communicate by writing (if he or she is able to see, read, and write) or pictures of familiar phrases and objects. Many television programs are now closed captioned or video described (subtitled). When available, use the assistive devices described on p. 1011 to increase communication.

Chart 48-10 Best Practice for Patient Safety & Quality Care QSEN

Communicating with a Hearing-Impaired Patient

- Position yourself directly in front of the patient.
- Make sure that the room is well lighted.
- Get the patient's attention before you begin to speak.
- Move closer to the better-hearing ear.
- Speak clearly and slowly.
- Do not shout (shouting often makes understanding more difficult).
- Keep hands and other objects away from your mouth when talking to the patient.

- Have conversations in a quiet room with minimal distractions.
- Have the patient repeat your statements, not just indicate assent.
- Rephrase sentences and repeat information to aid understanding.
- Use appropriate hand motions.
- Write messages on paper if the patient is able to read.

Lip-reading and *sign language* can increase communication. In lip-reading, patients are taught special cues to look for when lip-reading and how to understand body language. However, the best lip-reader still misses more than half of what is being said. Because hearing is assisted by even minimal lip-reading, urge patients to wear their eyeglasses when talking with someone to see lip movement.

Sign languages, such as American Sign Language (ASL), combine speech with hand movements that signify letters, words, and phrases. These languages take time and effort to learn, and many people are unable to use them effectively (Richardson, 2014).

Managing anxiety can increase the effectiveness of communication efforts. One source of anxiety is the possibility of permanent hearing loss. Provide accurate information about the likelihood of hearing returning. When the hearing impairment is likely to be permanent, reassure patients that communication and social interaction can be maintained.

To reduce anxiety and prevent social isolation, assist patients to use resources and communication to make social contact satisfying. Identify the patient's most satisfying activities and social interactions, and determine the effort necessary to continue them. The patient can alter activities to improve satisfaction. Instead of large gatherings, the patient might choose smaller groups. A meal at home with friends can substitute for dining in a noisy restaurant.

Community-Based Care

Lengthy hospitalization is rare for ear and hearing disorders. If surgery is needed and the procedure is completed without complications, it may be performed in an ambulatory surgery center.

Home Care Management.

Patients who have persistent vertigo are in danger of falling. Assess the home for potential hazards and to determine whether family or significant others are available to assist with meal preparation and other ADLs. A nurse case manager can coordinate with the home care nurse to assist patients and their families in determining how to maintain

adequate self-care abilities, maintain a safe environment, decide about assistance needs, and provide needed care.

Self-Management Education.

Provide written instructions to the patient and family about how to take drugs and when to return for follow-up care. Teach patients how to instill eardrops (see Chart 48-3) and irrigate the ears (see Chart 48-2), and obtain a return demonstration.

To prevent infection after surgery, instruct patients to follow the suggestions in Chart 48-9. Teach patients who use a hearing aid how to use it effectively.

Health Care Resources.

If patients do not have family or friends to help before or after surgery, a referral to a home care agency is needed. Help with meal preparation, cleaning, and personal hygiene can be arranged by the case manager.

Follow-up hearing tests are scheduled when the lesions are well healed, in about 6 to 8 weeks. Audiograms done before and after treatment are compared, and evaluation for further intervention to improve hearing begins. A complication of surgery is continued disability or complete loss of hearing in the affected ear. Surgery is performed first on the ear with the greatest hearing loss. If the surgery does not improve hearing, patients must decide to either attempt surgical correction of the other ear or continue to use an amplification device. When the underlying disorder causing the hearing impairment is progressive, this decision is difficult. Support patients by listening to their concerns and giving additional information when needed.

Costs to the person with a hearing impairment can be extensive. Information and support can come from public and private agencies that specialize in counseling patients with disorders affecting auditory sensory perception.

◆ Evaluation: Outcomes

Evaluate the care of the patient with hearing loss or hearing impairment based on the identified priority patient problems. The expected outcomes include that the patient will:

- Have at least partial improvement of hearing
- Have minimal anxiety
- Use appropriate hearing compensation behaviors
- Communicate effectively in most situations

Specific indicators for these outcomes are listed for each priority

problem under the Planning and Implementation section (see earlier).

Clinical Judgment Challenge

Ethical/Legal

The patient is a 78-year-old man whose hearing loss has progressed to the extent that hearing aids are no longer helpful. His only other health problems are early-stage prostate cancer (for which he is undergoing "watchful waiting") and type 2 diabetes mellitus (which is well controlled by diet and exercise). He lives alone in a condominium complex with many amenities. His son has voiced concern that his father should not live alone but should go into assisted living. The patient insists that this is not necessary because he can still drive, cook, and take care of himself. He also states that he has many friends in the condo complex and wants to remain active within the social groups there.

1. What should be your question when you meet with the father and the son?
2. Are there any major concerns for the father's immediate safety or health because of the hearing loss?
3. Are there any ethical or legal considerations in play here? If so, which one(s)?
4. What accommodations or environmental alterations can you recommend that would make it easier for the father to continue to live alone?
5. What other health care professionals should you consult with or bring in to this situation?

Nursing Concepts and Clinical Judgment Review

What might you NOTICE if the patient has auditory sensory perception problems?

- Person tilts head to one side or leans forward to listen when another person speaks.
- Person watches the lips of a speaker closely.
- Person does not startle when a loud or unexpected sound occurs in the environment.
- Person frequently asks the speaker to repeat statements or questions.
- Person does not verbally interact with those around him or her.
- When a sentence is whispered to the person, he or she does not accurately repeat it back to the speaker.

• Person responds inappropriately to questions.

How should you RESPOND to a patient who has auditory sensory perception problems?

• Reduce the background sound when speaking to the person (close the door to the hall, use a private area, turn off televisions and radios).
• Speak slowly, distinctly, and with a deeper tone.
• Face the patient while speaking.
• Ensure that all members of the health care team are aware of the patient's impairment and use an appropriate method to communicate with him or her.
• Determine whether the patient can communicate by sign language.
• Identify safety issues specific for the patient with a hearing impairment.
• Use a certified medical interpreter when taking a history from, explaining procedures to, or teaching the patient who has a hearing impairment.

Get Ready for the NCLEX® Examination!

Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Use Contact Precautions with any patient who has drainage from the ear canal. **Safety** QSEN
- Use a separate speculum cover for each ear when conducting an otoscopic examination. **Safety** QSEN
- Slowly and gently introduce the otoscopic speculum into the external ear canal during assessment. **Safety** QSEN
- Do not perform an otoscopic examination on a confused patient. **Safety** QSEN
- Use the suggestions presented in the Patient History section (p. 998) to enhance communication with a patient who has an impairment of auditory sensory perception. **Safety** QSEN
- Protect the patient with vertigo or dizziness from injury by assisting with ambulation. **Safety** QSEN
- Follow the guidelines in Chart 48-4 when irrigating the ear canal. **Safety** QSEN

Health Promotion and Maintenance

- Teach patients the proper way to clean the pinna and external ear canal and how to remove cerumen from the external canal. **Evidence-Based Practice** QSEN
- Identify patients at risk for hearing impairment as a result of work environment or leisure activities. **Patient-Centered Care** QSEN
- Encourage all patients, even if they already have a hearing impairment, to use ear protection in loud environments. **Patient-Centered Care** QSEN
- Inform all patients who smoke that smoking increases the risk for development of hearing problems. **Evidence-Based Practice** QSEN
- Teach patients how to properly care for their hearing aids. **Patient-Centered Care** QSEN
- Instruct patients to avoid closing off one naris when blowing the nose. **Patient-Centered Care** QSEN
- Remind patients who engage in water sports and who are at risk for external otitis to wear earplugs when in the water. **Patient-Centered Care** QSEN

- Teach patients the proper techniques for self-instillation of eardrops and ear irrigation. **Patient-Centered Care** QSEN

Psychosocial Integrity

- Allow the patient the opportunity to express fear or anxiety about a change in hearing status. **Patient-Centered Care** QSEN
- Explain all diagnostic and therapeutic procedures, restrictions, and follow-up care to the patient and family. **Patient-Centered Care** QSEN
- Refer patients newly diagnosed with hearing impairment or any chronic ear problem to appropriate local resources and support groups.
- Teach family members ways to communicate with a hearing-impaired patient with and without a hearing aid. **Patient-Centered Care** QSEN
- Assess the degree to which hearing problems interfere with the patient's ability to interact with others. **Patient-Centered Care** QSEN
- Remind patients having ear surgery that hearing in the affected ear may be reduced immediately after surgery because of packing, swelling, or surgical manipulation. **Patient-Centered Care** QSEN

Physiological Integrity

- Ask the patient about hearing problems in any other members of the family, because many hearing problems have a genetic component. **Patient-Centered Care** QSEN
- Check the hearing of any patient receiving an ototoxic drug for more than 5 days. **Evidence-Based Practice** QSEN
- Ask the patient about current and past drug use (prescribed, over-the-counter), and check with a pharmacist to evaluate for ototoxicity. **Patient-Centered Care** QSEN
- Avoid ear canal irrigation if the eardrum is perforated or if the canal contains vegetative matter. **Safety** QSEN
- Stress the importance of completing an antibiotic regimen for an ear infection. **Evidence-Based Practice** QSEN
- Remind patients to move the head slowly after ear surgery to prevent dizziness or vertigo. **Patient-Centered Care** QSEN
- Use upper siderails for any patient experiencing dizziness or vertigo. **Safety** QSEN
- Work with the case manager, home care nurse, speech-language pathologist, and occupational therapist to ensure safety and optimal function for the patient with a hearing or balance problem in the

community setting. **Teamwork and Collaboration** QSEN

UNIT XII

Problems of Mobility: Management of Patients with Problems of the Musculoskeletal System

OUTLINE

CHAPTER 49

Assessment of the Musculoskeletal System

Donna D. Ignatavicius

PRIORITY CONCEPTS

- Mobility
- Pain
- Sensory Perception

Learning Outcomes

Safe and Effective Care Environment

1. Collaborate with the physical and occupational therapists to perform a complete musculoskeletal assessment, including functional status, as needed.

Health Promotion and Maintenance

2. Explain how physiologic aging changes of the musculoskeletal system affect care of older adults.

Psychosocial Integrity

3. Assess the patient's and family's reaction to change in body image caused by a major musculoskeletal health problem.

Physiological Integrity

4. Recall the basic anatomy and physiology of the musculoskeletal system.
5. Assess patients for mobility, gait, motor skills, pain, sensory perception, and the use of assistive devices.
6. Interpret assessment findings in a patient with a musculoskeletal health

problem.

7. Explain the use of laboratory testing for a patient with a musculoskeletal health problem.
8. Develop a teaching plan to educate the patient and family about diagnostic procedures.

http://evolve.elsevier.com/Iggy/

The musculoskeletal system is the second largest body system. It includes the bones, joints, and skeletal muscles, as well as the supporting structures needed to move them. mobility (movement) is a basic human need that is essential for performing ADLs. When a patient cannot move to perform ADLs or other daily routines, self-esteem and a sense of self-worth can be diminished.

Disease, surgery, and trauma can affect one or more parts of the musculoskeletal system, often leading to decreased mobility. When mobility is impaired for a long time, other body systems can be affected. For example, prolonged immobility can lead to skin breakdown, constipation, and thrombus formation. If nerves are damaged by trauma or disease, patients may also have problems with sensory perception, also known as *sensation*.

Anatomy and Physiology Review

Skeletal System

The skeletal system consists of 206 bones and multiple joints. The growth and development of these structures occur during childhood and adolescence and are not discussed in this text. Common physical skeletal differences among selected racial/ethnic groups are listed in Table 49-1.

TABLE 49-1

Musculoskeletal Differences in Selected Racial/Ethnic Groups

GROUP	MUSCULOSKELETAL DIFFERENCES
African Americans	Greater bone density than Europeans, Asians, and Hispanics. Accounts for decreased incidence of osteoporosis.
Amish	Greater incidence of dwarfism than in other populations.
Chinese Americans	Bones are shorter and smaller with less bone density. Increased incidence of osteoporosis.
Egyptian Americans	Shorter in stature than Euro-Americans and African Americans.
Filipino/Vietnamese	Short in stature; adult height about 5 feet.
Irish Americans	Taller and broader than other Euro-Americans. Less bone density than African Americans.
Navajo American Indians	Taller and thinner than other American Indians.

Bones

Types and Structure.

Bone can be classified in two ways—by shape and by structure. **Long bones,** such as the femur, are cylindric with rounded ends and often bear weight. **Short bones,** such as the phalanges, are small and bear little or no weight. **Flat bones,** such as the scapula, protect vital organs and often contain blood-forming cells. Bones that have unique shapes are known as **irregular bones.** The carpal bones in the wrist and the small bones in the inner ear are examples of **irregular bones**. The sesamoid bone is the least common type and develops within a tendon; the patella is a typical example.

The second way bone is classified is by *structure* or composition. As shown in Fig. 49-1, the outer layer of bone, or cortex, is composed of dense, compact bone tissue. The inner layer, in the medulla, contains spongy, cancellous tissue. Almost every bone has both tissue types but in varying quantities. The long bone typically has a shaft, or diaphysis, and two knoblike ends, or epiphyses.

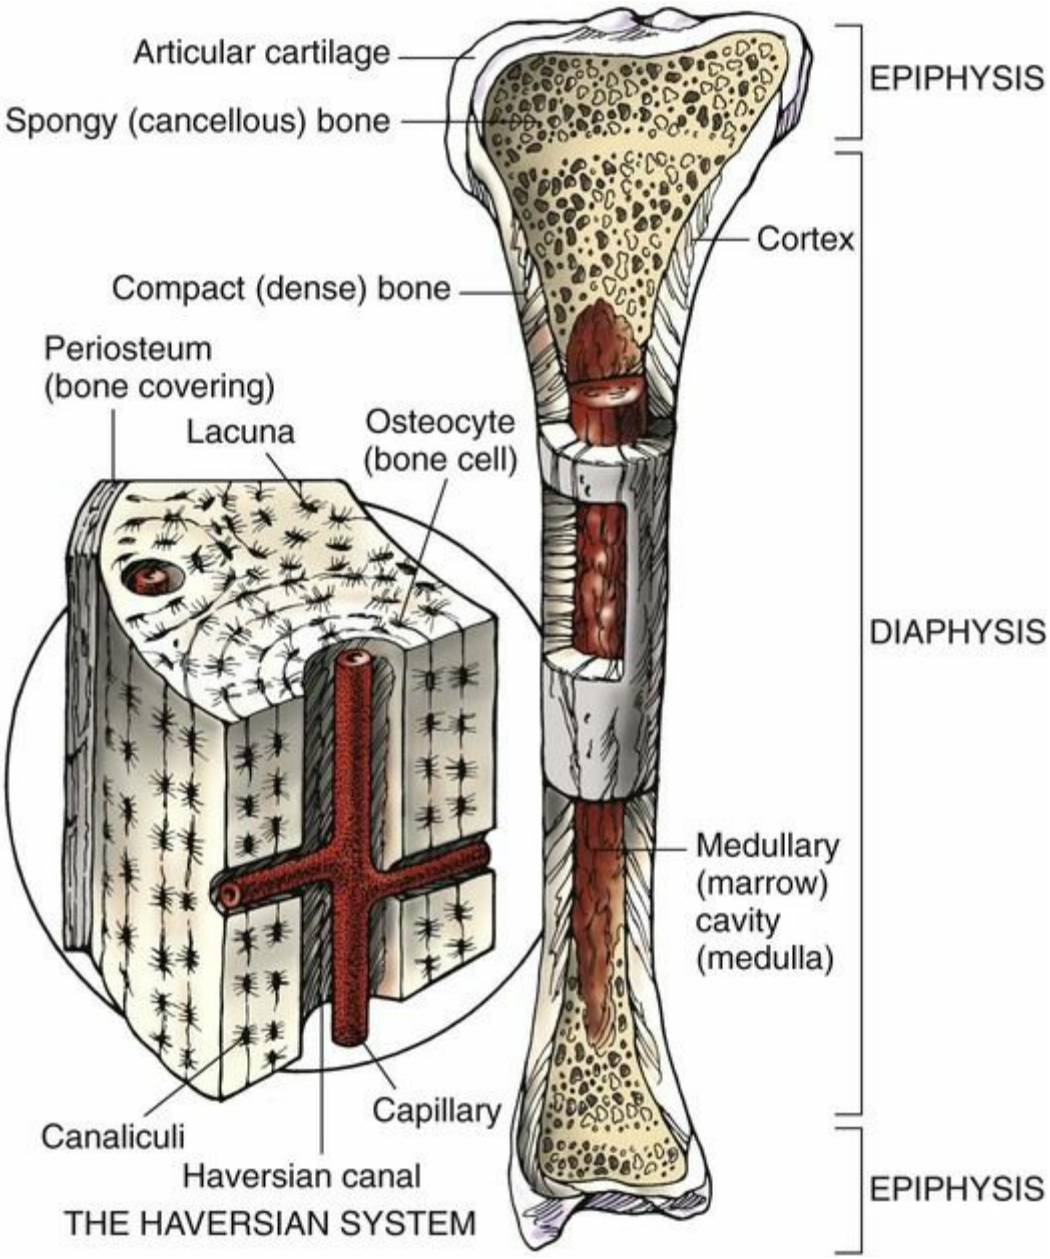

FIG. 49-1 The structure of a typical long bone. The cortex, or outer layer, is composed of dense, compact tissue. The microscopic structure of this compact cortical tissue is the haversian system.

The structural unit of the cortical compact bone is the haversian system, which is detailed in Fig. 49-1. The haversian system is a complex canal network containing microscopic blood vessels that supply nutrients and oxygen to bone, as well as lacunae, which are small cavities that house **osteocytes** (bone cells). The canals run vertically within the hard cortical bone tissue.

The softer **cancellous** tissue contains large spaces, or trabeculae, which are filled with red and yellow marrow. **Hematopoiesis** (production of blood cells) occurs in the red marrow. The yellow marrow contains fat cells, which can be dislodged and enter the bloodstream to cause fat

embolism syndrome (FES), a life-threatening complication. Volkmann's canals connect bone marrow vessels with the haversian system and periosteum, the outermost covering of the bone. In the deepest layer of the periosteum are osteogenic cells, which later differentiate into **osteoblasts** (bone-forming cells) and **osteoclasts** (bone-destroying cells).

Bone also contains a matrix consisting chiefly of collagen, mucopolysaccharides, and lipids. Deposits of inorganic calcium salts (carbonate and phosphate) in the matrix provide the hardness of bone.

Bone is a very vascular tissue. Its estimated total blood flow is between 200 and 400 mL/min. Each bone has a main nutrient artery, which enters near the middle of the shaft and branches into ascending and descending vessels. These vessels supply the cortex, the marrow, and the haversian system. Very few nerve fibers are connected to bone. Sympathetic nerve fibers control dilation of blood vessels. Sensory nerve fibers transmit pain signals experienced by patients who have primary lesions of the bone, like bone tumors.

Function.

The skeletal system:

- Provides a framework for the body and allows the body to be weight bearing, or upright
- Supports the surrounding tissues (e.g., muscle and tendons)
- Assists in movement through muscle attachment and joint formation
- Protects vital organs, such as the heart and lungs
- Manufactures blood cells in red bone marrow
- Provides storage for mineral salts (e.g., calcium and phosphorus)

After puberty, bone reaches its maturity and maximum growth. Bone is a dynamic tissue. It undergoes a continuous process of formation and **resorption,** or destruction, at equal rates until the age of 35 years. In later years, bone resorption increases, decreasing bone mass and predisposing patients to injury, especially older women.

Numerous minerals and hormones affect bone growth and metabolism, including:

- Calcium
- Phosphorus
- Calcitonin
- Vitamin D
- Parathyroid hormone (PTH)
- Growth hormone
- Glucocorticoids
- Estrogens and androgens

• Thyroxine
• Insulin

Bone accounts for about 99% of the *calcium* in the body and 90% of the *phosphorus.* In healthy adults, the serum concentrations of calcium and phosphorus maintain an inverse relationship. As calcium levels rise, phosphorus levels decrease. When serum levels are altered, calcitonin and PTH work to maintain equilibrium. If the calcium in the blood is decreased, the bone, which stores calcium, releases calcium into the bloodstream in response to PTH stimulation.

Calcitonin is produced by the thyroid gland and *decreases* the serum calcium concentration if it is increased above its normal level. Calcitonin inhibits bone resorption and increases renal excretion of calcium and phosphorus as needed to maintain balance in the body.

Vitamin D and its metabolites are produced in the body and transported in the blood to promote the absorption of calcium and phosphorus from the small intestine. They also seem to enhance PTH activity to release calcium from the bone. A decrease in the body's vitamin D level can result in osteomalacia (softening of bone) in the adult. Vitamin D metabolism and osteomalacia are described in Chapter 50.

When serum calcium levels are lowered, *parathyroid hormone* (PTH, or parathormone) secretion increases and stimulates bone to promote osteoclastic activity and *release* calcium to the blood. PTH reduces the renal excretion of calcium and facilitates its absorption from the intestine. If serum calcium levels increase, PTH secretion diminishes to preserve the bone calcium supply. This process is an example of the feedback loop system of the endocrine system.

Growth hormone secreted by the anterior lobe of the pituitary gland is responsible for increasing bone length and determining the amount of bone matrix formed before puberty. During childhood, an increased secretion results in gigantism and a decreased secretion results in dwarfism. In the adult, an increase causes acromegaly, which is characterized by bone and soft-tissue deformities (see Chapter 62).

Adrenal glucocorticoids regulate protein metabolism, either increasing or decreasing catabolism to reduce or intensify the organic matrix of bone. They also aid in regulating intestinal calcium and phosphorus absorption.

Estrogens stimulate osteoblastic (bone-building) activity and inhibit PTH. When estrogen levels decline at menopause, women are susceptible to low serum calcium levels with increased bone loss (osteoporosis). *Androgens,* such as testosterone in men, promote anabolism (body tissue

building) and increase bone mass.

Thyroxine is one of the principal hormones secreted by the thyroid gland. Its primary function is to increase the rate of protein synthesis in all types of tissue, including bone. *Insulin* works together with growth hormone to build and maintain healthy bone tissue.

Joints

A **joint** is a space in which two or more bones come together. This is also referred to as *articulation* of the joint. The major function of a joint is to provide movement and flexibility in the body.

There are three types of joints in the body:

- Synarthrodial, or completely immovable, joints (e.g., in the cranium)
- Amphiarthrodial, or slightly movable, joints (e.g., in the pelvis)
- Diarthrodial (synovial), or freely movable, joints (e.g., the elbow and knee)

Although any of these joints can be affected by disease or injury, the synovial joints are most commonly involved as discussed in Chapter 18.

The diarthrodial, or synovial, joint is the most common type of joint in the body. **Synovial joints** are the only type lined with synovium, a membrane that secretes synovial fluid for lubrication and shock absorption. As shown in Fig. 49-2, the synovium lines the internal portion of the joint capsule but does not normally extend onto the surface of the cartilage at the spongy bone ends. Articular cartilage consists of a collagen fiber matrix impregnated with a complex ground substance. Patients with inflammatory types of arthritis often have synovitis (synovial inflammation) and breakdown of the cartilage. Bursae, small sacs lined with synovial membrane, are located at joints and bony prominences to prevent friction between bone and structures adjacent to bone. These structures can also become inflamed, causing bursitis.

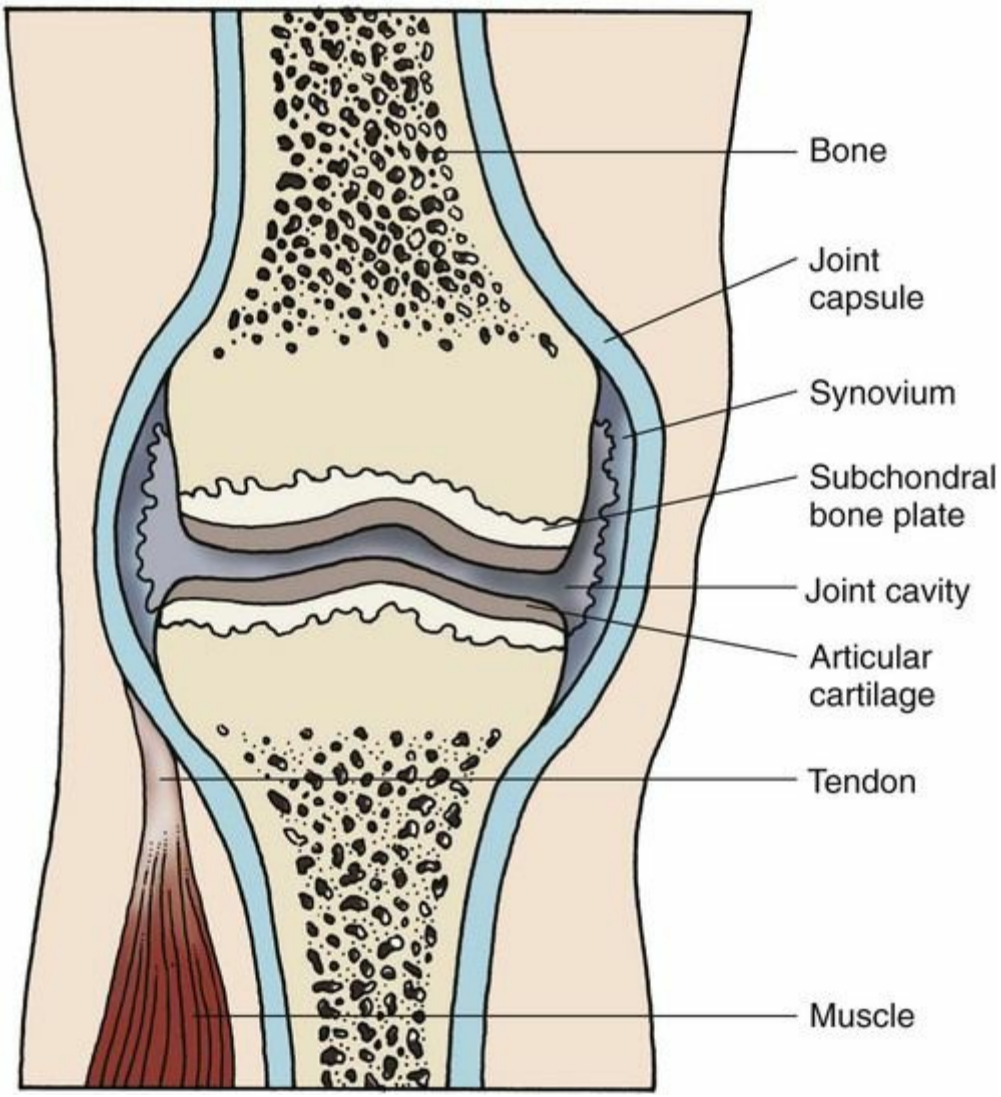

FIG. 49-2 The structure of a synovial joint. Synovium lines the joint capsule but does not extend into the articular cartilage.

Synovial joints are described by their anatomic structures. *Ball-and-socket* joints (shoulder, hip) permit movement in any direction. *Hinge* joints (elbow) allow motion in one plane—flexion and extension. The knee is often classified as a hinge joint, but it rotates slightly, as well as flexes and extends. It is best described as a *condylar* type of synovial joint. The gliding movement of the wrist is characteristic of the *biaxial* joint. *Pivot* joints permit rotation only, as in the radioulnar area.

Muscular System

There are three types of muscle in the body: smooth muscle, cardiac muscle, and skeletal muscle. Smooth, or non-striated, involuntary muscle is responsible for contractions of organs and blood vessels and is controlled by the autonomic nervous system. Cardiac or striated involuntary muscle is also controlled by the autonomic nervous system.

The smooth and cardiac muscles are discussed with the body systems to which they belong in the assessment chapters.

In contrast to smooth and cardiac muscle, skeletal muscle is striated voluntary muscle controlled by the central and peripheral nervous systems. The junction of a peripheral motor nerve and the muscle cells that it supplies is sometimes referred to as a **motor end plate.** Muscle fibers are held in place by connective tissue in bundles, or fasciculi. The entire muscle is surrounded by dense fibrous tissue, or fascia, which contains the muscle's blood, lymph, and nerve supply.

The main function of skeletal muscle is *movement* of the body and its parts. When bones, joints, and supporting structures are adversely affected by injury or disease, the adjacent muscle tissue is often involved, limiting mobility. During the aging process, muscle fibers decrease in size and number, even in well-conditioned adults. Atrophy results when muscles are not regularly exercised, and they deteriorate from disuse.

Supporting structures for the muscular system are very susceptible to injury. They include **tendons** (bands of tough, fibrous tissue that attach muscles to bones) and **ligaments,** which attach bones to other bones at joints.

Musculoskeletal Changes Associated with Aging

Osteopenia, or decreased bone density (bone loss), occurs as one ages. Many older adults, especially white, thin women, have severe osteopenia, a disease called *osteoporosis.* This condition causes postural and gait changes and predisposes the person to fractures. Chapter 50 discusses this health problem in detail.

Synovial joint cartilage can become less elastic and compressible as a person ages. As a result of these cartilage changes and continued use of joints, the joint cartilage becomes damaged, leading to osteoarthritis (OA). Genetic defects in cartilage may also contribute to joint disease. The most common joints affected are the weight-bearing joints of the hip, knee, and cervical and lumbar spine, but joints in the shoulder and upper extremity, feet, and hands also can be affected. Refer to Chapter 18 for a complete discussion of OA.

As one ages, muscle tissue atrophies. Increased activity and exercise can slow the progression of atrophy and restore muscle strength (Touhy & Jett, 2014). Musculoskeletal changes cause decreased coordination, loss of muscle strength, gait changes, and a risk for falls with injury. (See Chapter 2 for discussion on fall prevention.) Chart 49-1 lists the major anatomic and physiologic changes and implications for nursing care.

Chart 49-1 Nursing Focus on the Older Adult

Changes in the Musculoskeletal System Related to Aging

PHYSIOLOGIC CHANGE	NURSING INTERVENTIONS	RATIONALES
Decreased bone density	Teach safety tips to prevent falls.	Porous bones are more likely to fracture.
	Reinforce need to exercise, especially weight-bearing exercise.	Exercise slows bone loss.
Increased bone prominence	Prevent pressure on bone prominences.	There is less soft tissue to prevent skin breakdown.
Kyphotic posture: widened gait, shift in the center of gravity	Teach proper body mechanics; instruct the patient to sit in supportive chairs with arms.	Correction of posture problems prevents further deformity; the patient should have support for bony structures.
Cartilage degeneration	Provide moist heat, such as a shower or warm, moist compresses.	Moist heat increases blood flow to the area.
Decreased range of motion (ROM)	Assess the patient's ability to perform ADLs and mobility.	The patient may need assistance with self-care skills.
Muscle atrophy, decreased strength	Teach isometric exercises.	Exercises increase muscle strength.
Slowed movement	Do not rush the person; be patient.	The patient may become frustrated if hurried.

Assessment Methods

Patient History

In the assessment of a patient with an actual or potential musculoskeletal problem, a detailed and accurate history is helpful in identifying priority problems and nursing interventions. The history reveals information about the patient that can direct the physical assessment.

Accidents, illnesses, lifestyle, and drugs may contribute to a patient's current problem. Young men are at the greatest risk for trauma related to motor vehicle crashes. Older adults are at the greatest risk for falls that result in fractures and soft-tissue injury. When taking a personal health history, question the patient about any traumatic injuries and sports activities, no matter when they occurred. An injury to the lumbar spine 30 years ago may have caused a patient's current low back pain. A motor vehicle crash or sports injury can cause osteoarthritis years after the event.

Previous or current illness or disease may affect musculoskeletal status. For example, a patient with diabetes who is treated for a foot ulcer is at high risk for acute or chronic osteomyelitis (bone infection). In addition, diabetes slows the healing process. Ask the patient about any previous hospitalizations and illnesses or complications. Inquire about his or her ability to perform ADLs independently or if assistive/adaptive devices are used.

Current lifestyle also contributes to musculoskeletal health. Weight-bearing activities such as walking can reduce risk factors for osteoporosis and maintain muscle strength (McCance et al., 2014). High-impact sports, such as excessive jogging or running, can cause musculoskeletal injury to soft tissues and bone. Tobacco use slows the healing of musculoskeletal injuries. Excessive alcohol intake can decrease vitamins and nutrients the person needs for bone and muscle tissue growth.

When assessing a patient with a possible musculoskeletal alteration, inquire about occupation or work life. A person's occupation can cause or contribute to an injury. For instance, fractures are not uncommon in patients whose jobs require manual labor, such as housekeepers, mechanics, and industrial workers. Certain occupations, such as computer-related jobs, may predispose a person to carpal tunnel syndrome (entrapment of the median nerve in the wrist) or neck pain. Construction workers and health care workers may experience back injury from prolonged standing and excessive lifting. Amateur and professional athletes often experience acute musculoskeletal injuries

(e.g., joint dislocations and fractures) and chronic disorders (e.g., joint cartilage trauma), which can lead to osteoarthritis.

Ask about allergies, particularly allergy to dairy products, and previous and current use of drugs—prescribed, over-the-counter, and illicit. Allergy to dairy products could cause decreased calcium intake. Some drugs, such as steroids, can negatively affect calcium metabolism and promote bone loss. Other drugs may be taken to relieve musculoskeletal pain. Inquire about herbs, vitamin and mineral supplements, or biologic compounds that may be used for arthritis and other musculoskeletal problems, such as glucosamine and chondroitin. Complementary and alternative therapies are commonly used by patients with various types of arthritis and **arthralgias** (joint aching). Chapter 18 discusses these therapies in detail.

Nutrition History

A brief review of the patient's nutrition history helps determine any risks for inadequate nutrient intake. For example, most people, especially women, do not get enough calcium in their diet. Determine if the patient has had a significant weight gain or loss.

Ask the patient to recall a typical day of food intake to help identify deficiencies and excesses in the diet. Lactose intolerance is a common problem that can cause inadequate calcium intake. People who cannot afford to buy food are especially at risk for undernutrition. Some older adults and others are not financially able to buy the proper foods for adequate nutrition.

Inadequate protein or insufficient vitamin C or D in the diet slows bone and tissue healing. Obesity places excess stress and strain on bones and joints, with resulting trauma to joint cartilage. In addition, obesity inhibits mobility in patients with musculoskeletal problems, which predisposes them to complications such as respiratory and circulatory problems. People with eating disorders such as anorexia nervosa and bulimia nervosa are also at risk for osteoporosis related to decreased intake of calcium and vitamin D.

Family History and Genetic Risk

Obtaining a family history assists in identifying disorders that have a familial or genetic tendency. Osteoporosis (age-related bone loss) and gout, for instance, often occur in several generations of a family. Osteogenic sarcoma, a type of bone cancer, may be genetically influenced by *Tp53* gene mutation (Nussbaum et al., 2007). Positive family history of

these types of disorders can increase risks to the patient. Chapters 18 and 50 provide a more complete description of musculoskeletal problems that have strong genetic links.

Current Health Problems

The most common reports of persons with a musculoskeletal problem are pain and weakness, either of which can impair mobility. Collect data pertinent to the patient's presenting health problem:

- Date and time of onset
- Factors that cause or exacerbate (worsen) the problem
- Course of the problem (e.g., intermittent or continuous)
- Clinical manifestations (as expressed by the patient) and the pattern of their occurrence
- Measures that improve clinical manifestations (e.g., heat, ice)

Assessment of pain can present many challenges. Pain can be related to bone, muscle, or joint problems. It may be described as acute or chronic, depending on the onset and duration. Pain with movement could indicate a fracture and/or muscle or joint injury. Assess the intensity of pain by using a pain scale and asking the patient to rate the level he or she is experiencing. Quality of pain may be described as dull, burning, aching, or stabbing. Determine the location of pain and areas to which it radiates. With any assessment, it is always best if the patient describes the pain in his or her own words and points to its location, if possible. Chapter 3 describes acute and chronic pain in detail.

Weakness may be related to individual muscles or muscle groups. Determine if weakness occurs in proximal or distal muscles or muscle groups. Proximal weakness (near trunk of body) may indicate **myopathy** (a problem in muscle tissue), whereas distal weakness (in extremities) may indicate **neuropathy** (a problem in nerve tissue). Muscle weakness in the lower extremities may increase the risk for falls and injury. Weakness in the upper extremities may interfere with ADLs.

Assessment of the Skeletal System

Although bones, joints, and muscles are usually assessed simultaneously in a head-to-toe approach, each subsystem is described separately for emphasis and understanding. For physical assessment of the musculoskeletal system, use inspection, palpation, and range of motion (ROM). A general assessment is described in this chapter. More specific assessment techniques are discussed in the musculoskeletal problem chapters in this unit.

General Inspection

Observe the patient's posture, gait, and general mobility for gross deformities and impairment. Note unusual findings, and coordinate with the physical or occupational therapist for an in-depth physical assessment.

Posture and Gait.

Posture includes the person's body build and alignment when standing and walking. Assess the curvature of the spine and the length, shape, and symmetry of extremities. Fig. 49-3 illustrates several common spinal deformities. Inspect muscle mass for size and symmetry.

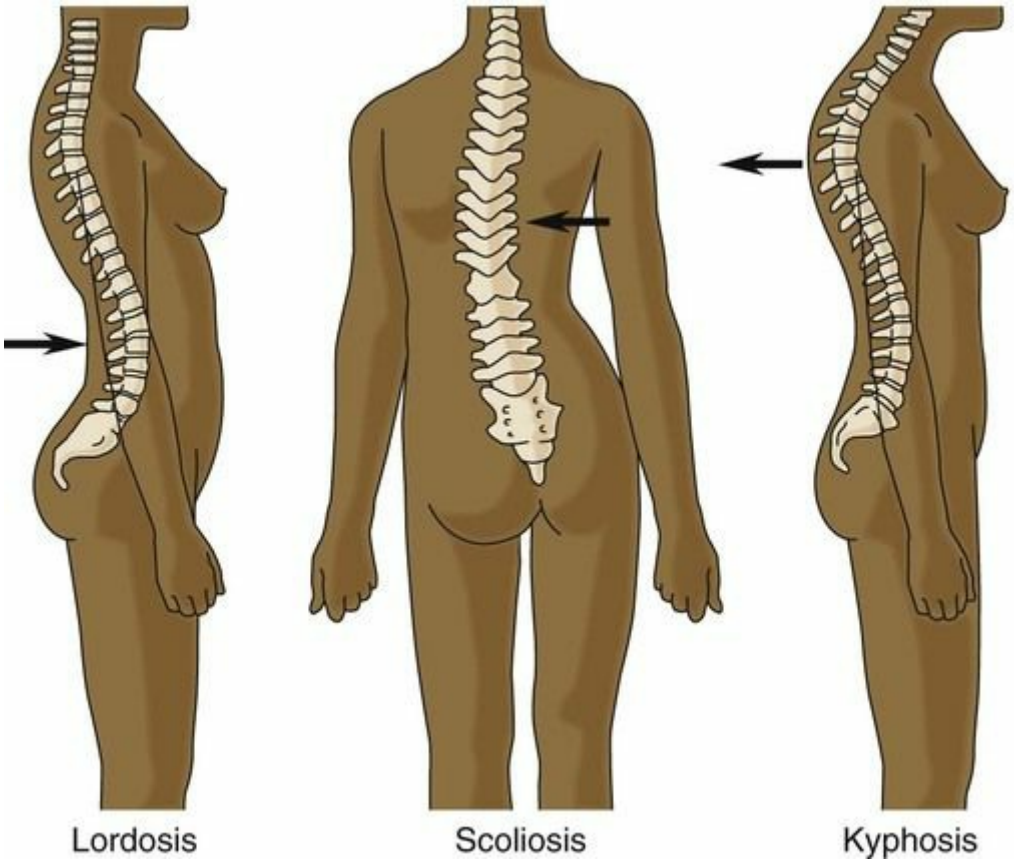

FIG. 49-3 Common spinal deformities.

Most patients with musculoskeletal problems eventually have a problem with *gait*. The nurse or therapist evaluates the patient's balance, steadiness, and ease and length of stride. Any limp or other asymmetric leg movement or deformity is noted. An abnormality in the stance phase of gait is called an **antalgic** gait. When part of one leg is painful, the patient shortens the stance phase on the affected side. An abnormality in the swing phase is called a **lurch.** This abnormal gait occurs when the muscles in the buttocks and/or legs are too weak to allow the person to

change weight from one foot to the other. In this case, the shoulders are moved either side-to-side or front-to-back for help in shifting the weight from one leg to the other. Some patients, such as those with chronic hip pain and muscle atrophy from arthritic disorders, have a combination of an antalgic gait and lurch.

Mobility and Functional Assessment.

In collaboration with the physical or occupational therapist, assess the patient's need for ambulatory devices, such as canes and walkers, during transfer from bed to chair and while walking and climbing stairs. Observe his or her ability to perform ADLs, such as dressing and bathing. Pain and deformity may limit physical mobility and function. Coordinate with the physical and occupational therapists to assess the patient's functional status. A complete discussion of functional assessment is found in Chapter 6.

Assess major bones, joints, and muscles by inspection, palpation, and determination of ROM. Pay special attention to areas that are affected or may be affected, according to the patient's history or current problem.

A **goniometer** is a tool that may be used by rehabilitation therapists or nurses to provide an exact measurement of flexion and extension or joint ROM. Active range of motion (AROM) can be evaluated by asking the patient to move each joint through the ROM himself or herself. If the patient cannot actively move a joint through range of motion, ask him or her to relax the muscles in the extremity. Hold the part with one hand above and one hand below the joint to be evaluated and allow passive range of motion (PROM) to evaluate joint mobility. Movements shown in Fig. 49-4 may be used to evaluate active and passive ROM. Circumduction is a movement that can also be evaluated in the shoulder by having the patient move the arm in circles from the shoulder joint. As long as the patient can function to meet personal needs, a limitation in ROM may not be significant. For each anatomic location, observe the skin for color, elasticity, and lesions that may relate to musculoskeletal dysfunction. For instance, redness or warmth may indicate an inflammatory process and/or pressure injury to skin.

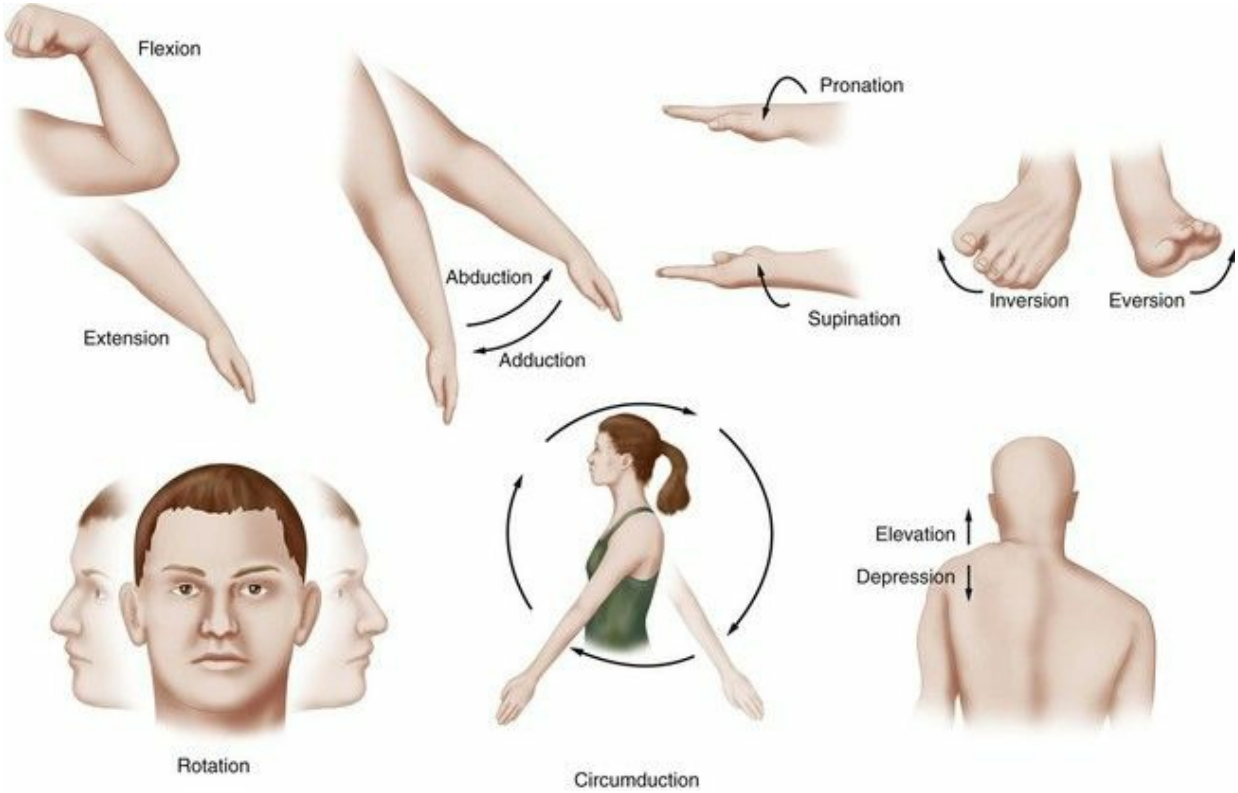

FIG. 49-4 Movements of the skeletal muscles.

NCLEX Examination Challenge

Health Promotion and Maintenance

A nurse is performing a musculoskeletal assessment on an older adult living independently in a senior housing apartment. What normal physiologic changes of aging does the nurse expect? **Select all that apply.**

A Muscle contractures
B Slowed movement
C Lordosis
D Antalgic gait
E Decreased coordination

Specific Assessments

If the patient has pain or weakness in the *face* or *neck*, inspect and palpate this area for tenderness and masses. Ask the patient to open his or her mouth while palpating the temporomandibular joints (TMJs). Common abnormal findings are tenderness or pain, **crepitus** (a grating sound), and a spongy swelling caused by excess synovium and fluid.

Inspect and palpate each vertebra of the spine in the neck. Proceed cautiously and gently if pain is present. Clinical findings may include malalignment; tenderness; or inability to flex, extend, and rotate the neck

as expected. Muscle and nerve pain often accompany neck pain if spinal nerves are involved.

The thoracic spine, lumbar spine, and sacral spine are evaluated in the same manner as the neck. Spinal alignment problems are common (see Fig. 49-3). Place both hands over the posterior iliac crests with the thumbs over the lumbosacral area. Apply pressure with the thumbs along the lumbosacral spine to elicit tenderness. Many patients do not have discomfort until the area is palpated. **Lordosis** is a common finding in adults who have abdominal obesity. During screening for **scoliosis,** ask the patient to flex forward from the hips and inspect for a lateral curve in the spine.

If the extremities are affected by a musculoskeletal problem, assess arms or legs at the same time for side-to-side comparisons. For example, inspect and palpate both shoulders for size, swelling, deformity, poor alignment, tenderness or pain, and mobility. A shoulder injury may prevent the patient from combing his or her hair with the affected arm, but severe arthritis may inhibit movement in both arms. Assess the elbows and wrists in a similar way.

Because the hand has multiple joints in a single digit, assessment of hand function is perhaps the most critical part of the examination. If the hands are affected, inspect and palpate the metacarpophalangeal (MCP), proximal interphalangeal (PIP), and distal interphalangeal (DIP) joints. The same digits are compared on the right and left hands (Fig. 49-5). Determine the range of motion (ROM) for each joint by observing active movement. If movement is not possible, evaluate passive motion. For a quick and easy assessment of ROM, ask the patient to make a fist and then appose each finger to the thumb. If he or she can perform these maneuvers, ROM of the hand is not seriously restricted.

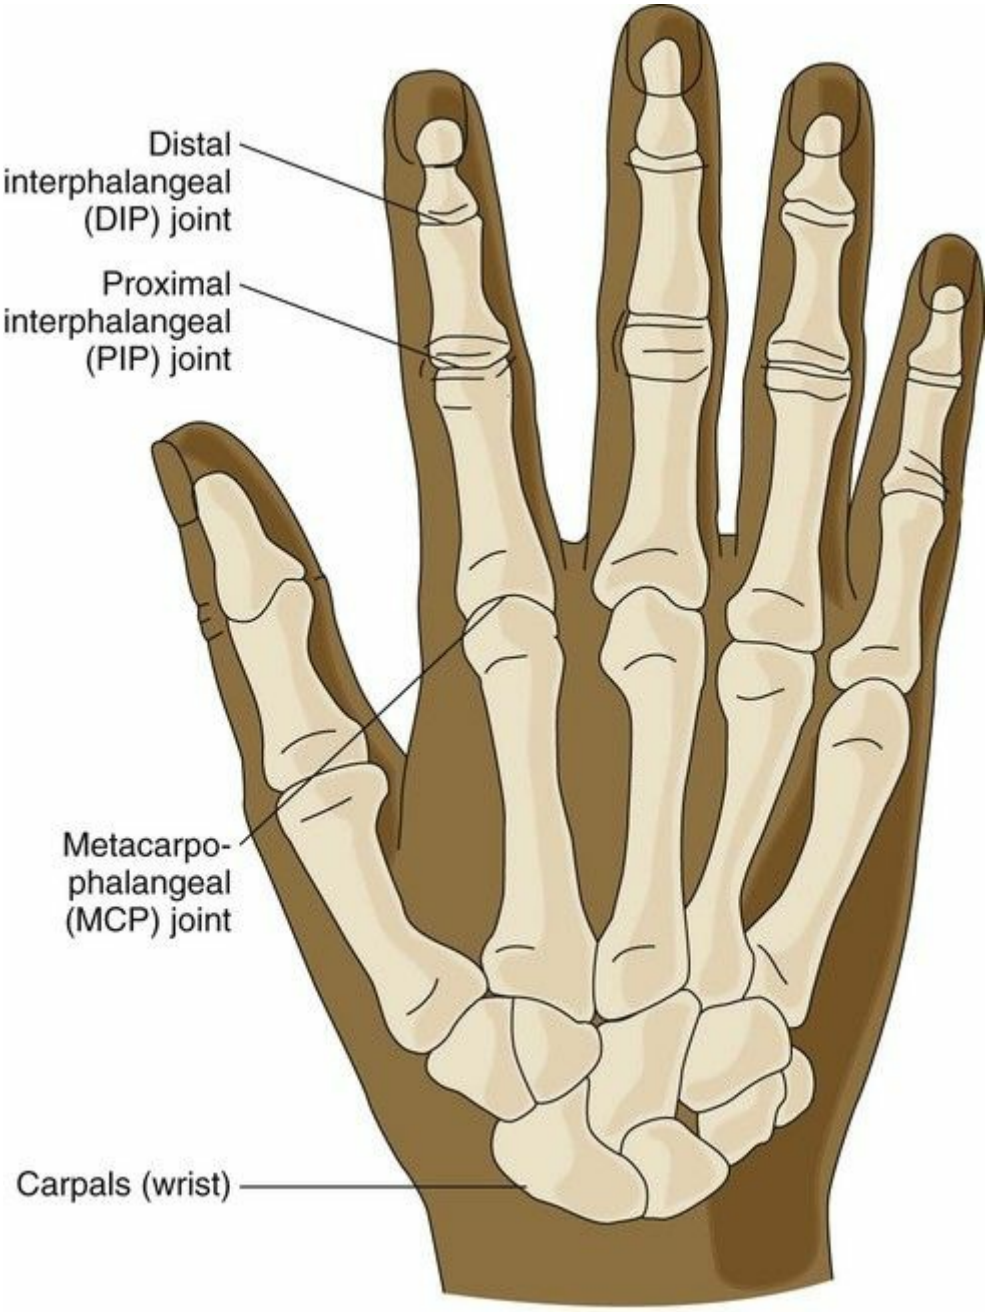

FIG. 49-5 The small joints of the hand.

Evaluation of the hip joint relies primarily on determination of its degree of mobility, because the joint is deep and difficult to inspect or palpate. *The patient with hip pain usually experiences it in the groin or has pain that radiates to the knee.* The knee is readily accessible for physical assessment, particularly when the patient is sitting and the knee is flexed. Fluid accumulation, or **effusion,** is easily detected in the knee joint. Limitations in movement with accompanying pain are common findings. The knees may be poorly aligned, as in **genu valgum** ("knock-knee") or **genu varum** ("bowlegged") deformities.

The ankles and feet are often neglected in the physical examination. However, they contain multiple bones and joints that can be affected by disease and injury. Observe and palpate each joint and test for ROM if

feet are affected by musculoskeletal problems.

Neurovascular Assessment

While completing a physical assessment of the musculoskeletal system, perform an assessment of peripheral vascular and nerve integrity. Beginning with the injured side, always compare one extremity with the other.

Nursing Safety Priority QSEN

Action Alert

Perform a complete **neurovascular assessment** (also called a "circ check"), which includes *palpation of pulses in the extremities below the level of injury and assessment of sensation, movement, color, temperature, and pain in the injured part*. If pulses are not palpable, use a Doppler to find pulses in the extremities. See Chart 51-3 in Chapter 51 for more details about neurovascular assessment.

Assessment of the Muscular System

During the skeletal assessment, notice the size, shape, tone, and strength of major skeletal muscles. The circumference of each muscle may be measured and compared for symmetry for an estimation of muscle mass if abnormalities are observed.

Ask the patient to demonstrate muscle strength. Apply resistance by holding the extremity and asking the patient to move against resistance. As an option, place your hands on the patient's upper arms and ask the patient to try to raise the arms. Although movement against resistance is not easily quantified, several scales used by nurses and therapists are available for grading the patient's strength. A commonly used scale is shown in Table 49-2.

TABLE 49-2

Common Scale for Grading Muscle Strength

RATING	DESCRIPTION
5	Normal: ROM unimpaired against gravity with full resistance
4	Good: can complete ROM against gravity with some resistance
3	Fair: can complete ROM against gravity
2	Poor: can complete ROM with gravity eliminated
1	Trace: no joint motion and slight evidence of muscle contractility
0	Zero: no evidence of muscle contractility

ROM, Range of motion.

Psychosocial Assessment

The data from the history and physical assessment provide clues for anticipating psychosocial problems. For instance, prolonged absence from employment or permanent disability may cause job or career loss. Further stress may be experienced if chronic pain continues and the patient cannot cope with numerous stressors. Anxiety and depression are common when patients have chronic pain. Deformities resulting from musculoskeletal disease or injury, such as an amputation, can affect a person's body image and self-concept. Help the patient identify support systems and coping mechanisms that may be useful if he or she has long-term musculoskeletal health problems. Encourage him or her to verbalize feelings related to loss and body image changes. Refer the patient for psychological or spiritual counseling if needed and if it is culturally appropriate.

Diagnostic Assessment

Laboratory Assessment

Chart 49-2 lists the common laboratory tests used in assessing patients with musculoskeletal disorders. There is no special patient preparation or follow-up care for any of these tests. Teach the patient about the purpose of the test and the procedure that can be expected. Additional tests performed for patients with connective tissue diseases, such as rheumatoid arthritis, are described in Chapter 18.

Chart 49-2 Laboratory Profile

Musculoskeletal Assessment

TEST	NORMAL RANGE FOR ADULTS	SIGNIFICANCE OF ABNORMAL FINDINGS
Serum calcium	9.0-10.5 mg/dL (2.25-2.75 mmol/L) *Older adults:* decreased	*Hypercalcemia* (increased calcium) • Metastatic cancers of the bone • Paget's disease • Bone fractures in healing stage *Hypocalcemia* (decreased calcium) • Osteoporosis • Osteomalacia
Serum phosphorus (phosphate)	3.0-4.5 mg/dL (0.97-1.45 mmol/L) *Older adults:* decreased	*Hyperphosphatemia* (increased phosphorus) • Bone fractures in healing stage • Bone tumors • Acromegaly *Hypophosphatemia* (decreased phosphorus) • Osteomalacia
Alkaline phosphatase (ALP)	30-120 units/L *Older adults:* slightly increased	*Elevations* may indicate: • Metastatic cancers of the bone • Paget's disease • Osteomalacia
Serum muscle enzymes Creatine kinase (CK-MM)	Total CK: *Men:* 55-170 units/L *Women:* 30-135 units/L	*Elevations* may indicate: • Muscle trauma • Progressive muscular dystrophy • Effects of electromyography
Lactic dehydrogenase (LDH)	Total LDH: 100-190 units/L LDH_1: 17%-27% LDH_2: 27%-37% LDH_3: 18%-25% LDH_4: 3%-8% LDH_5: 0% to 5%	*Elevations* may indicate: • Skeletal muscle necrosis • Extensive cancer • Progressive muscular dystrophy
Aspartate aminotransferase (AST)	0-35 units/L *Older adults:* slightly increased	*Elevations* may indicate: • Skeletal muscle trauma • Progressive muscular dystrophy
Aldolase (ALD)	3.0-8.2 units/dL	*Elevations* may indicate: • Polymyositis and dermatomyositis • Muscular dystrophy

Disorders of bone and the parathyroid gland are often reflected in an alteration of the serum calcium or phosphorus level. Therefore these electrolytes, especially calcium, are monitored. A decrease in serum calcium could indicate bone density loss.

Alkaline phosphatase (ALP) is an enzyme normally present in blood. The concentration of ALP increases with bone or liver damage. In metabolic bone disease and bone cancer, the enzyme concentration rises in proportion to the osteoblastic activity, which indicates bone formation. The level of ALP is normally slightly increased in older adults (Pagana & Pagana, 2014).

The major *muscle enzymes* affected in skeletal muscle disease or injuries are:

- Creatine kinase (CK-MM)
- Aspartate aminotransferase (AST)

• Aldolase (ALD)
• Lactic dehydrogenase (LDH)

As a result of damage, the muscle tissue releases additional amounts of these enzymes, which increases serum levels.

The serum CK level begins to rise 2 to 4 hours after muscle injury and is elevated early in muscle disease, such as muscular dystrophy. The CK molecule has two subunits: M (muscle) and B (brain). Three isoenzymes have been identified. Skeletal muscle CK (CK-MM, or CK_3) is the only isoenzyme that rises in concentration with damage to skeletal muscle, such as trauma, surgery, and neuromuscular disease. This test is 90% accurate because it is affected by exercise and certain drugs, such as anticoagulants, furosemide, and statins (Kress et al., 2008).

AST is moderately elevated (3 to 5 times normal) in certain muscle diseases, such as muscular dystrophy. The levels of the isoenzymes *aldolase A (ALD-A)* and LDH_5 also increase in patients with these disorders.

Imaging Assessment

The skeleton is very visible on *standard x-rays*. Anteroposterior and lateral projections are the initial screening views used most often. Other approaches, such as oblique or stress views, depend on the part of the skeleton to be evaluated and the reason for the x-ray.

Radiography.

Bone density, alignment, swelling, and intactness can be seen on x-ray. The conditions of joints can be determined, including the size of the joint space, the smoothness of articular cartilage, and synovial swelling. Soft-tissue involvement may be evident but not clearly differentiated.

Inform the patient that the x-ray table is hard and cold, and instruct him or her to remain still during the filming process. Coordinate with the radiology department or clinic to keep older adults and those at risk for hypothermia as warm as possible (e.g., by using blankets).

Myelography involves the injection of contrast medium into the subarachnoid space of the spine, usually by spinal puncture. The vertebral column, intervertebral disks, spinal nerve roots, and blood vessels can be visualized. Although this test is still performed, CT and MRI have often replaced such invasive and potentially painful and risky diagnostic techniques. The post-test care is similar to that for lumbar puncture, except that the patient is usually placed with the head of the bed elevated 30 to 50 degrees to prevent the contrast medium from

getting into the brain (see Chapter 41).

An **arthrogram** is an x-ray study of a joint after contrast medium (air or solution) has been injected to enhance its visualization. Double-contrast arthrography, which uses both air and solution, may be performed when a traumatic injury is suspected. The physician can often determine bone chips, torn ligaments, or other loose bodies within the joint. This test is not used commonly because of newer advances in diagnostic imaging. Most joints are now studied by MRI and magnetic resonance (MR) arthrography.

CT has gained wide acceptance for detecting musculoskeletal problems, particularly those of the vertebral column and joints. The scanned images can be used to create additional images from other angles or to create three-dimensional images and view complex structures from any position. The nurse or radiology technologist should ask the patient about iodine-based contrast allergies.

Nuclear Scans.

The **bone scan** is a radionuclide test in which radioactive material is injected for viewing the entire skeleton. It may be used primarily to detect tumors, arthritis, osteomyelitis, osteoporosis, vertebral compression fractures, and unexplained bone pain. Bone scans are used less commonly today as more sophisticated MRI equipment becomes more available. However, it may be very useful for detecting hairline fractures in patients with unexplained bone pain and diffuse metastatic bone disease.

The **gallium** and **thallium scans** are similar to the bone scan but are more specific and sensitive in detecting bone problems. Gallium citrate (^{67}Ga) is the radioisotope most commonly used. This substance also migrates to brain, liver, and breast tissue and therefore is used in examination of these structures when disease is suspected.

For patients with osteosarcoma, thallium (^{201}Tl) is better than gallium or technetium for diagnosing the extent of the disease. Thallium has traditionally been used for the diagnosis of myocardial infarctions but can be used for additional evaluation of cancers of the bone.

Because bone takes up gallium slowly, the nuclear medicine physician or technician administers the isotope 4 to 6 hours before scanning. Other tests that require contrast media or other isotopes cannot be given during this time.

Instruct the patient that the radioactive material poses no threat because it readily deteriorates in the body. Because gallium is excreted

through the intestinal tract, it tends to collect in feces after the scanning procedure.

Depending on the tissue to be examined, the patient is taken to the nuclear medicine department 4 to 6 hours after injection. The procedure takes 30 to 60 minutes, during which time the patient must lie still for accurate test results to be achieved. The scan may be repeated at 24, 48, and/or 72 hours. Mild sedation may be necessary to facilitate relaxation and cooperation during the procedure for confused older adults or those in severe pain.

No special care is required after the test. The radioisotope is excreted in stool and urine, but no precautions are taken in handling the excreta. Remind the patient to push fluids to facilitate urinary excretion.

Magnetic Resonance Imaging.

MRI, with or without the use of contrast media, is commonly used to diagnose musculoskeletal disorders. It is more accurate than CT and myelography for many spinal and knee problems. MRI is most appropriate for joints, soft tissue, and bony tumors that involve soft tissue. CT is still the test of choice for injuries or pathology that involves only bone.

The image is produced through the interaction of magnetic fields, radio waves, and atomic nuclei showing hydrogen density. Simply put, the radio waves "bounce" off the body tissues being examined. Because each tissue has its own density, the computer image clearly distinguishes normal and abnormal tissues. For some tissues, the cross-sectional image is better than that produced by radiography or CT. The lack of hydrogen ions in cortical bone makes it easily distinguishable from soft tissues. The test is particularly useful in identifying problems with muscles, tendons, and ligaments.

Ensure that the patient removes all metal objects and checks for clothing zippers and metal fasteners. Although joint implants made of titanium or stainless steel are usually safe, depending on the age of the MRI equipment, pacemakers, stents, and surgical clips usually are not. Chart 49-3 lists questions that the nurse or technician should consider in preparing the patient for MRI. Open MRIs prevent the claustrophobia that occurs with the older, encased machines.

Chart 49-3 Best Practice for Patient Safety & Quality Care QSEN

Preparing the Patient for Magnetic Resonance Imaging

- Is the patient pregnant?
- Does the patient have ferromagnetic fragments or implants, such as an older-style aneurysm clip?
- Does the patient have a pacemaker, stent, or electronic implant?
- Does the patient have chronic kidney disease? (Gadolinium contrast agents may cause severe systemic complications if the kidneys do not function.)
- Can the patient lie still in the supine position for 45 to 60 minutes? (May require sedation.)
- Does the patient need life-support equipment available?
- Can the patient communicate clearly and understand verbal communication?
- Did the patient get any tattoo *more than* 35 years ago? (If so, metal particles *may* be in the ink.)
- Is the patient claustrophobic? (Ask this question for closed MRI scanners; open MRIs do not cause claustrophobia.)

MR arthrography combines arthrography and magnetic resonance imaging. It is particularly useful for diagnosing problems of the shoulder. The patient's shoulder is injected with gadolinium contrast medium under fluoroscopy. Then the patient is taken for an MRI where the shoulder is examined. This test is particularly useful for diagnosing the type and degree of rotator cuff tears (Smith & Smith, 2010).

Ultrasonography.

Sound waves produce an image of the tissue in ultrasonography. An ultrasound procedure may be used to view:

- Soft-tissue disorders, such as masses and fluid accumulation
- Traumatic joint injuries
- Osteomyelitis
- Surgical hardware placement

A jelly-like substance applied to the skin over the site to be examined promotes the movement of a metal probe. No special preparation or post-test care is necessary. A quantitative ultrasound (QUS) may be done for determining fractures or bone density. Bone density testing is discussed in Chapter 50.

Other Diagnostic Assessment

Biopsies.

In a **bone biopsy,** the physician extracts a specimen of the bone tissue for microscopic examination. This invasive test may confirm the presence of infection or neoplasm, but it is not commonly done today. One of two techniques may be used to retrieve the specimen: needle (closed) biopsy or incisional (open) biopsy.

Nursing Safety Priority QSEN

Action Alert

After a bone biopsy, watch for bleeding from the puncture site and for tenderness, redness, or warmth that could indicate infection. Mild analgesics may be used.

Muscle biopsy is done for the diagnosis of atrophy (as in muscular dystrophy) and inflammation (as in polymyositis). The procedure and care for patients undergoing muscle biopsy are the same as those for patients undergoing bone biopsy.

Electromyography.

Although not commonly used today, electromyography (EMG) may be performed to evaluate diffuse or localized muscle weakness. EMG is usually accompanied by nerve conduction studies for determining the electrical potential generated in an individual muscle. This test helps in the diagnosis of neuromuscular, lower motor neuron, and peripheral nerve disorders.

Inform the patient that EMG may cause temporary discomfort, especially when the patient is subjected to episodes of electrical current. For selected patients, mild sedation is prescribed. The physician may also prescribe a temporary discontinuation of skeletal muscle relaxants several days before the procedure to prevent drugs from affecting the test results.

Arthroscopy.

Arthroscopy may be used as a diagnostic test or a surgical procedure. An arthroscope is a fiberoptic tube inserted into a joint for direct visualization of the ligaments, menisci, and articular surfaces of the joint. The knee and shoulder are most commonly evaluated. In addition, synovial biopsy and surgery to repair traumatic injury can be done through the arthroscope as an ambulatory care or same-day surgical

procedure.

Patient Preparation.

Arthroscopy is performed on an ambulatory care basis or as same-day surgery. The patient must have mobility in the joint being examined. Those who cannot move the joint or who have an infected joint are not candidates for the procedure.

If the procedure is done for surgical repair, the patient may have a physical therapy consultation before arthroscopy to learn the exercises that are necessary after the test. ROM exercises are also taught but may not be allowed immediately after arthroscopic surgery. The nurse in the surgeon's office or at the surgical center can teach these exercises or reinforce the information provided by the physical therapist. The nurse also reinforces the explanation of the procedure and post-test care and ensures that the patient has signed an informed consent.

Procedure.

The patient is usually given local, light general, or epidural anesthesia, depending on the purpose of the procedure. As shown in Fig. 49-6, the arthroscope is inserted through a small incision less than ¼-inch (0.6 cm) long. Multiple incisions may be required to allow inspection at a variety of angles. After the procedure, a dressing may be applied, depending on the amount of manipulation during the test or surgery.

FIG. 49-6 An arthroscope is used in the diagnosis of pathologic changes in the joints. This patient is undergoing arthroscopy of the shoulder.

Postprocedure Care.

The immediate care after an arthroscopy is the same for patients having the procedure for diagnostic purposes as for those having it for surgical intervention.

Nursing Safety Priority QSEN

Action Alert

The priority for postprocedure care after arthroscopy is to assess the neurovascular status of the patient's affected limb every hour or according to agency or surgeon protocol. Monitor and document distal pulses, warmth, color, capillary refill, pain, movement, and sensation of the affected extremity.

Encourage the patient to perform exercises as taught before the procedure, if appropriate. For the mild discomfort experienced after the diagnostic arthroscopy, the surgeon prescribes a mild analgesic, such as acetaminophen (Tylenol, Ace-Tabs). If postoperative, the patient may have short-term activity restrictions, depending on the musculoskeletal problem. Ice is often used for 24 hours, and the extremity should be

elevated for 12 to 24 hours. When arthroscopic surgery is performed, the health care provider usually prescribes an opioid-analgesic combination, such as oxycodone and acetaminophen (Percocet, Tylox).

Although complications are not common, monitor and teach the patient to observe for:

- Swelling
- Increased joint pain attributable to mechanical injury
- Thrombophlebitis
- Infection

Severe joint or limb pain after discharge may indicate a possible complication. Teach the patient to contact the physician immediately. The surgeon usually sees the patient about 1 week after the procedure to check for complications.

NCLEX Examination Challenge

Safe and Effective Care Environment

A client returns to the postanesthesia care unit (PACU) after an arthroscopy for a shoulder rotator cuff tear. What is the nurse's priority when caring for this client?

A Perform passive range-of-motion exercises.
B Keep the affected arm immobilized.
C Ensure that the patient uses the patient-controlled analgesia (PCA) pump.
D Check the neurovascular status of the affected arm.

Nursing Concepts and Clinical Judgment Review

What might you NOTICE in a patient with adequate mobility and sensory perception related to the musculoskeletal system?

Physical assessment:

- No gross deformities or impairments in posture or gait
- Adequate size, strength, and symmetry of muscle for age
- Can perform ADLs independently
- Can perform other routine daily activities independently
- Can ambulate with or without assistive devices
- No pain or tenderness on palpation or passive range-of-motion (ROM) of joints
- Active ROM of joints within normal limits for age

- No crepitus when moving joints
- No swelling of joints or extremities
- Equal size and alignment of extremities
- Equal sensation in extremities

Diagnostic assessment:

- Muscle enzymes (e.g., CK-MM, ALD) within normal limits for age
- Bone density adequate for age and gender
- Joint changes within normal limits for age

Get Ready for the NCLEX® Examination!

Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Collaborate with the physical and/or occupational therapist to perform a complete musculoskeletal assessment, including gait, muscle strength, and ADL ability, as indicated. **Teamwork and Collaboration** QSEN

Health Promotion and Maintenance

- Be aware that older adults have physiologic changes that affect their musculoskeletal system, such as decreased bone density and joint cartilage degeneration (see Chart 49-1). **Patient-Centered Care** QSEN

Psychosocial Integrity

- Assess the patient's support systems and coping mechanisms when musculoskeletal trauma or disease affects his or her body image. **Patient-Centered Care** QSEN
- Ask about the patient's occupation, because heavy manual labor may cause back injury and other musculoskeletal trauma.

Physiological Integrity

- Assess the patient's pain intensity, quality, duration, and location.
- Assess the patient's mobility, including gait, posture, and muscle strength.
- Interpret the patient's laboratory values that are related to musculoskeletal disease (see Chart 49-2).
- Teach the patient that mild discomfort can be expected during electromyography, a test to assess the electrical potential of muscles and their innervation.
- Instruct the patient to report swelling, infection, and increased pain after an arthroscopy.
- Ask the patient questions to ensure safety before an MRI (see Chart 49-3). **Safety** QSEN
- Ask the patient about allergy to contrast media before diagnostic testing such as CT scans.
- Evaluate the neurovascular status of the patient's affected extremity

after an arthroscopic procedure as the *priority for care*. **Safety** QSEN

CHAPTER 50

Care of Patients with Musculoskeletal Problems

Donna D. Ignatavicius

PRIORITY CONCEPTS

- Pain
- Mobility
- Inflammation
- Infection

Learning Outcomes

Safe and Effective Care Environment

1. Coordinate with health care team members when planning and providing high quality care for patients with musculoskeletal problems.
2. Teach the patient and family about home safety when the patient has a metabolic bone problem such as osteoporosis.

Health Promotion and Maintenance

3. Identify community resources for patients with musculoskeletal problems that impair mobility.
4. Develop a patient-centered teaching plan for all age-groups about ways to decrease the risk for osteoporosis.
5. Assess the genetic risk for patients who have parents with muscular dystrophy.

Psychosocial Integrity

6. Assess the patient's and family's responses to a bone cancer diagnosis and treatment options.

Physiological Integrity

7. Educate the patient and family about common drugs used for bone diseases, such as calcium supplements and bisphosphonates, to promote patient safety.
8. Compare and contrast osteoporosis and osteomalacia.
9. Identify key features of Paget's disease of the bone.
10. Prioritize care for patients with osteomyelitis.
11. Identify collaborative management options for treating patients with primary and metastatic bone cancer.
12. Describe common disorders of the foot, including hallux valgus and plantar fasciitis, that can affect mobility.
13. Explain the role of the nurse when caring for an adult patient with muscular dystrophy.

 http://evolve.elsevier.com/Iggy/

Musculoskeletal disorders include metabolic bone diseases (e.g., osteoporosis and Paget's disease), bone tumors, and a variety of deformities and syndromes. Older adults are at the greatest risk for most of these problems, although *primary* bone cancer is most often found in adolescents and young adults. As technology advances and patients survive longer with primary cancers, metastatic lesions have become more prevalent among older adults. Almost all musculoskeletal health problems can cause the patient to have difficulty meeting the human need of mobility. This chapter focuses on selected disorders not covered in Chapter 18 on arthritis and other connective tissue diseases.

Metabolic Bone Diseases

Osteoporosis

Pathophysiology

Osteoporosis is a chronic metabolic disease in which bone loss causes decreased density and possible fracture. It is often referred to as a "silent disease" or "silent thief" because the first sign of osteoporosis in most people follows some kind of a fracture (Kamienski et al., 2011). The spine, hip, and wrist are most often at risk, although any bone can fracture (National Osteoporosis Foundation [NOF], 2010).

Osteoporosis is a major health problem in the world. The estimated cost for osteoporosis-related health care alone in the United States is more than $18 billion each year with continual cost increases each year. By 2040, that number is expected to double or triple as baby boomers become older adults (NOF, 2010).

Bone is a dynamic tissue that is constantly undergoing changes in a process referred to as **bone remodeling.** Osteoporosis and **osteopenia** (low bone mass) occur when osteoclastic (bone resorption) activity is greater than osteoblastic (bone building) activity. The result is a decreased **bone mineral density (BMD).** BMD determines bone strength and peaks between 25 and 30 years of age. Before and during the peak years, osteoclastic activity and osteoblastic activity work at the same rate. After the peak years, bone resorption activity exceeds bone-building activity and bone density decreases. BMD decreases most rapidly in postmenopausal women as serum estrogen levels diminish. Although estrogen does not build bone, it helps prevent bone loss. Trabecular, or cancellous (spongy), bone is lost first, followed by loss of cortical (compact) bone. This results in thin, fragile bone tissue that is at risk for fracture.

Standards for the diagnosis of osteoporosis are based on BMD testing that provides a T-score for the patient. A T-score represents the number of standard deviations above or below the average BMD for young, healthy adults. *Osteopenia is present when the T-score is at −1 and above −2.5. Osteoporosis is diagnosed in a person who has a T-score at or lower than −2.5.* Medicare reimburses for BMD testing every 2 years in people ages 65 years and older who (NOF, 2010):

- Are estrogen deficient
- Have vertebral abnormalities
- Receive long-term steroid therapy
- Have primary hyperparathyroidism

• Are being monitored while on osteoporosis drug therapy

Osteoporosis can be classified as generalized or regional. *Generalized* osteoporosis involves many structures in the skeleton and is further divided into two categories—primary and secondary. *Primary* osteoporosis is more common and occurs in postmenopausal women and in men in their seventh or eighth decade of life. Even though men do not experience the rapid bone loss that postmenopausal women have, they do have decreasing levels of testosterone (which builds bone) and altered ability to absorb calcium. This results in a slower loss of bone mass in men, especially those older than 75 years. *Secondary* osteoporosis may result from other medical conditions, such as hyperparathyroidism; long-term drug therapy, such as with corticosteroids; or prolonged immobility, such as that seen with spinal cord injury (Table 50-1). Treatment of the secondary type is directed toward the cause of the osteoporosis when possible.

TABLE 50-1

Causes of Secondary Osteoporosis

Diseases/Conditions
• Diabetes mellitus • Hyperthyroidism • Hyperparathyroidism • Cushing's syndrome • Growth hormone deficiency • Metabolic acidosis • Female hypogonadism • Paget's disease • Osteogenesis imperfecta • Rheumatoid arthritis • Prolonged immobilization • Bone cancer • Cirrhosis • HIV/AIDS • Chronic airway limitation
Drugs (Chronic Use)
• Corticosteroids • Anti-epileptic drugs (AEDs) (e.g., phenytoin) • Barbiturates (e.g., phenobarbital) • Ethanol (alcohol) • Drugs that induce hypogonadism (decreased levels of sex hormones) • High levels of thyroid hormone • Cytotoxic agents • Immunosuppressants • Loop diuretics • Aluminum-based antacids

AIDS, Acquired immune deficiency syndrome; HIV, human immune deficiency virus.

Regional osteoporosis, an example of secondary disease, occurs when a limb is immobilized related to a fracture, injury, or paralysis. Immobility for longer than 8 to 12 weeks can result in this type of osteoporosis. Bone loss also occurs when people spend prolonged time in a gravity-free or

weightless environment (e.g., astronauts).

Etiology and Genetic Risk

Primary osteoporosis is caused by a combination of genetic, lifestyle, and environmental factors. Chart 50-1 lists the major factors that contribute to the development of this disease.

Chart 50-1 Best Practice for Patient Safety & Quality Care QSEN

Assessing Risk Factors for Primary Osteoporosis

Assess for:

- Older age in both genders and all races
- Parental history of osteoporosis, especially mother
- History of low-trauma fracture after age 50 years
- Low body weight, thin build
- Chronic low calcium and/or vitamin D intake
- Estrogen or androgen deficiency
- Current smoking (active or passive)
- High alcohol intake (3 or more drinks a day)
- Lack of physical exercise or prolonged immobility

Genetic/Genomic Considerations

Patient-Centered Care QSEN

The genetic and immune factors that cause osteoporosis are very complex. Strong evidence demonstrates that genetics is a significant factor, with a heritability of 50% to 90% (Chang et al., 2010). Many genetic changes have been identified as possible causative factors, but there is no agreement about which ones are most important or constant in all patients. For example, changes in the vitamin D_3 receptor *(VDR)* gene and calcitonin receptor *(CTR)* gene have been found in some patients with the disease. Receptors are essential for the uptake and use of these substances by the cells.

The bone morphogenetic protein-2 *(BMP-2)* gene has a key role in bone formation and maintenance. Some osteoporotic patients who had fractures have changes in their *BMP-2* gene. Alterations in growth hormone-1 (GH-1) have been discovered in petite Asian-American women, those who are predisposed to developing osteoporosis.

Hormones, tumor necrosis factor (TNF), interleukins, and other substances in the body help control osteoclasts in a very complex pathway. The identification of the importance of the cytokine receptor activator of nuclear factor kappa-B ligand *(RANKL)*, its receptor *RANK*, and its decoy receptor osteoprotegerin *(OPG)* has helped researchers understand more about the activity of osteoclasts in metabolic bone disease. Disruptions in the *RANKL, RANK,* and *OPG* system can lead to increased osteoclast activity in which bone is rapidly broken down (McCance et al., 2014).

Gender Health Considerations

Patient-Centered Care QSEN

Primary osteoporosis most often occurs in women after menopause as a result of decreased estrogen levels. Women lose about 2% of their bone mass every year in the first 5 years after natural or surgical (ovary removal) menopause. Obese women can store estrogen in their tissues for use as necessary to maintain a normal level of serum calcium.

Men also develop osteoporosis after the age of 50 years because their testosterone levels decrease. Testosterone is the major sex hormone that builds bone tissue. Men are often underdiagnosed, even when they become older adults (Swislocki et al., 2010; Voda, 2009b). In a large experimental study, Doheny et al. (2011) found that men lacked knowledge about osteoporosis and their risk for the disease (see the Evidence-Based Practice box).

Evidence-Based Practice QSEN

What Do Men Know About Their Risk of Osteoporosis?

Doheny, M.O., Sedlak, C.A., Estok, P.J., & Zeller, R.A. (2011). Bone density, health beliefs, and osteoporosis preventing behaviors in men. *Orthopaedic Nursing, 30*(4), 266-272.

The researchers conducted an experimental, two-group longitudinal study to examine the effect of dual-energy x-ray absorptiometry (DXA) results on osteoporosis preventing behaviors (OPB), health beliefs, and knowledge of osteoporosis of men ages 50 years or older. The sample was obtained through a community call for volunteers, and the participants were randomly assigned to either the control or experimental group. At the beginning of the study, all 196 subjects received information on osteoporosis diagnosis and management and

completed a series of questionnaires. All subjects also had a free DXA test in which 50 men were found to be osteopenic or osteoporotic. Knowledge about osteoporosis was not a predictor of calcium intake or exercise. Although the osteoporotic men increased their calcium and increased their exercise, the amount of each intervention was below the national recommendations. Health beliefs predicted both calcium intake and exercise.

Level of Evidence: 2

This study used an experimental design over a period of time to determine changes in behavior.

Commentary: Implications for Practice and Research

Very little research has been done on the diagnosis and management of osteoporosis in men. This study used an experimental design to examine multiple factors. Nurses and other health care professionals need to educate men older than 50 years about the risk for and prevention of osteoporosis. The cost of DXA screening is far less than the financial, social, and health care costs of osteoporosis.

The subjects in the convenience sample were fairly well educated, almost all were white, and most were married. Further studies are needed using more diverse samples to allow generalization of the findings of this research.

The relationship of osteoporosis to nutrition is well established. For example, excessive caffeine in the diet can cause calcium loss in the urine. A diet lacking enough calcium and vitamin D stimulates the parathyroid gland to produce parathyroid hormone (PTH). PTH triggers the release of calcium from the bony matrix. Activated vitamin D is needed for calcium uptake in the body. Malabsorption of nutrients in the GI tract also contributes to low serum calcium levels. Institutionalized or homebound patients who are not exposed to sunlight may be at a higher risk because they do not receive adequate vitamin D for the metabolism of calcium.

Calcium loss occurs at a more rapid rate when phosphorus intake is high. (Chapter 11 describes the usual relationship between calcium and phosphorus in the body.) People who drink large amounts of carbonated beverages each day (over 40 ounces) are at high risk for calcium loss and subsequent osteoporosis, regardless of age or gender.

Protein deficiency may also reduce bone density. Because 50% of serum calcium is protein bound, protein is needed to use calcium. However,

excessive protein intake may increase calcium loss in the urine. For instance, people who are on high-protein, low-carbohydrate diets, like the Atkins diet, may consume too much protein to replace other food not allowed. Dietary protein intake in healthy adults is recommended at 0.8 grams per kilogram of body weight. Protein is needed for bone healing when a fracture occurs.

Excessive alcohol and tobacco use are other risk factors for osteoporosis. Although the exact mechanisms are not known, these substances promote acidosis, which in turn increases bone loss. Alcohol also has a direct toxic effect on bone tissue, resulting in decreased bone formation and increased bone resorption. For those people who have excessive alcohol intake, alcohol calories decrease hunger and the need to take in adequate amounts of nutrients.

Incidence and Prevalence

Osteoporosis is a potential health problem for more than 44 million Americans. About 10 million people in the United States have the disease, and about 34 million people 50 years of age and older have osteopenia and are at risk for development of osteoporosis. Women remain the largest group affected by osteoporosis, although some men, especially those older than 75 years, also have the disease.

Cultural Considerations

Patient-Centered Care QSEN

Body build, weight, and race/ethnicity seem to influence who gets the disease. Osteoporosis occurs most often in older, lean-built Euro-American and Asian women, particularly those who do not exercise regularly. However, African Americans are at risk for decreased vitamin D, which is needed for adequate calcium absorption in the small intestines. Dietary preferences or intolerances or the inability to afford high-nutrient food may influence anyone's rate of bone loss. For example, many blacks have lactose intolerance and cannot drink regular milk or eat other dairy-based foods (NOF, 2010). Lactose-free milk (e.g., Lactaid) or soy milk provides calcium. Milk and cheese are good sources of protein, a nutrient needed to bind calcium for use by the body.

Osteoporosis results in more than 1.5 million fragility fractures each year (NOF, 2010). A woman who experiences a hip fracture has a 4 times greater risk for a second fracture. Fractures as a result of osteoporosis

and falling can decrease a patient's mobility and quality of life. The mortality rate for older patients with hip fractures is very high, especially within the first 6 months, and the debilitating effects can be devastating.

Health Promotion and Maintenance

Peak bone mass is achieved by about 30 years of age in most women. *Building strong bone as a young person may be the best defense against osteoporosis in later adulthood.* Young women need to be aware of appropriate health and lifestyle practices that can prevent this potentially disabling disease. Teaching should begin with young women because they begin to lose bone after 30 years of age. Nurses can play a vital role in patient education for women of any age to prevent and manage osteoporosis.

The focus of osteoporosis prevention is to decrease modifiable risk factors. For example, teach patients who do not include enough dietary calcium which foods to eat, such as dairy products and dark green leafy vegetables. Teach them to read food labels for sources of calcium content. Explain the importance of sun exposure (but not so much as to get sunburned) and adequate vitamin D in the diet. The National Osteoporosis Foundation recommends taking a vitamin D_3 supplement for all adults. Patients being treated for osteopenia or osteomalacia (vitamin D deficiency) may be prescribed high therapeutic doses up to 20,000 international units a week (NOF, 2010).

Teach the need to limit the amount of carbonated beverages consumed each day. Remind patients who have sedentary lifestyles about the importance of exercise and what types of exercise builds bone tissue. Weight-bearing exercises, such as regularly scheduled walking, are preferred. Teach high-risk people to avoid activities that cause jarring, such as horseback riding and jogging, to prevent potential vertebral compression fractures.

Patient-Centered Collaborative Care

Assessment

A complete health history with assessment of risk factors is important in the prevention, early detection, and treatment of osteoporosis. Patients who have risk factors for osteoporosis are at increased risk for fractures when falls occur. Include a fall risk assessment in the health history, especially for older adults. Assess for fall risk factors as described in Chapter 2. The Joint Commission's National Patient Safety Goals

(NPSGs) specify the need to reduce risk for harm to patients resulting from falls. People with osteoporosis are at an increased risk for fracture if a fall occurs.

Physical Assessment/Clinical Manifestations.

When performing a musculoskeletal assessment, inspect and palpate the vertebral column. The classic "dowager's hump," or kyphosis of the dorsal spine, is often present (Fig. 50-1). The patient may state that he or she has gotten shorter, perhaps as much as 2 to 3 inches (5 to 7.5 cm) within the previous 20 years. Take or delegate height and weight measurements, and compare with previous measurements if they are available.

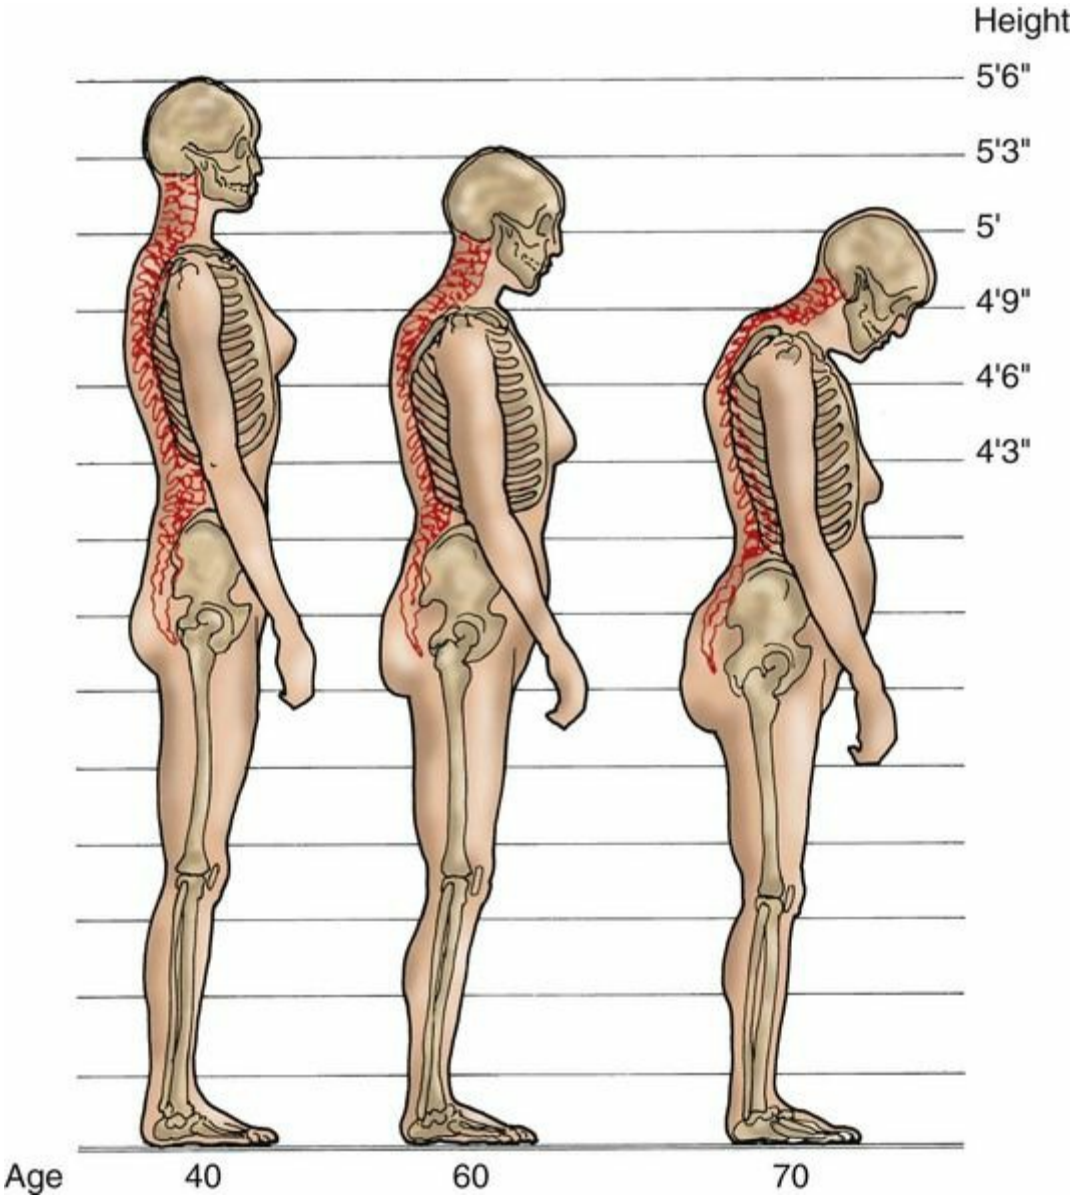

FIG. 50-1 A normal spine at age 40 years and osteoporotic changes at ages 60 and 70 years. These changes can cause a loss of as much as 6 inches in height and can result in the so-called *dowager's hump (far right)* in the upper thoracic vertebrae.

The patient may have back pain, which often occurs after lifting, bending, or stooping. The pain may be sharp and acute in onset. Pain is worse with activity and is relieved by rest. Palpation of the vertebrae, particularly the lower thoracic and lumbar vertebrae, can increase the patient's discomfort. Therefore palpation should be gentle.

Back pain accompanied by tenderness and voluntary restriction of spinal movement suggests one or more compression vertebral fractures—the most common type of osteoporotic fracture. Movement restriction and spinal deformity may result in constipation, abdominal distention, reflux esophagitis, and respiratory compromise in severe cases. The most likely

area for spinal fracture is between T8 and L3.

Fractures are also common in the distal end of the radius (wrist) and the upper third of the femur (hip). Ask the patient to locate all areas that are painful, and observe for signs and symptoms of fractures, such as swelling and malalignment. Fractures are discussed in Chapter 51.

Psychosocial Assessment.

Women associate osteoporosis with menopause, getting older, and becoming less independent. The disease can result in suffering, deformity, and disability that can affect the patient's well-being and life satisfaction. The quality of life may be further impacted by pain, insomnia, depression, and **fallophobia** (fear of falling) (Touhy & Jett, 2014).

Assess the patient's concept of body image, especially if he or she is severely kyphotic. For example, the patient may have difficulty finding clothes that fit properly. Social interactions may be avoided because of a change in appearance or the physical limitations of being unable to sit in chairs in restaurants, movie theaters, and other places. Changes in sexuality may occur as a result of poor self-esteem or the discomfort caused by positioning during intercourse.

Because osteoporosis poses a risk for fractures, teach the patient to be extremely cautious about activities. As a result, the threat of fracture can create anxiety and fear and result in further limitation of social or physical activities. Assess for these feelings to assist in treatment decisions and health teaching. For example, the patient may not exercise as prescribed for fear that a fracture will occur.

Laboratory Assessment.

No definitive laboratory tests confirm a diagnosis of primary osteoporosis, although a number of *biochemical markers* can provide information about bone resorption and formation activity. Although not commonly tested, these biochemical markers are sensitive to bone changes and can be used to monitor effectiveness of treatment for osteoporosis. *Bone-specific alkaline phosphatase (BSAP)* is found in the cell membrane of the osteoblast and indicates bone formation status. *Osteocalcin* is a protein substance in bone and increases during bone resorption activity. Pyridinium (PYD) cross-links are released into circulation during bone resorption. *N-telopeptide (NTX)* and *C-telopeptide (CTX)* are proteins released when bone is broken down. Some laboratories require a 24-hour urine collection for testing, whereas others use a double-voided specimen. Some markers, like NTX and CTX, can

also be measured in the blood using immunoassay techniques. Increased levels of any of these markers indicate a risk for osteoporosis. Increased levels are found in patients with osteoporosis, Paget's disease, and bone tumors (Pagana & Pagana, 2014).

Serum calcium and vitamin D_3 levels should be routinely monitored (at least once a year) for all women and men older than 50 years who are at a high risk for the disease. These results determine the need for drug supplements.

A battery of tests can be performed to rule out secondary osteoporosis or other metabolic bone diseases, such as osteomalacia and Paget's disease. These include measurements of serum calcium, vitamin D, and phosphorus. Urinary calcium levels may also be assessed.

Imaging Assessment.

Conventional x-rays of the spine and long bones show decreased bone density but only after a 25% to 40% bone loss has occurred. Fractures can also be seen on x-ray.

The most commonly used screening and diagnostic tool for measuring bone mineral density (BMD) is **dual x-ray absorptiometry (DXA**, or **DEXA).** The spine and hip are most often assessed when central DXA (cDXA) scan is performed. Many physicians recommend that women in their 40s have a baseline screening DXA scan so that later bone changes can be detected and compared. DXA is a painless scan that emits less radiation than a chest x-ray. *It is the best tool currently available for a definite diagnosis of osteoporosis.* A height is taken prior to performing the test. The patient stays dressed but is asked to remove any metallic objects such as belt buckles, coins, keys, or jewelry that might interfere with the test. The results are displayed on a computer graph, and a T-score is calculated. No special follow-up care for the test is required. However, the patient needs to discuss the results with the primary care provider for any decisions about possible preventive or management interventions.

A peripheral DXA (pDXA) scan assesses BMD of the heel, forearm, or finger. It is often used for large-scale screening purposes. The pDXA is commonly used for screening at community health fairs, skilled nursing facilities, and women's health centers.

Peripheral quantitative ultrasound (pQUS) is an effective and low-cost peripheral screening tool that can detect osteoporosis and predict risk for hip fracture. The heel, tibia, and patella are most commonly tested. The procedure requires no special preparation, is quick, and has no radiation exposure or specific follow-up care (Pagana & Pagana, 2014). The

National Osteoporosis Foundation recommends that men older than 70 years have the pQUS as a screening tool for the disease (NOF, 2010).

Analysis

The most common problem for patients with osteoporosis or osteopenia is *potential for fractures related to weak, porous bone tissue.*

Planning and Implementation

Planning: Expected Outcomes.

The expected outcome is that the patient avoids fractures by preventing falls, managing risk factors, and adhering to preventive or treatment measures for bone loss.

Interventions.

Because the patient is predisposed to fractures, nutritional therapy, exercise, lifestyle changes, and drug therapy are used to slow bone resorption and form new bone tissue. Self-management education (SME) can help prevent osteoporosis or slow the progress.

Nutrition Therapy.

The nutritional considerations for the treatment of a patient with a diagnosis of osteoporosis are the same as those for preventing the disease. Teach patients about the adequate amounts of protein, magnesium, vitamin K, and trace minerals that are needed for bone formation. Calcium and vitamin D intake should be increased. Teach patients to avoid excessive alcohol and caffeine consumption. For the patient who has sustained a fracture, adequate intake of protein, vitamin C, and iron is important to promote bone healing. People who are lactose intolerant can choose a variety of soy and rice products that are fortified with calcium and vitamin D. In addition, calcium and vitamin D are added to many fruit juices, bread, and cereal products.

A variety of nutrients are needed to maintain bone health. *The promotion of a single nutrient will not prevent or treat osteoporosis.* Help the patient develop a nutritional plan that is most beneficial in maintaining bone health; the plan should emphasize fruits and vegetables, low-fat dairy and protein sources, increased fiber, and moderation in alcohol and caffeine (NOF, 2010).

Lifestyle Changes.

Exercise is important in the prevention and management of osteoporosis.

It also plays a vital role in pain management, cardiovascular function, and an improved sense of well-being.

In collaboration with the health care provider, the physical therapist may prescribe exercises for strengthening the abdominal and back muscles for those at risk for vertebral fractures. These exercises improve posture and support for the spine. Abdominal muscle tightening, deep breathing, and pectoral stretching are stressed to increase lung capacity. Exercises for the extremity muscles include muscle-tightening, resistive, and range-of-motion (ROM) exercises. Encourage active ROM exercises, which improve joint mobility and increase muscle tone, as well as prescribed exercise activities. Swimming provides overall muscle exercise.

In addition to exercises for muscle strengthening, a general weight-bearing exercise program should be implemented. Teach patients that walking for 30 minutes 3 to 5 times a week is the single most effective exercise for osteoporosis prevention.

In addition to nutrition and exercise, other lifestyle changes may be needed. Teach the patient to avoid tobacco in any form, especially cigarette smoking. Remind women not to consume more than one alcoholic drink per day (5 ounces each); instruct men not to have more than two alcoholic drinks per day.

Hospitals and long-term care facilities have risk management programs to assess for the risk for falls. For those patients at high risk, communicate this information to other members of the health care team, using colored armbands or other easy-to-recognize methods (National Patient Safety Goals). Chapter 2 discusses fall prevention in health care agencies and at home in more detail.

NCLEX Examination Challenge

Health Promotion and Maintenance

Which statement by the client regarding lifestyle changes to prevent osteoporosis indicates a need for further teaching by the nurse?

A "I should get rid of the scatter rugs and clutter in my house."

B "I will cut down to only three martinis at night."

C "I plan to increase calcium and vitamin D_3 foods in my diet."

D "I am going to walk every day for at least 30 minutes."

Drug Therapy.

Drug therapy is used when the BMD T-score for the hip is below −2.0 with

no other risk factors or when the T-score is below −1.5 with one or more risk factors or previous fracture (NOF, 2010). The health care provider may prescribe calcium and vitamin D_3 supplements, bisphosphonates, or estrogen agonist/antagonists (formerly called *selective estrogen receptor modulators*) or a combination of several drugs to treat or prevent osteoporosis (Chart 50-2). Estrogen and combination hormone therapy are not used solely for osteoporosis prevention or management because they can increase other health risks such as breast cancer and myocardial infarction.

Chart 50-2 Common Examples of Drug Therapy

Osteoporosis

DRUG AND USUAL DOSAGE	PURPOSE OF DRUG	NURSING INTERVENTIONS	RATIONALES
Supplements			
Calcium (with vitamin D if needed) (e.g., Os-Cal, Citracal) 1-1.5 g in divided doses orally daily	Increases calcium intake (and vitamin D if needed)	Give a third of daily dose at bedtime. Push fluids.	Calcium is most readily utilized by the body when the patient is fasting and immobile. Increased fluid intake aids in preventing the formation of calcium-based urinary stones.
		Assess for a history of urinary stones.	Calcium supplements are not given to patients who are susceptible to urinary stone formation.
		Monitor serum calcium level.	Hypercalcemia, or calcium excess, is a side effect of calcium supplementation.
		Monitor urinary calcium level (no more than 4 mg/kg in 24 hr).	The kidneys attempt to excrete excess calcium.
		Observe for signs of hypercalcemia.	Hypercalcemia can result in urinary stones, cardiac dysrhythmias, and an increase or decrease in skeletal muscle tone.
Bisphosphonates			
Alendronate (Fosamax) or (Fosamax plus D) **For Prevention:** 5 mg orally daily or 35 mg orally weekly (available as tablet or liquid) **For Treatment:** 10 mg orally daily or 70 mg orally weekly with 2800-5600 international units of vitamin D	Prevents bone loss and increases bone density	Take on an empty stomach, first thing in the morning with a full glass of water. Take 30 minutes before food, drink, or other drugs. Remain upright, sitting or standing, for 30 minutes after administration. Take liquid (75 mL) and follow with 2 ounces of water.	Difficulty swallowing, esophagitis, esophageal ulcers, and gastric ulcers can result from alendronate therapy. Any of these should be reported to a health care provider as soon as possible.
Risedronate (Actonel) or (Actonel with Calcium) 5 mg orally daily, 35 mg orally every week, or 150 mg monthly	Same as for alendronate	Follow interventions for alendronate.	Same as for alendronate.
		Observe for CNS side/adverse effects, such as drowsiness, anxiety, agitation.	Drug can also cause CNS effects that may not be tolerated.
Ibandronate (Boniva) 150 mg orally once every month or 3.375 mg IV every 3 months	Same as for alendronate	Take on the same day each month. Take on an empty stomach, first thing in the morning with a full glass of water. Take 60 minutes before food, drink, or other drugs. Remain upright for 1 hour after administration.	Same as for alendronate.
Zoledronic acid (Reclast, Zometa) **For Prevention:** 5 mg IV once every 2 years **For Treatment:** 5 mg IV once a year	Same as for other bisphosphonates	Infuse over 15-30 minutes.	The drug should not be infused too quickly to prevent rare complications such as atrial fibrillation.
		Make sure the patient has a dental examination before starting the drug.	The drug can cause jaw or maxillary osteonecrosis, particularly if oral hygiene is poor.
		Do not give to patients who are sensitive to aspirin.	The patient may experience bronchoconstriction.
		Check serum creatinine before and after administering the drug.	The drug can cause renal insufficiency or kidney failure.
Estrogen Agonist/Antagonists*			
Raloxifene (Evista) 60 mg orally daily	Prevents bone loss and increases bone density	Teach patient signs and symptoms of VTE.	Raloxifene can cause increased risk for VTE, especially in the first 4 months of therapy.
		Monitor liver function tests (LFTs) in collaboration with health care provider.	Raloxifene can cause increased LFT values or worsen hepatic disease (should not be given to patient who has liver disease).

CNS, Central nervous system; *VTE*, venous thromboembolism.

*Formerly Selective Estrogen Receptor Modulators (SERMs).

Calcium and Activated Vitamin D (D_3).

Intake of *calcium* alone is not a treatment for osteoporosis, but calcium is an important part of a *prevention* program to promote bone health. Most people cannot or do not have enough calcium in their diet, and therefore calcium supplements are needed. Calcium carbonate, found in over-the-counter (OTC) drugs such as Os-Cal, is one of the most cost-effective supplement formulas. Calcium citrate, available OTC as Citracal, is often recommended for those who have gastric upset when taking a calcium supplement. Teach patients to take calcium supplements with food and 6

to 8 ounces of water, although Citracal can be taken anytime. It is best to divide the daily dose, with at least one third of the daily dose being taken in the evening. Teach women to start taking supplements in young adulthood to assist in maintaining peak bone mass. Instruct patients of any age to take calcium supplements that also contain a small amount of activated vitamin D (D_3), such as Os-Cal Ultra.

Because vitamin D is needed for calcium absorption by the body, vitamin D_3 supplementation is often indicated. Both calcium and vitamin D_3 are OTC supplements. Remind patients to take these drugs under the supervision of a health care provider. **Hypercalcemia** (excess serum calcium) can cause serious damage to the urinary system and other body systems. Teach patients to drink plenty of fluids to prevent urinary calculi (stones). Remind them to have regular laboratory assessments of their calcium and vitamin D_3 serum levels. Chapter 11 describes the clinical manifestations of hypercalcemia.

Bisphosphonates.

Bisphosphonates (BPs) slow bone resorption by binding with crystal elements in bone, especially spongy, trabecular bone tissue. They are the most common drugs used for osteoporosis, but some are also approved for Paget's disease and hypercalcemia related to cancer. Three Food and Drug Administration (FDA)–approved BPs—alendronate (Fosamax), ibandronate (Boniva), and risedronate (Actonel, Atelvia)—are commonly used for the *prevention and treatment* of osteoporosis (Lilley et al., 2014). These drugs are available as oral preparations, with ibandronate (Boniva) also available as an IV preparation.

After taking any of these drugs for 3 years, the patient has a DXA scan. If bone density has improved or is maintained, the primary care provider may discontinue the bisphosphonate until the next scan in another 3 years. At that time, the provider will determine if the drug needs to be restarted. For some patients, long-term bisphosphonate use may cause osteonecrosis (discussed below) or a long-bone fracture.

Nursing Safety Priority QSEN

Drug Alert

Do not confuse Fosamax with Flomax, a selective alpha-adrenergic blocker used for benign prostatic hyperplasia (BPH).

Oral BPs are commonly associated with a serious problem called

esophagitis (inflammation of the esophagus). Esophageal ulcers have also been reported with the use of BPs, especially when the tablet is not completely swallowed.

Nursing Safety Priority QSEN

Drug Alert

To promote safety, teach patients to take bisphosphonates (BPs) early in the morning with 8 ounces of water and wait 30 to 60 minutes in an upright position before eating. If chest discomfort occurs, a symptom of esophageal irritation, instruct patients to discontinue the drug and contact their health care provider. Patients with poor renal function, hypocalcemia, or gastroesophageal reflux disease (GERD) should not take BPs.

The most recent additions to the bisphosphonates are IV zoledronic acid (Reclast) and IV pamidronate (Aredia). For management of osteoporosis, Reclast is needed only once a year and Aredia is given every 3 to 6 months. Both drugs have been linked to a complication called jaw **osteonecrosis** (also known as *avascular necrosis,* or *bone death*) in which infection and necrosis of the mandible or maxilla occur (Lilley et al., 2014). The incidence of this serious problem is low but can be a complication of this infusion therapy.

Nursing Safety Priority QSEN

Drug Alert

Teach patients to have an oral assessment and preventive dentistry before beginning any bisphosphonate therapy. To promote safety, instruct them to inform any dentist who is planning invasive treatment, such as a tooth extraction or implant, that they are taking a BP drug (Cohen, 2010).

Estrogen Agonist/Antagonists.

Formerly called the *selective estrogen receptor modulators (SERMs),* estrogen agonist/antagonists are a class of drugs designed to mimic estrogen in some parts of the body while blocking its effect elsewhere. Raloxifene (Evista) is currently the only approved drug in this class and is used for *prevention and treatment* of osteoporosis in postmenopausal women. Raloxifene increases bone mineral density (BMD), reduces bone resorption, and reduces the incidence of osteoporotic vertebral fractures.

The drug should not be given to women who have a history of thromboembolism.

Monoclonal Antibodies.

A newer type of drug is denosumab (Prolia, Xgeva), a monoclonal antibody that has been approved for treatment of osteoporosis when other drugs are not effective (Lilley et al., 2014). The drug binds to a protein that is essential for the formation, function, and survival of osteoclasts and is given subcutaneously twice a year. By preventing the protein from activating its receptor, the drug decreases bone loss and increases bone mass and strength. The most common side effects of denosumab are back pain, high cholesterol, urinary tract infection, and muscle pain. The drug can also cause a decrease in serum calcium levels. Therefore patients who already have a low calcium level should not take the drug. Like other drugs used for osteoporosis, denosumab can cause fractures, especially of the femur, and jaw osteonecrosis.

Clinical Judgment Challenge

Patient-Centered Care; Evidence-Based Practice QSEN

A 71-year-old Caucasian (Euro-American) woman has been diagnosed with osteoporosis for over 15 years. She has been on calcium and vitamin D_3 supplements since her diagnosis and has been taking risedronate (Actonel) on and off for the past 12 years. According to her most recent DXA scan, the patient continues to lose bone density despite being on drug therapy. Last year she sustained a fracture of her humerus after she tripped over her small dog. When reviewing her history, you note that her mother and older sister had osteoporosis for many years. Her sister recently died less than a year after fracturing her hip. The patient expresses her fear of having another fracture and wants to be considered for Prolia therapy.

1. What risk factors does this patient have for osteoporosis? What other information do you need to do a complete assessment?
2. Is this patient a good candidate for beginning denosumab? Why or why not? Will you need more information? If so, what do you need to know?
3. If the patient begins the new drug, what health teaching will she need?
4. How will you respond to her fear of having more fractures?

Community-Based Care

Patients with osteoporosis are usually managed at home unless they have major fragility fractures. Osteoporosis disease-management programs managed by nurse practitioners have helped diagnose and treat the disease. Greene and Dell (2010) reported that over a 6-year period, a large osteoporosis disease-management program resulted in a 263% increase in the number of DXA scans done each year, a 153% increase in the number of patients treated with drug therapy, and a 38.1% decrease in the expected hip fracture rate.

Refer patients to the National Osteoporosis Foundation (www.nof.org) in the United States for information regarding the disease and its treatment. The Osteoporosis Society of Canada (www.osteoporosis.ca) has similar services. Large health care systems often have osteoporosis specialty clinics and support groups for patients with osteoporosis.

Osteomalacia

Pathophysiology

Osteomalacia is loss of bone related to a vitamin D deficiency. It causes softening of the bone resulting from inadequate deposits of calcium and phosphorus in the bone matrix. Normal remodeling of the bone is disrupted, and calcification does not occur. Osteomalacia is the adult equivalent of **rickets,** or vitamin D deficiency, in children.

Vitamin D deficiency is the most important factor in development of osteomalacia. In its natural form, vitamin D is activated by the ultraviolet radiation of the sun and obtained from certain foods as a nutritional supplement. In combination with calcium and phosphorus, the vitamin is necessary for bone formation.

Osteomalacia may be confused with osteoporosis because of similar characteristics shared by the two disease processes. Table 50-2 compares and contrasts osteoporosis and osteomalacia.

TABLE 50-2

Differential Features of Osteoporosis and Osteomalacia

CHARACTERISTIC	OSTEOPOROSIS	OSTEOMALACIA
Definition	Decreased bone mass	Demineralized bone
Pathophysiology	Lack of calcium	Lack of vitamin D
Radiographic findings	Osteopenia, fractures	Pseudofractures, Looser's zones, fractures
Calcium level	Low or normal	Low or normal
Phosphate level	Normal	Low or normal
Parathyroid hormone	Normal	High or normal
Alkaline phosphatase	Normal	High

In addition to primary disease related to lack of sunlight exposure or dietary intake, vitamin D deficiency caused by various health problems may result in osteomalacia (Table 50-3). Malabsorption of vitamin D from the small bowel is a common complication of partial or total gastrectomy and bypass or resection surgery of the small intestine. Disease of the small bowel, such as Crohn's disease, may cause decreased vitamin and mineral absorption.

TABLE 50-3

Causes of Osteomalacia

Vitamin D Disturbance

• Inadequate production
• Lack of sunlight exposure
• Dietary deficiency
• Abnormal metabolism
• Drug therapy
  • Phenytoin (Dilantin)
  • Fluoride
  • Barbiturates
• Liver disease
• Renal disease

• Inadequate absorption
  • Postgastrectomy
  • Malabsorption syndrome
• Inflammatory bowel disease

Kidney Disease

• Chronic kidney disease
• Acute tubular disorders
  • Acidosis
  • Hypophosphatemia

Familial Metabolic Error
• Hypophosphatemia

Liver and pancreatic disorders disrupt vitamin D metabolism and decrease its production. Chronic kidney disease (CKD) interferes with the synthesis of calcitriol, the most active vitamin metabolite. Osteomalacia can also be caused by bone tumors (oncogenic or tumor-induced osteomalacia).

Conditions that contribute to phosphate depletion (hypophosphatemia) lead to osteomalacia because they stimulate movement from bone and prevent calcium uptake in the bone. Osteomalacia is also an adverse effect of long-term therapy with certain drugs such as antiepileptic drugs (AEDs) and barbiturates. The exact mechanism for the drug effects is not known. Genetic deviations in vitamin D or phosphate metabolism may contribute to bone changes seen in osteomalacia.

Osteomalacia is not common in the United States and Western Europe.

However, it is more common in less affluent nations and in countries where famine is common. Newcomers from these countries may seek health care in the United States. Older adults are most at risk. This group may have inadequate exposure to sunlight or intake of vitamin D–fortified foods. People who adhere to very restrictive vegan diets without adequate supplement of vitamin D can also be at risk. Assess for the risk for osteomalacia in anyone who has poor nutritional intake related to homelessness, who severely abuses drugs or alcohol, or who is very poor.

Health Promotion and Maintenance

To prevent or help treat osteomalacia, teach patients to increase vitamin D through dietary intake, sun exposure, and drug supplements. Instruct the at-risk patient about foods high in vitamin D, such as milk and food that has had it added. Remind patients that cheese and yogurt rarely contain vitamin D although they are rich in calcium. Instruct them to read food labels for nutrient content. Remind patients, especially those who are homebound, about the importance of daily sun exposure (at least 5 minutes each day) for the most important source of vitamin D.

Some people are lactose intolerant or do not use dairy products because of their vegan diets. However, many products are available for people who avoid dairy products. Soy and rice milk, tofu, and soy products are substitutes, but they are expensive. Teach patients to choose those products that are fortified with vitamin D. Other foods rich in the vitamin are eggs, swordfish, chicken, and liver, as well as enriched cereals and bread products. The at-risk patient should also take vitamin D supplements as prescribed by his or her health care provider.

Patient-Centered Collaborative Care

Assessment

Collect important data for the patient with osteomalacia or suspected osteomalacia, including age, ability to be exposed to sunlight, and skin pigmentation. The older adult who has been homebound or chronically institutionalized is at the greatest risk. People who have dark skin and who may consume minimal protein are more at risk than light-skinned people with the same dietary habits. Dark-skinned people may avoid the sun and need protein for calcium binding. Take a thorough nutritional history to determine the intake of foods containing vitamin D and calcium. Coordinate the assessment with the dietitian.

Assessment includes any history of chronic disease processes of the GI

tract including inflammatory bowel disease, gastric or intestinal bypass surgery, or any problem that interferes with absorption from the GI tract. A history of renal or liver dysfunction may lead to ineffective metabolism of vitamin D. Drugs such as phenytoin (Dilantin) or fluoride preparations may also interfere with metabolism of vitamin D.

Osteomalacia and osteoporosis may occur at the same time (see Table 50-2). In the early stages of osteomalacia, the manifestations are nonspecific. Muscle weakness and bone pain may be misdiagnosed as arthritis or another connective tissue disorder. In some cases, proximal muscle weakness in the shoulder and pelvic girdle area is the only presenting symptom.

Muscle weakness in the lower extremities may cause a waddling and unsteady gait, which contributes to falls and subsequent fractures. Hypophosphatemia leads to an inadequate production of muscle cell adenosine triphosphate, thus resulting in a decrease in muscle cell energy. If hypocalcemia is present, muscle cramping may occur with weakness.

In collaboration with the physical therapist, assess muscle strength and observe the patient's gait. Document concerns about muscle cramps and bone pain. Skeletal discomfort is often vague and generalized. The spine, ribs, pelvis, and lower extremities are most often affected. The patient usually describes the pain as aggravated by activity and worse at night.

Palpate the affected bones for tenderness. Bone tenderness may occur when pressure is applied to the tibia or rib cage. Skeletal malalignment, like long-bone bowing or spinal deformity, may be similar to that seen in osteoporosis. In extreme cases, the pelvis narrows, so vaginal childbirth is difficult. If osteomalacia is untreated, vertebral, rib, and long-bone fractures may occur. The patient may be misdiagnosed as having bone cancer or osteoporosis.

X-rays of bone in patients with osteomalacia reveal a decrease in the cancellous bone and lack of osteoid sharpness. The classic diagnostic finding specific to the disease, however, is the presence of radiolucent bands (Looser's lines or zones). Looser's zones represent stress fractures that have not mineralized. They often appear symmetrically in the medial area of the femoral neck, ribs, and pelvis and may progress to complete fractures with minimal trauma. Bone biopsy of these areas may be needed for complete diagnosis. DXA scan may assist in diagnosis of osteomalacia.

Interventions

The major treatment for osteomalacia is vitamin D in an active form, such as ergocalciferol. Vitamin D is needed to adequately absorb and utilize calcium in the body.

Nurses play a vital role in educating other health care professionals about the need to screen patients for low vitamin D levels. For all at-risk patients, teach them about which high calcium and vitamin D foods to eat and the importance of adequate daily sunlight. Additional health teaching is discussed above in the Health Promotion and Maintenance section.

Paget's Disease of the Bone

Pathophysiology

Paget's disease, or **osteitis deformans,** is a chronic metabolic disorder in which bone is excessively broken down (osteoclastic activity) and re-formed (osteoblastic activity). The result is bone that is structurally disorganized, causing bones to be weak with increased risk for bowing of long bones and fractures. Two types of Paget's disease can occur—familial and sporadic.

Three pathophysiologic phases of the disorder have been described: active, mixed, and inactive. In the first phase (the active phase), a rapid increase in osteoclasts (cells that break down bone) causes massive bone destruction and deformity. The osteoclasts of pagetic bone are large and multinuclear, unlike the osteoclasts of normal bone tissue.

In the mixed phase, the osteoblasts (bone-forming cells) react to compensate in forming new bone. The result is bone that is vascular, structurally weak, and deformed. Paget's disease occurs in one bone or in multiple sites. The most common areas of involvement are the vertebrae, femur, skull, clavicle, humerus, and pelvis.

When the osteoblastic activity exceeds the osteoclastic activity, the inactive phase occurs. The newly formed bone becomes sclerotic and very hard (McCance et al., 2014).

Genetic/Genomic Considerations

Patient-Centered Care QSEN

Because Paget's disease is often present in identical twins, an autosomal dominant pattern has been suggested. The disease has been noted in up to 30% of people with a positive family history for Paget's disease. Several complex genetic factors have been identified in families

with the disease (Najat et al., 2009), including mutations in the:

- *RANKL/RANK/OPG* system, which is needed for osteoclast development and activity (see p. 1030 in the Osteoporosis section)
- Valosin-containing gene of complement binding protein (valosin-containing protein [*VCP*]), an important inflammatory factor
- Sequestosome 1 *(SQSTM1)* or *p62*, an expressed adaptor protein that can bind to ubiquitin and the atypical protein kinase C

Teach patients the importance of genetics in familial Paget's disease, and refer them to the appropriate genetics counseling resource. Ask the patient if genetic testing is desired.

Paget's disease is second only to osteoporosis as one of the most common bone diseases in the United States, affecting about one million people. The disease is seen more frequently in people ages 50 years and older and in those of European heritage. The reason for this pattern is not known. The risk for developing Paget's disease increases as a person ages, particularly in those 80 years old and older. Men are affected twice as often as women (National Institute of Arthritis and Musculoskeletal and Skin Diseases, 2013).

Patient-Centered Collaborative Care

Assessment

Physical Assessment/Clinical Manifestations.

Most patients are asymptomatic, and the disease may be confined to one bone. It may be accidentally discovered during a routine laboratory or x-ray examination. In more severe disease, the manifestations are diverse and potentially fatal (Chart 50-3).

Chart 50-3 Key Features

Paget's Disease of the Bone

Musculoskeletal Manifestations

- Bone and joint pain (may be in a single bone) that is aching, poorly described, and aggravated by walking
- Low back and sciatic nerve pain
- Bowing of long bones
- Loss of normal spinal curvature
- Enlarged, thick skull

- Pathologic fractures
- Osteogenic sarcoma (bone cancer)

Skin Manifestations

- Flushed, warm skin

Other Manifestations

- Apathy, lethargy, fatigue
- Hyperparathyroidism
- Gout
- Urinary or renal stones
- Heart failure from fluid overload

Ask the patient about a history of fracture and current bone pain. Bone pain, usually described as mild to moderate, may cause the patient to seek medical attention. The most common sites for pain are the hip and pelvis, but even the bones in the ear may be affected, causing hearing loss. The pain is usually described as aching, poorly defined, deep, and worsened by pressure. It is most noticeable at night or when the patient is resting. Patients may report redness and warmth at affected sites. These manifestations may be related to increased vascularity and blood flow.

The pain associated with the disorder may result from metabolic bone activity, secondary arthritis, impending fracture, or nerve impingement. Arthritis often occurs at the joints (cartilage) of the affected bones, resulting from bowing in the long bones of the leg. Some patients have joint replacements as a result of very painful weight-bearing joints. Nerve impingement is particularly common in the lumbosacral area of the vertebral column, presenting as back pain that radiates along one or both legs.

Observe posture, stance, and gait to identify gross bony deformities. Because of the enlargement of the vertebrae, loss of normal spinal curvature, and lower extremity malalignment, the patient may have decreased height. Assess for kyphosis or scoliosis of the spinal column. Note any long-bone bowing in the legs with subsequent varus (bow-leg) deformity. Long bones of the arms may also develop bowing. Flexion contracture in the hip joint is often present. Any of these deformities may be asymmetric. This weakened bone is at risk for fracture from even a minor injury. All of these problems interfere with the patient's need for independent mobility.

When performing a musculoskeletal assessment in a patient with

Paget's disease, pay particular attention to the size and shape of the skull, which is typically soft, thick, and enlarged. Pressure from an enlarged temporal bone may lead to deafness and vertigo (dizziness). Basilar (in the occipital area) complications can compress any of the cranial nerves and result in neurologic problems. Assess the patient for changes in vision, swallowing, hearing, and speech. Platybasia, or basilar invagination, causes brainstem (vital sign center) damage that threatens life. In some cases, the bony enlargement of the skull blocks cerebrospinal fluid (CSF), resulting in hydrocephalus.

Fragility (pathologic) fractures may be the presenting clinical manifestation of the disorder. The femur and the tibia are most often affected, and fracture of these bones can result from minimal trauma. The fracture line is usually perpendicular to the long axis of the bone, and healing is unpredictable because of abnormal metabolic activity within the bone.

Although rare, bones affected by Paget's disease may develop malignant changes. The most dreaded complication of Paget's disease is cancer, most commonly osteogenic sarcoma. It affects the femur, humerus, and old fracture sites and has a grave prognosis because of early metastasis to the lung or extensive local invasion. When severe bone pain is present in a patient with Paget's disease, bone cancer is suspected.

Assess the skin for its color and temperature. In people with Paget's disease, the skin is typically flushed and warm because of increased blood flow. In addition, assess the patient's energy level because apathy, lethargy, and fatigue are common.

Other less common manifestations of Paget's disease include hyperparathyroidism and gout. Secondary hyperparathyroidism leads to an increase in serum and urinary calcium levels. In severe cases, serum calcium excess results from prolonged immobilization. Calcium deposits occur in joint spaces or as stones in the urinary tract. **Hyperuricemia** (serum uric acid excess) and gout occur because the increased metabolic activity of bone creates an increase in nucleic acid catabolism. Therefore kidney stones are more common in people with Paget's disease.

In a few cases, increased blood flow causes the heart to work harder to increase cardiac output, resulting in heart failure if not treated. Cardiac complications tend to occur only when more than a third of the skeleton is involved.

Diagnostic Assessment.

Increases in *serum alkaline phosphatase (ALP)* and urinary hydroxyproline levels are the primary laboratory findings indicating possible Paget's

disease. Overactive osteoblasts cause an altered ALP level. ALP can be further evaluated by alkaline phosphatase isoenzymes. The isoenzyme testing can further break ALP into three fractions—liver, bone, and intestinal. Elevated bone isoenzymes can help in a more definitive diagnosis of Paget's disease. Serum isoenzyme levels of bone ALP are used to monitor effectiveness of treatment (Pagana & Pagana, 2014).

The 24-hour *urinary hydroxyproline* level reflects bone collagen turnover and indicates the degree of disease severity. The higher the hydroxyproline, the more severe is the disease.

The *calcium* levels in blood and urine may be low, normal, or elevated. The immobilized patient is more likely to have an increase in calcium levels as a result of calcium moving from bone into the blood.

Paget's disease often causes an elevated *uric acid* because nucleic acid from overactive bone metabolism increases. This finding may be misinterpreted as primary gout.

X-rays are also used to diagnose Paget's disease. They reveal characteristic changes including the presence of osteolytic lesions and enlarged bones with radiolucent, or punched-out, appearance. Decrease in joint space may be seen with arthritic changes in joints. Malalignment deformities, fractures, and secondary arthritic changes may be present.

Radionuclide bone scan may be most sensitive in detecting Paget's disease. A radiolabeled bisphosphonate is injected IV and shows pagetic bone in areas of high bone turnover activity. This test can determine the extent of Paget's disease in the skeleton. CT and MRI are useful in the detection of cancerous tumors, changes in the skull, and spinal cord or nerve compression (Pagana & Pagana, 2014).

Interventions

Nonsurgical or surgical management may be necessary to reduce pain and promote mobility. Nonsurgical interventions are used first.

Drug Therapy.

The primary intervention for Paget's disease is drug therapy. The purpose of *drug therapy* in Paget's disease is to relieve pain and to decrease bone resorption.

Management of mild to moderate pain may include the use of aspirin or NSAIDs such as ibuprofen (Motrin, Apo-Ibuprofen). When the calcium level is more than twice the normal value and the disease is widespread, the health care provider usually prescribes more potent drugs, such as selected bisphosphonates. Treatment with these agents for Paget's disease requires dosages and duration of therapy different from

those for osteoporosis. Chart 50-2 includes information about some of these commonly used drugs.

Oral bisphosphonates are a first-line treatment choice for Paget's disease when alkaline phosphatase levels are at least twice the normal serum level. Alendronate (Fosamax), risedronate (Actonel), etidronate (Didronel), or tiludronate (Skelid) is given in tablet form. When oral agents are not effective, pamidronate (Aredia) or zoledronic acid (Reclast, Zometa) is administered IV (Lilley et al., 2014). Aredia is given once every 3 months, and Reclast is given once a year as a single IV dose. These drugs are usually highly effective. To reduce the risk for hypocalcemia, patients should receive 1500 mg of calcium daily in divided doses and 800 international units of vitamin D_3 daily for at least 2 weeks after zoledronic acid infusion unless they are prone to kidney stones. Chart 50-2 provides additional information about caring for patients receiving bisphosphonates.

Denosumab (Prolia) is a monoclonal antibody that is also approved for Paget's disease. The drug binds to a protein that is essential for the formation, function, and survival of osteoclasts and is given subcutaneously twice a year. By preventing the protein from activating its receptor, the drug decreases bone loss and increases bone mass and strength. This drug is discussed in the Osteoporosis section of this chapter.

Calcitonin is a hormone that seems to reduce bone resorption and, subsequently, relieve pain. The drug often causes a dramatic decrease in the alkaline phosphatase level in a few weeks. Calcitonin is approved for subcutaneous administration in treating Paget's disease because the nasal spray is not effective. The drug binds to osteoclast receptors, therefore slowing bone breakdown (Lilley et al., 2014). The drug may be used for those patients who do not tolerate bisphosphonates. Side effects of calcitonin include nausea, flushing, and skin rash. Skin testing may be done before administration of the first dose.

Other Interventions.

In addition to administering drugs, implement physical measures to reduce pain and increase mobility. These measures may include application of heat and gentle massage. An exercise program may be started with the help of a physical therapist. Exercise may be difficult because of pain and danger of fracture. Non-impact exercise should be used, but the patient may benefit from strengthening and weight-bearing exercises. In collaboration with the physical therapist, teach the patient about ROM and gentle stretching. Additional interventions for pain relief, such as

relaxation techniques, are discussed in Chapter 3.

Measures to promote bone health are also important and include a diet rich in calcium and vitamin D. Nutrition therapy for bone health is described on p. 1033 in the discussion of Interventions in the Osteoporosis section.

Provide the patient with information to contact the U.S. local chapter of The Paget Foundation (www.paget.org) and the Arthritis Foundation (www.arthritis.org). The Arthritis Society in Canada (www.arthritis.ca) is also an excellent service. These resources provide information and support for the patient and family or significant others.

NCLEX Examination Challenge

Physiological Integrity

A client is starting on risedronate (Actonel) for treatment of Paget's disease. What precaution does the nurse include in the client's health teaching about this drug?

A "This drug can cause serious infections."
B "Monitor the drug injection site for redness or itching."
C "Drink a full glass of water after taking the drug."
D "Do not take calcium and vitamin D while on the drug."

Osteomyelitis

Infection in bony tissue can be a severe and difficult-to-treat problem. Bone infection can result in chronic recurrence of infection, loss of function and mobility, amputation, and even death.

Pathophysiology

Bacteria, viruses, or fungi can cause infection in bone, known as **osteomyelitis.** Invasion by one or more pathogenic microorganisms stimulates the inflammatory response in bone tissue. The inflammation produces an increased vascular leak and edema, often involving the surrounding soft tissues. Once inflammation is established, the vessels in the area become thrombosed and release exudate (pus) into bony tissue. Ischemia of bone tissue follows and results in necrotic bone. This area of necrotic bone separates from surrounding bone tissue, and **sequestrum** is formed. The presence of sequestrum prevents bone healing and causes superimposed infection, often in the form of bone abscess. As shown in Fig. 50-2, the cycle repeats itself as the new infection leads to further inflammation, vessel thromboses, and necrosis.

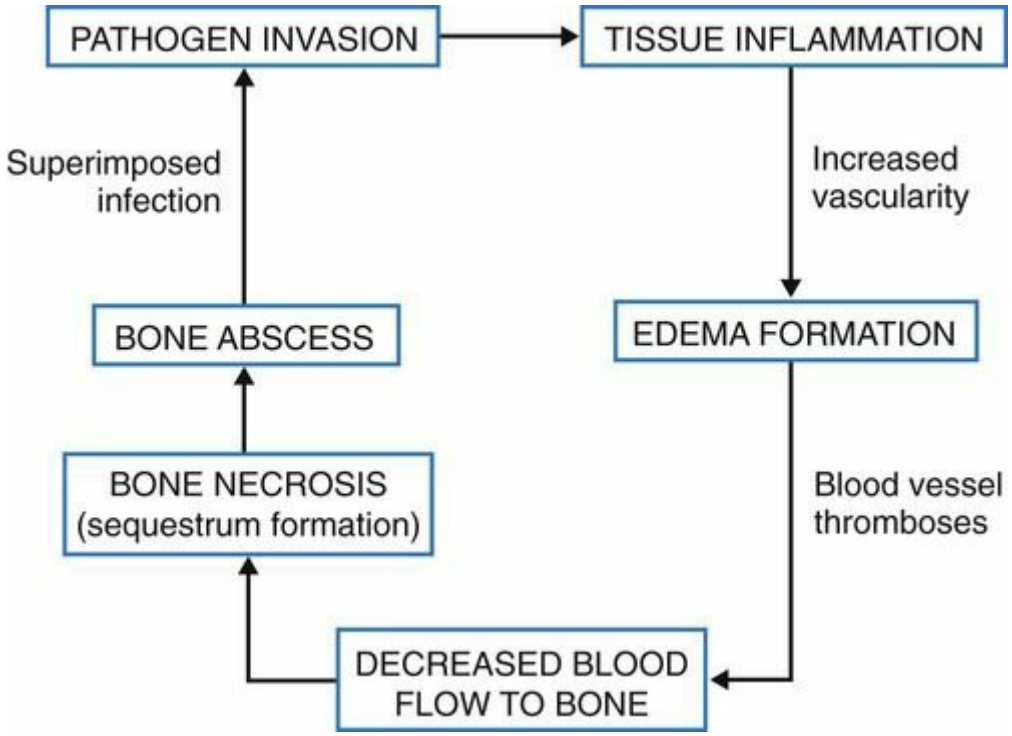

FIG. 50-2 Infection cycle of osteomyelitis.

Osteomyelitis is categorized as *exogenous*, in which infectious organisms enter from outside the body as in an open fracture, or **endogenous** (**hematogenous**), in which organisms are carried by the

bloodstream from other areas of infection in the body. A third category is *contiguous*, in which bone infection results from skin infection of adjacent tissues. Osteomyelitis can be further divided into two major types: acute osteomyelitis and chronic osteomyelitis.

Each type of bone infection has its own causative factors. Pathogenic microbes favor bone that has a rich blood supply and a marrow cavity. **Acute hematogenous infection** results from bacteremia, underlying disease, or nonpenetrating trauma. Urinary tract infections, particularly in older men, tend to spread to the lower vertebrae. Long-term IV catheters (e.g., Hickman catheters) can be primary sources of infection. Patients undergoing long-term hemodialysis and IV drug users are also at risk for osteomyelitis. *Salmonella* infections of the GI tract may spread to bone. Patients with sickle cell disease and other hemoglobinopathies often have multiple episodes of salmonellosis, which can cause bone infection (McCance et al., 2014).

Poor dental hygiene and periodontal (gum) infection can be causative factors in **contiguous** osteomyelitis in facial bones. Minimal nonpenetrating trauma can cause hemorrhages or small-vessel occlusions, leading to bone necrosis. Regardless of the source of infection, many infections are caused by *Staphylococcus aureus.* Treatment of infection may be complicated further by the presence of methicillin-resistant *Staphylococcus aureus* (MRSA) or other multiple drug-resistant organisms (MDRO), which is very common in hospitalized and other institutionalized patients. One of the major desired outcomes in health care settings today is to reduce the number of MRSA infections from any source.

Considerations for Older Adults

Patient-Centered Care QSEN

Malignant external otitis media involving the base of the skull is sometimes seen in older adults with diabetes. The most common cause of contiguous spread in older adults, however, is found in those who have slow-healing foot ulcers. Multiple organisms tend to be responsible for the resulting osteomyelitis (McCance et al., 2014).

Penetrating trauma leads to acute osteomyelitis by direct inoculation. A soft-tissue infection may be present as well. Animal bites, puncture wounds, skin ulcerations, and bone surgery can result in bone infection. The most common offending organism is *Pseudomonas aeruginosa*, but other gram-negative bacteria may be found.

If bone infection is misdiagnosed or inadequately treated, **chronic osteomyelitis** may develop, especially in older adults who have foot ulcers. Inadequate care management results when the treatment period is too short or when the treatment is delayed or inappropriate. About half of cases of chronic osteomyelitis are caused by gram-negative bacteria. Although bacteria are the most common causes of osteomyelitis, viruses and fungal organisms also may cause infection.

Patient-Centered Collaborative Care

Assessment

Bone pain, with or without other manifestations, is a common concern of patients with bone infection. The pain is described as a constant, localized, pulsating sensation that worsens with movement.

The patient with *acute* osteomyelitis has fever, usually with temperature greater than 101° F (38.3° C). *Older adults may not have an extreme temperature elevation because of lower core body temperature and compromised immune system that occur with normal aging*. The area around the infected bone swells and is tender when palpated. Erythema (redness) and heat may also be present. When vascular compromise is severe, patients may not feel discomfort because of nerve damage from lack of blood supply.

When vascular insufficiency is suspected, assess circulation in the distal extremities. Ulcerations may be present on the feet or hands, indicating inadequate healing ability as a result of poor circulation.

Fever, swelling, and erythema are less common in those with *chronic* osteomyelitis. Ulceration resulting in sinus tract formation, localized pain, and drainage is more characteristic of chronic infection (Chart 50-4).

Chart 50-4 Key Features

Acute and Chronic Osteomyelitis

Acute Osteomyelitis

- Fever; temperature usually above 101° F (38.3° C)
- Swelling around the affected area
- Erythema of the affected area
- Tenderness of the affected area
- Bone pain that is constant, localized, and pulsating; intensifies with movement

Chronic Osteomyelitis

- Foot ulcer(s) (most commonly)
- Sinus tract formation
- Localized pain
- Drainage from the affected area

The patient with osteomyelitis may have an elevated white blood cell (leukocyte) count, which may be double the normal value. The erythrocyte sedimentation rate (ESR) may be normal early in the course of the disease but rises as the condition progresses. It may remain elevated for as long as 3 months after drug therapy is discontinued.

If bacteremia is present, a potentially life-threatening complication that could lead to septic shock, a blood culture identifies the offending organisms to determine which antibiotics should be used in treatment. Both aerobic and anaerobic blood cultures are collected before drug therapy begins.

Although bone changes cannot be detected early with standard x-rays, changes in blood flow can be seen early in the course of the disease by radionuclide scanning or MRI.

Interventions

The specific treatment protocol depends on the type and number of microbes present in the infected tissue. If other measures fail to resolve the infectious process, surgical management may be needed.

Nonsurgical Management.

The health care provider starts antimicrobial (e.g., antibiotic) therapy as soon as possible. In the presence of copious wound drainage, Contact Precautions are used to prevent the spread of the offending organism to other patients and health care personnel. Teach patients, visitors, and staff members how to use these precautions. (See Chapter 23 for a discussion of Contact Precautions.)

More than one agent may be needed to combat multiple types of organisms. The hospital or home care nurse gives the drugs at specifically prescribed times so that therapeutic serum levels are achieved. Observe for the actions, side effects, and toxicity of these drugs. *Teach family members or other caregivers in the home setting how to administer antimicrobials if they are continued after hospital discharge or are used only at home.*

The optimal drug regimen for patients with chronic osteomyelitis is

not well established. Prolonged therapy for more than 3 months may be needed to eliminate the infection. Because of the cost of lengthy hospital stays, patients are typically cared for in the home or long-term care (LTC) setting with long-term vascular access catheters, such as the peripherally inserted central catheter (PICC), for drug administration. After discontinuation of IV drugs, oral therapy may be needed for weeks or months. Patients and families must understand the complications of inadequate treatment or failure to follow up with health care providers. Teach them that drug therapy must be continued over a long period to be effective.

Nursing Safety Priority QSEN

Drug Alert

Even when symptoms of osteomyelitis appear to be improved, teach the patient and family that the full course of IV and oral antimicrobials must be completed to ensure that the infection is resolved.

In addition to systemic drug therapy, the wound may be irrigated, either continuously or intermittently, with one or more antibiotic solutions. A medical technique in which beads made of bone cement are impregnated with an antibiotic and packed into the wound can provide direct contact of the antibiotic with the offending organism.

Drugs are also needed to control pain. Patients experience acute and chronic pain and must receive a regimen of drug therapy for control. Chapter 3 describes pharmacologic and nonpharmacologic interventions for both acute and chronic pain.

A treatment to increase tissue perfusion for patients with chronic, unremitting osteomyelitis is the use of a hyperbaric chamber or portable device to administer hyperbaric oxygen (HBO) therapy. These devices are usually available in large tertiary care centers and may not be accessible to all patients who might benefit from them. With HBO therapy, the affected area is exposed to a high concentration of oxygen that diffuses into the tissues to promote healing. In conjunction with high-dose drug therapy and surgical débridement, HBO has proven very useful in treating a number of anaerobic infections. Other wound-management therapies are described in Chapter 25.

Surgical Management.

Antimicrobial therapy alone may not meet the desired outcome of

treatment. Surgical techniques may be used to minimize the disfigurement that can be a devastating result of severe osteomyelitis. Surgery is reserved for patients with chronic osteomyelitis.

Because bone cannot heal in the presence of necrotic tissue, a *sequestrectomy* may be performed to débride the necrotic bone and allow revascularization of tissue. The excision of dead and infected bone often results in a sizable cavity, or bone defect. Bone *grafts* to repair bone defects are also widely used.

When infected bone is extensively resected, reconstruction with *microvascular bone transfers* may be done. This procedure is reserved for larger skeletal defects. The most common donor sites are the patient's fibula and iliac crest. The bone graft may have an attached muscle or skin flap, if necessary. The steps of the procedure are similar to those of bone grafting in that débridement of dead or necrotic bone is done before bone transfer.

Nursing care of the patient after surgery is similar to that for any postoperative patient (see Chapter 16). However, the important difference is that neurovascular (NV) assessments must be done frequently because the patient experiences increased swelling after the surgical procedure. Elevate the affected extremity to increase venous return and thus control swelling. Assess and document the patient's NV status, including:

- Pain
- Movement
- Sensation
- Warmth
- Temperature
- Distal pulses
- Capillary refill (not as reliable as the above indicators)

Nursing Safety Priority QSEN

Critical Rescue

After surgery to treat osteomyelitis, frequently check for signs of neurovascular compromise, including the six *P*s: **p**ain that cannot be controlled, **p**ressure, paresis or **p**aralysis (weakness or inability to move), **p**aresthesia (abnormal, tingling sensation), **p**allor, and **p**ulselessness. If any of these findings occur, report them immediately to the surgeon.

If the bony defect is small, a *muscle flap* may be the only surgery

required. Local muscle flaps are used in the treatment of chronic osteomyelitis when soft tissue does not fill the dead space, or cavity, that results from bone débridement. The flap provides wound coverage and enhances blood flow to promote healing. A split-thickness skin graft is often applied several days after the muscle flap.

When the previously described surgical procedures are not appropriate or successful and as a last resort, the affected limb may need to be amputated. The physical and psychological care for a patient who has undergone an amputation is discussed in Chapter 51.

Benign Bone Tumors

Pathophysiology

Benign (noncancerous) bone tumors are often asymptomatic and may be discovered on routine x-ray examination or as the cause of pathologic fractures. The cause of benign bone tumors is not known. Tumors may arise from several types of tissue. The major classifications include *chondrogenic* tumors (from cartilage), *osteogenic* tumors (from bone), and *fibrogenic* tumors (from fibrous tissue and found most often in children). Although many specific benign tumors have been identified, only the common ones are described here.

The most common benign bone tumor is the *osteochondroma*. Although its onset is usually in childhood, the tumor grows until skeletal maturity and may not be diagnosed until adulthood. The tumor may be a single growth or multiple growths and can occur in any bone. The femur and the tibia are most often involved.

The *chondroma*, or endochondroma, is a lesion of mature hyaline cartilage affecting primarily the hands and the feet. The ribs, sternum, spine, and long bones may also be involved. Chondromas are slow growing and often cause pathologic fractures after minor injury. They are found in people of all ages, occur in both men and women, and can affect any bone.

The origin of the *giant cell tumor* remains uncertain. This lesion is aggressive and can be extensive and may involve surrounding soft tissue. Although classified as benign, giant cell tumors can metastasize (spread) to the lung. The peak incidence occurs in patients in their 30s.

Patient-Centered Collaborative Care

Assess for pain, the most common manifestation of benign bone tumors. Pain can range from mild to moderate. It can be caused by direct tumor invasion into soft tissue, compressing peripheral nerves, or by a resulting pathologic fracture.

In addition, observe and palpate the suspected involved area. When the tumor affects the lower extremities or the small bones of the hands and feet, local swelling may be detected as the tumor enlarges. In some cases, muscle atrophy or muscle spasm may be present. Carefully palpate the bone and muscle to detect these changes and elicit tenderness.

Routine x-rays and tomography are used to find bone tumors. Tumors are characterized by sharp margins, intact cortices, and smooth, uniform periosteal bone.

CT is less useful except in complex anatomic areas, such as the spinal column and sacrum. The test is helpful in evaluating the extent of soft-tissue involvement. MRI may be especially helpful in viewing problems of the spinal column.

The health care provider uses drug therapy and surgery in combination when possible. Non-drug pain-relief measures are also used. Depending on the patient's preference and tolerance, measures such as heat or cold may help relieve pain.

In addition to prescribing analgesics to reduce pain, the health care provider usually prescribes one or more NSAIDs to inhibit prostaglandin synthesis that increases pain and inflammation. Give these drugs after meals or with food to reduce GI side effects. Teach patients to report any signs of bleeding to the primary health care provider immediately.

The most common surgical procedure used for benign bone tumors is removal. If the tumor is small, surgery may not be needed. When the tumor is very extensive, as in a giant cell tumor, it is removed with care to restore or maintain the function of the adjacent joint, most often the knee. In some cases, the knee is replaced with a prosthetic device and, less often, is fused **(arthrodesis).** Bone grafting may be needed. The collaborative care for patients undergoing total knee replacement is discussed in Chapter 18.

Bone Cancer

Cancerous bone tumors may be primary or secondary (those that originate in other tissues and metastasize to bone). *Primary tumors* occur most often in people between 10 and 30 years of age and make up a small percentage of bone cancers. As for other forms of cancer, the exact cause of bone cancer is unknown but genetic and environmental factors are likely causes. *Metastatic lesions* most often occur in the older age-group and account for most bone cancers (McCance et al., 2014).

Previous radiation therapy in the anatomic area is a big risk factor. For example, bone cancer of the ribs in the path of radiation for breast cancer is fairly common.

Pathophysiology

Osteosarcoma, or osteogenic sarcoma, is the most common type of *primary* malignant bone tumor. More than 50% of cases occur in the distal femur, followed in decreasing order of occurrence by the proximal tibia and humerus.

The tumor is relatively large, causing acute pain and swelling. The involved area is usually warm because the blood flow to the site increases. The center of the tumor is sclerotic from increased osteoblastic activity. The periphery is soft, extending through the bone cortex in the classic sunburst appearance associated with the neoplasm. An inward spread into the medullary canal is also common. Osteosarcoma typically **metastasizes** (spreads), which results in death.

Although *Ewing's sarcoma* is not as common as other tumors, it is the most malignant. Like other primary tumors, it causes pain and swelling. In addition, systemic manifestations, particularly low-grade fever, leukocytosis, and anemia, characterize the lesions. The pelvis and the lower extremity are most often affected. Pelvic involvement is a poor prognostic sign. It often extends into soft tissue. Death results from metastasis to the lungs and other bones. Although the tumor can be seen in patients of any age, it usually occurs in children and young adults in their 20s. Men are affected more often than women (McCance et al., 2014). The reason for this pattern is not known.

In contrast to the patient with osteosarcoma, the patient with *chondrosarcoma* experiences dull pain and swelling for a long period. The tumor typically affects the pelvis and proximal femur near the diaphysis. Arising from cartilaginous tissue, it destroys bone and often calcifies. The patient with this type of tumor has a better prognosis than one with osteogenic sarcoma. Chondrosarcoma occurs in middle-aged and older

people, with a slight predominance in men.

Arising from fibrous tissue, *fibrosarcomas* can be divided into subtypes, of which malignant fibrous histiocytoma (MFH) is the most malignant. Usually the clinical presentation of MFH is gradual, without specific symptoms. Local tenderness, with or without a palpable mass, occurs in the long bones of the lower extremity. As with other bone cancers, the lesion can metastasize to the lungs (McCance et al., 2014).

Primary tumors of the prostate, breast, kidney, thyroid, and lung are called *bone-seeking* cancers because they spread to the bone more often than other primary tumors. The vertebrae, pelvis, femur, and ribs are the bone sites commonly affected. Simply stated, primary tumor cells, or seeds, are carried to bone through the bloodstream. *Fragility fractures caused by metastatic bone are a major concern in patient care management.*

Patient-Centered Collaborative Care

Assessment

The data collected for the patient suspected of having a malignant bone tumor are similar to the data needed for the patient with a benign growth. In addition, ask whether the patient has had previous radiation therapy for cancer and determine the status of the patient's general health.

The clinical manifestations seen in the patient with primary bone cancer or metastatic disease vary, depending on the specific type of lesion. Usually the patient has a group of nonspecific concerns, including pain, local swelling, and a tender, palpable mass. Marked disability and impaired mobility may occur in those with advanced metastatic bone disease.

In a patient with Ewing's sarcoma, a low-grade fever may occur because of the systemic features of the neoplasm. For this reason, it is often confused with osteomyelitis. Fatigue and pallor resulting from anemia are also common.

In performing a musculoskeletal assessment, inspect the involved area and palpate the mass for size and tenderness. In collaboration with the physical and occupational therapists, assess the patient's ability to perform mobility tasks and ADLs.

Patients with malignant bone tumors may be young adults whose productive lives are just beginning. They need strong support systems to help cope with the diagnosis and its treatment. Family, significant others, and health care professionals are major components of the needed support. Determine what systems or resources are available.

Patients often experience a loss of control over their lives when a diagnosis of cancer is made. As a result, they become anxious and fearful about the outcome of their illness. Coping with the diagnosis becomes a challenge. As patients progress through the grieving process, there may be initial denial. Identify the anxiety level, and assess the stage or stages of the grieving process. Explore any maladaptive behavior, indicating ineffective coping mechanisms. Chapter 22 further describes the psychosocial assessment for patients with cancer.

The patient with a malignant bone tumor typically shows elevated serum alkaline phosphatase (ALP) levels, indicating the body's attempt to form new bone by increasing osteoblastic activity. The patient with Ewing's sarcoma or metastatic bone cancer often has anemia. In addition, leukocytosis is common with Ewing's sarcoma. The progression of Ewing's sarcoma may be evaluated by elevated serum lactic dehydrogenase (LDH) levels.

In some patients with bone metastasis from the breast, kidney, or lung, the serum calcium level is elevated. Massive bone destruction stimulates release of the mineral into the bloodstream. In patients with Ewing's sarcoma and bone metastasis, the erythrocyte sedimentation rate (ESR) may be elevated because of secondary tissue inflammation (Pagana & Pagana, 2014).

As with benign bone tumors, routine x-rays and CT reveal malignant lesions. Metastatic lesions may increase or decrease bone density, depending on the amount of osteoblastic and osteoclastic activity. CT is helpful in determining the extent of soft-tissue damage. The patient may have an MRI for difficult-to-visualize areas such as the vertebrae.

In some cases a needle bone biopsy may be performed, usually under fluoroscopy to guide the surgeon. Needle biopsy is an ambulatory care procedure with rare complications. After biopsy, the cancer is staged for size and degree of spread. One popular method is the TNM system, based on tumor size and number (T), the presence of cancer cells in lymph nodes (N), and metastasis (spread) to distant sites (M) (see Chapter 21 for further discussion).

Another method is to correlate the tumor grade (high or low), tumor site (intracompartmental or extracompartmental), and presence of metastatic disease (positive or negative). Staging guides the health care team in their decision regarding patient-centered collaborative care.

Interventions

Because the pain is often due to direct primary tumor invasion, treatment is aimed at reducing the size of or removing the tumor. The expected

outcome of treating metastatic bone tumors is palliative rather than curative. Palliative therapies may prevent further bone destruction and improve patient function. A combination of nonsurgical and surgical management is used. Collaborate with members of the interdisciplinary health care team to plan high quality care to achieve positive patient outcomes.

Nonsurgical Management.

In addition to analgesics for local pain relief, chemotherapeutic agents and radiation therapy are often administered to shrink the tumor. In patients with spinal involvement, bracing and immobilization with cervical traction may reduce back pain. Interventional radiology techniques are used to decrease vertebral pain and treat compression fractures (see Chapter 51).

Drug Therapy.

The physician may prescribe *chemotherapy* to be given alone or in combination with radiation or surgery. Certain proliferating tumors, such as Ewing's sarcoma, are sensitive to cytotoxic drugs. Others, such as chondrosarcomas, are often totally drug resistant. Chemotherapy seems to work best for small, metastatic tumors and may be administered before or after surgery. In most cases the physician prescribes a combination of agents. At present, there is no one universally accepted protocol of chemotherapeutic agents. The drugs selected are determined in part by the primary source of the cancer in metastatic disease. For example, when metastasis occurs from breast cancer, estrogen and progesterone blockers may be used. Chapter 22 describes the general nursing care of patients who receive chemotherapy. *Remember that all chemotherapeutic agents are categorized as high-alert medications* (Institute for Safe Medication Practices, 2013).

Other drugs are given for specific metastatic cancers, depending on the location of the primary site. For example, biologic agents, such as cytokines, are given to stimulate the immune system to recognize and destroy cancer cells, especially in patients with renal cancer. Zoledronic acid (Zometa) and pamidronate (Aredia) are two IV bisphosphonates that are approved for bone metastasis from the breast, lung, and prostate (Lilley et al., 2014). These drugs help protect bones and prevent fractures. Inform patients that osteonecrosis of the jaw may also occur, especially in those who have invasive dental procedures. Monitor associated laboratory tests, such as serum creatinine and electrolytes, because these drugs can be toxic to the kidneys. Bisphosphonates are described earlier

in the Osteoporosis section.

Denosumab (Prolia) is a monoclonal antibody that is also approved for metastatic bone disease (Lilley et al., 2014). The drug binds to a protein that is essential for the formation, function, and survival of osteoclasts and is given subcutaneously twice a year. By preventing the protein from activating its receptor, the drug decreases bone loss and increases bone mass and strength. This drug is discussed earlier in the Osteoporosis section.

Radiation Therapy.

Radiation, either brachytherapy or external radiation, is used for selected types of malignant tumors. For patients with Ewing's sarcoma and early osteosarcoma, radiation may be the treatment of choice in reducing tumor size and thus pain.

For patients with metastatic disease, radiation is given primarily for palliation. The therapy is directed toward the painful sites to provide a more comfortable life. One or more treatments are given, depending on the extent of disease. With precise planning, radiation therapy can be used with minimal complications. The general nursing care for patients receiving radiation therapy is described in Chapter 22.

Interventional Radiology.

Interventional radiologists can perform several noninvasive procedures to help relieve pain in the patient with metastasis to the spinal column. Two types of *thermal ablation techniques, radiofrequency ablation (RFA)* and *cryoablation*, can be done under moderate sedation or general anesthesia. RFA kills the targeted tissue with heat using a small needle inserted into the tumor. Most patients have pain relief or control after this ambulatory care procedure. Cryoablation is similar to RFA, but the radiologist uses an extremely cold gas through a probe into the tumor. Although this procedure has been available for years, newer surgical equipment allows a small incision and the patient can return to usual daily activities in a day or two.

The radiologist may also perform a *vertebroplasty* if the patient with spinal metastasis has pathologic compression fractures. After making a small incision, bone cement is injected through a needle into the fractured area. The cement hardens within 15 minutes. Like thermal ablation, this procedure is done in an ambulatory care setting and the patient is placed under moderate sedation.

Surgical Management.

Primary bone tumors are usually reduced or removed with surgery, and surgery may be combined with radiation or chemotherapy.

Preoperative Care.

In addition to the nature, progression, and extent of the tumor, the patient's age and general health state are considered. Chemotherapy may be administered preoperatively.

As for any patient preparing for cancer surgery, the patient with bone cancer needs psychological support from the nurse and other members of the health care team. Assess the level of the patient's and family's understanding about the surgery and related treatments. As an advocate, encourage the patient and family to discuss concerns and questions and provide information regarding hospital routines and procedures. Spiritual support is important to some patients. They may prefer to contact a member of the clergy or a spiritual leader or talk with a clergy member affiliated with the hospital. Offer assistance in arranging for spiritual assistance if requested.

Anticipate postoperative needs as much as possible before the patient undergoes surgery. Remind the patient what to expect postoperatively and how to help ensure adequate recovery.

Operative Procedures.

Wide or radical resection procedures are used for patients with bone sarcomas to salvage the affected limb. Wide excision is removal of the lesion surrounded by an intact cuff of normal tissue and leads to cure of low-grade tumors only. A radical resection includes removal of the lesion, the entire muscle, bone, and other tissues directly involved. It is the procedure used for high-grade tumors.

Large bone defects that result from tumor removal may require either:

- Total joint replacements with prosthetic implants, either whole or partial
- Custom metallic implants
- Allografts from the iliac crest, rib, or fibula

As an alternative to total replacement, an allograft may be implanted with internal fixation for those patients who do not have metastases. This is a common procedure for sarcomas of the proximal femur. Allograft procedures for the knee are also performed, particularly in young adults. Preoperative chemotherapy is given to enhance the likelihood of success. **Allografts** with adjacent tendons and ligaments are harvested from cadavers and can be frozen or freeze-dried for a prolonged period. The graft is fixed with a series of bolts, screws, or plates.

Postoperative Care.

The surgical incision for a limb salvage procedure is often extensive. A pressure dressing with wound suction is typically maintained for several days. The patient who has undergone a limb salvage procedure has some degree of impaired physical mobility and a self-care deficit. The nature and extent of the alterations depend on the location and extent of the surgery.

Nursing Safety Priority QSEN

Action Alert

For patients who have allografts, observe for signs of hemorrhage, infection, and fracture. Report these complications to the surgeon immediately.

After upper extremity surgery, the patient can engage in active-assistive exercises by using the opposite hand to help achieve motions such as forward flexion and abduction of the shoulder. Continuous passive motion (CPM) using a CPM machine may be initiated as early as the first postoperative day for either upper extremity or lower extremity procedures.

After lower extremity surgery, the emphasis is on strengthening the quadriceps muscles by using passive and active motion when possible. Maintaining muscle tone is an important prerequisite to weight bearing, which progresses from toe touch or partial weight bearing to full weight bearing by 3 months postoperatively. Coordinate the patient's plan of care for ambulation and muscle strengthening with the physical therapist.

The patient who has had a bone graft may have a cast or other supportive device for several months. Weight bearing is prohibited until there is evidence that the graft is incorporated into the adjacent bone tissue.

During the recovery phase, the patient may also need assistance with ADLs, particularly if the surgery involves the upper extremity. Assist if needed, but at the same time encourage the patient to do as much as possible unaided. Some patients need assistive/adaptive devices for a short period while they are healing. Coordinate the patient's plan of care for promoting independence in ADLs with the occupational therapist.

Surrounding tissues, including nerves and blood vessels, may be removed during surgery. Vascular grafting is common, but the lost

nerve(s) is (are) usually not replaced. Assess the neurovascular status of the affected extremity and hand or foot every 1 to 2 hours immediately after surgery. Splinting or casting of the limb may also cause neurovascular (NV) compromise and needs to be checked for proper placement.

In addition to needing emotional support to cope with physical disabilities, the patient may need help coping with the surgery and its effects. Help identify available support systems as soon as possible.

As a result of most of the surgical procedures, the patient experiences an altered body image. Suggest ways to minimize cosmetic changes. For example, a lowered shoulder can be covered by a custom-made pad worn under clothing. The patient can cover lower extremity defects with pants.

Advocate for the patient and the family to promote the physician-patient relationship. For instance, the patient may not completely understand the medical or surgical treatment plan but may hesitate to question the physician. The nurse's intervention can increase communication, which is essential in successful management of the patient with cancer.

Clinical Judgment Challenge

Patient-Centered Care; Teamwork and Collaboration; Safety

QSEN

A 77-year-old widower reports pain in his back and abdomen. He had a radical prostatectomy for prostate cancer 5 years ago and was thought to be cancer-free until this time. A chest x-ray revealed bone metastasis in his vertebral spine. The patient is admitted to the cancer center for intensive treatment.

1. What other patient history information do you need to provide quality care for this patient and why?
2. What treatment options does this patient have to manage his bone cancer? What is the purpose of treating the cancer at this time?
3. For what major complications might this patient be most at risk, and how will you plan to help prevent them? *(Hint: see Chapter 22.)*
4. With what health care team members will you collaborate and why?
5. What are the major considerations for discharge planning?

Community-Based Care

After medical treatment for a primary malignant tumor, the patient is usually managed at home with follow-up care. The patient with

metastatic disease may remain in the home or, when home support is not available, may be admitted to a long-term care facility for extended or hospice care. Coordinate the patient's discharge plan and continuity of care with the case manager and other health care team members, depending on the patient's needs.

Home Care Management.

In collaboration with the occupational therapist, evaluate the patient's home environment for structural barriers that may hinder mobility. The patient may be discharged with a cast, walker, crutches, or a wheelchair. Assess the patient's support system for availability of assistance if needed.

Accessibility to eating and toileting facilities is essential to promote ADL independence. Because the patient with metastatic disease is susceptible to pathologic fractures, potential hazards that may contribute to falls or injury should be removed.

Self-Management Education.

For the patient receiving intermittent chemotherapy or radiation on an ambulatory care basis, emphasize the importance of keeping appointments. Review the expected side and toxic effects of the drugs with the patient and family. Teach how to treat less serious side effects and when to contact the health care provider. If the drugs are administered at home via long-term IV catheter, explain and demonstrate the care involved with daily dressing changes and potential catheter complications. Chapter 13 describes the health teaching required for a patient receiving infusion therapy at home.

If the patient has undergone surgery, he or she has a wound and limited mobility. Teach the patient, family, and/or significant others how to care for the wound. Help the patient learn how to perform ADLs and mobility activities independently for self-management. Coordinate with the physical and occupational therapists to assist in ADL teaching, and provide or recommend assistive and adaptive devices, if necessary. The physical therapist also teaches the proper use of ambulatory aids, such as crutches, and exercises.

Pain management can be a major challenge, particularly for the patient with metastatic bone disease. Discuss the various options for pain relief, including relaxation and music therapy. Emphasize the importance of those techniques that worked during hospitalization. See Chapter 3 for cancer pain assessment and management.

The patient with bone cancer may fear that the malignancy will return.

Acknowledge this fear, but reinforce confidence in the health care team and medical treatment chosen. Mutually establish realistic outcomes regarding returning to work and participating in recreational activities. Encourage the patient to resume a functional lifestyle, but caution that it should be gradual. Certain activities, such as participating in sports, may be prohibited.

Help the patient with advanced metastatic bone disease prepare for death. The nurse and other support personnel assist the patient through the stages of death and dying. Identify resources that can help the patient write a will, visit with distant family members, or do whatever he or she thinks is needed for a peaceful death. Chapter 7 describes end-of-life care in detail.

Health Care Resources.

In addition to family and significant others, cancer support groups are helpful to the patient with bone cancer. Some organizations, such as *I Can Cope*, provide information and emotional support. Others, such as *CanSurmount*, are geared more toward patient and family education. The American Cancer Society (www.cancer.org) and the Canadian Cancer Society (www.cancer.ca) can also provide education and resources for patients and families.

The hospital staff nurse, discharge planner, or case manager also ensures that follow-up care, including nursing care and physical or occupational therapy, is available in the home. The patient with terminal cancer may choose to become part of a hospice program as described in Chapter 7.

Disorders of the Hand

Dupuytren's Contracture

Dupuytren's contracture, or deformity, is a slowly progressive thickening of the palmar fascia, resulting in flexion contracture of the fourth (ring) and fifth (little) fingers of the hand. The third or middle finger is occasionally affected. Although Dupuytren's contracture is a common problem, the cause is unknown. It usually occurs in older Euro-American men, tends to occur in families, and can be bilateral.

When function becomes impaired, surgical release is required. A partial or selective fasciectomy (cutting of fascia) is performed. After removal of the surgical dressing, a splint may be used. Nursing care is similar to that for the patient with carpal tunnel repair (see Chapter 51).

Ganglion

A **ganglion** is a round, benign cyst, often found on a wrist or foot joint or tendon. The synovium surrounding the tendon degenerates, allowing the tendon sheath tissue to become weak and distended. Ganglia are painless on palpation, but they can cause joint discomfort after prolonged joint use or minor trauma or strain. The lesion can rapidly disappear and then recur. Ganglia are most likely to develop in people between 15 and 50 years of age. With local or regional anesthesia in a physician's office or clinic, the fluid within the cyst can be aspirated through a small needle. A cortisone injection may follow. If the cyst is very large, it is removed using a small incision. Patients should avoid strenuous activity for 48 hours after surgery and report any signs of inflammation to their health care provider.

Disorders of the Foot

Foot Deformities

The **hallux valgus** deformity is a common foot problem in which the great toe drifts laterally at the first metatarsophalangeal (MTP) joint (Fig. 50-3). The first metatarsal head becomes enlarged, resulting in a **bunion.** As the deviation worsens, the bony enlargement causes pain, particularly when shoes are worn. Women are affected more often than men. Hallux valgus often occurs as a result of poorly fitted shoes—in particular, those with narrow toes and high heels. Other causes include osteoarthritis, rheumatoid arthritis, and family history.

FIG. 50-3 Appearance of hallux valgus with a bunion.

For some patients who are of advanced age or are not surgical candidates, custom-made shoes can be made to fit the deformed feet and provide comfort and support. A plaster mold is made to conform to each foot from which shoes can be made. Teach the patient to consult with a podiatrist or foot clinic to be evaluated for custom shoes.

The surgical procedure, a simple **bunionectomy,** involves removal of the bony overgrowth and bursa and realignment. When other toe deformities accompany the condition or if the bony overgrowth is large, several **osteotomies,** or bone resections, may be performed. Fusions may also be performed. Screws or wires are often inserted to stabilize the

bones in the great toe and first metatarsal during the healing process. If both feet are affected, one foot is usually treated at a time. Surgery usually is performed as a same-day procedure.

Most patients are allowed partial weight bearing while wearing an orthopedic boot or shoe. Walking is difficult because the feet bear body weight. The healing time after surgery may be more than 6 to 12 weeks because the feet receive less blood flow than other parts of the body because of their distance from the heart.

Often patients have hammertoes and hallux valgus deformities at the same time. As shown in Fig. 50-4, a **hammertoe** is the dorsiflexion of any MTP joint with plantar flexion of the proximal interphalangeal (PIP) joint next to it. The second toe is most often affected. As the deformity worsens, uncomfortable corns may develop on the dorsal side of the toe and calluses may appear on the plantar surface. Patients are uncomfortable when wearing shoes and walking.

FIG. 50-4 Hammertoe of the second metatarsophalangeal joint.

Hammertoe may be treated by surgical correction of the deformity with osteotomies (bone resections) and the insertion of wires or screws for fixation. The postoperative course is similar to that for the patient with hallux valgus repair. The patient uses crutches until full weight bearing is allowed several weeks after surgery.

Morton's Neuroma

In the patient with **Morton's neuroma,** or plantar digital neuritis, a small tumor grows in a digital nerve of the foot. The patient usually describes the pain as an acute, burning sensation in the web space. The pain involves the entire surface of the third and fourth toes. Management involves surgical removal of the neuroma and application of a pressure dressing. Ambulation is usually permitted immediately after surgery.

Plantar Fasciitis

Plantar fasciitis is an inflammation of the plantar fascia, which is located in the area of the arch of the foot. It is often seen in middle-aged and older adults, as well as in athletes, especially runners. Obesity is also a contributing factor. Patients report severe pain in the arch of the foot, especially when getting out of bed. The pain is worsened with weight bearing. Although most patients have unilateral plantar fasciitis, the problem can affect both feet (McCance et al., 2014).

Most patients respond to conservative management, which includes rest, ice, stretching exercises, strapping of the foot to maintain the arch, shoes with good support, and orthotics. NSAIDs or steroids may be needed to control pain and inflammation. If conservative measures are unsuccessful, endoscopic surgery to remove the inflamed tissue may be required. Teach the patient about the importance of adhering to the treatment plan and coordinating care with the physical therapist for instruction in exercise.

Other Problems of the Foot

Table 50-4 lists other common foot problems and how they are managed. Although patients are usually not hospitalized for these conditions, the nurse may recognize a foot disorder and alert the physician. Even small deformities or other foot deformities can be very annoying and painful for the patient and may hinder ambulation, as well as interfere with ADLs.

TABLE 50-4

Treatment of Common Foot Problems

DESCRIPTION/CAUSE	TREATMENT
Corn	
Induration and thickening of the skin caused by friction and pressure; painful conical mass	Surgical removal by podiatrist
Callus	
Flat, poorly defined mass on the sole over a bony prominence caused by pressure	Padding and lanolin creams; overall good skin hygiene
Ingrown Nail	
Nail sliver penetration of the skin, causing inflammation	Removal of sliver by podiatrist; warm soaks; antibiotic ointment
Hypertrophic Ungual Labium	
Chronic hypertrophy of nail lip caused by improper nail trimming; results from untreated ingrown nail	Surgical removal of necrotic nail and skin; treatment of secondary infection

Scoliosis

Pathophysiology

Scoliosis occurs when the vertebrae rotate and begin to compress. The spinal column begins to move into a lateral curve, most commonly in the right lateral thoracic area (see Fig. 49-3 in Chapter 49). As the degree of curvature increases, damage to the vertebral bodies results. The degree of the curvature increases during periods of growth, such as in adolescence. Curvature of greater than 50 degrees results in an unstable spine, and curvature of greater than 60 degrees in the thoracic spine results in compromise of cardiopulmonary function.

The exact cause of scoliosis is not well understood, yet it affects about 6 million people in the United States. The process may result from some problem in the balance mechanism located in the central nervous system. Females are affected more often than males, and onset is often in adolescence (Voda, 2009a). School health nurses screen children for scoliosis during the middle school years. Information about caring for children with scoliosis is found in most pediatric nursing textbooks. Scoliosis that occurs in childhood or early adolescence may persist into adulthood. Adults often develop scoliosis as a result of spinal degeneration.

Three types of scoliosis can be described: congenital, neuromuscular, and idiopathic; the most common curve pattern in adults is idiopathic scoliosis and the cause is unknown (Voda, 2009a). Congenital scoliosis occurs during embryonic development. Neuromuscular scoliosis can result from a neuromuscular condition in childhood or adulthood, such as cerebral palsy or spinal cord tumors. Untreated scoliosis can lead to back pain, deformity, and cardiopulmonary complications.

Patient-Centered Collaborative Care

Assessment

A complete history of the patient with spinal deformity should include onset of problem, in adolescence or adulthood, and what treatments may have been used in the past. Patients who had surgery for scoliosis during adolescence are returning with progressive, debilitating back pain from degenerative disk disease below the level of vertebral fusion. A loss of lumbar curvature, or **lordosis,** described as "flat back" syndrome, may also be present (Voda, 2009a). Complete a thorough pain assessment for patients reporting back pain.

Observe the patient from the front and back, while standing and during forward flexion from the hips. Physical examination usually reveals asymmetry of hip and shoulder height, prominence of the thoracic ribs and scapula on one side, and visible curve in the spinal column. Observation from the side may reveal kyphosis of the thoracic spine. Assess for leg length differences as well.

Methods of managing adult scoliosis differ from those used for children. The adult spinal column is less flexible and therefore less likely to respond to exercises, weight reduction, bracing, and casting for correction of the deformity. In the adult, the disorder is progressive and can result in an additional one degree of deviation each year.

Interventions

Adults with less than 50 degrees of curvature of the spine may be treated conservatively with moist heat, pain medication, and exercise. Those with greater than 50 degrees of curvature may require surgical intervention to prevent shortness of breath and fatigue, osteoarthritis, and severe back pain (Voda, 2009a).

The traditional open *surgical* reconstructive procedure consists of surgical fusion and insertion of instrumentation, including plates, screws, or rods to stabilize the spine. The surgeon performs spinal fusion by packing cancellous bone chips, usually from the iliac crest, between the affected vertebrae for support and stabilization. Both an anterior and a posterior approach may be needed. If so, the surgeon may perform both procedures during the same operative day or may stage them 7 to 10 days apart. The metal instrumentation supports the spine and immobilizes the fused area during healing.

Nursing Safety Priority QSEN

Action Alert

The priority for nursing care after open spinal reconstructive surgery for scoliosis is to assess the patient's respiratory status and encourage deep breathing. Teach the patient how to use the incentive spirometer to prevent atelectasis.

Either an anterior or posterior surgical thoracic or abdominal approach may be used. For anterior thoracic surgery, a chest tube is in place for about 72 hours; for anterior abdominal surgery, the patient has a nasogastric tube for 24 hours. Chapter 16 discusses general postoperative

care for patients who have general anesthesia. Other nursing care is similar to that for the patient undergoing a laminectomy or spinal fusion, including teaching the patient how to log roll, keeping the body in alignment. The traditional surgery for treating scoliosis has a high percentage of complications and results in major scarring.

Several newer minimally invasive surgical (MIS) procedures are being performed at major neurosurgery centers to treat degenerative and idiopathic adult scoliosis. These surgeries are done in stages, usually several days apart, using special endoscopic instrumentation that does not require large incisions. The advantages of these procedures include shorter hospital stays, far fewer complications, less pain, and very small incisions (Voda, 2009a).

Teach patients and their families about home care, including how to care for the wound; body mechanics to prevent bending, twisting, and lifting; and how to adapt to achieve ADLs independently. Some patients may require home care nursing, physical therapy, or a home health aide for a short time after discharge if a traditional surgical approach was used (Voda, 2009a). Collaborate with the case manager to make the appropriate arrangements for continuity of care to meet the patient's needs.

For some patients, a return to work in about 3 to 6 weeks is realistic. Other surgical procedures may prevent the patient from performing these activities until 3 to 6 months postoperatively. Refer patients and their families to the National Scoliosis Foundation (www.scoliosis.org) for information and support services.

Progressive Muscular Dystrophies

Many types of **muscular dystrophy (MD)** have been categorized as slowly progressive or rapidly progressive. The slowly progressive types are most commonly seen in adults. Most pediatric nursing books describe the care for patients with MD in detail. Four forms of MD are often seen in adults. Each type has its own distinct characteristics and causes, but all are progressive (Table 50-5).

TABLE 50-5

Differential Features of Common Muscular Dystrophies Seen in Adults

ONSET	GENETIC LINK	CLINICAL MANIFESTATIONS	PROGRESSION
Becker (Benign X-Linked) Dystrophy			
5-25 yr	Sex-linked recessive; expression in males	Wasting of pelvic and shoulder muscles; normal cardiac and mental function	Gradual progression; inability to walk 25 yr after onset; usually normal life span
Limb-Girdle Dystrophy			
Usually 20s or 30s	Usually autosomal dominant; expression in either gender	Upper extremity and neck muscles and lower extremity and hip muscle weakness	Extremely variable; severe disability within 10-20 yr after onset; life span shortened by 10-20 yr
Facioscapulohumeral (Landouzy-Dejerine) Dystrophy			
Usually in 20s	Autosomal dominant; expression in either gender	Facial and shoulder girdle muscle involvement	Usually benign; normal life span
Myotonic (Steinert) Dystrophy			
Birth to 40s	Autosomal dominant; expression in either gender	Muscle atrophy with multiple organ involvement (e.g., heart, lungs, smooth muscle, and endocrine system)	Usually gradual if onset in adulthood

The exact pathophysiologic mechanisms are unknown, but several causes are possible. These include:

- Poor blood flow to muscle resulting in reduced tissue oxygenation
- Disturbance in nerve-muscle interaction
- Loss of cell membrane integrity as a result of increased enzyme activity

Genetic/Genomic Considerations

Patient-Centered Care QSEN

The major pathologic change that occurs in most types of MD is the production or faulty action of a muscle protein called **dystrophin**. The purpose of this protein is to maintain muscle integrity by sending signals to coordinate smooth, synchronous muscle fiber contraction. The coding of this protein is by a large gene that has many parts located on the X chromosome. Different mutations of the gene where dystrophin is located determine the degree of muscle weakness. Because this protein connects with other substances for final muscle action, genetic mutations of these other substances can make dystrophin fail to work properly.

The most common forms of MD are Duchenne MD (DMD) and Becker MD (BMD). Both are X-linked recessive disorders. Women who are *carriers* (able to pass on the gene without having the disorder) have a 50% chance of passing the MD gene to their daughters, who are then carriers, and to their sons, who then have the disease. These types of MD, then, affect only males. In DMD, most patients die very young and therefore do not have children. In BMD, the patient lives longer and may have children. None of these men's sons will have the disease, but their daughters will be carriers (Nussbaum et al., 2007). Refer carriers for genetic testing and counseling.

Regardless of the type of MD, the primary problem is progressive muscle weakness. The major cause of death is respiratory failure caused by profound respiratory muscle weakness. Cardiac failure also occurs because dystrophin activity is needed for cardiac muscle contraction and maintenance (McCance et al., 2014).

Diagnosis of MD is often difficult because the clinical manifestations are similar to those of other muscular disorders. Muscle biopsy often confirms the diagnosis. Muscle weakness and trophic changes are characteristic of all types of MD. Serum muscle enzyme values, such as aldolase and creatine kinase, may be elevated, and electromyographic (EMG) findings are often abnormal (Pagana & Pagana, 2014).

Collaborative care of the patient with MD is supportive and involves the entire health care team. Physical and occupational therapy help the patient maintain as much function, mobility, and independence as possible. A neurologist is often the specialist who diagnoses and treats patients with MD. Refer the patient and family to the local chapter of the Muscular Dystrophy Association (www.mda.org) for support services and information.

Major organ or body system involvement is medically managed, but the life span is often shortened from these manifestations of the disease. With the exception of steroids, no drug has been found to slow the progression of the disorder, although immunosuppressive agents, anabolic steroids, and growth factors have been tried.

Nursing interventions focus on making the patient as comfortable as possible, providing supportive care, and reinforcing techniques and exercises taught in the physical therapy program. The nurse's role in caring for a patient with cardiac or other organ involvement is the same as for any patient with dysfunction of these systems.

What might you NOTICE if the patient has impaired mobility as a result of chronic musculoskeletal disorders?

- Spinal deformity (e.g., kyphosis, lateral deviation)
- Bone malalignment (e.g., leg bowing)
- Muscle weakness
- Bone swelling or deformity
- Fracture
- Joint inflammation
- Flushed skin (Paget's disease)
- Fever (bone infection)
- Report of pain
- Report of weight loss

What should you INTERPRET and how should you RESPOND to a patient with impaired mobility as a result of chronic musculoskeletal disorders?

Perform and interpret focused physical assessment findings, including:

- Ability to ambulate (with or without assistive device)
- ADLs ability
- Body weight
- Pain intensity and quality
- Neurovascular assessment findings
- Ability to cope with decreased mobility

Respond by:

- Providing pain control interventions, including drugs and nonpharmacologic measures
- Collaborating with members of the health care team, including physical therapist (PT), occupational therapist (OT), dietitian, as needed
- Teaching about drugs that may be needed for long-term use, including side and toxic effects
- Explaining about the need for adequate calcium and vitamin D for healthy bones and bone healing
- Assisting with ADLs and ambulation as needed, but encouraging independence when possible
- Implementing measures to prevent patient falls in the inpatient and

home setting
- Encouraging the patient to discuss feelings related to disorders causing impaired mobility
- Referring patients to appropriate community resources, such as the National Osteoporosis Foundation and Paget Disease Foundation

On what should you REFLECT?

- Monitor the patient's response to pain control interventions.
- Prevent and monitor the patient for falls.
- Evaluate the patient's knowledge of nutrition and drug therapy.
- Evaluate the patient's coping ability related to disease diagnosis and treatment.
- Think about what else you might do to promote mobility.
- Decide whether you need to provide alternative interventions or additional health teaching.

Get Ready for the NCLEX® Examination!

Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Coordinate with health care team members when assessing patients with osteoporosis for risk for falls. **Safety** QSEN
- In coordination with the physical and occupational therapists, educate the patient and family on home safety when the patient has a metabolic bone disease, such as osteoporosis. **Teamwork and Collaboration** QSEN
- Refer to The Joint Commission for information about National Patient Safety Goals related to fall injury prevention.

Health Promotion and Maintenance

- Teach patients at risk for osteoporosis to minimize risk factors, such as stopping smoking, decreasing alcohol intake, exercising regularly, and increasing dietary calcium.
- Remind patients at risk for osteoporosis to have regular screening tests, such as the DXA scan.
- Instruct older adults to have at least 5 minutes of sun per day and to eat vitamin D–fortified foods to prevent osteomalacia.
- Assess the genetic risk for patients who have parents with muscular dystrophy, and refer them for genetic testing and counseling if the patient desires. **Patient-Centered Care** QSEN
- Refer patients with musculoskeletal problems to appropriate community resources, such as the Paget Disease Foundation and the National Osteoporosis Foundation.

Psychosocial Integrity

- Assess the patient's and family's responses to a diagnosis of bone cancer and treatment options. Be aware that they will progress through the grieving process.

Physiological Integrity

- Remind patients taking bisphosphonates (BPs) to take them early in the morning, at least 30 to 60 minutes before breakfast, with a full glass of water and to remain sitting upright during that time to prevent

esophagitis, a common complication of BP therapy.
- Most patients are unaware that they have osteoporosis until they experience a fracture, the most common complication of the disease.
- Osteomalacia, the result of a deficiency in vitamin D, can be caused by the factors listed in Table 50-3.
- Priority care for patients with osteomyelitis is to treat the infection and maintain Contact Precautions for open wounds. For patients having surgical intervention, assess the affected extremity for neurovascular status to ensure adequate tissue perfusion.
- For patients who have surgery for bone cancer, report postoperative manifestations of infection, dislocation, or neurovascular compromise to the surgeon promptly.
- Assess for key features of Paget's disease as summarized in Chart 50-3.
- Remember that bone tumors can be benign or malignant.
- Remember that severe chronic pain is a priority for patients with metastatic bone disease.
- Be aware that even minor hand and foot problems can be very painful. Common foot problems are described in Table 50-4.
- In collaboration with the health care team (physical therapist, occupational therapist, neurologist), provide supportive care for patients with muscular dystrophy and bone cancer.
- Recognize that most major types of muscular dystrophy are genetic and manifest usually in childhood. Care is supportive.
- Foot disorders can be treated with custom-made shoes or surgery to repair deformities. Recall that foot disorders are painful, and a plan for pain management is essential.

CHAPTER 51

Care of Patients with Musculoskeletal Trauma

Donna D. Ignatavicius

PRIORITY CONCEPTS

- Mobility
- Sensory Perception
- Pain
- Perfusion
- Infection

Learning Outcomes

Safe and Effective Care Environment

1. Explain the importance of collaborating with the health care team when providing care for patients with fractures and amputations.

Health Promotion and Maintenance

2. Identify community resources about amputations for patients and their families.
3. Teach the public about ways to prevent fractures and other musculoskeletal injuries.
4. Plan discharge teaching for patients with fractures and amputations.

Psychosocial Integrity

5. Describe how to assess the patient's and family's reaction to changes in body image and sensory perception resulting from amputation.

Physiological Integrity

6. Compare and contrast open versus closed fractures and their potential complications.
7. Assess patients with musculoskeletal trauma to prioritize interventions for their care.
8. Delineate nursing care needed to maintain casts for patients with fractures.
9. Plan nursing care needed to maintain traction and external fixation for patients with fractures.
10. Implement measures to prevent complications of fractures, including infection and decreased perfusion.
11. Develop an evidence-based postoperative plan of care, including health teaching, for a patient after fracture repair.
12. Describe emergency care for people who have a traumatic amputation.
13. Plan postoperative care, including health teaching, after an elective amputation.
14. Describe the patient-centered care needed to manage complex regional pain syndrome.
15. Plan care for patients with common types of soft tissue injuries, such as carpal tunnel syndrome.

 http://evolve.elsevier.com/Iggy/

Musculoskeletal trauma accounts for about two thirds of all injuries and is one of the primary causes of disability in the United States. It ranges from simple muscle strain to multiple bone fractures with severe soft-tissue damage.

Fractures and other musculoskeletal trauma impair a patient's mobility in varying degrees, depending on the severity and extent of the injury. These injuries also affect sensory perception and pain because of pressure on nerve endings from edema. In some cases, peripheral nerves are directly damaged as a result of musculoskeletal injury.

Fractures

Pathophysiology

A **fracture** is a break or disruption in the continuity of a bone that often affects mobility and sensory perception. It can occur anywhere in the body and at any age. All fractures have the same basic pathophysiologic mechanism and require similar patient-centered collaborative care, regardless of fracture type or location.

Classification of Fractures

A fracture is classified by the extent of the break:

- *Complete fracture.* The break is across the entire width of the bone in such a way that the bone is divided into two distinct sections.
- *Incomplete fracture.* The fracture does not divide the bone into two portions because the break is through only part of the bone.

A fracture is described by the extent of associated soft-tissue damage as **open** (or **compound**) or **closed** (or **simple**). The skin surface over the broken bone is disrupted in a *compound* fracture, which causes an external wound. These fractures are often graded to define the extent of tissue damage. A *simple* fracture does not extend through the skin and therefore has no visible wound.

Fig. 51-1 shows common types of fractures. In addition to being identified by type, fractures are described by their cause. A **pathologic (spontaneous) fracture** occurs after minimal trauma to a bone that has been weakened by disease. For example, a patient with bone cancer or osteoporosis can easily have a pathologic fracture. A **fatigue (stress) fracture** results from excessive strain and stress on the bone. This problem is commonly seen in recreational and professional athletes. **Compression fractures** are produced by a loading force applied to the long axis of cancellous bone. They commonly occur in the vertebrae of older patients with osteoporosis and are extremely painful.

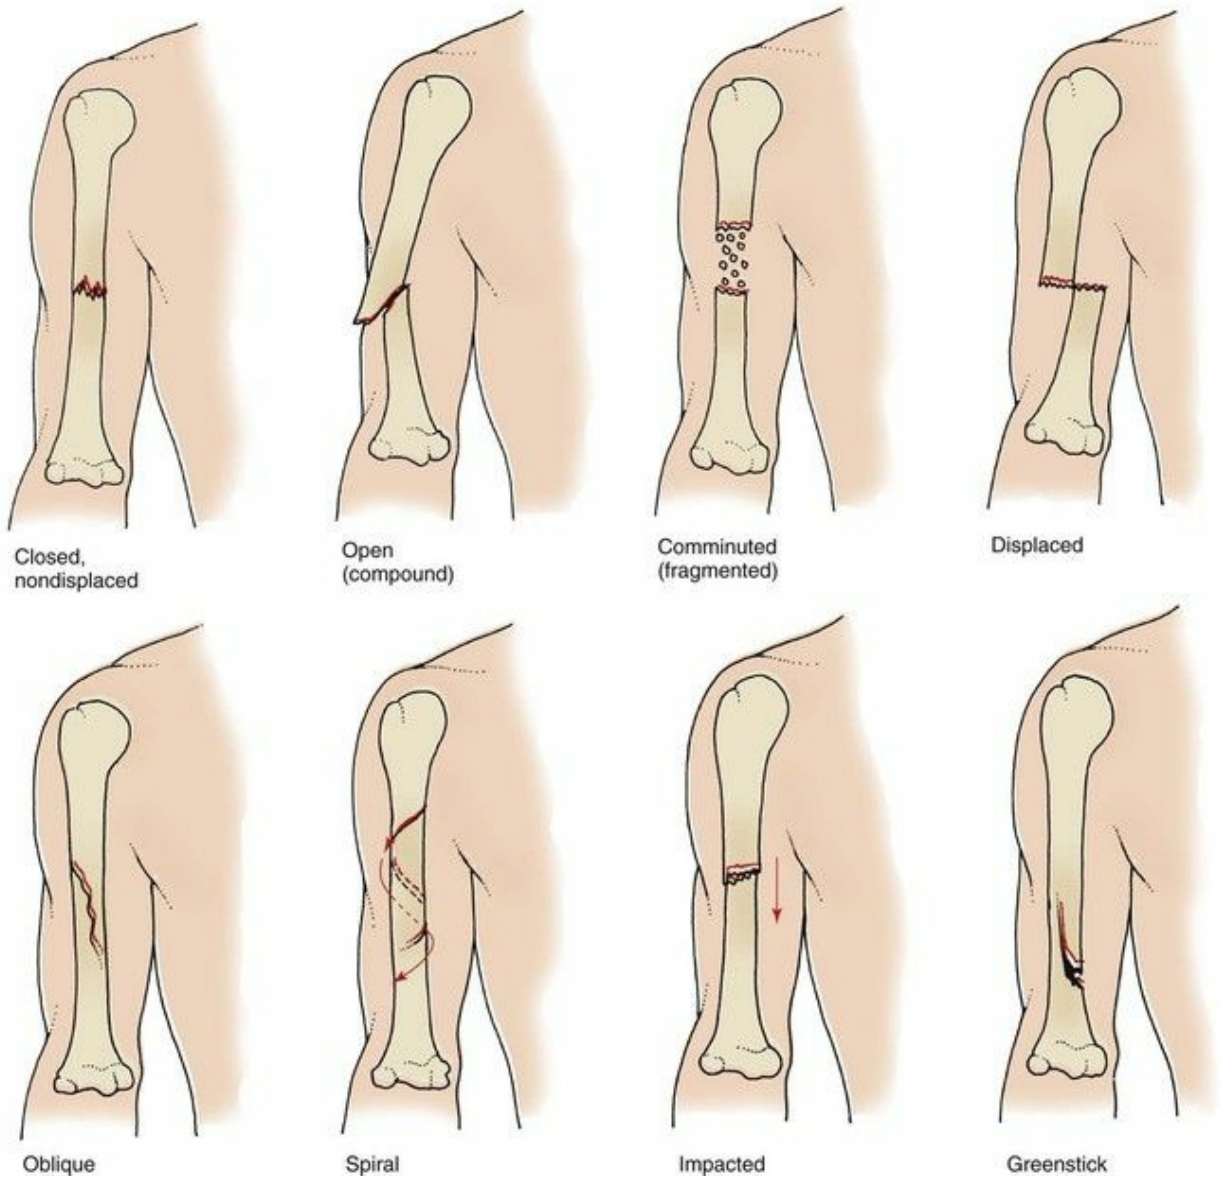

FIG. 51-1 Common types of fractures.

Stages of Bone Healing

When a bone is fractured, the body immediately begins the healing process to repair the injury and restore the body's equilibrium. Fractures heal in five stages that are a continuous process and not single stages.

- In stage one, within 24 to 72 hours after the injury, a hematoma forms at the site of the fracture because bone is extremely vascular.
- Stage two occurs in 3 days to 2 weeks when granulation tissue begins to invade the hematoma. This then prompts the formation of fibrocartilage, providing the foundation for bone healing.
- Stage three of bone healing occurs as a result of vascular and cellular proliferation. The fracture site is surrounded by new vascular tissue known as a *callus* (within 3 to 6 weeks). **Callus** formation is the beginning of a nonbony union.

- As healing continues in stage four, the callus is gradually resorbed and transformed into bone. This stage usually takes 3 to 8 weeks.
- During the fifth and final stage of healing, consolidation and remodeling of bone continue to meet mechanical demands. This process may start as early as 4 to 6 weeks after fracture and can continue for up to 1 year, depending on the severity of the injury and the age and health of the patient. Fig. 51-2 summarizes the stages of bone healing.

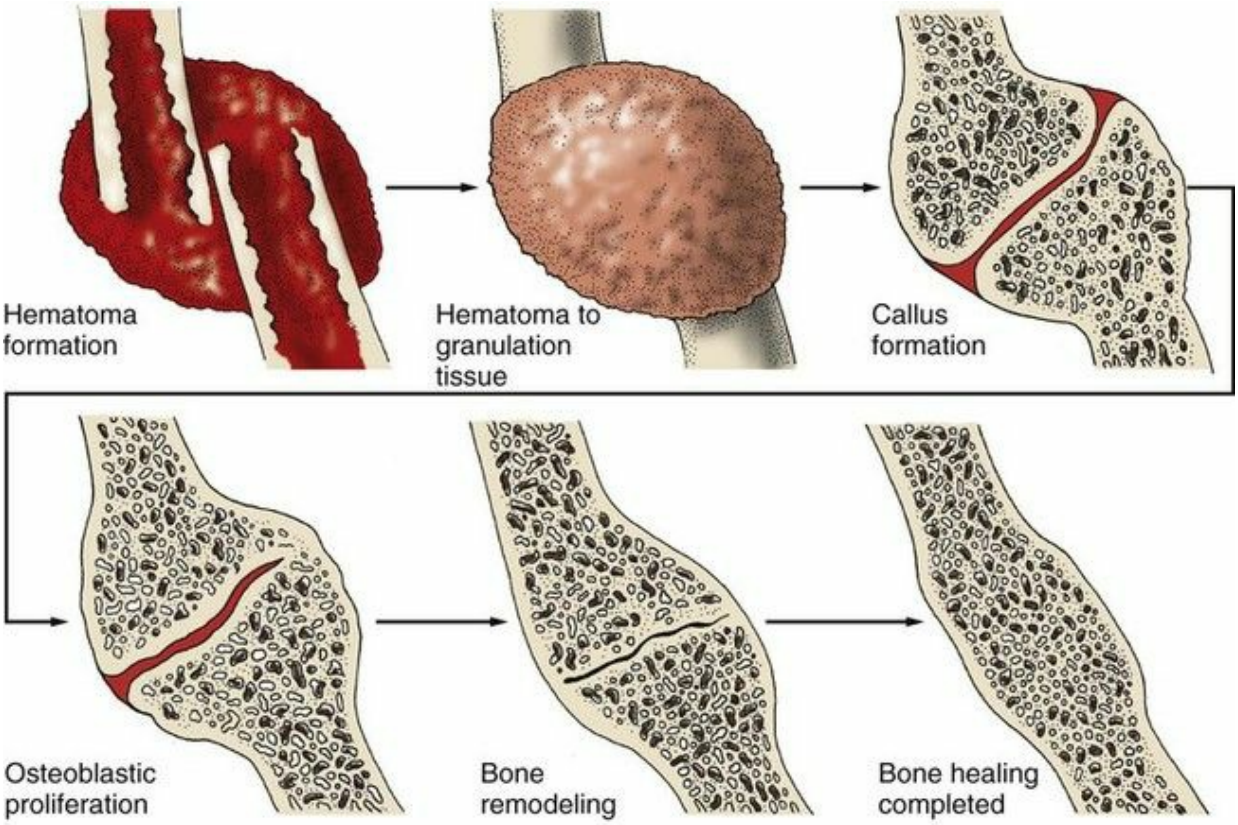

FIG. 51-2 The stages of bone healing.

In young, healthy adult bone, healing takes about 4 to 6 weeks. In the older person who has reduced bone mass, healing time is lengthened. Complete healing often takes 3 months or longer in people who are older than 70 years. Other factors also affect healing. Examples include the severity of the trauma, the type of bone injured, how the fracture is managed, infections at the fracture site, and ischemic or avascular necrosis (AVN), also called **osteonecrosis**.

Considerations for Older Adults

Patient-Centered Care QSEN

Bone healing is often affected by the aging process. Bone formation

and strength rely on adequate nutrition. Calcium, phosphorus, vitamin D, and protein are necessary for the production of new bone (see Chapter 50). For women, the loss of estrogen after menopause decreases the body's ability to form new bone tissue. Chronic diseases can also affect the rate at which bone heals. For instance, peripheral vascular diseases, such as arteriosclerosis, reduce arterial circulation to bone. Thus the bone receives less oxygen and fewer nutrients, both of which are needed for repair.

Complications of Fractures

Regardless of the type or location of the fracture, several limb- and life-threatening acute and chronic complications can result from the injury. Clinical manifestations of beginning complications must be treated early to prevent serious consequences. In some cases, careful monitoring and assessment can prevent these complications:

- Acute compartment syndrome
- Crush syndrome
- Hypovolemic shock
- Fat embolism syndrome
- Venous thromboembolism
- Infection
- Chronic complications, such as ischemic necrosis and delayed union

Acute Compartment Syndrome.

Compartments are areas in the body in which muscles, blood vessels, and nerves are contained within fascia. Most compartments are located in the extremities. **Fascia** is an inelastic tissue that surrounds groups of muscles, blood vessels, and nerves in the body. **Acute compartment syndrome (ACS)** is a serious condition in which increased pressure within one or more compartments reduces circulation to the area. The most common sites for this problem in patients with musculoskeletal trauma are the compartments in the lower leg (tibial fractures) and forearm (Hershey, 2013).

The pathophysiologic changes of increased compartment pressure are sometimes referred to as the *ischemia-edema cycle.* Capillaries within the muscle dilate, which raises capillary (arterial) pressure and venous pressure (Hershey, 2013). Capillaries become more permeable because of the release of histamine by the ischemic muscle tissue, and venous drainage decreases (Friedrich & Shin, 2012). As a result, plasma proteins leak into the interstitial fluid space and edema occurs. Edema increases

pressure on nerve endings and causes pain. perfusion to the area is reduced, and further ischemia results. Sensory perception deficits or paresthesia generally appears before changes in vascular or motor signs. The color of the tissue pales, and pulses begin to weaken but rarely disappear. The affected area is usually palpably tense, and pain occurs with passive motion of the extremity. If the condition is not treated, cyanosis, tingling, numbness, paresis, necrosis, and severe pain can occur. Chart 51-1 summarizes the sequence of pathophysiologic events in compartment syndrome and the associated clinical assessment findings.

Chart 51-1 Key Features

Compartment Syndrome

PHYSIOLOGIC CHANGE	CLINICAL FINDINGS
Increased compartment pressure	No change
Increased capillary permeability	Edema
Release of histamine	Increased edema
Increased blood flow to area	Pulses present Pink tissue
Pressure on nerve endings	Pain
Increased tissue pressure	Referred pain to compartment
Decreased tissue perfusion	Increased edema
Decreased oxygen to tissues	Pallor
Increased production of lactic acid	Unequal pulses Flexed posture
Anaerobic metabolism	Cyanosis
Vasodilation	Increased edema
Increased blood flow	Tense muscle swelling
Increased tissue pressure	Tingling Numbness
Increased edema	Paresthesia
Muscle ischemia	Severe pain unrelieved by drugs
Tissue necrosis	Paresis/paralysis

The pressure to the compartment can be from an external or internal source, but fracture is present in 75% of all cases of ACS (Hershey, 2013). Tight, bulky dressings and casts are examples of *external* pressure. Blood or fluid accumulation in the compartment is a common source of *internal* pressure. The injury or trauma causing the problem is above the compartment involved, which decreases blood flow to the more distal area of injury. ACS is not limited to patients with musculoskeletal problems. It can also occur in those with severe burns, extensive insect bites or snakebites, or massive infiltration of IV fluids. In these

situations, edema increases internal pressure in one or more compartments.

Problems resulting from compartment syndrome include infection, persistent motor weakness in the affected extremity, contracture, and myoglobinuric renal failure. In extreme cases, amputation becomes necessary (Hershey, 2013).

Infection from necrosis may become severe enough that amputation of the limb is needed. *Motor weakness* from injured nerves is not reversible, and the patient may require an orthotic device for assistance in mobility. Volkmann's *contractures* of the forearm, which can begin within 12 hours of the pressure increase, result from shortening of the ischemic muscle and from nerve involvement.

Hypovolemic Shock.

Bone is very vascular. Therefore bleeding is a risk with bone injury. In addition, trauma can cut nearby arteries and cause hemorrhage, resulting in rapidly developing hypovolemic shock. (The pathophysiology of hypovolemic shock is described in Chapter 37.)

Fat Embolism Syndrome.

Fat embolism syndrome (FES) is another serious complication in which fat globules are released from the yellow bone marrow into the bloodstream within 12 to 48 hours after an injury or other illness (mechanical theory). These globules clog small blood vessels that supply vital organs, most commonly the lungs, and impair organ perfusion. The biochemical theory for FES may be considered as a separate cause or as an additive process to the mechanical theory. The embolized fat degrades into free fatty acids and C-reactive protein, which results in capillary leakage, lipid and platelet aggregation, and clot formation (Hershey, 2013).

FES usually results from fractures or fracture repair but occasionally is seen in patients who have a total joint replacement. It may also occur, although less often, in those with pancreatitis, osteomyelitis, blunt trauma, or sickle cell disease.

The problem can occur at any age or in either gender, but young men between ages 20 and 40 years and older adults between ages 70 and 80 years are at the greatest risk. Patients with fractured hips have the highest risk, but FES is also common in those with fractures of the pelvis within 24 to 72 hours after injury or surgery (Hershey, 2013).

The earliest manifestations of FES are a low arterial oxygen level (hypoxemia), dyspnea, and tachypnea (increased respirations). Headache,

lethargy, agitation, confusion, decreased level of consciousness, seizures, and vision changes may follow (Hershey, 2013). Nonpalpable, red-brown **petechiae**—a macular, measles-like rash—may appear over the neck, upper arms, and/or chest. This rash is a classic manifestation but is usually the last sign to develop (Hershey, 2013).

Abnormal laboratory findings include:

- Decreased Pa_{O_2} level (often below 60 mm Hg)
- Increased erythrocyte sedimentation rate (ESR)
- Decreased serum calcium levels
- Decreased red blood cell and platelet counts
- Increased serum level of lipids

These changes in blood values are poorly understood, but they aid in diagnosis of the condition.

The chest x-ray often shows bilateral infiltrates but may be normal. The chest CT often reveals a patchy distribution of opacities. An MRI of the brain can show evidence of neurologic deficits from hypoxemia. FES can result in respiratory failure or death, often from pulmonary edema. When the lungs are affected, the complication may be misdiagnosed as a pulmonary embolism from a blood clot (Chart 51-2).

Chart 51-2 Key Features

Pulmonary Emboli: Fat Embolism Versus Blood Clot Embolism

FAT EMBOLISM	BLOOD CLOT EMBOLISM
Definition	
Obstruction of the pulmonary vascular bed by fat globules	Obstruction of the pulmonary artery by a blood clot or clots
Origin	
95% from fractures of the long bones; occurs usually within 48 hr of injury	85% from deep vein thrombosis in the legs or pelvis; can occur anytime
Assessment Findings	
Altered mental status (earliest sign) Increased respirations, pulse, temperature Chest pain Dyspnea Crackles Decreased Sao_2 Petechiae (50%-60%) Retinal hemorrhage (not common) Mild thrombocytopenia	Same as for fat embolism, except no petechiae
Treatment	
Bedrest Gentle handling Oxygen Hydration (IV fluids) Possibly steroid therapy Fracture immobilization	Preventive measures (e.g., leg exercises, antiembolism stockings, SCDs) Bedrest Oxygen Possibly mechanical ventilation Anticoagulants Thrombolytics Possible surgery: pulmonary embolectomy, vena cava umbrella

Sao_2, Arterial oxygen saturation; *SCD,* sequential compression device.

Venous Thromboembolism.

Venous thromboembolism (VTE) includes deep vein thrombosis (DVT) and its major complication, pulmonary embolism (PE). It is the most common complication of lower extremity surgery or trauma and the most often fatal complication of musculoskeletal surgery. Factors that make patients with fractures most likely to develop VTE include:

- Cancer or chemotherapy
- Surgical procedure longer than 30 minutes
- History of smoking
- Obesity
- Heart disease
- Prolonged immobility
- Oral contraceptives or hormones
- History of VTE complications
- Older adults (especially with hip fractures)

The pathophysiology and management of VTE are described in Chapter 36.

Infection.

Whenever there is trauma to tissues, the body's defense system is disrupted. Wound infections are the most common type of infection resulting from orthopedic trauma. They range from superficial skin infections to deep wound abscesses. Infection can also be caused by

implanted hardware used to repair a fracture surgically, such as pins, plates, or rods. Clostridial infections can result in gas gangrene or tetanus and can prevent the bone from healing properly.

Bone infection, or **osteomyelitis**, is most common with open fractures in which skin integrity is lost and after surgical repair of a fracture (see Chapter 50 for discussion of osteomyelitis). For patients experiencing this type of trauma, the risk for hospital-acquired infections is increased. These infections are common, and many are from multidrug-resistant organisms, such as methicillin-resistant *Staphylococcus aureus* (MRSA). Reducing MRSA infections is a primary desired outcome for all health care agencies.

Chronic Complications.

Avascular necrosis and delayed bone healing are later complications of musculoskeletal trauma. Blood supply to the bone is disrupted causing decreased perfusion and death of bone tissue. This problem is most often a complication of hip fractures or any fracture in which there is displacement of bone. Surgical repair of fractures also can cause necrosis because the hardware can interfere with circulation. Patients on long-term corticosteroid therapy, such as prednisone, are also at high risk for ischemic necrosis.

Delayed union is a fracture that has not healed within 6 months of injury. Some fractures never achieve union; that is, they never completely heal *(nonunion)*. Others heal incorrectly *(malunion)*. These problems are most common in patients with tibial fractures, fractures that involve many treatment techniques (e.g., cast, traction), and pathologic fractures. Union may also be delayed or not achieved in the older patient. If bone does not heal, he or she typically has chronic pain and immobility from deformity.

Etiology and Genetic Risk

The primary cause of a fracture is trauma from a motor vehicle crash or fall, especially in older adults. The trauma may be a direct blow to the bone or an indirect force from muscle contractions or pulling forces on the bone. Sports, vigorous exercise, and malnutrition are contributing factors. Bone diseases, such as osteoporosis, increase the risk for a fracture in older adults (see Chapter 50). Genetic factors that increase risk for fracture are discussed with these specific health problems throughout this text.

Incidence and Prevalence

The incidence of fractures depends on the location of the injury. Rib fractures are the most common type in the adult population. Femoral shaft fractures occur most often in young and middle-aged adults. The incidence of proximal femur (hip) fractures is highest in older adults. Humeral fractures are common in adults; the older the person, usually the more proximal is the fracture. Wrist (Colles') fractures are typically seen in middle and late adulthood and usually result from a fall. Middle-aged and older adults, especially women, have a higher incidence of osteoporosis, which increases the risk for fragility fractures.

Health Promotion and Maintenance

Airbags and seat belts have decreased the number of severe injuries and deaths, but they have increased the number of leg and ankle fractures, especially in older adults. Health teaching should also focus on other risks for musculoskeletal injury, including:

- Osteoporosis screening and self-management education
- Fall prevention
- Home safety assessment and modification, if needed
- Dangers of drinking and driving
- Drug safety (prescribed, over-the-counter, and illicit)
- Older adults and driving
- Helmet use when riding bicycles, motorcycles, all-terrain vehicles (ATVs), and skateboards

These educational interventions are discussed throughout this book and in other texts. Fall prevention is discussed in detail in Chapter 2 as part of care for older adults.

❖ Patient-Centered Collaborative Care

◆ Assessment

History.

If the patient is in severe pain, delay the interview until he or she is more comfortable. Then ask about the cause of the fracture, which helps in developing an individualized plan of care. Certain types of force (e.g., incisional, crush, acceleration or deceleration), shearing, and friction lead to most musculoskeletal injuries. As a result, several body systems are often affected.

Incisional injuries, as from a knife wound, and *crush* injuries cause

hemorrhage and decrease blood flow to major organs. *Acceleration or deceleration* injuries cause direct trauma to the spleen, brain, and kidneys when these organs are moved from their fixed locations in the body. *Shearing and friction* damage the skin and cause a high level of wound contamination.

Asking about the events leading to the injury helps identify which forces have been experienced and therefore which body systems or parts of the body to assess. For example, a forward fall often results in Colles' fracture of the wrist because the person tries to catch himself or herself with an outstretched hand. Knowing the mechanism of injury also helps determine whether other types of injury, such as head and spinal cord injury, might be present.

A drug history, including substance use, is important regardless of the patient's age. For example, a young adult may have had an excessive amount of alcohol, which contributed to a motor vehicle crash or to a fall at the work site. Many older adults also consume alcohol and an assortment of prescribed and over-the-counter drugs, which can cause dizziness and loss of balance.

A medical history may identify possible causes of the fracture and gives clues as to how long it will take for the bone to heal. Certain diseases such as bone cancer and Paget's disease cause fragility fractures that often do not achieve total healing or union.

Ask about the patient's occupation and recreational activities. Some occupations are more hazardous than others. For instance, construction work is potentially more physically dangerous than office work. Certain hobbies and recreational activities are also extremely hazardous, such as skiing. Contact sports, such as football and ice hockey, often result in musculoskeletal injuries, including fractures. Other activities do not have such an obvious potential for injury but can cause fractures nonetheless. For instance, daily jogging or running can lead to fatigue fractures.

Physical Assessment/Clinical Manifestations.

The patient with a fracture often has trauma to other body systems. Therefore assess all major body systems *first* for life-threatening complications, including head, chest, and abdominal trauma. Some fractures can cause internal organ damage resulting in hemorrhage. When a pelvic fracture is suspected, assess vital signs, skin color, and level of consciousness for indications of possible hypovolemic shock. Check the urine for blood, which indicates possible damage to the urinary system, often the bladder. If the patient cannot void, suspect that the bladder or urethra has been damaged. Complete assessment of these

areas is described elsewhere in this text.

The most common manifestation of fractures is moderate to often severe pain. Patients with severe or multiple fractures of the arms, legs, or pelvis have severe pain. Vertebral compression factures are also extremely painful. Patients *with a fractured hip may have groin pain or pain referred to the back of the knee or lower back.* Pain is usually due to muscle spasm and edema, which result from the fracture.

Nursing Safety Priority QSEN

Action Alert

Patients with one or more fractured ribs have severe pain when they take deep breaths. Monitor respiratory status, which may be severely compromised from pain or pneumothorax (air in the pleural cavity). Assess the patient's pain level and manage pain *before* continuing the physical assessment.

For fractures of the shoulder and upper arm, the physical assessment is best done with the patient in a sitting or standing position, if possible, so that shoulder drooping or other abnormal positioning can be seen. Support the affected arm and flex the elbow to promote comfort during the assessment. For more distal areas of the arm, perform the assessment with the patient in a supine position so that the extremity can be elevated to reduce swelling.

Place the patient in a supine position for assessment of the legs and pelvis. A patient with an impacted hip fracture may be able to walk for a short time after injury, although this is not recommended.

When inspecting the site of a possible fracture, look for a change in bone alignment. The bone may appear deformed, a limb may be internally or externally rotated, and/or one or more bones may also be dislocated (out of their joint capsules). Observe for extremity shortening or a change in bone shape.

If the skin is intact (closed fracture), the area over the fracture may be **ecchymotic** (bruised) from bleeding into the underlying soft tissues. **Subcutaneous emphysema**, the appearance of bubbles under the skin because of air trapping, may be present but is usually seen later.

Nursing Safety Priority QSEN

Action Alert

Swelling at the fracture site is rapid and can result in marked neurovascular compromise due to decreased arterial perfusion. *Gently perform a thorough neurovascular assessment, and compare extremities.* Assess skin color and temperature, sensation, mobility, pain, and pulses distal to the fracture site. If the fracture involves an extremity and the patient is not in severe pain, check the nails for capillary refill by applying pressure to the nail and observing for the speed of blood return. If nails are brittle or thick, assess the skin next to the nail. Checking for capillary refill is not as reliable as other indicators of perfusion. Chart 51-3 describes the procedure for a neurovascular assessment, which evaluates **c**irculation, **m**ovement, and **s**ensation (sensory perception) (CMS function).

Chart 51-3 Best Practice for Patient Safety & Quality Care QSEN

Assessment of Neurovascular Status in Patients with Musculoskeletal Injury

ASSESSMENT METHOD	NORMAL FINDINGS
Skin Color	
Inspect the area distal to the injury.	No change in pigmentation compared with other parts of the body.
Skin Temperature	
Palpate the area distal to the injury (the dorsum of the hands is most sensitive to temperature).	The skin is warm.
Movement	
Ask the patient to move the affected area or the area distal to the injury (active motion).	The patient can move without discomfort.
Move the area distal to the injury (passive motion).	No difference in comfort compared with active movement.
Sensation	
Ask the patient if numbness or tingling is present (paresthesia).	No numbness or tingling.
Palpate with a paper clip (especially the web space between the first and second toes or the web space between the thumb and forefinger).	No difference in sensation in the affected and unaffected extremities. (Loss of sensation in these areas indicates peroneal nerve or median nerve damage.)
Pulses	
Palpate the pulses distal to the injury.	Pulses are strong and easily palpated; no difference in the affected and unaffected extremities.
Capillary Refill (Least Reliable)	
Press the nail beds distal to the injury until blanching occurs (or the skin near the nail if nails are thick and brittle).	Blood returns (return to usual color) within 3 sec (5 sec for older patients).
Pain	
Ask the patient about the location, nature, and frequency of the pain.	Pain is usually localized and is often described as stabbing or throbbing. (Pain out of proportion to the injury and unrelieved by analgesics might indicate compartment syndrome.)

Clinical Judgment Challenge

Patient-Centered Care; Evidence-Based Practice QSEN

A 63-year-old woman fell while standing on a step ladder to reach an item on the top shelf of her closet. After calling 911, she sat in a recliner chair while protecting her swollen right arm. When the paramedics

arrived, the woman was drowsy but could be awakened. She had no other apparent injury or problem. Upon arrival at the emergency department (ED), you greet the patient and help her transfer into a room. The patient continues to become very drowsy at times but stated that she did not "hit her head" when she fell.

1. What are your priority evidence-based assessments for the patient when coming into the ED?
2. What history questions will you ask the patient once her pain is controlled?
3. The patient has a fractured right distal radius and reports that she is still in pain even though the emergency medical technician (EMT) gave her IV fentanyl. How will you respond to this patient, and what action will you take?
4. The patient's husband comes to the ED and asks you if his wife's history of bone loss may have caused the fracture. How will you answer him?

Psychosocial Assessment.

The psychosocial status of a patient with a fracture depends on the extent of the injury, possible complications, coping ability, and the availability of support systems. Hospitalization is not required for a single, uncomplicated fracture, and the patient returns to usual daily activities within a few days. Examples include a single fracture of a bone in the finger, wrist, foot, or toe.

In contrast, a patient suffering severe or multiple traumas may be hospitalized for weeks and may undergo many surgical procedures, treatments, and prolonged rehabilitation. These disruptions in lifestyle can create a high level of stress.

The stresses that result from a long-term condition affect relationships between the patient and family members or friends. Assess the patient's feelings, and ask how he or she coped with previously experienced stressful events. Body image and sexuality may be altered by deformity, treatment modalities for fracture repair, or long-term immobilization. Assess the availability of needed support systems, such as family, church, or community groups, who can help patients during the acute and rehabilitation phases when multiple or severe fractures occur. Active patients of any age or those who are older and live alone may become depressed during the healing process. Acute and chronic pain can decrease energy levels and may also cause sadness, depression, and/or anxiety.

Laboratory Assessment.

No special laboratory tests are available for assessment of fractures. Hemoglobin and hematocrit levels may often be low because of bleeding caused by the injury. If extensive soft-tissue damage is present, the erythrocyte sedimentation rate (ESR) may be elevated, which indicates the expected inflammatory response. If this value and the white blood cell (WBC) count increase during fracture healing, the patient may have a bone infection. During the healing stages, serum calcium and phosphorus levels are often increased as the bone releases these elements into the blood.

Imaging Assessment.

The health care provider requests standard *x-rays* to confirm a diagnosis of fracture. These reveal the bone disruption, malalignment, or deformity. If the x-ray does not show a fracture but the patient is symptomatic, the x-ray is usually repeated with additional views.

The *CT* scan is useful in detecting fractures of complex structures, such as the hip and pelvis. It also identifies compression fractures of the spine. *MRI* is useful in determining the amount of soft-tissue damage that may have occurred with the fracture.

Analysis

The priority NANDA-I nursing diagnoses and collaborative problems for patients with fractures include:

1. Acute Pain related to one or more fractures, soft-tissue damage, muscle spasm, and edema (NANDA-I)
2. Potential for neurovascular compromise related to tissue edema and/or bleeding
3. Risk for Infection related to a wound caused by an open fracture (NANDA-I)
4. Impaired Physical Mobility related to need for bone healing and/or pain (NANDA-I)

Planning and Implementation

Managing Acute Pain

Planning: Expected Outcomes.

The patient with a fracture is expected to state that he or she has adequate pain control after fracture reduction and immobilization.

Interventions.

A fracture can happen anywhere and may be accompanied by multiple injuries to vital organs. Patient-centered collaborative care depends on the severity and extent of the injury and the number of fractures the patient has.

Emergency Care: Fracture.

For any patient who experiences trauma in the community, first call 911 and assess for **a**irway, **b**reathing, and **c**irculation (ABCs, or primary survey). Then provide lifesaving care if needed before being concerned about the fracture (Chart 51-4). If cardiopulmonary resuscitation (CPR) is needed, ensure circulation first, followed by airway and breathing (see Chapter 34).

Chart 51-4 Best Practice for Patient Safety & Quality Care QSEN

Emergency Care of the Patient with an Extremity Fracture

1. Assess the patient's airway, breathing, and circulation, and perform a quick head-to-toe assessment.
2. Remove the patient's clothing (cut if necessary) to inspect the affected area while supporting the area above and below the injury. Do not remove shoes because this can cause increased trauma.
3. Remove jewelry on the affected extremity in case of swelling.
4. Apply direct pressure on the area if there is bleeding and pressure over the proximal artery nearest the fracture.
5. Keep the patient warm and in a supine position.
6. Check the neurovascular status of the area distal to the fracture, including temperature, color, sensation, movement, and capillary refill. Compare affected and unaffected limbs.
7. Immobilize the extremity by splinting; include joints above and below the fracture site. Recheck circulation after splinting.
8. Cover any open areas with a dressing (preferably sterile).

If the person is clothed, cut away clothing from the fracture site, and remove any jewelry from the affected extremity. Control any bleeding by direct pressure on the area and digital pressure over the artery above the fracture. To prevent shock, place the patient in a supine position and keep him or her warm.

After a head-to-toe assessment (secondary survey) and patient

stabilization by the prehospital team, pain is managed with IV opioids such as fentanyl, hydromorphone (Dilaudid), or morphine sulfate. Cardiac monitoring for patients who are older than 50 years is established before drug administration. To prevent further tissue damage, reduce pain, and increase circulation, the prehospital or emergency team immobilizes the fracture by splinting. An air splint or any object or device that extends to the joints above and below the fracture to immobilize it can be used as a **splint**. Sterile gauze is placed loosely over open areas to prevent further contamination of the wound.

In the emergency department (ED), physician's office, or urgent care center, fracture management begins with reduction and immobilization of the fracture while attending to continued pain assessment and management.

Bone reduction, or realignment of the bone ends for proper healing, is accomplished by a closed method or an open (surgical) procedure. In some cases, dislocated bones are also reduced, such as when the distal tibia and fibula are dislocated with a fractured ankle. Immobilization is achieved by the use of bandages, casts, traction, internal fixation, or external fixation.

The health care provider selects the treatment method based on the type, location, and extent of the fracture. These interventions prevent further injury and reduce pain.

Nonsurgical Management.

Nonsurgical management includes closed reduction and immobilization with a bandage, splint, cast, or traction. For some small, closed incomplete bone fractures in the hand or foot, reduction is not required. Immobilization with an orthotic device or special orthopedic shoe or boot may be the only management during the healing process.

For each modality, the primary nursing concern is assessment and prevention of neurovascular dysfunction or compromise. Assess the patient's neurovascular status every hour for the first 24 hours and every 1 to 4 hours thereafter, depending on the injury (see Chart 51-3). The patient usually reports discomfort that is unrelieved by analgesics if the bandage, splint, or cast is too tight. Elevate the fractured extremity higher than the heart, and apply ice for the first 24 to 48 hours as needed to reduce edema.

Closed Reduction and Immobilization.

Closed reduction is the most common nonsurgical method for managing a simple fracture. While applying a manual pull, or traction, on the bone,

the health care provider moves the bone ends so that they realign. Moderate sedation and/or analgesia is used during this procedure to decrease pain. The nurse monitors the patient's oxygen saturation (and possibly end-tidal carbon dioxide [$EtCO_2$] level) to ensure adequate rate and depth of respirations during the procedure. An x-ray confirms that the bone ends are approximated (aligned) before the bone is immobilized, and a splint is usually applied to keep the bone in alignment.

Splints and Orthopedic Boots/Shoes.

For certain areas of the body, such as the scapula (shoulder) and clavicle (collarbone), a commercial immobilizer may be used to keep the bone in place during healing. Because upper extremity bones do not bear weight, splints may be sufficient to keep bone fragments in place for a closed fracture. Fig. 51-3 shows a wrist splint for fracture immobilization. Thermoplastic, a durable, flexible material for splinting, allows custom fitting to the patient's body part. Splints for lower extremities are also custom-fitted using flexible materials and held in place with elastic bandages (e.g., ACE wrap). When possible, splints are preferred over casts to prevent the complications that can occur with casting. Splints also allow room for extremity swelling without causing decreased arterial perfusion.

FIG. 51-3 A universal wrist and forearm splint used for immobilization.

For foot or toe fractures, orthopedic shoes may be used to support the injured area during healing. For ankles or the lower part of the leg, padded orthopedic boots supported by multiple Velcro straps to hold the boot in place may be used. These devices are especially useful when the patient is allowed to bear weight on the affected leg.

Casts.

For more complex fractures or fractures of the lower extremity, the physician or orthopedic technician may apply a cast to hold bone fragments in place after reduction. A **cast** is a rigid device that immobilizes the affected body part while allowing other body parts to move. It also allows early mobility and reduces pain. Although its most common use is for fractures, a cast may be applied for correction of deformities (e.g., clubfoot) or for prevention of deformities (e.g., those seen in some patients with rheumatoid arthritis).

Fiberglass is the most common material used for casting and is typically the preferred method for immobilization with a cast (Fig. 51-4) (Satryb et al., 2011). Fiberglass can dry and become rigid within minutes and decreases the risk for skin breakdown. Waterproof casting is designed to get wet in the shower or pool and is used most commonly for athletes, especially during the summer (Satryb et al., 2011). Plaster is the traditional material used for casts but is not as commonly used today for management of most fractures. It requires application of a well-fitted stockinette under the material. If the stockinette is too tight, it may impair circulation. If it is too loose, wrinkles can lead to the development of pressure ulcers. Padding is applied over the stockinette, followed by wet plaster rolls wrapped around the extremity or other body part. The cast feels hot because an immediate chemical reaction occurs, but it soon becomes damp and cool. This type of cast takes at least 24 hours to dry, depending on the size and location of the cast. A wet cast feels cold, smells musty, and is grayish. The cast is dry when it feels hard and firm, is odorless, and has a shiny white appearance.

FIG. 51-4 Application of a fiberglass synthetic cast.

If the skin under the cast is open, the health care provider, orthopedic technician, or specially trained nurse cuts a window in the cast so that the wound can be observed and cared for. The piece of cast removed to make the window must be retained and replaced after wound care to prevent localized edema in the area. This is most important when a window is cut from a cast on an extremity. Tape or elastic bandage wrap may be used to keep the "window" in place. A window is also an access for taking pulses, removing wound drains, or preventing abdominal distention when the patient is in a body or spica cast.

If the cast is too tight, it may be cut with a cast cutter to relieve pressure or allow tissue swelling. The health care provider may choose to **bivalve** the cast (i.e., cut it lengthwise into two equal pieces) if bone healing is almost complete. Either half of the cast can be removed for inspection or for provision of care. The two halves are then held in place by an elastic bandage wrap (Satryb et al., 2011).

When a patient is in bed with an *arm cast,* teach him or her to elevate the arm above the heart to reduce swelling. The hand should be higher than the heart. Ice may be prescribed for the first 24 to 48 hours. When the patient is out of bed, the arm is supported with a sling placed around the neck to alleviate fatigue caused by the weight of the cast. The sling should distribute the weight over a large area of the shoulders and trunk, not just the neck. Some health care providers prefer that the patient not use a sling after the first few days in an arm cast, particularly a short-arm cast. This encourages normal movement of the mobile joints and

enhances bone healing. For many wrist fractures, a splint is used to immobilize the area instead of a cast to accommodate for edema formation.

A *leg cast* allows mobility and requires the patient to use ambulatory aids such as crutches. A cast shoe, sandal, or boot that attaches to the foot or a rubber walking pad attached to the sole of the cast assists in ambulation (if weight bearing is allowed) and helps prevent damage to the cast. Teach the patient to elevate the affected leg on several pillows to reduce swelling and to apply ice for the first 24 hours or as prescribed. Table 51-1 describes specific casts that are used for various parts of the body.

TABLE 51-1

Types of Casts Used for Musculoskeletal Trauma

TYPE AND CHARACTERISTICS OF CAST	USE
Upper Extremity Casts	
Short-arm cast (SAC) (extends from below the elbow to and including part of the hand)	Stable fractures of the wrist (metacarpals, carpals, or distal radius)
Long-arm cast (LAC) (includes the upper arm to and including part of the hand)	Unstable fractures of the wrist, distal humerus, radius, or ulna
Hanging-arm cast (same as LAC but heavier, with added loop at the mid-forearm)	Fractures of the humerus that cannot be aligned by LAC (light traction is possible while the patient is in bed or by an attached strap that extends around the neck)
Thumb spica (gauntlet) cast (similar to SAC with the thumb casted in abduction)	Fractures of the thumb
Shoulder spica cast (the shoulder is casted in abduction with the elbow flexed)	Unstable fractures of the shoulder girdle or humerus; dislocations of the shoulder
Lower Extremity Casts	
Short-leg cast (SLC) (from below the knee to the base of the toes)	Fractures of the ankle, metatarsals, or foot
Long-leg cast (LLC) (from the mid-upper thigh to the base of the toes)	Unstable fractures of the tibia, fibula, or ankle
Walking cast (a walking device on the bottom of SLC or LLC)	Same as for SLC or LLC
Leg cylinder (similar to SLC, but the ankle and foot are not casted)	Stable fractures of the tibia, fibula, or knee
Long-leg cylinder (similar to LLC, but the ankle and foot are not casted)	Stable fractures of the distal femur, proximal tibia, or knee
Cast Braces (or Brace Casts) (not as common)	
Patellar weight-bearing cast (similar to SLC or leg cylinder)	Mid-shaft or distal shaft fractures of the femur
External polycentric knee hinge cast (a hinge connects the lower and upper leg and allows 90 degrees of knee flexion)	Same as for the patellar weight-bearing cast

Before the cast is applied, explain its purpose and the procedure for its application. With a plaster cast, warn the patient about the heat that will be felt immediately after the wet cast is applied. Do not cover the new cast. Allow for air-drying.

Nursing Safety Priority QSEN

Action Alert

When moving a patient with a wet plaster cast, handle it with the palms of the hands to prevent indentations and resulting areas of pressure on the skin. Turn the patient every 1 to 2 hours to allow air to

circulate and dry all parts of the cast. Be sure to remind unlicensed assistive personnel (UAP) and the family that the cast is wet and requires special handling. If the health care provider requests that the cast be elevated to reduce swelling, use a cloth-covered pillow instead of one encased in plastic, which could cause the cast to retain heat and prevent drying. Elevation of the casted extremity reduces edema but may impair arterial circulation to the affected limb. Therefore performing a neurovascular assessment of the limb distal to (below) the cast is very important.

Nursing Safety Priority QSEN

Action Alert

Check to ensure that any type of cast is not too tight, and frequently monitor neurovascular status—usually every hour for the first 24 hours after application if the patient is hospitalized. You should be able to insert a finger between the cast and the skin. Teach the patient to apply ice for the first 24 to 36 hours to reduce swelling and inflammation.

Once the plaster cast is dry, inspect it at least once every 8 hours for drainage, cracking, crumbling, alignment, and fit. Plaster casts act like sponges and absorb drainage, whereas synthetic casts act like a wick pulling drainage away from the drainage site. Padding can also absorb wound drainage. Document the presence of any drainage on the cast. However, the evidence is not clear on whether drainage should be circled on the cast because it may increase anxiety and is not a reliable indicator of drainage amount. *Immediately report to the health care provider any sudden increases in the amount of drainage or change in the integrity of the cast.* After swelling decreases, it is not uncommon for the cast to become too loose and need replacement. If the patient is not admitted to the hospital, provide instructions regarding cast care.

During hospitalization, assess for other complications resulting from casting that can be serious and life threatening, such as infection, circulation impairment, and peripheral nerve damage. If the patient returns home after cast application, teach him or her how to monitor for these complications and when to notify the health care provider.

Infection most often results from the breakdown of skin under the cast (pressure necrosis). If pressure necrosis occurs, the patient typically reports a very painful "hot spot" under the cast and the cast may feel warmer in the affected area. Teach the patient or family to smell the area

for mustiness or an unpleasant odor that would indicate infected material. If the infection progresses, a fever may develop.

Circulation impairment causing decreased perfusion and *peripheral nerve damage* can result from tightness of the cast. Teach the patient to assess for circulation at least daily, including the ability to move the area distal to the extremity, numbness, and increased pain.

The patient with a cast may be immobilized for a prolonged period, depending on the extent of the fracture and the type of cast. Assess for complications of immobility, such as skin breakdown, pneumonia, atelectasis, thromboembolism, and constipation. Before the cast is removed, inform the patient that the cast cutter will not injure the skin but that heat may be felt during the procedure.

Because of prolonged immobilization, a joint may become contracted, usually in a fixed state of flexion. Osteoarthritis and osteoporosis may develop from lack of weight bearing. Muscle can also atrophy from lack of exercise during prolonged immobilization of the affected body part, usually an extremity.

Traction.

Traction is the application of a pulling force to a part of the body to provide reduction, alignment, and rest. It is also used as a last resort to decrease muscle spasm (thus relieving pain) and prevent or correct deformity and tissue damage. A patient in traction is often hospitalized, but in some cases, home care is possible even for skeletal traction.

Traction may be classified as running traction or balanced suspension. In *running* traction, the pulling force is in one direction and the patient's body acts as countertraction. Moving the body or bed position can alter the countertraction force. *Balanced suspension* provides the countertraction so that the pulling force of the traction is not altered when the bed or patient is moved. This allows for increased movement and facilitates care (Table 51-2).

TABLE 51-2

Types of Traction Used for Musculoskeletal Trauma

TYPE AND CHARACTERISTICS OF TRACTION	USE
Upper Extremity Traction	
Sidearm skin or skeletal traction (the forearm is flexed and extended 90 degrees from the upper part of the body)	Fractures of the humerus with or without involvement of the shoulder and clavicle
Overhead or 90-90 traction, skin or skeletal (the elbow is flexed and the arm is at a right angle to the body over the upper chest)	Same as above (depends on the physician's preference)
Plaster traction (pins inserted through the bone are fixed in the cast)	Fractures of the wrist
Lower Extremity Traction	
Buck's extension traction (skin) (the affected leg is in extension)	Fractures of the hip or femur preoperatively Prevention of hip flexion contractures Hip dislocation
Russell's traction (similar to Buck's traction, but a sling under the knee suspends the leg)	Fractures of the hip or distal end of the femur
Balanced skin or skeletal traction (the limb is usually elevated in a Thomas splint with Pearson's attachment, or a Böhler-Braun splint is used)	Fractures of the femur or pelvis (acetabulum)
Spinal Column and Pelvic Traction	
Cervical halter (a strap under the chin)	Cervical muscle spasms, strain/sprain, or arthritis
Cervical skeletal (e.g., halo brace)	Cervical fractures of the spine; muscle spasms
Pelvic belt (a strap around the hips at the iliac crests is attached to weights at the foot of the bed)	Pain, strain, sprain, or muscle spasms in the lower back
Pelvic sling (a wide strap around the hips is attached to an overhead bar to keep the pelvis off the bed)	Pelvic fractures; other pelvic injuries

Although not used as often today, the two most common types of traction are skin and skeletal traction. *Skin traction* involves the use of a Velcro boot (Buck's traction) (Fig. 51-5), belt, or halter, which is usually secured around the affected leg. The primary purpose of skin traction is to decrease painful muscle spasms that accompany hip fractures. A weight is used as a pulling force, which is limited to 5 to 10 pounds (2.3 to 4.5 kg) to prevent injury to the skin.

FIG. 51-5 Skin traction with a hook-and-loop fastener (Velcro) boot, commonly used for hip fractures.

In *skeletal traction,* screws are surgically inserted directly into bone (e.g., Halo traction). These allow the use of longer traction time and heavier weights—usually 15 to 30 pounds (6.8 to 13.6 kg). Skeletal traction aids in bone realignment. Pin site care is an important part of nursing management to prevent infection.

The nurse may set up or assist in the setup of traction if specially educated. In larger or specialty hospitals or units, orthopedic technicians or physician assistants often set up traction. Once traction is applied, maintain the correct balance between traction pull and countertraction force.

Nursing Safety Priority QSEN

Action Alert

When patients are in traction, weights usually are not removed without a prescription. They should not be lifted manually or allowed to rest on the floor. Weights should be freely hanging at all times. Teach this important point to UAP on the unit, to other personnel such as

those in the radiology department, and to visitors. Inspect the skin at least every 8 hours for signs of irritation or inflammation. When possible, remove the belt or boot that is used for skin traction every 8 hours to inspect under the device.

Check traction equipment frequently to ensure its proper functioning. Inspect all ropes, knots, and pulleys at least every 8 to 12 hours for loosening, fraying, and positioning. Check the weight for consistency with the health care provider's prescription. Sometimes one of the weights is accidentally removed by a staff member or visitor who bumps into it. Replace the weights if they are not correct, and notify the health care provider or orthopedic technician.

If the patient reports severe pain from muscle spasm, the weights may be too heavy or the patient may need realignment. Report the pain to the health care provider if body realignment fails to reduce the discomfort. Assess neurovascular status of the affected body part to detect circulatory compromise and tissue damage. The circulation is usually monitored every hour for the first 24 hours after traction is applied and every 4 hours thereafter.

NCLEX Examination Challenge

Physiological Integrity

A client has a new synthetic leg cast for a tibial fracture. What health care teaching does the nurse include for the client's self-management at home? **Select all that apply.**

A "Keep your leg elevated, preferably above your heart, as much as possible."

B "Apply ice on the cast for the first 24 hours to increase blood flow for healing."

C "Report severe numbness or inability to move your toes to your health care provider."

D "Take your pain medication as needed according to the prescription directions."

E "Don't cover the cast with anything because it will stay wet for 24 hours."

Drug Therapy.

After fracture treatment, the patient often has pain for a prolonged time during the healing process. The health care provider commonly

prescribes opioid and non-opioid analgesics, anti-inflammatory drugs, and muscle relaxants.

For patients with chronic, severe pain, opioid and non-opioid drugs are alternated or given together to manage pain both centrally in the brain and peripherally at the site of injury. For severe or multiple fractures, patient-controlled analgesia (PCA) with morphine, fentanyl, or hydromorphone (Dilaudid) is used. *Meperidine (Demerol) should never be used for older adults because it has toxic metabolites that can cause seizures and other complications. Most hospitals no longer use this drug for patients of any age.* Oxycodone and oxycodone with acetaminophen (Percocet) are common oral opioid drugs that are very effective for most patients with fracture pain. NSAIDs are given to decrease associated tissue inflammation.

For patients who have less severe injury, the analgesic may be given on an as-needed basis. Collaborate with the patient regarding the best times for the strong analgesics to be given (e.g., before a complex dressing change, after physical therapy sessions, and at bedtime). Assess the effectiveness of the analgesic and its side effects. Constipation is a common side effect of opioid therapy, especially for older adults. Assess for frequency of bowel movements, and administer stool softeners as needed. Encourage fluids and activity as tolerated. Chapter 3 discusses the various methods of pain management, including epidural analgesia and patient-controlled analgesia.

Some patients experience a long-term, intense burning pain and edema that are associated with *complex regional pain syndrome (CRPS).* This syndrome often results from fractures and other musculoskeletal trauma and is discussed on p. 1075 later in this chapter.

Surgical Management.

For some types of fractures, closed reduction is not sufficient. Surgical intervention may be needed to realign the bone for the healing process.

Preoperative Care.

Teach the patient and family what to expect during and after the surgery. The preoperative care for a patient undergoing orthopedic surgery is similar to that for anyone having surgery with general or epidural anesthesia. (See Chapter 14 for a thorough discussion of preoperative nursing care.)

Operative Procedures.

Open reduction with internal fixation (ORIF) is one of the most common

methods of reducing and immobilizing a fracture. External fixation with closed reduction is used when patients have soft-tissue injury (open fracture). Although nurses do not decide which surgical technique is used, understanding the procedures enhances patient teaching and care.

Because ORIF permits early mobility, it is often the preferred surgical method. **Open reduction** allows the surgeon to directly view the fracture site. **Internal fixation** uses metal pins, screws, rods, plates, or prostheses to immobilize the fracture during healing. The surgeon makes one or more incisions to gain access to the broken bone(s) and implants one or more devices into bone tissue after each fracture is reduced. A cast, boot, or splint is placed to maintain immobilization during the healing process, depending on the body part affected.

After the bone achieves union, the metal hardware may be removed, depending on the location and type of fracture. Hardware is removed most frequently in ankle fractures, depending on the severity of the injury. If the metal implants are not bothersome, they remain in place. Specific types of internal fixation devices are discussed later in the Selected Fractures of Specific Sites section.

An alternative modality for the management of fractures is the external fixation apparatus, as shown in Fig. 51-6. **External fixation** is a system in which pins or wires are inserted through the skin and affected bone and then connected to a rigid external frame. The system may be used for upper or lower extremity fractures or for fractures of the pelvis, especially for open fractures when wound management is needed. After a fixator is removed, the patient may be placed in a cast or splint until healing is complete.

FIG. 51-6 The Hex-Fix external fixation system for tibia-fibula fractures.

External fixation has several advantages over other surgical techniques:

- There is minimal blood loss compared with internal fixation.
- The device allows early ambulation and exercise of the affected body part while relieving pain.
- The device maintains alignment in closed fractures that will not maintain position in a cast and stabilizes comminuted fractures that require bone grafting.

In open fractures, in which skin and tissue trauma accompany the fracture, the device permits easy access to the wound while the bone heals. This method is usually preferred over the use of a window in a cast for wound care.

A disadvantage of external fixation is an increased risk for pin site infection. Pin site infections can lead to osteomyelitis, which is serious and difficult to treat (see Chapter 50).

Postoperative Care.

The postoperative care for a patient undergoing ORIF or external fixation is similar to that provided for any patient undergoing surgery (see Chapter 16). Because bone is a vascular, dynamic body tissue, the patient is at risk for complications specific to fractures and musculoskeletal surgery. IV ketorolac (Toradol) is often given in the postanesthesia care unit (PACU) or soon after discharge to the post-surgical area to reduce inflammation and pain. Aggressive pain management starts as soon as possible after surgery to prevent the development of chronic pain and

promote early mobility.

Additional information about postoperative care is found beginning on p. 1066 in the Selected Fractures of Specific Sites section. Depending on the fractures that are repaired, some ORIF procedures are performed as same-day surgeries. Patients stay in the hospital up to 23 hours after surgery.

For patients with an **external fixator**, pay particular attention to the pin sites for signs of inflammation or infection. In the first 48 to 72 hours, *clear* fluid drainage or weeping is expected. Although no standardized method or evidence-based protocol for pin site care has been established, recommendations have been made based on the evidence available regarding pin site care. Because the pins go through the skin and into bone, the risk for infection is high. Monitor the pin sites at least every 8 to 12 hours for drainage, color, odor, and severe redness, which indicate inflammation and possible infection. Follow agency policy for how to clean the pin site areas.

The patient with an external fixator may have a disturbed body image. The frame may be large and bulky, and the affected area may have massive tissue damage with dressings. Be sensitive to this possibility in planning care. Teach about alterations to clothing that may be required while the fixator is in place.

The Ilizarov technique of circular external fixation is sometimes used to treat new fractures (closed, comminuted fractures and open fractures with bone loss), as well as malunion or nonunion of fractures. It may also be used to treat congenital bone deformities, especially in "little people" (e.g., dwarfs).

The circular external fixation device is used to gently pull apart the cortex of the bone and stimulate new bone growth. Unlike the traditional fixator, the Ilizarov external fixator promotes rotation, angulation, lengthening, or widening of bone to correct bony defects and allows for healing of any soft-tissue defect. The nursing care associated with this device is similar to the care of the patient with other external fixation systems with one major exception. If the device is being used for filling bone gaps, teach the patient how to manually turn the four-sided nuts (also called *clickers*) up to 4 times a day. Daily distraction rates vary, but 1 mm daily is common. Screening and teaching are particularly important because the patient adjusts and cares for the apparatus over a long period of up to 6 months to 1 year. Pain control is a priority outcome for patients using this device.

Procedures for Nonunion.

Some management techniques are not successful because the bone does not heal. Several additional options are available to the physician to promote bone union, such as electrical bone stimulation, bone grafting, and ultrasound fracture treatment.

For selected patients, *electrical bone stimulation* may be successful. This procedure is based on research showing that bone has electrical properties that are used in healing. The exact mechanism of action is unknown. A noninvasive, external **electrical bone stimulation** system delivers a small continuous electrical charge directed toward the non-healed bone. There are no known risks with this system, although patients with pacemakers cannot use this device on an arm. Implanted direct-current stimulators are placed directly in the fracture site and have no external apparatus. Both systems require several months of treatment.

Another method of treating nonunion is *bone grafting.* A bone graft may also replace diseased bone or increase bone tissue for joint replacement. In most cases, chips of bone are taken from the iliac crest or other site and are packed or wired between the bone ends to facilitate union. Allografts from cadavers may also be used. These grafts are frozen or freeze-dried and stored under sterile conditions in a bone bank.

Bone banking from living donors is becoming increasingly popular. If qualified, patients undergoing total hip replacement may donate their femoral heads to the bank for later use as bone grafts for others. Careful screening ensures that the bone is healthy and that the donor has no communicable disease. The bone cannot be donated without written consent.

One of the newest modalities for fracture healing is **low-intensity pulsed ultrasound** (Exogen therapy). Used for slow-healing fractures or for new fractures as an alternative to surgery, ultrasound treatment has had excellent results. The patient applies the treatment for about 20 minutes each day. It has no contraindications or adverse effects.

Physical Therapy.

Many patients with musculoskeletal trauma, including fractures, are referred by their health care provider for rehabilitation therapy with a physical therapist (PT). The timing for this referral depends on the nature, severity, and treatment modality of the fracture(s).

For example, some patients who have an ORIF for one or more ankle fractures may begin therapy when the incisional staples or Steri-Strips are removed and an orthopedic boot is fitted. Based on the initial evaluation, the PT performs gentle manipulative exercises to increase range of motion. The therapist may also begin to help the patient with

laterality, a concept to help the brain identify the injured foot from the uninjured foot. Computer programs and mirror-box therapy can help reprogram the brain as part of cognitive retraining. In mirror-box therapy for an injured foot, the patient covers his or her affected foot while looking at and moving the uninjured foot in front of the mirror. The brain perceives the foot in the mirror as the injured foot.

Stimulation by touch also helps the brain acknowledge the injured foot. The PT teaches the patient to have someone frequently touch the injured area and use various materials and objects against the skin to desensitize it. These interventions decrease the risk for complex regional pain syndrome, discussed later in this chapter.

When weight bearing begins about 6 weeks after surgery, the PT teaches the patient how to begin with toe-touch or partial weight bearing using crutches or a walker. Muscle strengthening exercises of the affected leg help with ambulation because atrophy begins shortly after injury.

The PT also assists with pain control and edema reduction by using ice/heat packs, electrical muscle stimulation ("e-stim"), and special treatments such as dexamethasone iontophoresis. **Iontophoresis** is a method for absorbing dexamethasone, a synthetic steroid, through the skin near the painful area to decrease inflammation and edema. A small device delivers a minute amount of electricity via electrodes that are placed on the skin. The patient may describe the sensation as a pinch or slight sting. The electrical current increases the ability of the skin to absorb the drug from a topical patch into the affected soft tissue.

The success of rehabilitation is affected by the patient's motivation and willingness to perform prescribed exercises and activities between PT visits. Rehabilitation for ankle surgery, for example, may take several months, depending on the severity of the injury and the age and general health of the patient.

Preventing and Monitoring for Neurovascular Compromise

Planning: Expected Outcomes.

The patient with a fracture is expected to have no compromise in neurovascular status as evidenced by adequate circulation, movement, and sensory perception (CMS). If severe compromise occurs, the patient is expected to have early and prompt emergency treatment to prevent severe tissue damage.

Interventions.

Perform neurovascular (NV) assessments (also known as "circ checks" or

CMS assessments) frequently before and after fracture treatment. Patients who have extremity casts, splints with elastic bandage wraps, and open reduction with internal fixation (ORIF) or external fixation are especially at risk for NV compromise. If blood flow to the distal extremity is impaired, the patient reports increased pain and decreased sensory perception and movement. If these symptoms are allowed to progress, patients are at risk for acute compartment syndrome (ACS).

Early recognition of the signs and symptoms of ACS can prevent loss of function or loss of a limb. Identify patients who may be at risk, and monitor them closely. ACS can begin in 6 to 8 hours after an injury or take up to 2 days to appear. If it is suspected, notify the health care provider immediately, and if possible, implement interventions to relieve the pressure. For example, for the patient with tight, bulky dressings, loosen the bandage or tape. If the patient has a cast, follow agency protocol about who may cut the cast.

Nursing Safety Priority QSEN

Critical Rescue

Monitor for early signs of ACS. Assess for the "six Ps" including **p**ain, **p**ressure, **p**aralysis, **p**aresthesia, **p**allor, and **p**ulselessness (rare). Pain is increased even with passive motion and may seem out of proportion to the degree of injury. Analgesics that had controlled pain become less effective. Numbness and tingling or paresthesias are often one of the first signs of the problem. The affected extremity then becomes pale and cool as a result of decreased arterial perfusion to the affected area. Capillary refill is an important assessment of perfusion but may not be reliable in an older adult because of arterial insufficiency. Losses of movement and function and decreased pulses or pulselessness are late signs of ACS! Fortunately, ACS is not common, but it creates an emergency situation when it does occur.

In a few cases, compartment pressure may be monitored on a one-time basis with a handheld device with a digital display, or pressure can be monitored continuously. Monitoring is recommended for comatose or unresponsive high-risk patients with multiple trauma and fractures.

If ACS is verified, the surgeon may perform a **fasciotomy**, or opening in the fascia, by making an incision through the skin and subcutaneous tissues into the fascia of the affected compartment. This procedure relieves the pressure and restores circulation to the affected area. No consensus exists on what pressure requires fasciotomy (normal is 0 to

8 mm Hg). Compartment pressures must be considered in relation to the patient's hemodynamic status. After fasciotomy, the open wound is packed and dressed daily or more often until secondary closure occurs, usually in 4 to 5 days, depending on the patient's healing ability. Some surgeons use negative pressure wound therapy (e.g., Wound Vac) over a fasciotomy to decrease edema until the wound is closed. For other patients, a skin graft may be used to promote healing.

Preventing Infection

Planning: Expected Outcomes.

The patient with a fracture is expected to be free of wound or bone infection as evidenced by no fever, no increase in white blood cell count, and negative wound culture (if wound is present).

Interventions.

When caring for a patient with an open fracture, use clean or aseptic technique for dressing changes and wound irrigations. Check agency policy for specific protocols. *Immediately notify the health care provider if you observe inflammation and purulent drainage*. Other infections, such as pneumonia and urinary tract infection, may occur several days after the fracture. Monitor the patient's vital signs every 4 to 8 hours because increases in temperature and pulse often indicate systemic infection.

Considerations for Older Adults

Patient-Centered Care QSEN

Older adults may not have a temperature elevation even in the presence of severe infection. An acute onset of confusion (delirium) often suggests an infection in the older adult patient.

For most patients with an open fracture, the health care provider prescribes one or more broad-spectrum antibiotics prophylactically and performs surgical débridement of any wounds as soon as possible after the injury. First-generation cephalosporins, clindamycin (Cleocin), and gentamycin are commonly used. In addition to systemic antibiotics, local antibiotic therapy through wound irrigation is commonly prescribed, especially during débridement.

A very effective treatment is negative pressure wound therapy (e.g., vacuum-assisted closure [VAC] system) as a method of increasing the rate of wound healing for open fractures. This device allows quicker

wound closure, which decreases the risk for infection.

When the bone is surgically repaired, hardware and/or bone grafts have typically been implanted. However, they are limited in their use. The U.S. Food and Drug Administration (FDA) approved the use of recombinant human bone morphogenetic protein-2 (rhBMP-2) for tibial and spinal fractures. This implanted genetically engineered substance increases wound healing, decreases hardware failure, and decreases the risk for infection.

Improving Physical Mobility

Planning: Expected Outcomes.

The patient with a fracture is expected to increase physical mobility and be free of complications associated with impaired mobility. The patient is also expected to move purposefully in his or her own environment independently with or without an ambulatory device unless restricted by traction or other modality.

Interventions.

The interventions necessary for this diagnosis can be grouped into two types: those that help increase mobility and those that prevent complications of impaired mobility.

Promoting Mobility.

The use of crutches or a walker increases mobility and assists in ambulation. The patient may progress to using a walker or cane after crutches.

Crutches are the most commonly used ambulatory aid for many types of lower extremity musculoskeletal trauma (e.g., fractures, sprains, amputations). In most agencies, the physical therapist or emergency department/ambulatory care nurse fits the patient for crutches and teaches him or her how to ambulate with them. Reinforce those instructions, and evaluate whether the patient is using the crutches correctly.

Walking with crutches requires strong arm muscles, balance, and coordination. For this reason, crutches are not often used for older adults. Walkers and canes are preferred for the older adult. Crutches can cause upper extremity bursitis or axillary nerve damage if they are not fitted or used correctly. For that reason, the top of each crutch is padded. To prevent pressure on the axillary nerve, there should be two to three finger-breadths between the axilla and the top of the crutch when the

crutch tip is at least 6 inches (15 cm) diagonally in front of the foot. The crutch is adjusted so that the elbow is flexed no more than 30 degrees when the palm is on the handle (Fig. 51-7). The distal tips of each crutch are rubber to prevent slipping.

FIG. 51-7 Assisting the patient with crutch walking. Note how the therapist guards the patient and how the patient's elbows are at no more than 30 degrees of flexion.

There are several types of gaits for walking with crutches. The most common one for musculoskeletal injury is the three-point gait, which allows little weight bearing on the affected leg. The procedure for these gaits is discussed in fundamentals of nursing books.

A *walker* is most often used by the older patient who needs additional support for balance. The physical therapist assesses the strength of the upper extremities and the unaffected leg. Strength is improved with prescribed exercises as needed.

A *cane* is sometimes used if the patient needs only minimal support for an affected leg. The straight cane offers the least support. A hemi-cane or

quad-cane provides a broader base for the cane and therefore more support. The cane is placed on the *unaffected* side and should create no more than 30 degrees of flexion of the elbow. The top of the cane should be parallel to the greater trochanter of the femur or stylus of the wrist. Chapter 6 and fundamentals textbooks describe these ambulatory devices in more detail.

Preventing Complications of Immobility.

The nurse plays a vital role in preventing and assessing for complications in immobilized patients with fractures. Additional information about nursing care for preventing problems associated with immobility is found in Chapter 6.

Community-Based Care

The patient with an *uncomplicated* fracture is usually discharged to home from the emergency department or urgent care center. Older adults with hip or other fractures or patients with multiple traumas are hospitalized and then transferred to home, a rehabilitation setting, or a long-term care facility for rehabilitation. Collaborate with the case manager or the discharge planner in the hospital to ensure continuity of care. Be sure to communicate the plan of care clearly to the health care agency receiving the patient.

Home Care Management.

If the patient is discharged to home, the nurse, therapist, or case manager (CM) may assess the home environment for structural barriers to mobility, such as stairs. Be sure that the patient has easy access to the bathroom. Ask about scatter rugs, waxed floors, and walkway areas that could increase the risk for falls. If the patient needs to use a wheelchair or ambulatory aid, make sure that he or she can use it safely and that there is room in the house to ambulate with these devices. The physical therapist may teach the patient how to use stairs, but older adults or those using crutches may experience difficulty performing this task. Depending on the age and condition of the patient, a home health care nurse may make one or two visits to check that the home is safe and that the patient and family are able to follow the interdisciplinary plan of care.

Self-Management Education.

The patient with a fracture may be discharged from the hospital,

emergency department, office, or clinic with a bandage, splint, cast, or external fixator. Provide verbal and written instructions on the care of these devices. Chart 51-5 describes care of the affected extremity after removal of the cast.

Chart 51-5 Patient and Family Education: Preparing for Self-Management

Care of the Extremity After Cast Removal

- Remove scaly, dead skin carefully by soaking; do not scrub.
- Move the extremity carefully. Expect discomfort, weakness, and decreased range of motion.
- Support the extremity with pillows or your orthotic device until strength and movement return.
- Exercise slowly as instructed by your physical therapist.
- Wear support stockings or elastic bandages to prevent swelling (for lower extremity).

The patient may also need to continue wound care at home. Instruct the patient and family about how to assess and dress the wound to promote healing and prevent infection. Teach them how to recognize complications and when and where to seek professional health care if complications occur. Additional educational needs depend on the type of fracture and fracture repair.

Encourage patients and their families to ensure adequate foods high in protein and calcium that are needed for bone and tissue healing. For patients with lower extremity fractures, less weight bearing on long bones can cause anemia. The red bone marrow needs weight bearing to simulate red blood cell production. Encourage foods high in iron content. Teach the patient to take a daily iron-added multivitamin (take with food to prevent possible nausea).

Health Care Resources.

Arrange for follow-up care at home. A social worker may need to help the patient apply for funds to pay medical bills. If there is severe bone and tissue damage, be realistic and help the patient and family understand the long-term nature of the recovery period. Multiple treatment techniques and surgical procedures required for complications can be mentally and emotionally draining for the patient and family. A vocational counselor may be needed to help the patient find a different

type of job, depending on the extent of the fracture.

An older or incapacitated patient may need assistance with ADLs, which can be provided by home care aides if family or other caregiver is not available. In collaboration with the case manager, anticipate the patient's needs and arrange for these services.

Evaluation: Outcomes

Evaluate the care of the patient with one or more fractures based on the identified priority patient problems. The expected outcomes include that the patient:

- States that he or she has adequate pain control
- Has adequate blood flow to maintain tissue perfusion and function
- Is free of infection
- Is free of physiologic consequences of impaired mobility
- Ambulates or moves independently with or without an assistive device (if not restricted by traction or other device)

NCLEX Examination Challenge

Physiological Integrity

A client returns to the same-day surgical unit after having an ankle open reduction internal fixation (ORIF). What is the nurse's priority action when caring for this client?

A Monitor the client's vital signs frequently.
B Assess the client's abdomen for bowel sounds.
C Keep the client's affected leg on a pillow.
D Encourage the client to drink fluids.

Selected Fractures of Specific Sites

Upper Extremity Fractures

In addition to the general care discussed in the previous section, management of upper extremity fractures includes specific interventions related to the location and nature of the injury.

Fractures of the *proximal humerus,* particularly impacted or displaced fractures, are common in the older adult. An impacted injury is usually treated with a sling or other device for immobilization. A displaced fracture often requires ORIF with pins or a prosthesis. Humeral shaft fractures are generally corrected by closed reduction and a hanging-arm cast or splint. If necessary, the fracture is repaired surgically (with an intramedullary rod or metal plate and screws) or with external fixation.

The most common upper extremity (UE) fracture is the *distal radius fracture (DRF),* which occurs in both younger and older adults. Younger adults experience this injury from high-energy (high-impact) trauma as a result of motor vehicle crashes and sports. Older adults, particularly women with osteopenia, typically have low-impact DRFs as a result of falls (Voda, 2011).

Various names are used to classify DRFs, including Colles' and Smith fractures. A Colles' fracture can occur when a person attempts to break a fall by landing on the heel of the hand when the wrist is extended. The resulting deformity is often called a "dinner fork" injury (Fig. 51-8). Seen less commonly, a Smith fracture occurs from a fall on a flexed wrist (Voda, 2011).

FIG. 51-8 Colles' wrist fracture showing “dinner fork” deformity.

Initial nursing interventions for a patient with a DRF include:

- Removing jewelry on the affected hand and wrist before edema worsens (Walsh, 2013)
- Performing a neurovascular assessment of the affected UE
- Immobilizing the affected wrist and hand
- Elevating the affected UE
- Applying ice to the affected area
- Managing pain

After initial stabilization, the most common treatment for a DRF is closed reduction. The health care provider realigns the bone ends while the patient is moderately sedated. A splint is applied and held in place with an elastic bandage. The splint may be replaced several days later

with a cast after edema decreases.

For more complicated DRFs, an ORIF with pins and plates may be performed. The patient may have surgery in an ambulatory care or same-day surgical setting using general anesthesia, a peripheral nerve block, or a combination of both. The nerve block is often given as a single injection of levobupivacaine (Chirocaine) or bupivacaine (Marcaine), which provides pain relief for 12 to 20 hours (Guarin, 2013). Teach patients having a peripheral nerve block (e.g., supraclavicular block) that temporarily they will not be able to move their affected arm. Also observe, report, and document signs and symptoms of pneumothorax, including tachypnea, decreased breath sounds, or respiratory distress (Guarin, 2013).

For all patients who experience a DRF, assess for nerve compression, especially the radial and median nerves. Be sure to perform frequent neurovascular assessment with special attention to the presence of decreased sensory perception (e.g., numbness) or decreased movement.

Fractures of the *metacarpals* and *phalanges (fingers)* are usually not displaced, which makes their treatment less difficult than that of other fractures. Metacarpal fractures are immobilized for 3 to 4 weeks. Phalangeal fractures are immobilized in finger splints for 10 to 14 days.

Lower Extremity Fractures

Fractures of the Hip

Hip fracture is the most common injury in older adults and one of the most frequently seen injuries in any health care setting or community. It has a high mortality rate as a result of multiple complications related to surgery, depression, and prolonged immobility. Over half of older adults experiencing a hip fracture are unable to live independently, and many die within the first year (Sweitzer et al., 2013).

Hip fractures include those involving the upper third of the femur and are classified as **intracapsular** (within the joint capsule) or **extracapsular** (outside the joint capsule). These types are further divided according to fracture location (Fig. 51-9). In the area of the femoral neck, disruption of the blood supply to the head of the femur is a concern, which can result in ischemic or avascular necrosis (AVN) of the femoral head. AVN causes death and necrosis of bone tissue and results in pain and decreased mobility. This problem is most likely in patients with displaced fractures.

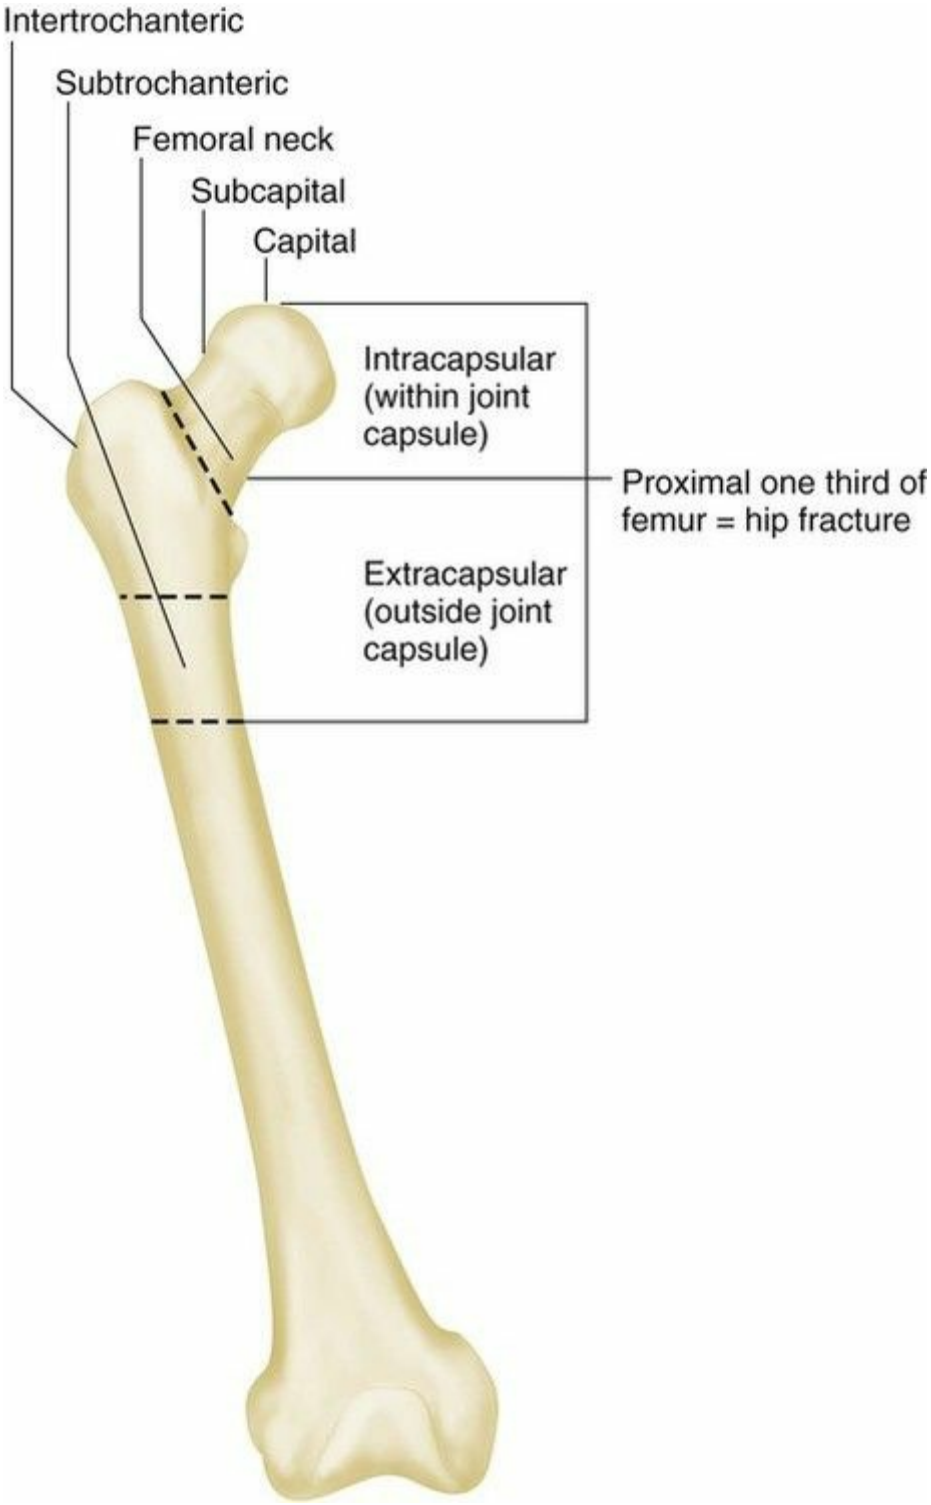

FIG. 51-9 Types of hip fractures.

Osteoporosis is the biggest risk factor for hip fractures (see Chapter 50). This disease weakens the upper femur (hip), which causes it to break and then causes the person to fall. The number of people with hip fracture is expected to continue to increase as the population ages, and the associated health care costs will be tremendous.

Considerations for Older Adults

Patient-Centered Care QSEN

Teach older adults about the risk factors for hip fracture including physiologic aging changes, disease processes, drug therapy, and environmental hazards. Physiologic changes include sensory changes such as diminished visual acuity and hearing; changes in gait, balance, and muscle strength; and joint stiffness. Disease processes like osteoporosis, foot disorders, and changes in cardiac function increase the risk for hip fracture. Drugs, such as diuretics, antihypertensives, antidepressants, sedatives, opioids, and alcohol, are factors that increase the risks for falling in older adults. Use of three or more drugs at the same time drastically increases the risk for falls. Throw rugs, loose carpeting, inadequate lighting, uneven walking surfaces or steps, and pets are environmental hazards that also cause falls.

The older adult with hip fracture usually reports groin pain or pain behind the knee on the affected side. In some cases, the patient has pain in the lower back or has no pain at all. However, the patient is not able to stand. X-ray or other imaging assessment confirms the diagnosis.

The treatment of choice is surgical repair by ORIF, when possible, to reduce pain and allow the older patient to be out of bed and ambulatory. Skin (Buck's) traction may be applied before surgery to help decrease pain associated with muscle spasm. Depending on the exact location of the fracture, an ORIF may include an intramedullary rod, pins, prostheses (for femoral head or femoral neck fractures), or a compression screw. Figs. 51-10 and 51-11 illustrate examples of these devices. Epidural or general anesthesia is used. Occasionally a patient will be so debilitated that surgery cannot be done. In these cases, nonsurgical options include pain management and bedrest to allow natural fracture healing.

FIG. 51-10 A hip prosthesis used for fractures.

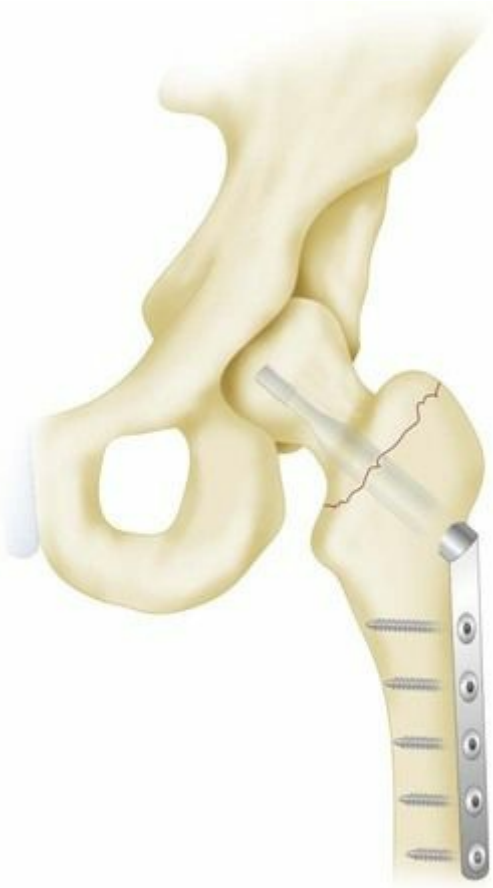

FIG. 51-11 A compression hip screw used for open reduction with internal fixation (ORIF) of the hip.

Patients usually receive IV morphine after admission to the emergency department and PCA morphine or epidural analgesia after surgery. In

some cases, a femoral nerve block may also be performed during surgery to help relieve pain for up to 24 hours after surgery (Guarin, 2013). Meperidine (Demerol) should not be used due to its toxic metabolites that can cause seizures and other adverse drug events, especially in the older adult population. Chapter 3 discusses the nursing care associated with pain management in detail.

After a hip repair, older adults frequently experience acute confusion, or delirium. They may pull at tubes or the surgical dressing or attempt to climb out of bed, possibly falling and causing self-injury. Other patients stay awake all night and sleep during the day. Keep in mind that some patients have a quiet delirium. Monitor the patient frequently to prevent falls. Ask the family or other visitors to let staff know if the patient is attempting to get out of bed. Chapter 2 describes fall prevention strategies and delirium management in detail.

Nursing Safety Priority QSEN

Action Alert

Patients who have an ORIF are at risk for hip dislocation or subluxation. Be sure to prevent hip adduction and rotation to keep the operative leg in proper alignment. Regular pillows or abduction devices can be used for patients who are confused or restless. If straps are used to hold the device in place, check the skin for signs of pressure. Perform neurovascular assessments to ensure that the device is not interfering with arterial circulation or peripheral nerve conduction.

The patient begins ambulating with assistance the day after surgery to prevent complications associated with immobility (e.g., pressure ulcers, atelectasis, venous thromboembolism). Early mobility and ambulation also decrease the chance of infection and increase surgical site healing.

Special considerations for the patient having a hip repair also include careful inspection of skin including areas of pressure, especially the heels. Use of skin traction to reduce muscle spasms may increase the period of bedrest before surgery. Decreased mobility after surgery can increase the risk for pressure injury in this area within 24 hours.

Nursing Safety Priority QSEN

Action Alert

Be sure that the patient's heels are up off the bed at all times. Inspect

the heels and other high-risk bony prominence areas every 8 to 12 hours. Delegate turning and repositioning every 1 to 2 hours to unlicensed assistive personnel (UAP), and supervise this nursing activity.

Other postoperative interventions to prevent complications, such as venous thromboembolism, are similar to those for total hip replacement (see Chapter 16).

Many patients recover fully from hip fracture repair and regain their functional ability. They are typically discharged to their home, rehabilitation unit or center, or a skilled nursing facility for physical and occupational therapy. However, some patients are not able to return to their pre-fracture ADLs and mobility level. Family caregivers often have unexpected responsibilities caring for patients during their recovery. Hip fracture resource centers can be very useful in providing caregiver support (see the Evidence-Based Practice box).

Evidence-Based Practice QSEN

Are Online Resources Helpful for Caregivers of Patients After Hip Fracture?

Nahm, E-S., Resnick, B., Plummer, L., & Park, B.K. (2013). Use of discussion boards in an online hip fracture resource center for caregivers. *Orthopaedic Nursing, 32*(2), 89-96.

Family caregivers (CGs) are important for the successful recovery of patients who have hip fracture repair. In a previous study the authors found that CGs lacked knowledge in understanding how to provide care during the rehabilitation and recovery phase. The purpose of this qualitative study was to explore the experiences of CGs while they were using an online hip resource center over an 8-week period. The majority of the 27 caregivers in the study were female and white. Most had some college education, and their average age was 55.5 years. Each CG posted comments related to specific topics posted on the online discussion boards. Examples of topics included the roles of therapists, awareness of bone health, and caregiver stress. Three coders recorded and analyzed the data using well-established coding rules to ensure validity and reliability.

The analysis revealed common themes, such as need for adjustment to the fracture event, and three categories: types of care provided by the CGs, strategies used by CGs to prevent fractures, and coping mechanisms used to handle stress. The researchers concluded that

discussion boards (DBs) can serve as a useful medium for CGs to share their experiences. They also noted that DBs can assist health care providers identify ways to support CGs.

Level of Evidence: 4

This study was a well-designed qualitative study to gain specific information about the needs of caregivers of patients with hip fractures.

Commentary: Implications for Practice and Research

Although this study was limited to a small sample size, the researchers were very careful to ensure validity and reliability of the coding process for data analysis. Additional studies with larger sample sizes that are more diverse are needed to provide generalization of results. Nurses caring for patients having surgical hip repair need to help families locate resources to provide information and support during the patients' rehabilitation and recovery period.

Other Fractures of the Lower Extremity

Other fractures of the lower extremity may or may not require hospitalization. However, if the patient has severe or multiple fractures, especially with soft-tissue damage, hospital admission is usually required. Patients who have surgery to repair their injury may also be hospitalized. Coordinate care with the physical therapist regarding mobility, transfers, positioning, and ambulation. Collaborate with the case manager regarding placement after discharge. Most patients go home unless there is no support system or additional rehabilitation is needed. Health teaching and ensuring continuity of care are essential.

Fractures of the *lower two thirds of the femur* usually result from trauma, often from a motor vehicle crash. A femur fracture is seldom immobilized by casting because the powerful muscles of the thigh become spastic, which causes displacement of bone ends. Extensive hemorrhage can occur with femur fracture.

Surgical treatment is ORIF with nails, rods, or a compression screw. In a few cases in which extensive bone fragmentation or severe tissue trauma is found, external fixation may be employed. Healing time for a femur fracture may be 6 months or longer. Skeletal traction, followed by a full-leg brace or cast, may be used in nonsurgical treatment.

Trauma to the lower leg most often causes fractures of both the *tibia* and the *fibula*, particularly the lower third, and is often referred to as a "tib-fib" fracture. The major treatment techniques are closed reduction with casting, internal fixation, and external fixation. If closed reduction is

used, the patient may wear a cast for 6 to 10 weeks. Because of poor perfusion to parts of the tibia and fibula, delayed union is not unusual with this type of fracture. Internal fixation with nails or a plate and screws, followed by a long-leg cast for 4 to 6 weeks, is another option. When the fractures cause extensive skin and soft-tissue damage, the initial treatment may be external fixation, often for 6 to 10 weeks, usually followed by application of a cast until the fracture is completely healed. The patient uses ambulatory aids, usually crutches.

Ankle fractures are described by their anatomic place of injury. For example, a bimalleolar (Pott's) fracture involves the medial malleolus of the tibia and the lateral malleolus of the fibula. The small talus that makes up the rest of the ankle joint may also be broken. An ORIF is usually performed using two incisions—one on the medial (inside) aspect of the ankle and one on the lateral (outer) side. Several screws or nails are placed into the tibia, and a compression plate with multiple screws keeps the fibula in alignment. Weight bearing is restricted until the bone heals.

Treatment of fractures of the foot or phalanges (toes) is similar to that of other fractures. Phalangeal fractures may be more painful but are not as serious as most other types of fractures. Crutches are used for ambulation if weight bearing is restricted, but many patients can ambulate while wearing an orthopedic shoe or boot while the bone heals.

Fractures of the Chest and Pelvis

Chest trauma may cause fractures of the ribs or sternum. The major concern with rib and sternal fractures is the potential for puncture of the lungs, heart, or arteries by bone fragments or ends. *Assess airway, breathing, and circulation status* ***first*** *for any patient having chest trauma!* Fractures of the lower ribs may damage underlying organs, such as the liver, spleen, or kidneys. These fractures tend to heal on their own without surgical intervention. Patients are often uncomfortable during the healing process and require analgesia. They also have a high risk for pneumonia because of shallow breathing caused by pain on inspiration. Encourage them to breathe normally if possible.

Because the pelvis is very vascular and is close to major organs and blood vessels, associated internal damage is the major focus in fracture management. After head injuries, pelvic fractures are the second most common cause of death from trauma. In young adults, pelvic fractures typically result from motor vehicle crashes or falls from buildings. Falls are the most common cause in older adults. The major concern related to pelvic injury

is venous oozing or arterial bleeding. Loss of blood volume leads to hypovolemic shock.

Assess for internal abdominal trauma by checking for blood in the urine and stool and by monitoring the abdomen for the development of rigidity or swelling. The trauma team may use peritoneal lavage, CT scanning, or ultrasound for assessment of hemorrhage. Ultrasound is noninvasive, rapid, reliable, and cost-effective and can be done at the bedside.

There are many classification systems for pelvic fractures. A system that is particularly useful divides fractures of the pelvis into two broad categories: non–weight-bearing fractures and weight-bearing fractures.

When a *non–weight-bearing* part of the pelvis is fractured, such as one of the pubic rami or the iliac crest, treatment can be as minimal as bedrest on a firm mattress or bed board. This type of fracture can be quite painful, and the patient may need stool softeners to facilitate bowel movements because of hesitancy to move. Well-stabilized fractures usually heal in 2 months.

A *weight-bearing* fracture, such as multiple fractures of the pelvic ring creating instability or a fractured acetabulum, necessitates external fixation or ORIF or both. Progression to weight bearing depends on the stability of the fracture after fixation. Some patients can fully bear weight within days of surgery, whereas others managed with traction may not be able to bear weight for as long as 12 weeks. For complex pelvic fractures with extensive soft-tissue damage, external fixation may be required.

Compression Fractures of the Spine

Most vertebral fractures are associated with osteoporosis, metastatic bone cancer, and multiple myeloma. Compression fractures result when trabecular or cancellous bone within the vertebra becomes weakened and causes the vertebral body to collapse. The patient has severe pain, deformity (kyphosis), and occasional neurologic compromise. As discussed in the Osteoporosis section of Chapter 50, the patient's quality of life is reduced by the impact of this problem.

Nonsurgical management includes bedrest, analgesics, nerve blocks, and physical therapy to maintain muscle strength. Vertebral compression fractures (VCFs) that remain painful and impair mobility may be surgically treated with **vertebroplasty** or kyphoplasty. These procedures are minimally invasive techniques in which bone cement is injected through the skin (percutaneously) directly into the fracture site to provide stability and immediate pain relief. **Kyphoplasty** includes the additional step of inserting a small balloon into the fracture site and

inflating it to contain the cement and to restore height to the vertebra. This procedure is preferred because it reduces the complication of leaking of bone cement outside the vertebral body and it may restore height to decrease kyphosis.

Minimally invasive surgeries can be done in an operating or interventional radiology suite by a surgeon or interventional radiologist. They can be done with moderate sedation or general anesthesia. IV ketorolac (Toradol) may be given before the procedure to reduce inflammation. Large-bore needles are placed into the fracture site using fluoroscopy or CT guidance. Then the deflated balloon is inserted through the needles and inflated in the fracture site, and the cement is injected.

Patients may have the procedures in an ambulatory care setting and return home after 2 to 4 hours or be admitted to the hospital for an overnight stay. Chart 51-6 describes the preoperative and postoperative care for percutaneous interventions for vertebral compression fractures.

Chart 51-6 Best Practice for Patient Safety & Quality Care QSEN

Nursing Care for Patients Having Vertebroplasty or Kyphoplasty

Provide *preoperative care* including:

- Check the patient's coagulation laboratory test results; platelet count should be more than 100,000/mm^3.
- Make sure that all anticoagulant drugs were discontinued as requested by the physician.
- Assess and document the patient's neurologic status, especially extremity movement and sensation.
- Assess the patient's pain level.
- Assess the patient's ability to lie prone for at least 1 hour.
- Establish an IV line, and take vital signs.

Provide *postoperative care* including:

- Place the patient in a flat supine position for 1 to 2 hours or as requested by the physician.
- Monitor and record vital signs and frequent neurologic assessments; report any change immediately to the physician.
- Apply an ice pack to the puncture site if needed to relieve pain.
- Assess the patient's pain level, and compare it with the preoperative level; give mild analgesic as needed.

- Monitor for complications such as bleeding at the puncture site or shortness of breath; report these findings immediately if they occur.
- Assist the patient with ambulation.

Before discharge, teach the patient and family the following:

- The patient should avoid driving or operating machinery for the first 24 hours because of drugs used during the procedure.
- Monitor the puncture site for signs of infection, such as redness, pain, swelling, or drainage.
- Keep the dressing dry, and remove it the next day.
- The patient should begin usual activities, including walking the next day, and should slowly increase activity level over the next few days.

Before discharge, teach the patient to report any signs or symptoms of infection from puncture sites. Remind him or her to not soak in a bath for 1 week, use analgesics as needed, resume activity, and contact the health care provider for questions or concerns.

Amputations

An **amputation** is the removal of a part of the body. Advances in microvascular surgical procedures, better use of antibiotic therapy, and improved surgical techniques for traumatic injury and bone cancer have reduced the number of elective amputations. The psychosocial aspects of the procedure are as devastating as the physical impairments that result. The loss is complete and permanent and causes a change in body image and self-esteem. Collaborate with members of the health care team, including prosthetists, rehabilitation therapists, psychologists, case managers, and physiatrists (rehabilitation physicians), when providing care to the patient who has an amputation.

❖ Pathophysiology

Types of Amputation

Amputations may be elective or traumatic. Most are *elective* and are related to complications of peripheral vascular disease and arteriosclerosis. These complications result in ischemia in distal areas of the lower extremity. Diabetes mellitus is often an underlying cause. Amputation is considered only after other interventions have not restored circulation to the lower extremity, sometimes referred to as *limb salvage procedures* (e.g., percutaneous transluminal angioplasty [PTA]). These procedures are discussed elsewhere in this text.

Traumatic amputations most often result from accidents or war and are the primary cause of *upper extremity* amputation. A person may clean lawn mower blades or a snow blower without disconnecting the machine. A motor vehicle crash or industrial machine accident may also cause an amputation. The number of traumatic amputations also increases during war as a result of hidden land mines and bombs (e.g., in Iraq and Afghanistan). Multiple limbs or parts of limbs may be amputated as a result of these devices. Thousands of veterans of war in the United States are amputees and have had to adjust to major changes in their lifestyles.

Levels of Amputation

Elective lower extremity (LE) amputations are performed much more frequently than upper extremity amputations. Several types of LE amputations may be performed (Fig. 51-12).

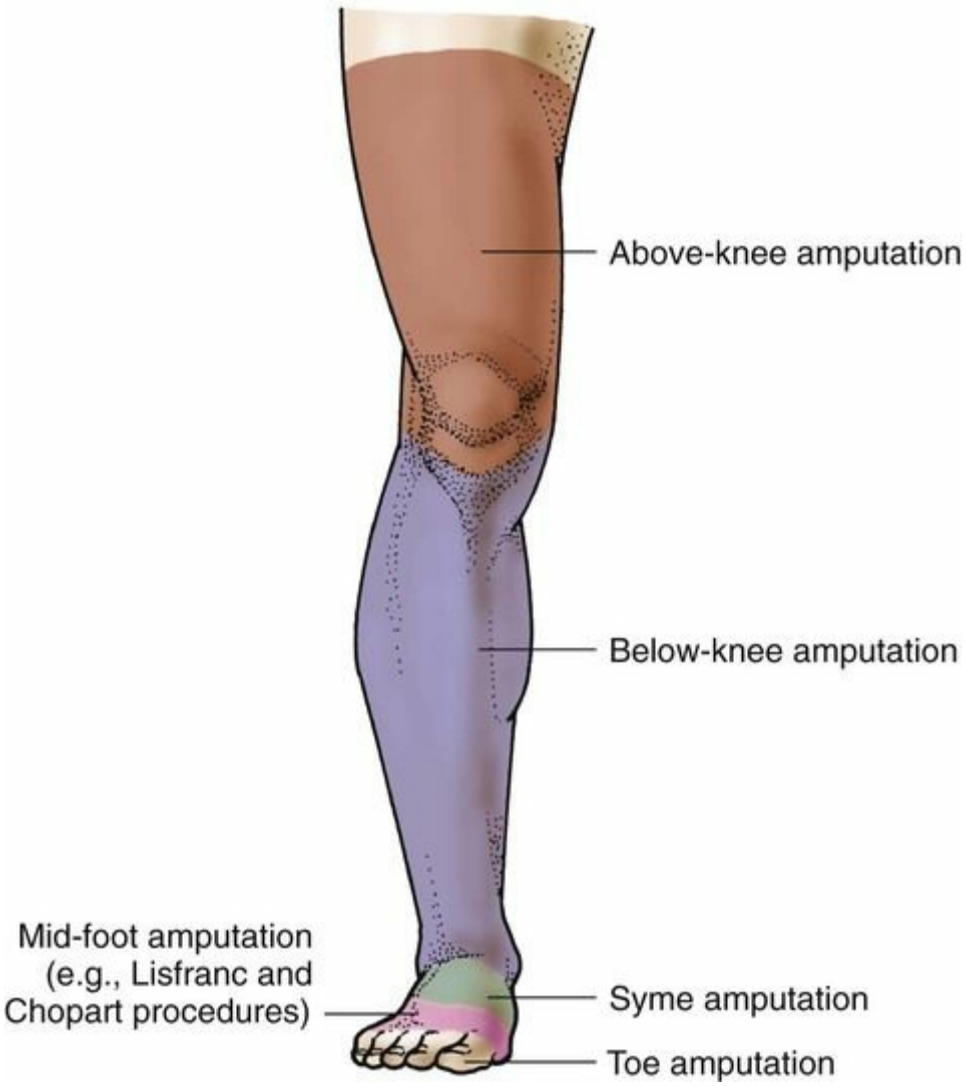

FIG. 51-12 Common levels of lower extremity amputation.

The loss of any or all of the small toes presents a minor disability. Loss of the great toe is significant because it affects balance, gait, and "push off" ability during walking. Midfoot amputations and the Syme amputation are common procedures for peripheral vascular disease. In the Syme amputation, most of the foot is removed but the ankle remains. The advantage of this surgery over traditional amputations below the knee is that weight bearing can occur without the use of a prosthesis and with reduced pain.

An intense effort is made to preserve knee joints with below-the-knee amputation (BKA). When the cause for the amputation extends beyond the knee, above-knee or higher amputations are performed. Hip disarticulation, or removal of the hip joint, and hemipelvectomy (removal of half of the pelvis with the leg) are more common in younger patients than in older ones who cannot easily handle the cumbersome prostheses required for ambulation. The higher the level of amputation, the more energy is required for mobility. These higher-level procedures are

typically done for cancer of the bone, osteomyelitis, or trauma as a last resort.

An amputation of any part of the upper extremity is generally more incapacitating than one of the leg. The arms and hands are necessary for ADLs such as feeding, bathing, dressing, and driving a car. In the upper extremity, as much length as possible is saved to maintain function. Early replacement with a prosthetic device is vital for the patient with this type of amputation.

Cultural Considerations

Patient-Centered Care QSEN

The incidence of lower extremity amputations is greater in black and Hispanic populations because the incidence of major diseases leading to amputation, such as diabetes and arteriosclerosis, is greater in these populations (Lowe & Tariman, 2008). Limited access to health care or lack of health insurance for these minority groups may also play a major role in limb loss. Language barriers may also be an obstacle to seeking health care providers.

Complications of Amputation

The most common complications of elective or traumatic amputations are:

- Hemorrhage
- Infection
- Phantom limb pain
- Neuroma
- Flexion contractures

When a person loses part or all of an extremity either by surgery or by trauma, major blood vessels are severed, which causes *bleeding*. If the bleeding is uncontrolled, the patient is at risk for hypovolemic shock and possibly death.

As with any surgical procedure or trauma, infection can occur in the wound or the bone (osteomyelitis). The older adult who is malnourished and confused is at the greatest risk because excreta may soil the wound or he or she may remove the dressing and pick at the incision. Preventing infection is a major emphasis in hospitals and other health care settings.

Pain is a frequent complication of amputation. Sensation is felt in the amputated part immediately after surgery and usually diminishes over time. When this sensation persists and is unpleasant or painful, it is

referred to as **phantom limb pain (PLP)**. PLP is more common in patients who had chronic limb pain before surgery and less common in those who have traumatic amputations. The patient reports pain in the removed body part shortly after surgery, usually after an above-the-knee amputation (AKA). The pain is often described as intense burning, crushing, or cramping. Some patients report that the removed part is in a distorted, uncomfortable position. They experience numbness and tingling, referred to as *phantom limb sensation,* as well as pain. Others state that the most distal area of the removed part feels as if it is retracted into the residual limb end. For most patients, the pain is triggered by touching the residual limb or by temperature or barometric pressure changes, concurrent illness, fatigue, anxiety, or stress. Routine activities such as urination can trigger the pain. If pain is long-standing, especially if it existed before the amputation, any stimulus can cause it, including touching any part of the body.

Neuroma—a sensitive tumor consisting of damaged nerve cells—forms most often in amputations of the upper extremity but can occur anywhere. The patient may or may not have pain. It is diagnosed by sonography and can be treated either surgically or nonsurgically. Surgery to remove the neuroma may be performed, but it often regrows and is more painful than before the surgery. Nonsurgical modalities include peripheral nerve blocks, steroid injections, and cognitive therapies such as hypnosis.

Flexion contractures of the hip or knee are seen in patients with amputations of the lower extremity. This complication must be avoided so that the patient can ambulate with a prosthetic device. Proper positioning and active range-of-motion exercises help prevent this complication.

Health Promotion and Maintenance

The typical patient undergoing elective amputation is a middle-aged or older man with diabetes and a lengthy history of smoking. He most likely has not cared for his feet properly, which has resulted in a nonhealing, infected foot ulcer and possibly gangrene. Therefore adherence to the disease management plan may help prevent the need for later amputation. Lifestyle habits like maintaining a healthy weight, regular exercise, and avoiding smoking can help prevent chronic diseases like diabetes and poor blood circulation.

The second largest group who have amputations comprise young men who have motorcycle or other vehicular crashes or who are injured by

industrial equipment or by combat or accidents in war. These men may either experience a traumatic amputation or undergo a surgical amputation because of a severe crushing injury and massive soft-tissue damage. Teach young male adults the importance of taking safety precautions to prevent injury at work and to avoid speeding or driving while drinking alcohol. An increasing number of young women also tend to speed and drive while drinking, which endangers themselves and others around them.

❖ Patient-Centered Collaborative Care

◆ Assessment

Physical Assessment/Clinical Manifestations.

Monitor neurovascular status in the affected extremity that will be amputated. When the patient has peripheral vascular disease, check circulation in both legs. Assess skin color, temperature, sensation, and pulses in both affected and unaffected extremities. Capillary refill can be difficult to determine in the older adult related to thickened and opaque nails. In this situation, the skin near the nail bed can be used (see Chart 51-3). Capillary refill may not be as reliable as other indicators. Observe and document any discoloration of the skin, edema, ulcerations, presence of necrosis, and hair distribution on the lower extremities.

Psychosocial Assessment.

People react differently to the loss of a body part. Be aware that an amputation of only a portion of one finger, especially the thumb, can be traumatic to the patient. The thumb is needed for hand activities. Therefore the loss must not be underestimated. Patients undergoing amputation face a complete, permanent loss. Evaluate their psychological preparation for a planned amputation, and expect them to go through the grieving process. Adjusting to a traumatic, unexpected amputation is often more difficult than accepting a planned one. The young patient may be bitter, hostile, and depressed. In addition to loss of a body part, the patient may lose a job, the ability to participate in favorite recreational activities, or a social relationship if other people cannot accept the body change.

The patient has an altered self-concept. The physical alteration that results from an amputation affects body image and self-esteem. For example, a patient may think that an intimate relationship with a partner is no longer possible. An older adult may feel a loss of independence.

Assess the patient's feelings about himself or herself to identify areas in which he or she needs emotional support. Consult with the certified hospital chaplain, other spiritual leader, or hospital social worker if the patient is hospitalized. Counseling resources are also available in the community.

Attempt to determine the patient's willingness and motivation to withstand prolonged rehabilitation after the amputation. Asking questions about how he or she has dealt with previous life crises can provide clues. Adjustment to the amputation and rehabilitation is less difficult if the patient is willing to make needed changes.

In addition to assessing the patient's psychosocial status, assess the family's reaction to the surgery or trauma. Their response usually correlates directly with the patient's progress during recovery and rehabilitation. Expect the family to grieve for the loss, and allow them time to adjust to the change.

Assess the patient's and family's coping abilities, and help them identify personal strengths and weaknesses. Assess the patient's religious, spiritual, and cultural beliefs. Certain groups require that the amputated body part be stored for later burial with the rest of the body or be buried immediately. Other cultural customs and rituals may apply, depending on the group with which the patient associates.

Diagnostic Assessment.

The surgeon determines which tests are performed to assess for viability of the limb based on blood flow. A large number of noninvasive techniques are available for this evaluation. For complete accuracy, the health care provider does not rely on any single test.

One procedure is measurement of segmental limb blood pressures, which can also be used by the nurse at the bedside. In this test, an **ankle-brachial index (ABI)** is calculated by dividing ankle systolic pressure by brachial systolic pressure. A normal ABI is 0.9 or higher.

Blood flow in an extremity can also be assessed by other noninvasive tests, including Doppler ultrasonography or laser Doppler flowmetry and transcutaneous oxygen pressure ($TcPO_2$). The ultrasonography and laser Doppler measure the speed of blood flow in the limb. The $TcPO_2$ measures oxygen pressure to indicate blood flow in the limb and has proved reliable for predicting healing.

Interventions

A traumatic amputation requires rapid emergency care to possibly save

the severed body part for reattachment and to prevent hemorrhage.

Emergency Care: Traumatic Amputation.

For a person who has a traumatic amputation in the community, first call 911. Assess the patient for airway or breathing problems. Examine the amputation site, and apply direct pressure with layers of dry gauze or other cloth, using clean gloves if available. Many nurses carry gloves and first aid kits for this type of emergency. Elevate the extremity above the patient's heart to decrease the bleeding. Do not remove the dressing to prevent dislodging the clot.

The fingers are the most likely part to be amputated and replanted. The current recommendation for prehospital care is to wrap the completely severed finger in dry sterile gauze (if available) or a clean cloth. Put the finger in a watertight, sealed plastic bag. *Place the bag in ice water, never directly on ice, at 1 part ice and 3 parts water*. Avoid contact between the finger and the water to prevent tissue damage. Do not remove any semidetached parts of the digit. Be sure that the part goes with the patient to the hospital.

Collaborative Care for the Patient with an Amputation.

Patient care depends on the type and location of the amputation. For example, an above-the-knee amputation (AKA) has the potential for more postoperative complications than does a partial foot amputation. Regardless of where the amputation occurs, collaborate with the rehabilitation therapists to improve ambulation and/or enable the patient to be independent in ADLs. For many amputations, prostheses can be used to substitute for the missing body part.

Patients undergoing lower extremity amputation today are not usually confined to a wheelchair. Advancements in the design of prosthetics have enabled them to become independent. Therefore complications from extended bedrest are not common, even for older adults.

Assessing Tissue Perfusion and Managing Pain.

The nurse's primary focus is to monitor for signs indicating that there is sufficient tissue perfusion and no hemorrhage. The skin flap at the end of the residual (remaining) limb should be pink in a light-skinned person and not discolored (lighter or darker than other skin pigmentation) in a dark-skinned patient. The area should be warm but not hot. Assess the closest proximal pulse for presence and strength, and compare it with that in the other extremity. If the patient has bilateral vascular disease, however, comparison of limbs may not be an accurate way of measuring blood

flow. Use a Doppler device to determine if the affected side is being perfused.

All patients experience pain as a result of either a traumatic or surgical (elective) amputation. Some patients also report pain in the missing body part (PLP). Be sure to determine which type the patient has, because they are managed very differently.

Nursing Safety Priority QSEN

Action Alert

If the patient reports PLP, recognize that the pain is real and should be managed promptly and completely! It is not therapeutic to remind the patient that the limb cannot be hurting because it is missing. To prevent increased pain, handle the residual limb carefully when assessing the site or changing the dressing.

Opioid analgesics are not as effective for PLP as they are for residual limb pain. IV infusions of calcitonin (Miacalcin, Calcimar) during the week after amputation can reduce phantom limb pain. The health care provider prescribes other drugs on the basis of the type of PLP the patient experiences. For instance, beta-blocking agents such as propranolol (Inderal, Apo-Propranolol, Detensol) are used for constant, dull, burning pain. Antiepileptic drugs such as pregabalin (Lyrica) and gabapentin (Neurontin) may be used for knifelike or sharp burning pain. Antispasmodics such as baclofen (Lioresal) may be prescribed for muscle spasms or cramping. Some patients improve with antidepressant drugs.

Other pain management modalities are described in Chapter 3. Incorporate them into the plan of care if agreeable with the patient by collaborating with specialists who are trained to perform them. For example, physical therapists often use massage, heat, transcutaneous electrical nerve stimulation (TENS), and ultrasound therapy for pain control. Consult with the certified hospital chaplain or social worker to provide emotional support. A psychologist may be needed to provide psychotherapy.

NCLEX Examination Challenge

Psychosocial Integrity

A client who had an elective above-the-knee amputation (AKA)

reports pain in the foot that was amputated. What is the nurse's best response to the client's pain?
A "The pain will go away in a few days or so."
B "That's phantom limb pain and every amputee has that."
C "On a scale of 0 to 10, how would you rate your pain?"
D "The pain is not real, so we don't treat it."

Preventing Infection.

The surgeon typically prescribes a broad-spectrum prophylactic antibiotic immediately before elective surgery to prevent infection. These may be continued for patients with *traumatic* amputations or for those who have open wounds on the residual limb. The initial pressure dressing and drains are usually removed by the surgeon 36 to 48 hours after surgery. Inspect the incision or wound for signs of infection. Record the appearance, amount, and odor of drainage, if present. The surgeon may want the incision open to air until staples or sutures are removed or may want the residual limb to have a continuous soft or rigid dressing made of fiberglass. A soft dressing is secured by an elastic bandage wrapped firmly around the residual limb.

Promoting Mobility and Preparing for Prosthesis.

Collaborate with the physical therapist to begin exercises as soon as possible after surgery. If the amputation is planned, the therapist may work with the patient before surgery to start muscle-strengthening exercises and evaluate the need for ambulatory aids, such as crutches. If the patient can practice with these devices before surgery, learning how to ambulate after surgery is much easier.

For patients with AKAs or BKAs, teach range-of-motion (ROM) exercises for prevention of flexion contractures, particularly of the hip and knee. A trapeze and an overhead frame aid in strengthening the arms and allow the patient to move independently in bed. Teach the patient how to perform range-of-motion exercises. Be sure to turn the patient every 2 hours, or teach the patient to turn independently. Move the patient slowly to prevent muscle spasms (Pullen, 2010).

A firm mattress is essential for preventing contractures with a leg amputation. Assist the patient into a prone position every 3 to 4 hours for 20- to 30-minute periods if tolerated and not contraindicated. This position may be uncomfortable initially but helps prevent hip flexion contractures. Instruct the patient to pull the residual limb close to the other leg and contract the gluteal muscles of the buttocks for muscle

strengthening. After staples are removed, the physical therapist may begin resistive exercises, which should also be done at home.

For above- and below-the-knee amputations, teach the patient how to push the residual limb down toward the bed while supporting it on a soft pillow at first. Then instruct him or her to continue this activity using a firmer pillow and then progress to a harder surface. This activity helps prepare the residual limb for prosthesis and reduces the incidence of phantom limb pain and sensation (Pullen, 2010).

Elevation of a lower-leg residual limb on a pillow while the patient is in a supine position is controversial. Some practitioners advocate avoiding this practice at all times because it promotes hip or knee flexion contracture. Others allow elevation for the first 24 to 48 hours to reduce swelling and subsequent discomfort. Inspect the residual limb daily to ensure that it lies completely flat on the bed.

Before an elective amputation, the patient often sees a certified prosthetist-orthotist (CPO) so that planning can begin for the postoperative period. Arrangements for replacing an arm part are especially important so that the patient can achieve self-management. Some patients are fitted with a temporary prosthesis at the time of surgery. Others, particularly older patients with vascular disease, are fitted after the residual limb has healed.

The patient being fitted for a leg prosthesis should bring a sturdy pair of shoes to the fitting. The prosthesis will be adjusted to that heel height.

Several devices help shape and shrink the residual limb in preparation for the prosthesis. Rigid, removable dressings are preferred because they decrease edema, protect and shape the limb, and allow easy access to the wound for inspection. The Jobst air splint, a plastic inflatable device, is sometimes used for this purpose. One of its disadvantages is air leakage and loss of compression. Wrapping with elastic bandages can also be effective in reducing edema, shrinking the limb, and holding the wound dressing in place.

For wrapping to be effective, reapply the bandages every 4 to 6 hours or more often if they become loose. *Figure-eight wrapping prevents restriction of blood flow. Decrease the tightness of the bandages while wrapping in a distal-to-proximal direction.* After wrapping, anchor the bandages to the highest joint, such as above the knee for BKAs (Fig. 51-13).

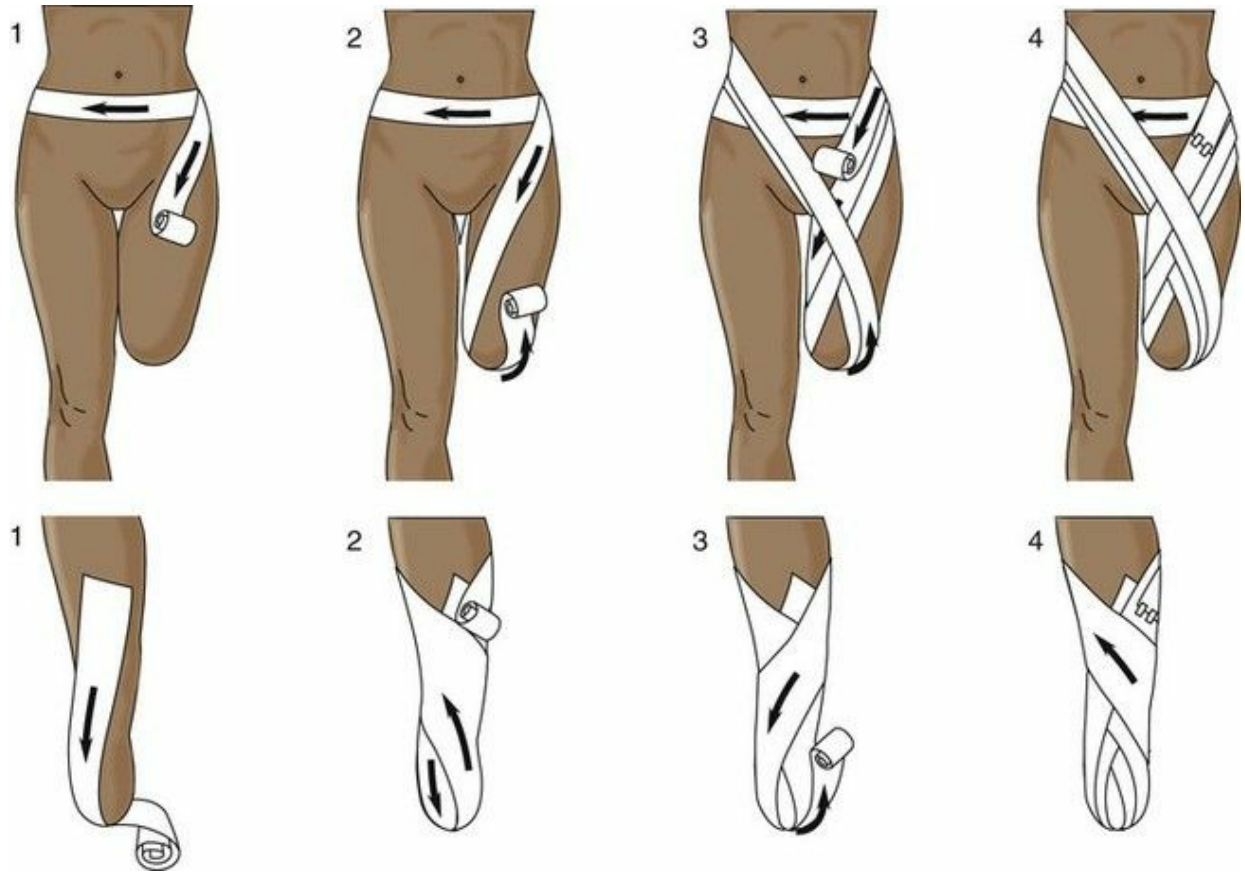

FIG. 51-13 A common method of wrapping an amputation stump. *Top,* Wrapping for above-knee amputation. *Bottom,* Wrapping for below-knee amputation.

The design of and materials for prostheses have improved dramatically over the years. Computer-assisted design and manufacturing (CAD-CAM) is used for a custom fit. One of the most important developments in lower extremity prosthetics is the ankle-foot prosthesis, such as the Flex-Foot for more active amputees.

Promoting Body Image and Lifestyle Adaptation.

The patient often experiences feelings of inadequacy as a result of losing a body part, especially the older adult who was in poor health before surgery and men who are often the main providers for their families. If possible, arrange for him or her to meet with a rehabilitated amputee who is about the same age as the patient.

Use of the word *stump* for referring to the remaining portion of the limb (residual limb) continues to be controversial. Patients have reported feeling as if they were part of a tree when the term was used. However, some rehabilitation specialists who routinely work with amputees believe the term is appropriate because it forces the patient to realize what has happened and promotes adjustment to the amputation. *Assess the patient to determine what term he or she prefers.*

Assess the patient's verbal and nonverbal references to the affected area. Some patients behave euphorically (extremely happy) and seem to have accepted the loss. *Do not jump to the conclusion that acceptance has occurred*. Ask the patient to describe his or her feelings about changes in body image and self-esteem. He or she may verbalize acceptance but refuse to look at the area during a dressing change. This inconsistent behavior is not unusual and should be documented and shared with other health care team members.

A patient who seems to adjust to the amputation during hospitalization may realize that it is difficult to cope with the loss after discharge from the hospital. Teach the patient and family about available resources and support from organizations such as the Amputee Coalition of America (ACA) (www.amputee-coalition.org) and the National Amputation Foundation (NAF) (www.nationalamputation.org). The NAF was originally started for veterans but has since expanded to offer services to civilians.

With advancements in prostheses and surgical techniques, most patients can return to their jobs and other activities. Professional athletes who use prostheses are often quite successful in sports. Patients with amputations ski, hike, golf, bowl, and participate in other physically demanding activities. Many amputees participate actively in organized and recreational sports.

If a job or career change is necessary, collaborate with a social worker or vocational rehabilitation specialist to evaluate the patient's skills. A supportive family or significant other is important for the adjustment to this change. The patient may also think that an intimate relationship is no longer possible because of physical changes. Discuss sexuality issues with the patient and his or her partner as needed. Professional assistance from a sex therapist, intimacy coach, or psychologist may be needed.

Help the patient and family set realistic desired outcomes and take one day at a time. Help them recognize personal strengths. If the desired outcomes are not realistic, frustration and disappointment may decrease motivation during rehabilitation. Basic principles of rehabilitation are discussed in Chapter 6.

Clinical Judgment Challenge

Patient-Centered Care; Teamwork and Collaboration; Informatics QSEN

A 45-year-old man attempted to remove excess grass from his electric

lawn mower blades while the mower continued to run. As a result, he severed part of his right hand. The amputated hand parts are mangled and cannot be salvaged. His wife called 911, and he was admitted to the emergency department (ED). He rates his pain as a 9 on a 0-to-10 pain intensity scale on admission.

1. As his nurse, what is your priority action when assessing this patient?
2. What other assessments will you perform and document in the electronic medical record (EMR)?
3. A hand surgeon evaluates the patient and finds that he will require surgery to débride and close the wound. What preoperative teaching will the patient require?
4. His wife is very concerned that he will lose his job if he cannot return to work soon. What is your best response at this time?
5. With what members of the health care team will you consult and collaborate?

Community-Based Care

The patient is discharged directly to home or to a skilled facility or rehabilitation facility, depending on the extent of the amputation. When rehabilitation is not feasible as in the debilitated or demented older adult, he or she may be discharged to a long-term care facility. Coordinate this transfer with the case manager or discharge planner to ensure continuity of care.

At home, the patient with a leg amputation needs to have enough room to use a wheelchair if the prosthesis is not yet available. He or she must be able to use toileting facilities and have access to areas necessary for self-management, such as the kitchen. Structural home modifications may be required before the patient goes home.

After the sutures or staples are removed, the patient begins residual limb care. A home care nurse may be needed to teach the patient and/or family how to care for the limb and the prosthesis if it is available (Chart 51-7). The limb should be rewrapped 3 times a day with an elastic bandage applied in a figure-eight manner (see Fig. 51-13). For many patients, a shrinker stocking or sock is easier to apply. After the limb is healed, it is cleaned each day with the rest of the body during bathing with soap and water. Teach the patient and/or family to inspect it every day for signs of inflammation or skin breakdown.

Chart 51-7 Home Care Assessment

The Patient with a Lower Extremity Amputation in the Home

- Assess the residual limb for:
  - Adequate circulation
  - Infection
  - Healing
  - Flexion contracture
  - Dressing/elastic wrap
- Assess the patient's ability to perform ADLs in the home.
- Evaluate the patient's ability to use ambulatory aids and to care for the prosthetic device (if available).
- Assess the patient's nutritional status.
- Assess the patient's ability to cope with body image change.

Nursing Safety Priority QSEN

Action Alert

Collaborate with the prosthetist to teach the patient about prosthesis care after amputation to ensure its reliability and proper function. These devices are custom made, taking into account the patient's level of amputation, lifestyle, and occupation. Proper teaching regarding correct cleansing of the socket and inserts, wearing the correct liners, assessing shoe wear, and a schedule of follow-up care is essential before discharge. This information may need to be reviewed by the home care nurse.

Complex Regional Pain Syndrome

Pathophysiology

Complex regional pain syndrome (CRPS), formerly called **reflex sympathetic dystrophy (RSD)**, is a poorly understood dysfunction of the central and peripheral nervous systems that leads to severe, chronic pain. Genetic factors may play a role in the development of this devastating complication. CRPS most often results from fractures or other traumatic musculoskeletal injury and commonly occurs in the feet and hands. In some cases, specific nerve injuries are present, but in others, no injury can be identified. A triad of clinical manifestations is present, including abnormalities of the autonomic nervous system (changes in color, temperature, and sensitivity of skin over the affected area, excessive sweating, edema), motor symptoms (paresis, muscle spasms, loss of function), and sensory perception symptoms (intense burning pain that becomes intractable [unrelenting]).

Over time, spotty and diffuse osteoporosis can be seen on x-ray examination. Timing of diagnosis is important because the syndrome is more difficult to treat when diagnosed in the later stages.

Patient-Centered Collaborative Care

The first priority of management is pain relief. Little research has been done to demonstrate the best practices for caring for a patient with CRPS (Hsu, 2009). Therefore a combination of interventions is used. Nurses play an important role in patient management, which includes drug therapy and a variety of nonpharmacologic modalities. Many classes of drugs may be used to manage the intense pain. These include topical analgesics, antiepileptic drugs, antidepressants, corticosteroids, bisphosphonates, and analgesics. Chapter 3 discusses pain management in detail.

In collaboration with the physical and occupational therapists, assist in maintaining adequate ROM and function. The skin of a patient with CRPS tends to alternate between warm, swollen, and red to cool, clammy, and bluish. Skin care needs to be gentle with minimal stimulation.

Peripheral or spinal cord neurostimulation using an external or internal implanted device delivers electrical pulses to block pain from getting to the brain where pain is perceived. The external or acupuncture method requires weekly sessions or a short-term continuous trial before the device is surgically implanted. Complications of implantable neurostimulators include spinal cord damage from hematoma or edema formation or other neurologic dysfunction.

A chemical sympathetic nerve block may be used. This procedure can be done by an IV infusion of phentolamine (Regitine), a drug that blocks sympathetic receptors, or by injecting an anesthetic agent next to the spine to block sympathetic nerves.

Minimally invasive surgical **sympathectomy**, or cutting of the sympathetic nerve branches via endoscopy through a small axillary incision, may be required. Topical skin adhesive is used to close the very small incision. The patient is discharged to home a few hours later with a follow-up examination the next day with the health care provider. Usual activities can resume a few days later.

Assist the patient in coping with CRPS because it often has a profound psychological effect. A referral for psychological counseling or psychotherapy may be indicated. The Reflex Sympathetic Dystrophy Syndrome Association (RSDSA) (www.rsds.org) and National Pain Association (www.nationalpainassociation.org) are available to help patients and their families organize or locate support groups and other resources.

NCLEX Examination Challenge

Physiological Integrity

The nurse is concerned that a client who had an ankle open reduction and internal fixation is at risk for complex regional pain syndrome. What assessment findings at the affected area are common when a client has this complication? **Select all that apply.**

A Burning pain
B Increase in sweating
C Muscle weakness
D Absent pedal pulse
E Edema

Knee Injuries

In addition to the bone and muscle problems already discussed, trauma can cause cartilage, ligament, and tendon injury. Many musculoskeletal injuries are the result of playing sports (professional and recreational) or doing other strenuous physical activities. The popularity of all-terrain vehicles (ATVs) and skateboarding has increased injuries in younger patients. Sports injuries have become so common that large metropolitan hospitals have sports medicine clinics and physicians who specialize in this field.

The principles of injury to one part of the body are similar to those of other sports injuries and accidents. For example, a tendon rupture in a knee is cared for in the same manner as a tendon rupture in the wrist. Chart 51-8 lists general emergency measures for sports-related injuries. All patients require frequent neurovascular monitoring.

Chart 51-8 Best Practice for Patient Safety & Quality Care QSEN

Emergency Care of Patients with Sports-Related Injuries

- Do not move the victim until spinal cord injury is ascertained (see Chapter 43 for assessment of spinal cord injury).
- Rest the injured part; immobilize the joint above and below the injury by applying a splint if needed.
- Apply ice intermittently for the first 24 to 48 hours (heat may be used thereafter).
- Elevate the affected limb to decrease swelling.
- Use compression for the first 24 to 48 hours (e.g., elastic wrap).
- Always assume the area is fractured until x-ray studies are done.
- Assess neurovascular status in the area distal to the injury.

Because the knee is most often injured, it is discussed as a typical example of other areas of the body. Trauma to the knee results in **internal derangement**, a broad term for disturbances of an injured knee joint. When surgery is required to resolve the problem, most surgeons prefer to perform the procedure through an arthroscope when possible. A description of arthroscopy is presented in Chapter 49.

Patellofemoral pain syndrome (PFPS) is the most common diagnosis in patients who have knee pain. It occurs most often in people who are runners or who overuse their knee joints. For that reason, it is sometimes referred to as "runner's knee." Patients with this problem describe pain

as being behind or around their patella (knee cap) in one or both knees. Swelling is not common although stiffness may be present, especially when the knee is flexed. Management usually involves rest, physical therapy, bracing or splinting, and mild analgesics. For patients who have pain lasting for more than 12 months, arthroscopic surgery is performed.

The patient with a **torn meniscus** (medial or lateral) typically has pain, swelling, and tenderness in the knee. A clicking or snapping sound can often be heard when the knee is moved. For a locked knee resulting from the tear, the treatment may be manipulation followed by splinting or casting for 3 to 6 weeks. If the problem recurs, a partial or total **meniscectomy** is performed through an arthroscope as a same-day surgical procedure. As described in Chapter 49, an arthroscope is a metal tubular instrument used for examination or surgery of joints. One or more small incisions (less than $\frac{1}{4}$-inch [0.6-cm] long) are made in the knee for insertion of the arthroscope. The surgeon threads a cutting device through the arthroscope for removal of the torn cartilage while the knee is irrigated. The surgeon may use a laser during the procedure, depending on the type and severity of the injury. A bulky pressure dressing is applied after the procedure, and the affected leg is wrapped in elastic bandages.

As for any postoperative patient, check the surgical dressing for bleeding and monitor vital signs after the patient is admitted to the same-day surgical unit. Perform neurovascular checks as outlined in Chart 51-3, usually every hour for the first few hours and then every 4 hours. Teach the patient and family what signs and symptoms to watch for after surgery and when to notify the health care provider.

The patient begins exercises immediately after surgery to strengthen the leg, prevent venous thromboembolism, and reduce swelling. Quadriceps setting, in which the patient straightens the leg while pushing the knee against the bed, is done in sets of 10 or more. Straight-leg raises are also performed. ROM exercises are usually not started for several days.

To prevent bending the affected knee, the health care provider often requests a knee immobilizer, such as the one shown in Fig. 51-14. Elevate the leg on one or two pillows according to the physician's preference, and apply ice to reduce postoperative swelling. Full weight bearing is restricted for several weeks, depending on the amount of cartilage removed. The patient is usually discharged from the hospital with crutches in less than 23 hours.

FIG. 51-14 A knee immobilizer.

The cruciate and collateral ligaments in the knee are predisposed to injury, often from sports or vehicular crashes. The most common ligament injury is an *anterior cruciate ligament (ACL) tear*. Athletes often get these injuries during skiing, skating, or gymnastics. Women have ACL tears more often than men, possibly related to hormonal influences, biomechanical factors, and anatomic differences. Proper athletic shoes and learning how to land when jumping can help prevent this injury.

When the ACL is torn, the patient feels a snap and the knee gives way because of ACL laxity. Within hours, the knee is swollen, stiff, and painful. Examination by the health care provider shows positive ligament laxity. The diagnosis of an ACL tear is best confirmed by MRI (Pagana & Pagana, 2014).

Treatment may be nonsurgical or surgical, depending on the severity of the injury and the activity of the patient. Exercises, bracing, and limits on activities while the ligament heals may be sufficient. If medical management is not effective or the tear is severe, surgery may be needed.

The surgeon repairs the tear by reattaching the torn portions of the ligament through arthroscopy. The leg is placed in a brace or

immobilizer. If the ligament cannot be repaired, reconstructive surgery may be performed with autologous grafts. A ligament from another part of the body is used to replace the torn knee ligament. Another option is artificial knee implants such as the GORE-TEX ligament.

Complete healing of knee ligaments after surgery can take 6 to 9 months or longer. These patients may use a continuous passive motion (CPM) machine at home. Teach the patient how to use and care for the machine. CPM use is discussed in Chapter 16 with the postoperative care of the patient who has had a total knee replacement.

Carpal Tunnel Syndrome

Pathophysiology

Carpal tunnel syndrome (CTS) is a common condition in which the median nerve in the wrist becomes compressed, causing pain and numbness. The carpal tunnel is a rigid canal that lies between the carpal bones and a fibrous tissue sheet. A group of tendons surround the synovium and share space with the median nerve in the carpal tunnel. When the synovium becomes swollen or thickened, this nerve is compressed.

The median nerve supplies motor, sensory, and autonomic function for the first three fingers of the hand and the palmar aspect of the fourth (ring) finger. Because the median nerve is close to other structures, wrist flexion causes nerve impingement and extension causes increased pressure in the lower portion of the carpal tunnel.

CTS usually presents as a chronic problem. Acute cases are rare. Excessive hand exercise, edema or hemorrhage into the carpal tunnel, or thrombosis of the median artery can lead to acute CTS. *Patients with hand burns or a Colles' fracture of the wrist are particularly at risk for this problem.* In most cases, the cause may not result in nerve deficit for years.

CTS is also a common complication of certain metabolic and connective tissue diseases. For example, **synovitis** (inflammation of the synovium) occurs in patients with rheumatoid arthritis (RA). The hypertrophied synovium compresses the median nerve. In other chronic disorders such as diabetes mellitus, inadequate blood supply can cause median nerve neuropathy or dysfunction, resulting in CTS.

CTS is the most common type of **repetitive stress injury (RSI)**. RSIs are the fastest growing type of occupational injury. People whose jobs require repetitive hand activities such as pinching or grasping during wrist flexion (e.g., factory workers, computer operators, jackhammer operators) are predisposed to CTS. It can also result from overuse in sports activities such as golf, tennis, or racquetball.

In a few cases, CTS may be a familial or congenital problem that manifests in adulthood. Space-occupying growths such as ganglia, tophi, and lipomas can also result in nerve compression.

Women, especially those older than 50 years, are much more likely than men to experience CTS, probably due to the higher prevalence of diseases such as RA in women. The problem usually affects the dominant hand but can occur in both hands simultaneously. CTS is beginning to be found in children and adolescents as a result of the increased use of computers and handheld devices.

Health Promotion and Maintenance

Most businesses recognize the hazards of repetitive motion as a primary cause of occupational injury and disability. Both men and women in the labor force are experiencing increasing numbers of RSIs. Occupational health nurses have played an important role in ergonomic assessments and in the development of ergonomically designed furniture and various aids to decrease CTS and other musculoskeletal injuries.

U.S federal and state legislation has been passed to ensure that all businesses, including health care organizations (HCOs), provide *ergonomically appropriate workstations* for their employees (Occupational Safety and Health Administration [OSHA]). The Joint Commission also requires that hospitals and other HCOs provide a safe work environment for all staff. In Canada, each province requires the work setting to have joint health and safety committees in which employees are actively involved in setting safety standards (Canadian Centre for Occupational Health and Safety). Chart 51-9 lists best practices for preventing CTS in the health care setting.

Chart 51-9 Best Practice for Patient Safety & Quality Care QSEN

Health Promotion Activities to Prevent Carpal Tunnel Syndrome

- Become familiar with federal and state laws regarding workplace requirements to prevent repetitive stress injuries such as carpal tunnel syndrome (CTS).
- When using equipment or computer workstations that can contribute to developing CTS, assess that they are ergonomically appropriate, including:
  - Specially designed wrist rest devices
  - Geometrically designed computer keyboards
  - Chair height that allows good posture
- Take regular short breaks away from activities that cause repetitive stress, such as working at computers.
- Stretch fingers and wrists frequently during work hours.
- Stay as relaxed as possible when using equipment that causes repetitive stress.

Patient-Centered Collaborative Care

Assessment

A medical diagnosis is often made based on the patient's history and report of hand pain and numbness and without further assessment. Ask about the nature, intensity, and location of the pain. Patients often state that the pain is worse at night as a result of flexion or direct pressure during sleep. The pain may radiate to the arm, shoulder and neck, or chest.

In addition to reports of numbness, patients with carpal tunnel syndrome (CTS) may also have **paresthesia** (painful tingling). *Sensory* changes usually occur weeks or months before *motor* manifestations.

The health care provider performs several tests for abnormal sensory findings. Phalen's wrist test, sometimes called **Phalen's maneuver**, produces paresthesia in the median nerve distribution (palmar side of the thumb, index and middle fingers, and half of the ring finger) within 60 seconds due to increased internal carpal pressure. The patient is asked to relax the wrist into flexion or to place the back of the hands together and flex both wrists at the same time. The Phalen's test is positive in most patients with CTS (Jarvis, 2016) (Fig. 51-15).

FIG. 51-15 Testing the patient for positive Phalen's sign (A) and Tinel's sign (B).

The same sensation can be created by tapping lightly over the area of the median nerve in the wrist (**Tinel's sign**). If the test is unsuccessful, a blood pressure cuff can be placed on the upper arm and inflated to the patient's systolic pressure (tourniquet). This often causes pain and tingling (Jarvis, 2016).

Motor changes in CTS begin with a weak pinch, clumsiness, and difficulty with fine movements. These changes progress to muscle weakness and wasting, which can impair self-management. If desired, test for pinching ability and ask the patient to perform a fine-movement task, such as threading a needle. Strenuous hand activity worsens the pain and numbness (McCance et al., 2014).

In addition to inspecting for muscle atrophy and task performance, observe the wrist for swelling. Gently palpate the area and note any

unusual findings. Autonomic changes may be evidenced by skin discoloration, nail changes (e.g., brittleness), and increased or decreased hand sweating.

Interventions

The health care provider uses conservative measures before surgical intervention. However, CTS can recur with either type of treatment. Management depends on the patient, but established best practices have not been determined (Uchiyama et al., 2010).

Nonsurgical Management.

Aggressive drug therapy and immobilization of the wrist are the major components of nonsurgical management. Teach the patient the importance of these modalities in the hope of preventing surgical intervention.

NSAIDs are the most commonly prescribed drugs for the relief of pain and inflammation, if present. In addition to or instead of systemic medications, the physician may inject corticosteroids directly into the carpal tunnel. If the patient responds to the injection, several additional weekly or monthly injections are given. Teach him or her to take NSAIDs with or after meals to reduce gastric irritation.

A splint or hand brace may be used to immobilize the wrist during the day, during the night, or both. Many patients experience temporary relief with these devices. The occupational therapist places the wrist in the neutral position or in slight extension.

Laser or ultrasound therapy may also be helpful. Some patients report fewer symptoms after beginning yoga or other exercise routine.

Surgical Management.

Surgery is necessary in about half of patients with CTS. Surgery can relieve the pressure on the median nerve by providing nerve decompression. Major surgical complications are rare after CTS surgery. In some cases, however, CTS recurs months to years after surgery.

The nurse in the physician's office or same-day surgical center reinforces the teaching provided by the surgeon regarding the nature of the surgery. Postoperative care is reviewed so the patient knows what to expect. Chapter 14 describes general preoperative care in detail.

Whatever the cause of nerve compression, the surgeon removes it either by cutting or by laser. The most common surgery is the endoscopic carpal tunnel release (ECTR). In this procedure, the surgeon makes a

very small incision (less than ½ inch [1.2 cm]) through which the endoscope is inserted. The surgeon then uses special instruments to free the trapped median nerve. Although ECTR is less invasive and costs less than the open procedure, the patient may have a longer period of postoperative pain and numbness compared with recovery from open carpal tunnel release (OCTR). A recent systematic review showed that surgical treatment seems to be more effective than conservative measures over the long term. However, there was no evidence that one type of procedure, open or endoscopic, was more effective than the other (Huisstede et al., 2010).

After surgery, monitor vital signs and check the dressing carefully for drainage and tightness. If ECTR has been performed, the dressing is very small. The surgeon may require that the patient's affected hand and arm be elevated above heart level for several days to reduce postoperative swelling. Check the neurovascular status of the fingers every hour during the immediate postoperative period, and encourage the patient to move them frequently. Offer pain medication, and assure him or her that a prescription for analgesics will be provided before discharge.

Hand movements, including lifting heavy objects, may be restricted for 4 to 6 weeks after surgery. The patient can expect weakness and discomfort for weeks or perhaps months. Teach him or her to report any changes in neurovascular status, including increased pain, to the surgeon's office immediately (Huisstede et al., 2010).

Remind the patient and family that the surgical procedure might not be a cure. For instance, synovitis may recur with rheumatoid arthritis and may recompress the median nerve. Multiple surgeries and other treatments are common with CTS.

The patient may need assistance with self-management activities during recovery. Ensure that assistance in the home is available before discharge; this is usually provided by the family or significant others.

Tendinopathy and Joint Dislocation

Other injuries can affect any synovial joint. The nursing management of each of these is similar to the collaborative care previously discussed for knee injuries. One of the most common injuries seen in general and sports medicine is Achilles tendon–related injuries (tendinopathy). *Rupture of the Achilles tendon* is common in adults who participate in strenuous sports or in women who wear high heels regularly. It can also occur after taking fluoroquinolone antibiotics, such as levofloxacin (Levaquin) and ciprofloxacin (Cipro) (Barry, 2010).

In the older adult, quadriceps tendon rupture may occur from a fall down several steps. Most cases of Achilles tendinopathy can be treated with RICE (see Chart 51-8):

- **R**est
- **I**ce
- **C**ompression
- **E**levation

Some evidence supports the use of NSAIDs, and changes in activity and shoes may be helpful (Chang et al., 2010). Ultrasound treatments may also be effective.

For severe damage and as a last resort, the tendon is surgically repaired and the leg is immobilized in a cast or brace for at least 6 to 8 weeks. If the tendon is beyond repair, a **tendon transplant** (also known as *tendon reconstruction*) may be performed. A tendon is removed from one part of the body and transplanted to the affected area, or a cadaver donor is used.

Dislocation of a joint occurs when the ends of two or more bones are moved away from each other. If the dislocation is not complete, the joint is partially dislocated, or **subluxed**. It can occur in any diarthrodial (synovial) joint but is most common in the shoulder, hip, knee, and fingers. This injury is usually the result of trauma but can be congenital or pathologic and can result from joint disease, such as arthritis.

The typical manifestations of dislocation are:

- Pain
- Decreased mobility
- Alteration in contour of the joint
- Deviation in length of the extremity
- Rotation of the extremity

The health care provider performs a closed reduction of the joint and moves the joint surfaces back into their normal anatomic position. The patient requires light anesthetic or moderate sedation. The joint is

immobilized by a cast, splint, brace, or immobilizer until healing occurs.

Recurrent dislocations are common in the knee and shoulder. For this problem, the joint may be fixed with wires or other device to prevent further displacement. A cast, splint, or traction is applied for 3 to 6 weeks.

Strains and Sprains

A **strain** is excessive stretching of a muscle or tendon when it is weak or unstable. Strains are sometimes referred to as *muscle pulls.* Falls, lifting a heavy item, and exercise often cause this injury.

Strains are classified according to their severity:

- A first-degree (mild) strain causes mild inflammation but little bleeding. Swelling, ecchymosis (bruising), and tenderness are usually present.
- A second-degree (moderate) strain involves tearing of the muscle or tendon fibers without complete disruption. Muscle function may be impaired.
- A third-degree (severe) strain involves a ruptured muscle or tendon with separation of muscle from muscle, tendon from muscle, or tendon from bone. Severe pain and disability result from severe strains.

Management usually involves cold and heat applications, exercise, and activity limitations. The health care provider may prescribe anti-inflammatory drugs to decrease inflammation and pain. Muscle relaxants may also be used. In third-degree strains, surgical repair of the ruptured muscle or tendon may be needed.

A **sprain** is excessive stretching of a ligament. Twisting motions from a fall or sports activity typically cause the injury. Sprains are also classified according to severity. Pain and swelling result from ligament injuries. The treatment for *mild (first-degree)* sprains includes RICE (rest, ice, compression, elevation) (see Chart 51-8).

Second-degree sprains require immobilization, such as elastic bandage and an air stirrup ankle brace or splint, and partial weight bearing while the tear heals. For severe ligament damage (*third-degree* sprain), immobilization for 4 to 6 weeks is necessary. Arthroscopic surgery may be done, particularly for chronic joint instability.

Rotator Cuff Injuries

The musculotendinous, or rotator, cuff of the shoulder functions to stabilize the head of the humerus in the glenoid cavity during shoulder abduction. Young adults usually sustain a tear of the cuff by substantial trauma, such as may occur during a fall, while throwing a ball, or with heavy lifting. Older adults tend to have small tears related to aging, repetitive motions, or falls, and the tears are usually painless.

The patient with a torn rotator cuff has shoulder pain and cannot easily abduct the arm at the shoulder. When the arm is abducted, he or she usually drops the arm because abduction cannot be maintained (drop arm test). Pain is more intense at night and with overhead activities. Partial-thickness tears are more painful that full-thickness tears, but full-thickness tears result in more weakness and loss of function. Muscle atrophy is commonly seen, and mobility is reduced. Diagnosis is confirmed with x-rays, MRI, ultrasonography, and/or CT scans.

The health care provider usually treats the patient with partial-thickness tears conservatively with NSAIDs, intermittent steroid injections, physical therapy, and activity limitations while the tear heals. Physical therapy treatments may include ultrasound, electrical stimulation, ice, and heat (Smith & Smith, 2010).

For patients who do not respond to conservative treatment in 3 to 6 months or for those who have a complete (full-thickness) tear, the surgeon repairs the cuff using mini-open or arthroscopic procedures. An interscalene nerve block may be used to extend analgesia for an open repair (Guarin, 2013). If a peripheral nerve block is used, remind the patient that the arm will feel numb and cannot be moved for up to 20 or more hours after surgery. Observe, report, and document complications of respiratory distress and neurovascular compromise.

After surgery the affected arm is usually immobilized for several weeks. Pendulum exercises are started on the third or fourth postoperative day and progress to active exercises in about 2 weeks. Patients then begin rehabilitation in the ambulatory care occupational therapy department. Teach them that they may not have full function for several months.

Nursing Concepts and Clinical Judgment Review

What might you NOTICE if the patient has impaired mobility and sensory perception as a result of acute musculoskeletal trauma?

- Extremity swelling, bleeding, bruising, shortening, malalignment,

and/or rotation
- Report of severe pain
- Break in skin integrity
- Report of decreased or unusual sensation in extremity
- Inability or decreased ability to move extremity
- Difficulty breathing (rib trauma)
- Severe kyphosis (compression fractures)

What should you INTERPRET and how should you RESPOND to a patient with impaired mobility and sensory perception as a result of acute musculoskeletal trauma?

Perform and interpret focused physical assessment findings, including:

- ABC (**a**irway, **b**reathing, **c**irculation) ability (first action!)
- Pain intensity and quality
- Vital signs
- Neurovascular assessment ("circ check")

Respond by:

- First, establishing ABCs if problem exists
- If skin is not intact, covering wound with dry, sterile dressing, if available, using clean cloth as an option; applying pressure to proximal pulse if patient is bleeding; for traumatic amputation, applying direct pressure to the residual body part
- Implementing measures to prevent hypovolemic shock if patient is bleeding, including having patient lie flat, keeping him or her warm, and elevating the bleeding part
- Splinting the extremity (in community setting) to prevent movement and further damage
- If in hospital setting, assisting health care provider in splinting
- Providing pain control interventions by drug therapy as soon as possible
- Providing emotional assurance for the patient by being present and comforting

On what should you REFLECT?

- Monitor the patient's response to pain control interventions.
- Think about what else you could do to prevent complications.
- Determine what health teaching will be needed, depending on the treatment that is provided (e.g., surgery, cast).

Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Collaborate with physical and occupational therapists for care of patients with extremity fractures to improve mobility and muscle strength. **Teamwork and Collaboration** QSEN
- Collaborate with the prosthetist, physical and occupational therapists, psychologist, and sex therapist or intimacy coach for care of patients with amputations to improve mobility, muscle strength, ADLs, and self-image. **Teamwork and Collaboration** QSEN

Health Promotion and Maintenance

- Teach people to avoid musculoskeletal injury by treating or preventing osteoporosis (see Chapter 50), being cautious when walking to prevent a fall, wearing supportive shoes, avoiding dangerous sports or activities, and decreasing time spent doing repetitive stress activities, such as using a computer keyboard.
- Several community organizations, such as the Amputee Coalition of America, are available to help patients and their families cope with the loss of a body part.
- Teach patients and their family members and significant others how to care for casts or traction at home.
- Reinforce teaching for ambulating with crutches, walkers, or canes.
- Provide special care for older adults with hip fractures, including preventing heel pressure ulcers and promoting early ambulation to prevent complications of immobility.
- Teach exercises to patients with leg amputation to prevent hip flexion contractures.

Psychosocial Integrity

- Be aware that patients with severe musculoskeletal trauma may have a prolonged hospitalization and recovery period.
- For patients with severe trauma or amputation, assess coping skills and encourage verbalization. **Patient-Centered Care** QSEN
- Recognize that the patient having an amputation may need to adjust to an altered lifestyle; however, new custom prosthetics improve mobility.

- Help the patient with an amputation or other musculoskeletal trauma and family to set realistic expected outcomes and take one day at a time.

Physiological Integrity

- Be aware that open fractures cause a higher risk for infection than do closed fractures; use strict aseptic technique when providing wound management.
- Assess the risk for and implement interventions to prevent complications of immobility in patients having musculoskeletal injury or surgery (e.g., pressure ulcers, venous thromboembolism [VTE]).
- Assess patients with fractures for complications, such as VTE, infection, and acute compartment syndrome.
- Recognize that fat embolism syndrome is different from pulmonary (blood clot) embolism as outlined in Chart 51-2.
- Provide emergency care of the patient with a fracture as described in Chart 51-4.
- Identify the patient at risk for acute compartment syndrome; loosen bandages, or request that the patient's cast be cut if neurovascular compromise is noted. **Evidence-Based Practice** QSEN
- As a priority, document neurovascular status frequently in patients with musculoskeletal injury, traction, or cast as described in Chart 51-3 and manage pain adequately. **Informatics** QSEN
- Provide evidence-based appropriate cast care, depending on the type of cast (plaster or synthetic); check for pressure necrosis under the cast by feeling for heat, assessing the patient's pain level, and smelling the cast for an unpleasant odor. **Evidence-Based Practice** QSEN
- Provide pin care for patients with skeletal traction or external fixation; assess for manifestations of infection at the pin sites.
- Provide postoperative care for the patient having a fracture repair, including promoting mobility and monitoring for complications of immobility.
- Provide care for patients having a vertebroplasty or kyphoplasty as described in Chart 51-6.
- Provide emergency care for a patient having a traumatic amputation in the community: Call 911, assess the patient for ABCs, apply direct pressure on the amputation site, and elevate the extremity above the patient's heart to decrease bleeding. For finger parts, wrap the amputated part with a clean cloth and place in a sealed bag, which is lowered into ice water. **Evidence-Based Practice** QSEN

- Observe for postoperative hemorrhage and infection in the patient having an amputation.
- Postoperatively, assess for and promptly manage phantom limb pain in the patient who has an amputation; collaborate with specialists to incorporate complementary and alternative therapies and drug therapy into the patient's plan of care.
- Provide emergency care for patients with a sports-related injury as outlined in Chart 51-8.
- Recall that carpal tunnel syndrome (CTS) is the most common type of repetitive stress injury (RSI) caused by certain occupations such as computer operators and factory workers.
- Many acute musculoskeletal injuries are initially treated by RICE: rest, ice, compression, and elevation.
- The priority for managing complex regional pain syndrome (CRPS) is prompt and effective pain relief. Consult with PT, OT, and the pharmacist/pain specialist to determine the most effective pain management plan based on the patient's and family's preferences, values, and beliefs. **Patient-Centered Care** QSEN

UNIT XIII

Problems of Digestion, Nutrition, and Elimination: Management of Patients with Problems of the Gastrointestinal System

OUTLINE

Concept Overview: Metabolism

The word *metabolism* means to change or transform. Humans transform the energy stored within food into the types of energy needed to make the body work. Thus maintaining homeostasis of metabolism involves balancing the concepts of nutrition and elimination—in this instance, bowel elimination (Giddens, 2013).

As shown in Fig. 1, nutrition is complex and involves ingesting all of the macronutrients and micronutrients needed for optimal cellular metabolism (Giddens, 2013). As humans, we ingest many types of foods that contain proteins, carbohydrates, fats, vitamins, and minerals. Once inside the GI tract, the processes of digestion break down food into its basic elements, which then are absorbed into the blood and delivered to cells. Through metabolism, cells convert these basic elements into chemical energy, mostly adenosine triphosphate (ATP). Different cells then use metabolism to further transform ATP into heat energy, mechanical energy, chemical energy, and electrical energy. The transformation of chemical energy into other types of energy within the human body is *irreversible.* It is lost from the body in the form of heat and work. Thus bringing food into the body on a daily basis is important in meeting the human needs of nutrition and metabolism.

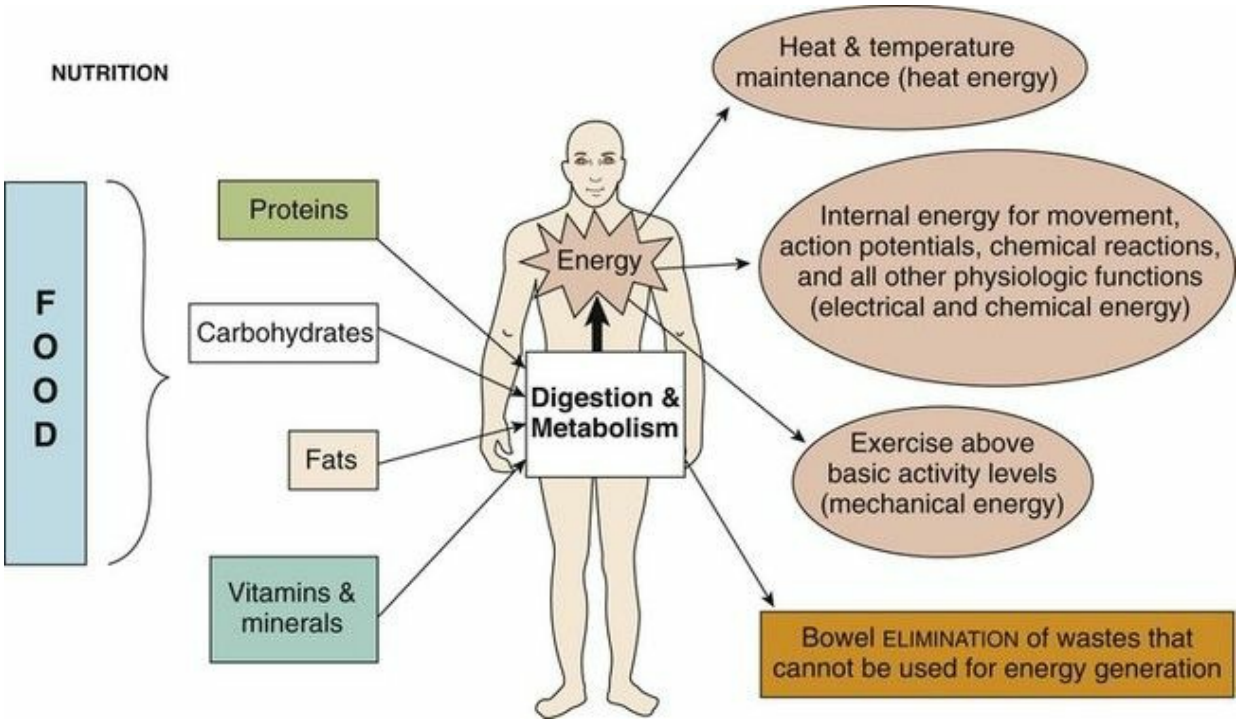

FIG. 1

Heat energy helps maintain the core body temperature at or near 98.6° F—the ideal temperature for important physiologic reactions. When environmental temperatures are low, more nutrition intake is needed to maintain body temperature. When environmental temperatures are high, less food is needed to maintain body temperature. Therefore, in general, more calories need to be consumed per day in the winter than in the summer.

Mechanical energy is used for cell and tissue movement, cell shape changes, and whole body movement. *Electrical energy* generates the action potentials that allow nerves to transmit impulses and muscles to contract. *Chemical energy* is used to drive every chemical reaction in the body. As long as it remains alive, the body continuously needs to change food into these different energies.

Bowel elimination is the excretion of waste products so that the body rids itself of those food components that cannot be absorbed into the blood and converted into energy, such as fiber and cellulose (Giddens, 2013). If these components remained in the GI tract, they would soon fill it to the point that no nutrients could be ingested.

Consider Fig. 1 as representing the entire nutrition, metabolism, and bowel elimination of a person throughout his or her lifetime. The energy ingested in the form of food exactly matches the energy transformed by metabolism and is used for all the different types of internal and external "work" of the body. When this ideal situation exists, the person always has the right amount of nutrients and neither stores excess nutrients nor

breaks down body tissues to use for energy.

In Fig. 2, the person is not ingesting enough nutrients to meet metabolic energy needs. As a result, the different types of work are less efficient and the person metabolizes his or her own body tissues to provide needed energy. If this situation continues, it will lead to death.

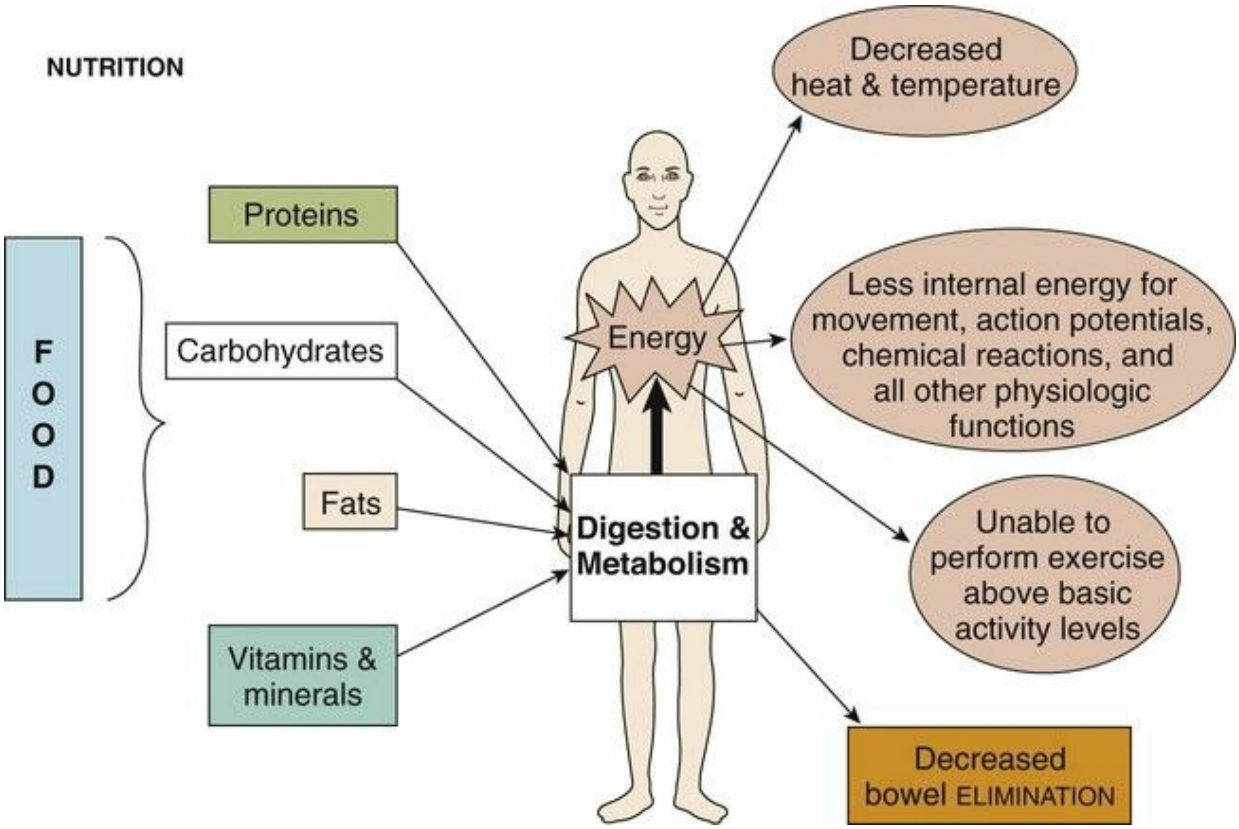

FIG. 2

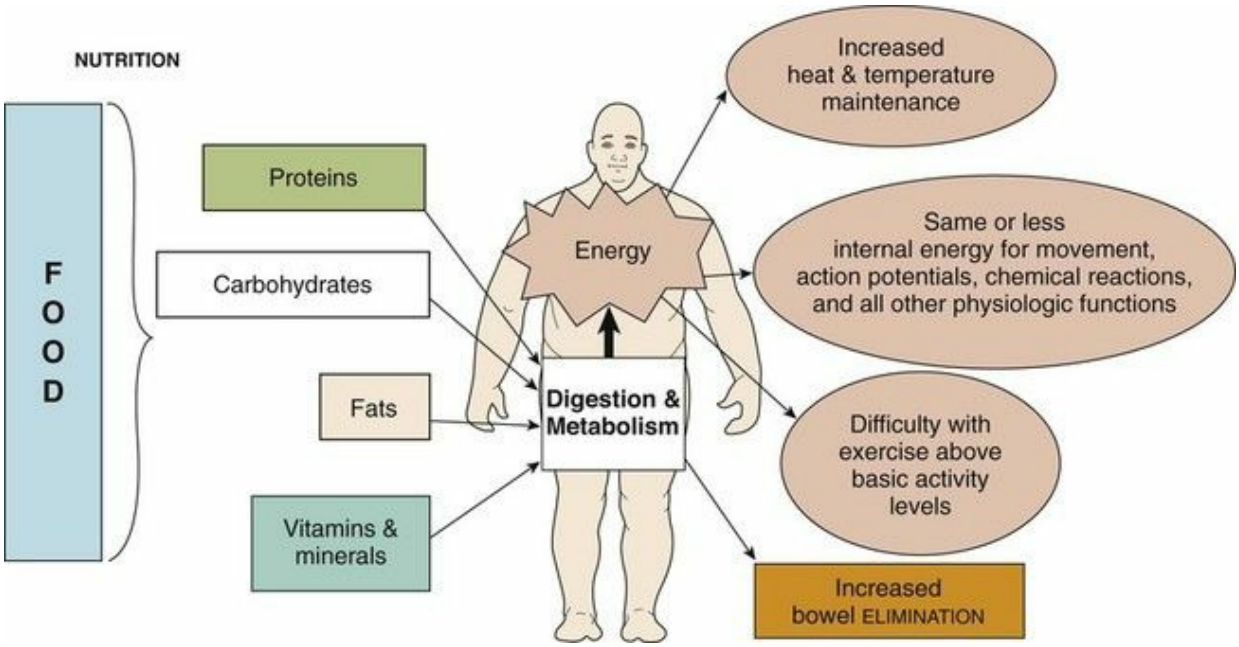
In Fig. 3, the person's nutrition intake is greater than is needed to meet energy needs. As a result, these extra energy compounds are converted first into glycogen and eventually into fat. Although fat represents stored energy, excessive fat can harm the body. Thus excessive nutrition is not necessarily adequate or healthy and does not represent a balanced metabolic state. In addition, when nutrition is excessive, metabolism and work energies are not increased. Only heat and bowel elimination increase.



NUTRITION
FOOD
Proteins
Carbohydrates
Fats
Vitamins & minerals
Digestion & Metabolism
Energy
Increased heat & temperature maintenance
Same or less internal energy for movement, action potentials, chemical reactions, and all other physiologic functions
Difficulty with exercise above basic activity levels
Increased bowel ELIMINATION

FIG. 3

CHAPTER 52

Assessment of the Gastrointestinal System

Donna D. Ignatavicius

PRIORITY CONCEPTS

- Nutrition
- Elimination

Learning Outcomes

Safe and Effective Care Environment

1. Assess patients for complications of esophagogastroduodenoscopy (EGD).

Health Promotion and Maintenance

2. Identify factors that place patients at risk for GI problems.
3. Teach pre-test and post-test care for diagnostic GI testing to patients and families to promote safety and comfort.

Psychosocial Integrity

4. Identify common psychological responses to GI health problems and diagnostic testing.

Physiological Integrity

5. Briefly review the anatomy and physiology of the GI system.
6. Describe nutrition and elimination changes associated with aging.
7. Perform focused physical assessment for patients with suspected or actual GI health problems.
8. Explain and interpret common laboratory tests for a patient with a GI

health problem.
9. Describe care for patients having selected GI diagnostic tests.

http://evolve.elsevier.com/Iggy/

The GI system includes the GI tract (alimentary canal), consisting of the mouth, esophagus, stomach, small and large intestines, and rectum. The salivary glands, liver, gallbladder, and pancreas secrete substances into this tract to form the GI system (Fig. 52-1). The main functions of the GI tract, with the aid of organs such as the pancreas and the liver, are the *digestion* of food to meet the body's *nutritional* needs and the elimination of waste resulting from digestion. Adequate nutrition is required for proper functioning of the body's organs and other cells (see the Concept Overview). The GI tract is susceptible to many health problems, including structural or mechanical alterations, impaired motility, infection, and cancer.

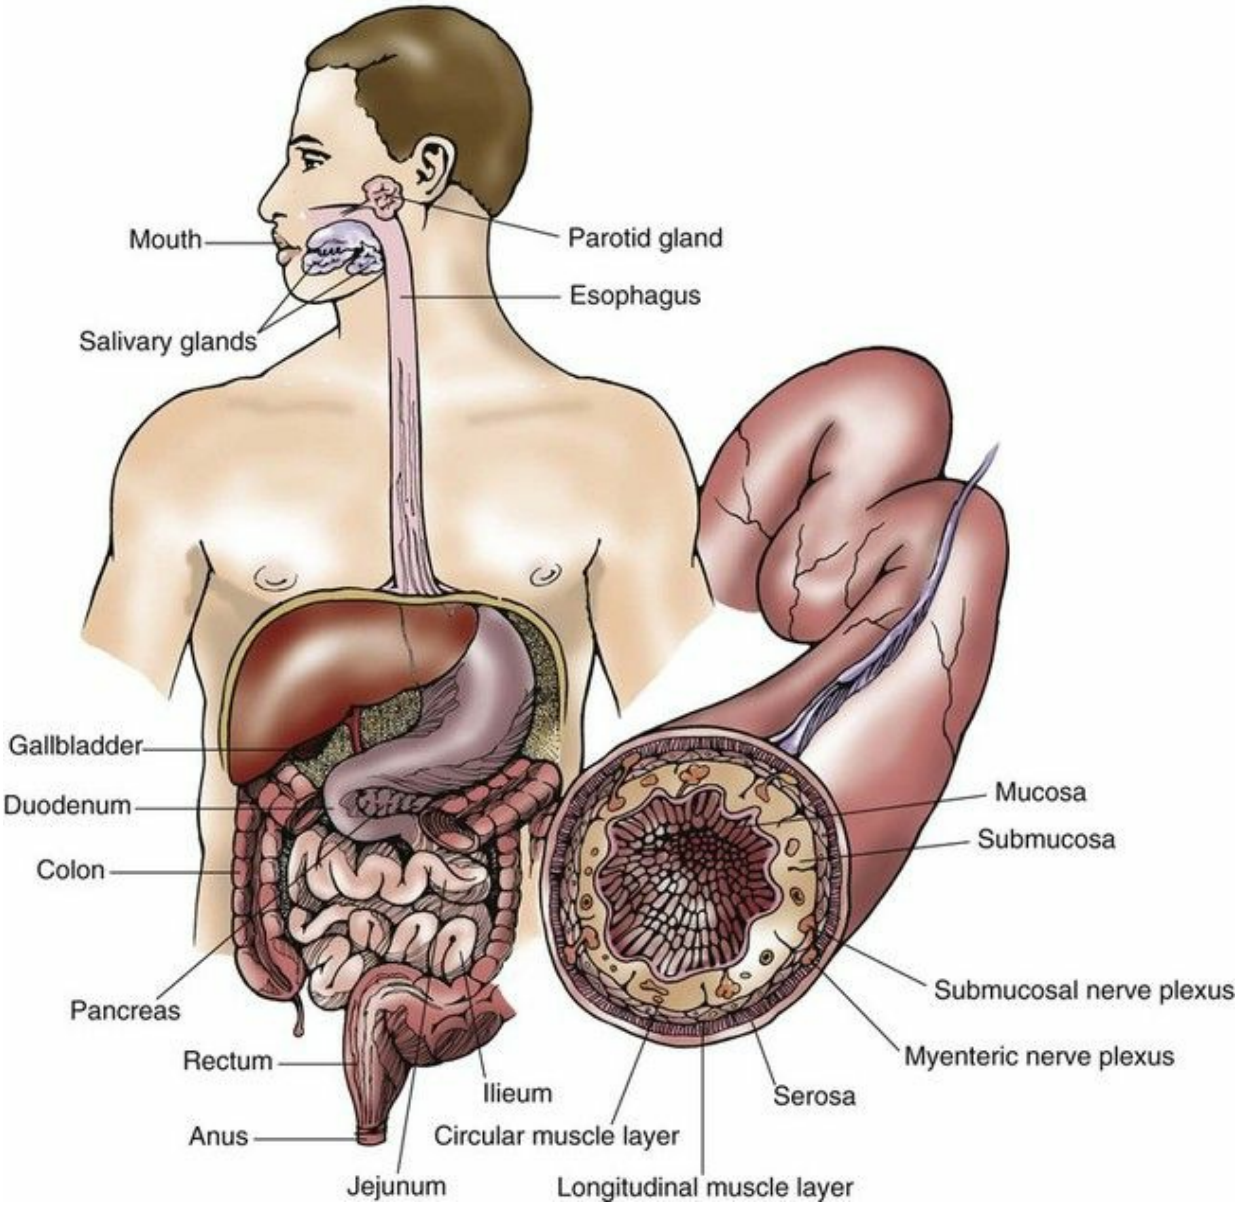


FIG. 52-1 The gastrointestinal system (GI tract) can be thought of as a tube (with necessary structures) extending from the mouth to the anus for a 25-foot length. The structure of this tube *(shown enlarged)* is basically the same throughout its length.

Anatomy and Physiology Review

Structure

The **lumen,** or inner wall, of the GI tract consists of four layers: mucosa, submucosa, muscularis, and serosa. The *mucosa,* the innermost layer, includes a thin layer of smooth muscle and specialized exocrine gland cells. It is surrounded by the *submucosa,* which is made up of connective tissue. The *submucosa* layer is surrounded by the muscularis. The *muscularis* is composed of both circular and longitudinal smooth muscles, which work to keep contents moving through the tract. The outermost layer, the *serosa,* is composed of connective tissue. Although the GI tract is continuous from the mouth to the anus, it is divided into specialized regions. The mouth, pharynx, esophagus, stomach, and small and large intestines each perform a specific function. In addition, the secretions of the salivary, gastric, and intestinal glands; liver; and pancreas empty into the GI tract to aid digestion.

Function

The functions of the GI tract include secretion, digestion, absorption, motility, and elimination. Food and fluids are ingested, swallowed, and propelled along the lumen of the GI tract to the anus for elimination. The smooth muscles contract to move food from the mouth to the anus. Before food can be absorbed, it must be broken down to a liquid, called **chyme. Digestion** is the mechanical and chemical process in which complex foodstuffs are broken down into simpler forms that can be used by the body. During digestion, the stomach secretes hydrochloric acid, the liver secretes bile, and digestive enzymes are released from accessory organs, aiding in food breakdown. After the digestive process is complete, absorption takes place. **Absorption** is carried out as the nutrients produced by digestion move from the lumen of the GI tract into the body's circulatory system for uptake by individual cells (Jarvis, 2016).

Oral Cavity

The oral cavity (mouth) includes the buccal mucosa, lips, tongue, hard palate, soft palate, teeth, and salivary glands. The buccal mucosa is the mucous membrane lining the inside of the mouth. The tongue is involved in speech, taste, and **mastication** (chewing). Small projections called *papillae* cover the tongue and provide a roughened surface, permitting the movement of food in the mouth during chewing. The hard

palate and the soft palate together form the roof of the mouth.

Adults have 32 permanent teeth: 16 each in upper and lower arches. The different types of teeth function to prepare food for digestion by cutting, tearing, crushing, or grinding the food. Swallowing begins after food is taken into the mouth and chewed. Saliva is secreted in response to the presence of food in the mouth and begins to soften the food. Saliva contains mucin and an enzyme called *salivary amylase* (also known as *ptyalin*), which begins the breakdown of carbohydrates.

Esophagus

The esophagus is a muscular canal that extends from the pharynx (throat) to the stomach and passes through the center of the diaphragm. Its primary function is to move food and fluids from the pharynx to the stomach. At the upper end of the esophagus is a sphincter referred to as the **upper esophageal sphincter (UES).** When at rest, the UES is closed to prevent air into the esophagus during respiration. The portion of the esophagus just above the gastroesophageal (GE) junction is referred to as the **lower esophageal sphincter (LES).** When at rest, the LES is normally closed to prevent reflux of gastric contents into the esophagus. If the LES does not work properly, gastroesophageal reflux disease (GERD) can develop (see Chapter 54).

Stomach

The stomach is located in the midline and left upper quadrant (LUQ) of the abdomen and has four anatomic regions (McCance et al., 2014). The *cardia* is the narrow portion of the stomach that is below the gastroesophageal (GE) junction. The *fundus* is the area nearest to the cardia. The main area of the stomach is referred to as the *body* or *corpus.* The *antrum* (pylorus) is the distal (lower) portion of the stomach and is separated from the duodenum by the pyloric sphincter. Both ends of the stomach are guarded by sphincters (cardiac [LES] and pyloric), which aid in the transport of food through the GI tract and prevent backflow.

Smooth muscle cells that line the stomach are responsible for gastric motility. The stomach is also richly innervated with intrinsic and extrinsic nerves. **Parietal cells** lining the wall of the stomach secrete hydrochloric acid, whereas chief cells secrete pepsinogen (a precursor to pepsin, a digestive enzyme). Parietal cells also produce **intrinsic factor,** a substance that aids in the absorption of vitamin B_{12}. Absence of the intrinsic factor causes pernicious anemia.

After ingestion of food, the stomach functions as a food reservoir

where the digestive process begins, using mechanical movements and chemical secretions. The stomach mixes or churns the food, breaking apart the large food molecules and mixing them with gastric secretions to form chyme, which then empties into the duodenum. The *intestinal phase* begins as the chyme passes from the stomach into the duodenum, causing distention. It is assisted by secretin, a hormone that inhibits further acid production and decreases gastric motility.

Pancreas

The pancreas is a fish-shaped gland that lies behind the stomach and extends horizontally from the duodenal C-loop to the spleen (Jarvis, 2016). The pancreas is divided into portions known as the *head,* the *body,* and the *tail* (Fig. 52-2).

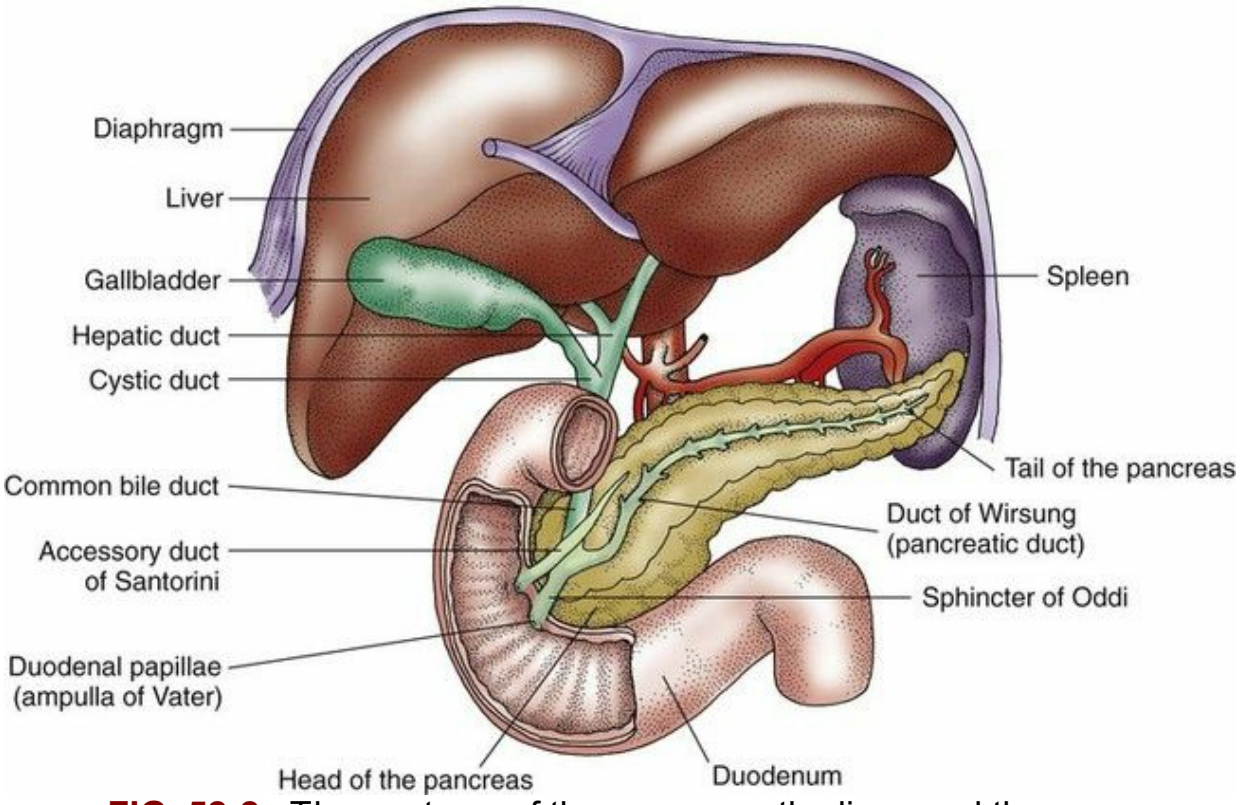

FIG. 52-2 The anatomy of the pancreas, the liver, and the gallbladder.

Two major cellular bodies (exocrine and endocrine) within the pancreas have separate functions. The *exocrine* part consists of cells that secrete enzymes needed for digestion of carbohydrates, fats, and proteins (trypsin, chymotrypsin, amylase, and lipase). The *endocrine* part of the pancreas is made up of the islets of Langerhans, with alpha cells producing glucagon and beta cells producing insulin. These hormones

produced are essential in the regulation of *metabolism*. Chapter 64 describes the endocrine function of the pancreas in detail.

Liver and Gallbladder

The *liver* is the largest organ in the body (other than skin) and is located mainly in the right upper quadrant (RUQ) of the abdomen. The right and left hepatic ducts transport bile from the liver. It receives its blood supply from the hepatic artery and portal vein, resulting in about 1500 mL of blood flow through the liver every minute.

The *liver* performs more than 400 functions in three major categories: storage, protection, and metabolism. It *stores* many minerals and vitamins, such as iron, magnesium, and the fat-soluble vitamins A, D, E, and K.

The *protective* function of the liver involves phagocytic **Kupffer cells,** which are part of the body's reticuloendothelial system. They engulf harmful bacteria and anemic red blood cells. The liver also detoxifies potentially harmful compounds (e.g., drugs, chemicals, alcohol). Therefore the risk for drug toxicity increases with aging because of decreased liver function.

The liver functions in the *metabolism* of proteins considered vital for human survival. It breaks down amino acids to remove ammonia, which is then converted to urea and is excreted via the kidneys (McCance et al., 2014). In addition, it synthesizes several plasma proteins, including albumin, prothrombin, and fibrinogen. The liver's role in carbohydrate metabolism involves storing and releasing glycogen as the body's energy requirements change. The organ also synthesizes, breaks down, and temporarily stores fatty acids and triglycerides.

The liver forms and continually secretes bile, which is essential for the breakdown of fat. The secretion of bile increases in response to gastrin, secretin, and cholecystokinin. Bile is secreted into small ducts that empty into the common bile duct and into the duodenum at the sphincter of Oddi. However, if the sphincter is closed, the bile goes to the gallbladder for storage.

The *gallbladder* is a pear-shaped, bulbous sac that is located underneath the liver. It is drained by the cystic duct, which joins with the hepatic duct from the liver to form the common bile duct (CBD). The gallbladder collects, concentrates, and stores the bile that has come from the liver. It releases the bile into the duodenum via the CBD when fat is present.

Small Intestine

The small intestine is the longest and most convoluted portion of the digestive tract, measuring 16 to 19 feet (5 to 6 m) in length in an adult. It is composed of three different regions: duodenum, jejunum, and ileum. The *duodenum* is the first 12 inches (30 cm) of the small intestine and is attached to the distal end of the pylorus. The common bile duct and pancreatic duct join to form the ampulla of Vater, emptying into the duodenum at the duodenal papilla. This papillary opening is surrounded by muscle known as the **sphincter of Oddi.** The 8-foot (2.5-m) portion of the small intestine that follows the sphincter of Oddi is the *jejunum.* The last 8 to 12 feet (2.5 to 4 m) of the small intestine is called the *ileum.* The ileocecal valve separates the entrance of the ileum from the cecum of the large intestine (McCance et al., 2014).

The inner surface of the small intestine has a velvety appearance because of numerous mucous membrane fingerlike projections. These projections are called *intestinal villi.* In addition to the intestinal villi, the small intestine has circular folds of mucosa and submucosa, which increase the surface area for digestion and absorption.

The small intestine has three main *functions:* movement (mixing and peristalsis), digestion, and absorption. Because the intestinal villi increase the surface area of the small intestine, it is the major organ of absorption of the digestive system. The small intestine mixes and transports the chyme to mix with many digestive enzymes. It takes an average of 3 to 10 hours for the contents to be passed by peristalsis through the small intestine. Intestinal enzymes aid in the digestion of proteins, carbohydrates, and lipids.

Large Intestine

The large intestine extends about 5 to 6 feet in length from the ileocecal valve to the anus and is lined with columnar epithelium that has absorptive and mucous cells. It begins with the *cecum,* a dilated, pouchlike structure that is inferior to the ileocecal opening. At the base of the cecum is the vermiform appendix, which has no known digestive function. The large intestine then extends upward from the cecum as the colon. The colon consists of four divisions: ascending colon, transverse colon, descending colon, and sigmoid colon (McCance et al., 2014). The sigmoid colon empties into the rectum.

Following the sigmoid colon, the large intestine bends downward to form the rectum. The last 1 to $1\frac{1}{2}$ inches (3 to 4 cm) of the large intestine is called the *anal canal,* which opens to the exterior of the body through

the anus. Sphincter muscles surround the anal canal.

The large intestine's *functions* are movement, absorption, and elimination. Movement in the large intestine consists mainly of segmental contractions, like those in the small intestine, to allow enough time for the absorption of water and electrolytes. In addition, peristaltic contractions are triggered by colonic distention to move the contents toward the rectum, where the material is stored until the urge to defecate occurs. Absorption of water and some electrolytes occurs in the large intestine to reduce the fluid volume of the chyme. This process creates a more solid material, the feces, for elimination.

Gastrointestinal Changes Associated with Aging

Physiologic changes occur in the GI system as people age, especially ages 65 years and older. Changes in digestion and elimination that can affect nutrition are common (McCance et al., 2014). For example, decreased gastric hydrochloric acid (HCl) can lead to decreased absorption of essential minerals like iron. Chart 52-1 lists common GI changes and nursing implications when caring for older adults.

Chart 52-1 Nursing Focus on the Older Adult

Changes in the Gastrointestinal System Related to Aging

PHYSIOLOGIC CHANGE	DISORDERS RELATED TO CHANGE	NURSING INTERVENTIONS	RATIONALES
Stomach			
Atrophy of the gastric mucosa is characterized by a decrease in the ratio of gastrin-secreting cells to somatostatin-secreting cells. This change leads to decreased hydrochloric acid levels (hypochlorhydria).	Decreased hydrochloric acid levels lead to decreased absorption of iron and vitamin B_{12} and to proliferation of bacteria. Atrophic gastritis occurs as a consequence of bacterial overgrowth.	Encourage bland foods high in vitamins and iron.	Bland foods help prevent gastritis.
		Assess for epigastric pain.	Assessment helps detect gastritis.
Large Intestine			
Peristalsis decreases, and nerve impulses are dulled.	Decreased sensation to defecate can result in postponement of bowel movements, which leads to constipation and impaction.	Encourage a high-fiber diet and 1500 mL of fluid intake daily (if not contraindicated). Encourage as much activity as tolerated.	These interventions increase the sensation of needing to defecate.
Pancreas			
Distention and dilation of pancreatic ducts change. Calcification of pancreatic vessels occurs with a decrease in lipase production.	Decreased lipase level results in decreased fat absorption and digestion. Steatorrhea, or excess fat in the feces, occurs because of decreased fat digestion.	Encourage small, frequent feedings.	Small, frequent feedings help prevent steatorrhea.
		Assess for diarrhea.	Diarrhea may be steatorrhea. Excessive diarrhea can lead to dehydration.
Liver			
A decrease in the number and size of hepatic cells leads to decreased liver weight and mass. This change and an increase in fibrous tissue lead to decreased protein synthesis and changes in liver enzymes. Enzyme activity and cholesterol synthesis are diminished.	Decreased enzyme activity depresses drug metabolism, which leads to accumulation of drugs—possibly to toxic levels.	Assess for adverse effects of all drugs.	Assessment can help detect drug toxicity.

Assessment Methods

Patient History

The purpose of the health history is to determine the events related to the current health problem (Chart 52-2). Focus questions about changes in appetite, weight, and stool. Determine the patient's pain experience.

Chart 52-2 Best Practice for Patient Safety and Quality Care QSEN

Questions for Gastrointestinal Health History

- What is your typical daily food intake? Do you take any supplements? If so, what are they?
- How is your appetite? Any recent change?
- Have you lost or gained weight recently? If so, was the weight loss or gain intentional?
- Are you on a special diet?
- Do you have any difficulty chewing or swallowing?
- Do you wear dentures? How well do they fit?
- Do you ever experience indigestion or "heartburn"? How often? What seems to cause it? What helps it?
- Have you had any GI disorders or surgeries? If so, what are they?
- Is there a family history of GI health problems?
- What medications are you taking? Be sure to include prescription and over-the-counter (OTC) drugs.
- Do you smoke or have you ever smoked? Do you chew or have you ever chewed tobacco?
- Do you drink alcoholic beverages? If so, how many each week?
- Do you have pain, diarrhea, gas, or any other problems? Do any specific foods cause the problem?
- Have you traveled out of the country recently? If so, where?
- What is your usual bowel elimination pattern? Frequency? Character? Discomfort? Laxatives?
- Do you have any pain or bleeding associated with bowel movements?
- Have you experienced any changes in your usual bowel pattern or stool?
- Have you ever had an endoscopy or a colonoscopy?

Collect data about the patient's age, gender, and culture. This information can be helpful in assessing who is likely to have particular

GI system disorders. For instance, older adults are more at risk for stomach cancer than are younger adults. Younger adults are more at risk for inflammatory bowel disease (IBD). The exact reasons for these differences continue to be studied.

Question the patient about previous GI disorders or abdominal surgeries. Ask about prescription medications being taken, including how much, when the drugs are taken, and why they have been prescribed. Inquire if the patient takes over-the-counter (OTC) drugs, herbs, and/or supplements. In particular, ask whether aspirin, NSAIDs (e.g., ibuprofen), laxatives, herbal preparations, or enemas are routinely taken. Large amounts of aspirin or NSAIDs can predispose the patient to peptic ulcer disease and GI bleeding. Long-term use of laxatives or enemas can cause dependence and result in constipation and electrolyte imbalance. Some herbal preparations, especially ayurvedic herbs, can affect appetite, absorption, and elimination. Determine if the patient smokes or has ever smoked cigarettes, cigars, or pipes. Smoking is a major risk factor for most GI cancers. Chewing tobacco is a major cause of oral cancer.

Finally, investigate the patient's travel history. Ask whether he or she has traveled outside of the country recently. This information may provide clues about the cause of symptoms like diarrhea.

Nutrition History

A nutrition history is important when assessing GI system function. Many conditions manifest themselves as a result of alterations in intake and absorption of nutrients. The purpose of a nutritional assessment is to gather information about how well the patient's needs are being met. Inquire about any special diet and whether there are any known food allergies. Ask the patient to describe the usual foods that are eaten daily and the times that meals are taken.

Cultural Considerations

Patient-Centered Care QSEN

Cultural and religious patterns are important in obtaining a complete nutritional history. Ask if certain foods pose a problem for the patient. For example, the spices or hot pepper used in cooking in many cultures can aggravate or precipitate GI tract symptoms such as indigestion. Note religious patterns such as fasting or abstinence.

Many black people are lactose intolerant. A much smaller percentage

of white people also have this problem. Lactose intolerance causes bloating, cramping, and diarrhea as a result of lack of the enzyme *lactase* (McCance et al., 2014). Lactase is needed to convert lactose in milk and other dairy products to glucose and galactose.

Health problems can also affect nutrition, so explore any changes that have occurred in eating habits as a result of illness. **Anorexia** (loss of appetite for food) can occur with GI disease. Assess changes in taste and any difficulty or pain with swallowing (dysphagia) that could be associated with esophageal disorders. Also ask if abdominal pain or discomfort occurs with eating and whether the patient has experienced any nausea, vomiting, or **dyspepsia** (indigestion or heartburn). Unknown food allergies often cause these symptoms. Inquire about any unintentional weight loss, because some cancers of the GI tract may present in this manner. Assess for alcohol and caffeine consumption, because both substances are associated with many GI disorders, such as gastritis and peptic ulcer disease.

The patient's socioeconomic status may have a profound impact on his or her nutrition. For example, people who have limited budgets, such as some older adults or the unemployed, may not be able to purchase foods required for a balanced diet. In addition, they may substitute less expensive and perhaps less effective OTC medications or herbs for prescription drugs. Necessary medical care may be delayed, and patients may not seek health care until conditions are well advanced.

Family History and Genetic Risk

Ask about a family history of GI disorders. Some GI health problems have a genetic predisposition. For example, familial adenomatous polyposis (FAP) is an inherited autosomal dominant disorder that predisposes the patient to colon cancer (McCance et al., 2014). Specific genetic risks are discussed with the GI problems in later chapters.

Current Health Problems

Because GI clinical manifestations are often vague and difficult for the patient to describe, it is important to obtain a chronologic account of the current problem, symptoms, and any treatments taken. Furthermore, ask about the location, quality, quantity, timing (onset, duration), and factors that may aggravate or alleviate each symptom (see Chart 52-2).

For example, a change in bowel habits is a common assessment finding. Obtain this information from the patient:

• Pattern of bowel movements
• Color and consistency of the feces
• Occurrence of diarrhea or constipation
• Effective action taken to relieve diarrhea or constipation
• Presence of frank blood or tarry stools
• Presence of abdominal distention or gas

An unintentional weight gain or loss is another symptom that needs further investigation. Assess the patient's:

• Normal weight
• Weight gain or loss
• Period of time for weight change
• Changes in appetite or oral intake

Pain is a common concern of patients with GI tract disorders. The mnemonic **PQRST** may be helpful in organizing the current problem assessment (Jarvis, 2016):

P: Precipitating or palliative. What brings it on? What makes it better? Worse? When did you first notice it?

Q: Quality or quantity. How does it look, feel, or sound? How intense/severe is it?

R: Region or radiation. Where is it? Does it spread anywhere?

S: Severity scale. How bad is it (on a scale of 0 to 10)? Is it getting better, worse, or staying the same?

T: Timing. Onset—Exactly when did it first occur? Duration—How long did it last? Frequency—How often does it occur?

Abdominal pain is often vague and difficult to evaluate. Ask the patient to describe the type of pain, such as burning, gnawing, or stabbing. The location of the pain can be determined by asking him or her to point to the involved site. Ask about the relationship of food intake to the onset or worsening of pain. For example, a high-fat meal may cause gallbladder pain.

Changes in the skin may result from several GI tract disorders, such as liver and biliary system obstruction. Ask about whether these clinical manifestations have occurred, or assess whether they are present:

• Skin discolorations or rashes
• Itching
• **Jaundice** (yellowing of skin caused by bilirubin pigments)
• Increased bruising
• Increased tendency to bleed

Physical Assessment

Physical assessment involves a comprehensive examination of the patient's nutritional status, mouth, and abdomen. Nutritional assessment is discussed in detail in Chapter 60. Oral assessment is described in Chapter 53.

In preparation for examination of the *abdomen,* ask the patient to empty his or her bladder and then to lie in a supine position with knees bent, keeping the arms at the sides to prevent tensing of the abdominal muscles.

The abdominal examination usually begins at the patient's right side and proceeds in a systematic fashion (Fig. 52-3):

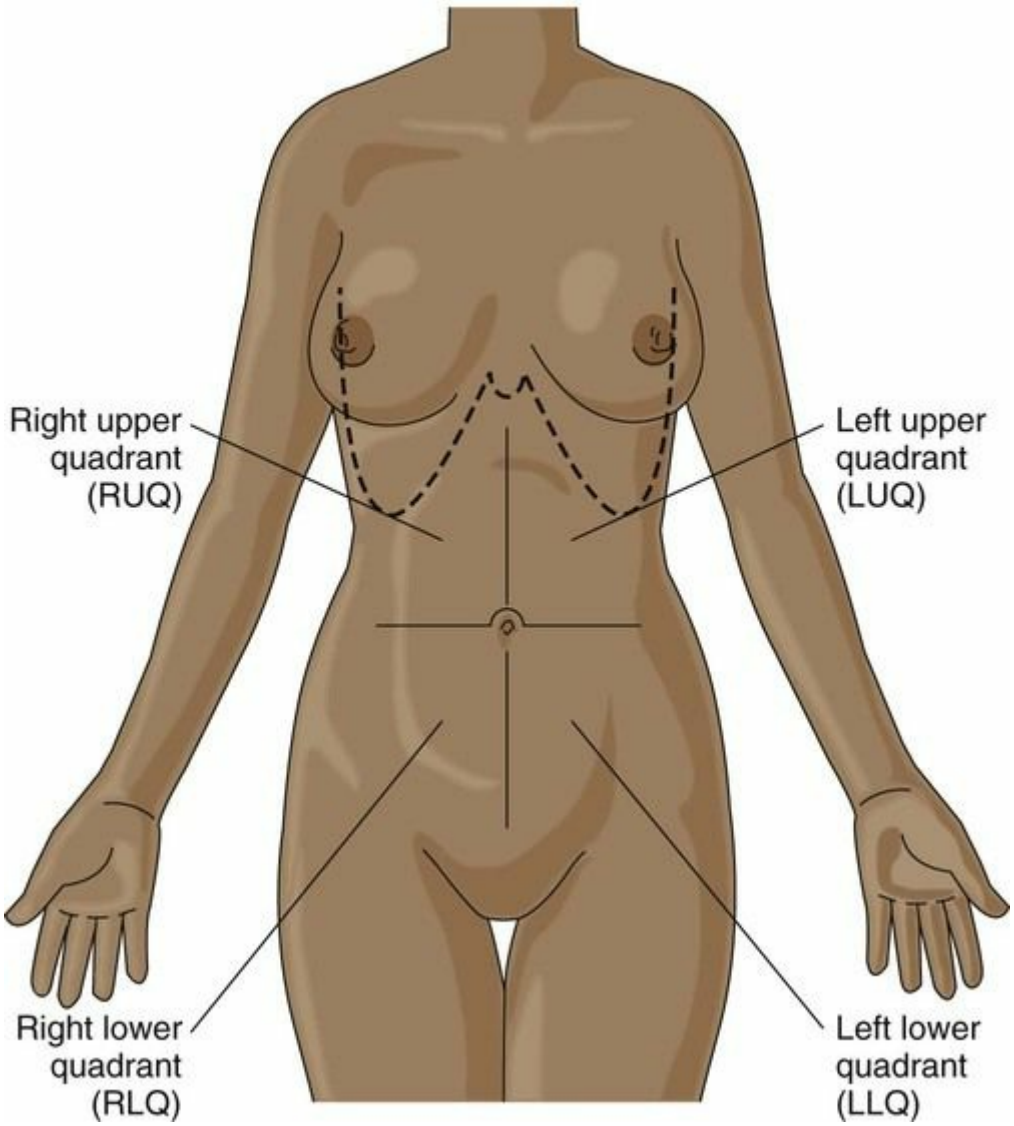

FIG. 52-3 A topographic division of the abdomen into quadrants.

- Right upper quadrant (RUQ)
- Left upper quadrant (LUQ)
- Left lower quadrant (LLQ)

• Right lower quadrant (RLQ)

Table 52-1 lists the organs that lie in each of these areas.

TABLE 52-1

Location of Body Structures in Each Abdominal Quadrant and Midline

Right Upper Quadrant (RUQ)
• Most of the liver • Gallbladder • Duodenum • Head of the pancreas • Hepatic flexure of the colon • Part of the ascending and transverse colon
Left Upper Quadrant (LUQ)
• Left lobe of the liver • Stomach • Spleen • Body and tail of the pancreas • Splenic flexure of the colon • Part of the transverse and descending colon
Midline
• Abdominal aorta • Uterus (if enlarged) • Bladder (if distended)
Right Lower Quadrant (RLQ)
• Cecum • Appendix • Right ureter • Right ovary and fallopian tube • Right spermatic cord
Left Lower Quadrant (LLQ)
• Part of the descending colon • Sigmoid colon • Left ureter • Left ovary and fallopian tube • Left spermatic cord

If areas of pain or discomfort are noted from the history, this area is examined last in the examination sequence. This sequence should prevent the patient from tensing abdominal muscles because of the pain, which would make the examination difficult. Examine any area of tenderness cautiously, and instruct the patient to state whether it is too painful. Observe his or her face for signs of distress or pain.

The abdomen is assessed by using the four techniques of examination, but in a sequence different from that used for other body systems: inspection, auscultation, percussion, and then palpation. This sequence is preferred so that palpation and percussion do not increase intestinal activity and bowel sounds. As a nurse generalist, perform inspection, auscultation, and light palpation. Percussion and deep palpation may be done by primary health care providers, including advanced practice nurses (APNs), or specialty nurses. If appendicitis or an abdominal

aneurysm is suspected, palpation is not done.

Inspection

Inspect the skin, and note any of these findings:

- Overall asymmetry of the abdomen
- Presence of discolorations or scarring
- Abdominal distention
- Bulging flanks
- Taut, glistening skin

Observe the shape of the abdomen by observing its contour and symmetry. The contour of the abdomen can be rounded, flat, concave, or distended. It is best determined when standing at the side of the bed or treatment table and looking down on the abdomen. View the abdomen at eye level from the side. Note whether the contour is symmetric or asymmetric. Asymmetry of the abdomen can indicate problems affecting the underlying body structures (see Table 52-1). Note the shape and position of the umbilicus for any deviations.

Finally, observe the patient's abdominal movements, including the normal rising and falling with inspiration and expiration, and note any distress during movement. Occasionally, pulsations may be visible, particularly in the area of the abdominal aorta.

Nursing Safety Priority QSEN

Action Alert

If a bulging, pulsating mass is present during assessment of the abdomen, do not touch the area because the patient may have an abdominal aortic aneurysm, a life-threatening problem. Notify the health care provider of this finding immediately! Peristaltic movements are rarely seen unless the patient is thin and has increased peristalsis. If these movements are observed, note the quadrant of origin and the direction of peristaltic flow. Report this finding to the health care provider because it may indicate an intestinal obstruction.

Auscultation

Auscultation of the abdomen is performed with the diaphragm of the stethoscope, because bowel sounds are usually high pitched. Place the stethoscope lightly on the abdominal wall while listening for bowel sounds in all four quadrants, beginning in the RLQ at the ileocecal valve area.

Bowel sounds are created as air and fluid move through the GI tract. They are normally heard as relatively high-pitched, irregular gurgles every 5 to 15 seconds, with a normal frequency range of 5 to 30 per minute (Jarvis, 2016). Bowel sounds are characterized as normal, hypoactive, or hyperactive. They are diminished or absent after abdominal surgery or in the patient with peritonitis or paralytic ileus.

For many years, nurses have been taught to count the number of bowel sounds in each quadrant as part of routine and postoperative abdominal assessment to assess for peristalsis. However, the best, most reliable method for assessing the return of peristalsis after abdominal surgery is to ask the patient if he or she has passed flatus within the past 8 hours or a stool within the past 12 to 24 hours.

Increased bowel sounds, especially loud, gurgling sounds, result from increased motility of the bowel **(borborygmus).** These sounds are usually heard in the patient with diarrhea or gastroenteritis or above a complete intestinal obstruction.

When auscultating the abdomen, also listen for vascular sounds or **bruits** ("swooshing" sounds) over the abdominal aorta, the renal arteries, and the iliac arteries. A bruit heard over the aorta usually indicates the presence of an aneurysm. *If this sound is heard, do not percuss or palpate the abdomen. Notify the health care provider of your findings!*

Percussion

Percussion may be used by APNs and other health care providers to determine the size of solid organs; to detect the presence of masses, fluid, and air; and to estimate the size of the liver and spleen. The percussion notes normally heard in the abdomen are termed *tympanic* (the high-pitched, loud, musical sound of an air-filled intestine) or *dull* (the medium-pitched, softer, thudlike sound over a solid organ, such as the liver).

The liver and spleen can be percussed. An enlarged liver is called **hepatomegaly.** Dullness heard in the left anterior axillary line indicates enlargement of the spleen **(splenomegaly).** Mild to moderate splenomegaly can be detected before the spleen becomes palpable.

Palpation

The purpose of palpation is to determine the size and location of abdominal organs and to assess for the presence of masses or tenderness. Palpation of the abdomen consists of two types: light palpation and deep palpation. Only physicians and APNs, such as

clinical nurse specialists and nurse practitioners, should perform deep palpation. Deep palpation is used to further determine the size and shape of abdominal organs and masses.

The technique of *light palpation* is used to detect large masses and areas of tenderness. Place the first four fingers of the palpating hand close together and then place them lightly on the abdomen and proceed smoothly and systematically from quadrant to quadrant. Depress the abdomen to a depth of ½ to 1 inch (1.25 to 2.5 cm). Proceed with a rotational movement of the palpating hand. Note any areas of tenderness or guarding because these areas will be examined last and cautiously during deep palpation. While performing light palpation, notice signs of rigidity, which, unlike voluntary guarding, is a sign of peritoneal inflammation.

NCLEX Examination Challenge

Physiological Integrity

The nurse auscultates a client's abdomen and hears a loud bruit near the umbilicus. What is the nurse's best action based on this assessment finding?

A Document the assessment finding in the medical record.
B Palpate the abdomen lightly in all four quadrants.
C Report the finding to the health care provider.
D Place the client in a semi-Fowler's position.

Psychosocial Assessment

Psychosocial assessment focuses on how the GI health problem affects the patient's life and lifestyle. Remember that patients are often reluctant to discuss elimination problems, which may be very personal and embarrassing. The interview focus is on whether usual activities have been interrupted or disturbed, including employment. Question the patient about recent stressful events. Emotional stress has been associated with the development or exacerbation (flare-up) of irritable bowel syndrome (IBS) and other GI disorders. If the patient is diagnosed with cancer, he or she is expected to experience the phases of the grieving process. Patients may be depressed, angry, or in denial. More specific psychosocial assessments are included in later GI chapters as part of each disease discussion.

Diagnostic Assessment

Laboratory Assessment

To make an accurate assessment of the many possible causes of GI system abnormalities, laboratory testing of blood, urine, and stool specimens may be performed.

Serum Tests.

A *complete blood count (CBC)* aids in the diagnosis of anemia and infection. It also detects changes in the blood's formed elements. In adults, GI bleeding is the most frequent cause of anemia. It is associated with GI cancer, peptic ulcer disease, diverticulitis, and inflammatory bowel disease.

Because the liver is the main site of all proteins involved in coagulation, *prothrombin time (PT)* is useful in evaluating the levels of these clotting factors. PT measures the rate at which prothrombin is converted to thrombin, a process that depends on vitamin K–associated clotting factors. Severe acute or chronic liver damage leads to a prolonged PT secondary to impaired synthesis of clotting proteins (Pagana & Pagana, 2014).

Many *electrolytes* are altered in GI tract dysfunction. For example, calcium is absorbed in the GI tract and may be measured to detect malabsorption. Excessive vomiting or diarrhea causes sodium or potassium depletion, thus requiring replacement.

Assays of serum enzymes are important in the evaluation of liver damage. *Aspartate aminotransferase (AST)* and *alanine aminotransferase (ALT)* are two enzymes found in the liver and other organs. These enzymes are elevated in most liver disorders, but they are highest in conditions that cause necrosis, such as severe viral hepatitis and cirrhosis.

Elevations in serum *amylase* and *lipase* may indicate acute pancreatitis. In this disease, serum amylase levels begin to elevate within 24 hours of onset and remain elevated for up to 5 days. Serum amylase and lipase are not elevated when *extensive* pancreatic necrosis is present because there are few pancreatic cells manufacturing the enzymes (Pagana & Pagana, 2014).

Bilirubin is the primary pigment in bile, which is normally conjugated and excreted by the liver and biliary system. It is measured as total serum bilirubin, conjugated (direct) bilirubin, and unconjugated (indirect) bilirubin. These measurements are important in the evaluation of jaundice and in the evaluation of liver and biliary tract functioning.

Elevations in direct and indirect bilirubin levels can indicate impaired secretion.

The serum level of *ammonia* may also be measured to evaluate hepatic function. Ammonia is normally used to rebuild amino acids or is converted to urea for excretion. Elevated levels are seen in conditions that cause severe hepatocellular injury, such as cirrhosis of the liver or fulminant hepatitis (Pagana & Pagana, 2014).

Two primary *oncofetal antigens*—*CA19-9* and *CEA*—are evaluated to diagnose cancer, monitor the success of cancer therapy, and assess for the recurrence of cancer in the GI tract. These antigens may also be increased in benign GI conditions. Chart 52-3 lists blood tests commonly used by the health care provider in the diagnosis of GI disorders.

Chart 52-3 Laboratory Profile

Gastrointestinal Assessment

TEST (SERUM)	NORMAL RANGE FOR ADULTS	SIGNIFICANCE OF ABNORMAL FINDINGS
Calcium (total)	9.0-10.5 mg/dL (values decrease in older adults)	*Decreased* values indicate possible: Malabsorption Kidney failure Acute pancreatitis
Potassium	3.5-5.0 mEq/L or 3.5-5.0 mmol/L	*Decreased* values indicate possible: Vomiting Gastric suctioning Diarrhea Drainage from intestinal fistulas
Albumin	3.5-5.0 g/dL	*Decreased* values indicate possible: Hepatic disease
Alanine aminotransferase (ALT)	4-36 units/L (may be slightly higher in older adults)	*Increased* values indicate possible: Liver disease Hepatitis Cirrhosis
Aspartate aminotransferase (AST)	0-35 units/L (may be slightly higher in older adults)	*Increased* values indicate possible: Liver disease Hepatitis Cirrhosis
Alkaline phosphatase	30-120 units/L (may be slightly higher in older adults)	*Increased* values indicate possible: Cirrhosis Biliary obstruction Liver tumor
Bilirubin (total)	0.3-1.0 mg/dL	*Increased* values indicate possible: Hemolysis Biliary obstruction Hepatic damage
Conjugated (direct) bilirubin	0.1-0.3 mg/dL	*Increased* values indicate possible: Biliary obstruction
Unconjugated (indirect) bilirubin	0.2-0.8 mg/dL	*Increased* values indicate possible: Hemolysis Hepatic damage
Ammonia	10-80 mg/dL	*Increased* values indicate possible: Hepatic disease such as cirrhosis
Xylose absorption	20-57 mg/dL (60-minute plasma) 30-58 mg/dL (20-minute plasma)	*Decreased* values in blood and urine indicate possible: Malabsorption in the small intestine
Serum amylase	30-220 units/L	*Increased* values indicate possible: Acute pancreatitis
Serum lipase	0-160 units/L	*Increased* values indicate possible: Acute pancreatitis
Cholesterol	<200 mg/dL	*Increased* values indicate possible: Pancreatitis Biliary obstruction *Decreased* values indicate possible: Liver cell damage
Carbohydrate antigen 19-9 (CA19-9)	<37 units/mL	*Increased* values indicate possible: Cancer of the pancreas, stomach, colon Acute pancreatitis Inflammatory bowel disease
Carcinoembryonic antigen (CEA)	<5 ng/mL	*Increased* values indicate possible: Colorectal, stomach, pancreatic cancer Ulcerative colitis Crohn's disease Hepatitis Cirrhosis

Additional serum tests are described in other chapters of this GI health unit.

Urine Tests.

The presence of amylase can be detected in the urine. In acute pancreatitis, renal clearance of amylase is increased. Amylase levels in the urine remain high even after serum levels return to normal. This becomes an important finding in patients who are symptomatic for 3 days or longer (Pagana & Pagana, 2014).

Urine *urobilinogen* is a form of bilirubin that is converted by the intestinal flora and excreted in the urine. Its measurement is useful in the evaluation of hepatic and biliary obstruction, because the presence of bilirubin in the urine often occurs before jaundice is seen.

Stool Tests.

The American Cancer Society screening guidelines (2014) recommend yearly guaiac fecal occult blood test (gFOBT) or yearly fecal immunochemical test (FIT) at unspecified intervals to detect colorectal cancer early when it can be treated. These tests use a take-home, multi-sample method rather than having the test done during a digital rectal examination.

The traditionally used **FOBT** (e.g., Hemoccult II) requires an active component of guaiac and is therefore more likely than the FIT (e.g., HemeSelect) to yield false-positive results. In addition, patients having the guaiac-based test must avoid certain foods before the test, such as raw fruits and vegetables and red meat. Vitamin C–rich foods, juices, and tablets must also be avoided. Anticoagulants, such as warfarin (Coumadin), and NSAIDs should be discontinued for 7 days before testing begins. Patient compliance is likely to be higher with the FIT method because drugs and food do not interfere with the test results.

Stool samples may also be collected to test for *ova and parasites* to aid in the diagnosis of parasitic infection. They may also be tested for *fecal fats* when **steatorrhea** (fatty stools) or malabsorption is suspected. Fat is normally absorbed in the small intestine in the presence of biliary and pancreatic secretions. In malabsorption, fat is abnormally excreted in the stool.

Other common stool tests—stool cytotoxic assay and stool culture—detect the presence of infectious agents, especially *Clostridium difficile.* Patients who are suspected of having *C. difficile* are usually symptomatic. Prolonged antibiotic therapy, especially in older adults, depresses the natural intestinal flora, causing an overgrowth of the pathogen. The bacterium releases a toxin that causes colonic epithelium necrosis resulting in severe diarrhea that is easily transmitted from person to person via the fecal-oral route.

A stool culture takes a longer time to get results and is not the test of

choice. Instead, the cytotoxic assay is considered the most reliable because it has a high sensitivity (Keske & Letizia, 2010). However, the results may not be available for up to 3 days. The most common test to detect *C. difficile* is the enzyme-linked immunosorbent assay (ELISA) toxin A+B. It is easy to use, and the results are usually available in 2 to 6 hours (Keske & Letizia, 2010).

Imaging Assessment

Radiographic examinations and similar diagnostic procedures are useful in detecting structural and functional disorders of the GI system. Teach the patient how to prepare for the examination, provide an explanation of the procedure, and teach the required postprocedure care.

A *plain film of the abdomen* may be the first x-ray study that the health care provider requests when diagnosing a GI problem. This film can reveal abnormalities such as masses, tumors, and strictures or obstructions to normal movement. Patterns of bowel gas appear light on the abdominal film and can be useful in detecting an obstruction (ileus). No preparation is required except to wear a hospital gown and remove any jewelry or belts, which may interfere with the film.

When abdominal pain is severe or when bowel perforation is suspected, an *acute abdomen series* may be requested. This procedure consists of a chest x-ray, supine abdomen film, and an upright abdomen film. The chest x-ray may reveal a hiatal hernia, and an upright abdomen film may show air in the peritoneum from a bowel perforation. Today CT and MRI scans or ultrasound scans are used more often than abdominal x-rays.

An **upper GI radiographic series** is an x-ray visualization from the mouth to the duodenojejunal junction. It may be done to detect disorders of structure or function of the esophagus (barium swallow), stomach, or duodenum. An extension of the upper GI series, the *small bowel follow-through* (SBFT), continues tracing the barium through the small intestine—up to and including the ileocecal junction—to detect disorders of the jejunum or ileum. These tests are seldom performed today because endoscopy procedures allow for direct visualization of the internal GI tract.

A double-contrast barium enema examination, also known as a lower GI series, is an x-ray of the large intestine. The 2014 American Cancer Society screening guidelines include this test every 5 years as an option to determine the presence of colorectal cancer and polyps for people older than 50 years. The other options include:

• Flexible sigmoidoscopy every 5 years, or
• CT colonography (virtual colonoscopy) every 5 years, or
• Colonoscopy every 10 years

Patient preparation is similar to that for colonoscopy. After the study is completed, the patient expels the barium. The radiology nurse or technician teaches the patient to drink plenty of fluids to assist in eliminating the barium and prevent an intestinal obstruction. A laxative is given to help remove the barium from the intestinal tract. Stools are chalky white for about 24 to 72 hours, until all barium is passed. If the patient has positive results, he or she is scheduled for a colonoscopy.

Percutaneous transhepatic cholangiography (PTC) is an x-ray of the biliary duct system using an iodinated dye instilled via a percutaneous needle inserted through the liver into the intrahepatic ducts. This procedure may be performed when a patient has jaundice or persistent upper abdominal pain, even after cholecystectomy, but is rarely done as a diagnostic procedure today. Better information about dilated biliary ducts can be obtained using ultrasound scans and endoscopic retrograde cholangiopancreatography (ERCP) (discussed on p. 1094).

CT, also referred to as a *CT scan,* provides a noninvasive cross-sectional x-ray view that can detect tissue densities and abnormalities in the abdomen, including the liver, pancreas, spleen, and biliary tract. It may be performed with or without contrast medium. If contrast medium is to be used, ask about allergies to seafood and iodine. The patient is NPO for at least 4 hours before the test if a contrast medium is to be used. IV access will be required for injection of the contrast medium. Advise the patient that he or she may feel warm and flushed upon injection. The patient who is mildly claustrophobic may require a mild sedative to tolerate the study. The radiologic technician instructs the patient to lie still and to hold his or her breath when asked, as the technician takes a series of images. The test takes about 30 minutes.

Like other parts of the body, the abdomen and its organs may also be evaluated by *MRI, such as magnetic resonance cholangiopancreatography (MRCP).* For many patients with abdominal symptoms, this may be the first diagnostic test requested by the health care provider.

NCLEX Examination Challenge

Health Promotion and Maintenance

A client is provided with materials to obtain three fecal occult blood tests (Hemoccult). What health teaching does the nurse provide? **Select**

all that apply.
A "Avoid red meat and raw vegetables for a week before getting the samples."
B "Drink a gallon of GoLYTELY before you collect the first sample."
C "Do not take food or fluids for 24 hours before the test."
D "Do not take ibuprofen for a week before obtaining the samples."
E "Avoid vitamin C tablets, foods, and juices a week before getting the samples."

Other Diagnostic Assessment

Endoscopy is direct visualization of the GI tract using a flexible fiberoptic endoscope. It is commonly requested to evaluate bleeding, ulceration, inflammation, tumors, and cancer of the esophagus, stomach, biliary system, or bowel. Obtaining specimens for biopsy and cell studies (e.g., *Helicobacter pylori*) is also possible through the endoscope. There are several types of endoscopic examinations. The patient must sign an informed consent form before having these invasive studies.

One of the challenges with endoscopic procedures is proper cleaning of equipment between patients to prevent the transmission of bacterial biofilms and *C. difficile* (see Chapter 23). Teach patients that these infections are possible but are not common (Muscarella, 2010).

Esophagogastroduodenoscopy.

Esophagogastroduodenoscopy (EGD) is a visual examination of the esophagus, stomach, and duodenum. This procedure has largely replaced upper GI series testing. If GI bleeding is found during an EGD, the physician can inject a sclerotherapy or other type agent into the affected area to stop the bleeding. If the patient has an esophageal stricture, it can be dilated during an EGD. In addition, gastric lesions and celiac disease can be diagnosed using this procedure.

Teach the patient preparing for an upper GI endoscopic examination to remain NPO for 6 to 8 hours before the procedure. Usual drug therapy for hypertension or other diseases may be taken the morning of the test. However, diabetic patients should consult their health care provider for special instructions. Patients are also usually asked to avoid anticoagulants, aspirin, or other NSAIDs for several days before the test unless it is absolutely necessary. Tell the patient that a flexible tube will be passed down the esophagus while he or she is under moderate sedation. Midazolam hydrochloride (Versed), fentanyl (Fentanyl, Sublimaze), and/or propofol (Diprivan) are commonly used drugs for

sedation. *These drugs can depress the rate and depth of the patient's respirations*. Atropine may be administered to dry secretions. In addition, a local anesthetic is sprayed to inactivate the gag reflex and facilitate passage of the tube. Explain that this anesthetic will depress the gag reflex and that swallowing will be difficult. If the patient has dentures, they are removed.

After the drugs are given, the patient is placed in a position with the head of the bed elevated. A bite block is inserted to prevent biting down on the endoscope and to protect the teeth. The physician passes the tube through the mouth and into the esophagus (Fig. 52-4). The procedure takes about 20 to 30 minutes.

FIG. 52-4 Esophagogastroduodenoscopy allows visualization of the esophagus, the stomach, and the duodenum. If the esophagus is the focus of the examination, the procedure is called *esophagoscopy*. If the stomach is the focus, the procedure is called *gastroscopy*.

During the test, the endoscopy nurse monitors the patient's respirations for rate and depth and the oxygen saturation level via pulse oximetry. Some agencies require the use of capnography to monitor the amount of carbon dioxide that the patient exhales (Welliver, 2012). Shallow respirations decrease the amount of carbon dioxide that the patient exhales. *If the patient's respiratory rate is below 10 breaths per minute or the exhaled carbon dioxide level falls below 20%, the nurse typically uses a stimulus such as a sternal rub to encourage deeper and faster respirations.*

After the test, the endoscopy nurse or technician checks vital signs frequently (usually every 30 minutes) until the sedation begins to wear off. The siderails of the bed are raised during this time. The patient

remains NPO until the gag reflex returns (usually in 30 to 60 minutes). Intravenous fluids that were started before the procedure are discontinued when the patient is able to tolerate oral fluids without nausea or vomiting.

Nursing Safety Priority QSEN

Action Alert

The priority for care to promote patient safety after esophagogastroduodenoscopy is to prevent aspiration. Do not offer fluids or food by mouth until you are sure that the gag reflex is intact! Monitor for signs of perforation, such as pain, bleeding, or fever.

Because the EGD is most often performed as an ambulatory care (outpatient) procedure requiring moderate sedation, be sure that the patient has someone to drive him or her home. Remind the patient to not drive for at least 12 to 18 hours after the procedure because of sedation. Teach him or her that a hoarse voice or sore throat may persist for several days after the test. Throat lozenges can be used to relieve throat discomfort. A few patients may also experience bruising around their eyes (periorbital ecchymosis), which usually resolves in about a week (Tas, 2013).

Endoscopic Retrograde Cholangiopancreatography.

Endoscopic retrograde cholangiopancreatography (ERCP) includes visual and radiographic examination of the liver, gallbladder, bile ducts, and pancreas to identify the cause and location of obstruction. It is commonly used today for therapeutic purposes rather than for diagnosis. After a cannula is inserted into the common bile duct, a radiopaque dye is instilled and then several x-ray images are obtained. The physician may perform a **papillotomy** (a small incision in the sphincter around the ampulla of Vater) to remove gallstones. If a biliary duct stricture is found, plastic or metal stents may be inserted to keep the ducts open. Biopsies of tissue are also frequently taken during this test.

The patient prepares for this test in the same manner as for an EGD, including being NPO for 6 to 8 hours before the test. The patient requires IV access for moderate sedation drugs. Ask about prior exposure to x-ray contrast media and any sensitivities or allergies. If the patient has dentures, they are removed.

Ask the patient if he or she has an implantable medical device, such as

a cardiac pacemaker. Electrocautery cannot be used with this type of device (Bruesehoff, 2010). Perform medication reconciliation to determine if the patient is taking anticoagulants, NSAIDs, antiplatelet drugs, or antihyperglycemic agents. The physician decides which of these drugs are safe to take and whether any will need to be stopped before the test.

The endoscopic procedure and nursing care for a patient having an ERCP are similar to those for the EGD procedure, except that the endoscope is advanced farther into the duodenum and into the biliary tract. Once the cannula is in the common duct, contrast medium is injected and x-rays are taken to view the biliary tract. A tilt table assists in distributing the contrast medium to all areas to be assessed. The patient is placed in a left lateral position for viewing the common bile duct. Once the cannula is placed, he or she is put in a prone position. After examination of the biliary tree, the cannula is directed into the pancreatic duct for examination. The ERCP lasts from 30 minutes to 2 hours, depending on the treatment that may be done.

After the test, assess vital signs frequently, usually every 15 minutes, until the patient is stable. To prevent aspiration, check to ensure that the gag reflex has returned before offering fluids or food. Discontinue intravenous fluids that were started before the procedure when the patient is able to tolerate oral fluids without nausea or vomiting.

Nursing Safety Priority QSEN

Action Alert

Teach the patient and family to monitor for severe postprocedure complications at home, including cholangitis (gallbladder inflammation), bleeding, perforation, sepsis, and pancreatitis. The patient has severe pain if any of these complications occur. Fever is present in sepsis. These problems do not occur immediately after the procedure; they may take several hours to 2 days to develop.

Colicky abdominal pain can result from air instilled during the procedure. Instruct the patient to report abdominal pain, fever, nausea, or vomiting that fails to resolve after returning home. Be sure that the patient has someone to drive him or her home if the test was done on an ambulatory care basis. Remind the patient to not drive for at least 12 to 18 hours after the procedure because of sedation.

Small Bowel Capsule Endoscopy.

Small bowel endoscopy, or **enteroscopy,** provides a view of the small intestine. Capsule video endoscopy (M2A) is a small bowel enteroscopy that visualizes the entire small bowel, including the distal ileum. It is used to evaluate and locate the source of GI bleeding. Before the development of the M2A Capsule Endoscope, viewing the small intestine was inadequate. The capsule battery lasts around 8 hours, so it is not used to view the colon.

Prepare the patient by explaining the procedure, the purpose, and what to expect during the testing. The patient must fast (water only) for 8 to 10 hours before the test and be NPO for the first 2 hours of the testing.

At the time of the procedure, the patient's abdomen is marked for the location of the sensors, and the eight-lead sensors (Sensor Array) are applied. The patient wears an abdominal belt that houses a data recorder to capture the transmitted images. After the capsule is swallowed with a glass of water, the patient may return to normal activity for the remainder of the study. He or she can resume a normal diet 4 hours after swallowing the capsule. At the end of the procedure, the patient returns to the facility with the capsule equipment for downloading to a central computer. The procedure lasts about 8 hours.

Because the M2A Capsule Endoscope is a single-use device that moves through the GI tract by peristalsis and is excreted naturally, explain to the patient that the capsule will be seen in the stool. No other follow-up is necessary.

Colonoscopy.

Colonoscopy is an endoscopic examination of the entire large bowel. The American Cancer Society recommends that, beginning at age 50 years, all healthy men and women should have a colonoscopy every 10 years or choose another equally effective recommended screening option (ACS, 2014). The colonoscopy, however, is considered the gold standard test for detecting colon cancer. Those at high risk for cancer (e.g., family history) or those who had polyps removed should have the test more often. The physician may also obtain tissue biopsy specimens or remove polyps through the colonoscope. A colonoscopy can also evaluate the cause of chronic diarrhea or locate the source of GI bleeding. A sclerotherapy drug may be injected at the site to manage bleeding.

An alternative to this invasive procedure is the *CT colonography (virtual colonoscopy),* which is not invasive and uses a CT scanner to view the colon. Patient preparation for this alternative is the same as that for the traditional colonoscopy and should be performed every 5 years.

Patient Preparation.

Patients who have their first colonoscopy are often very anxious. Provide information about the procedure, and reassure them that pain will be controlled with medication as needed (Mikocka-Walus et al., 2012).

To help cleanse the bowel, teach the patient to stay on a clear liquid diet the day before the scheduled colonoscopy. Instruct him or her to avoid red, orange, or purple (grape) beverages and to drink an abundant amount of Gatorade or other sports drink to replace electrolytes that are lost during bowel preparation. The patient should be NPO (except water) 4 to 6 hours before the procedure.

Remind patients to avoid aspirin, anticoagulants, and antiplatelet drugs for several days before the procedure. Diabetic patients should check with their health care provider about drug therapy requirements on the day of the test because they are NPO.

The patient may be required to drink an oral liquid preparation for cleaning the bowel (e.g., sodium phosphate [Phospho-Soda]) the evening before the examination and may repeat that procedure the morning of the study. Some physicians prescribe a gallon of GoLYTELY to cleanse the bowel the day before. *This regimen should not be used for older adults to prevent excessive fluid and electrolyte loss.* All solutions should be chilled to improve their taste. Remind the patient to drink them quickly to prevent nausea. Watery diarrhea usually begins in about an hour after starting the bowel preparation process. In some cases, the patient may also require laxatives, suppositories (e.g., bisacodyl [Dulcolax]), or one or more small-volume cleansing enemas (e.g., Fleet's).

Up to 25% of patients do not have an adequate bowel preparation, which prevents complete visualization of the entire colon. An integrative review of studies on bowel preparation procedures showed that split-dose preparations (the day before and the morning of the test) were better than bowel preparations done only on the day before the test (Van Dongen, 2012).

Procedure.

IV access is necessary for the administration of moderate sedation. The physician prescribes drugs to aid in relaxation, usually IV midazolam hydrochloride (Versed), propofol (Diprivan), and/or an opiate, such as Fentanyl. Complementary and alternative therapies, such as Reiki, have been found to decrease the amount of pain medication needed during the procedure (Bourque et al., 2012).

Initially, the patient is placed on the left side with the knees drawn up while the endoscope is placed into the rectum and moved to the cecum.

Air may be instilled for better visualization. The entire procedure lasts about 30 to 60 minutes. Atropine sulfate is kept available in case of bradycardia resulting from vasovagal response.

During the test, the endoscopy nurse monitors the patient's respirations for rate and depth and the oxygen saturation level via pulse oximetry. Shallow respirations decrease the amount of carbon dioxide that the patient exhales. *If the patient's respiratory rate is below 10 breaths per minute or the exhaled carbon dioxide level falls below 20%, the nurse typically uses a stimulus such as a sternal rub to encourage deeper and faster respirations.*

Follow-Up Care.

Check vital signs every 15 minutes until the patient is stable. Keep the siderails up until the patient is fully alert, and maintain NPO status. Ask the patient to lie on his or her left side to promote comfort and encourage passing flatus (see the Evidence-Based Practice box). Observe for signs of perforation (causes severe pain) and hemorrhage, such as a rapid drop in blood pressure. Reassure the patient that a feeling of fullness, cramping, and passage of flatus are expected for several hours after the test. Fluids are permitted after the patient passes flatus to indicate that peristalsis has returned. Discontinue intravenous fluids that were started before the procedure when the patient is able to tolerate oral fluids without nausea or vomiting.

Evidence-Based Practice QSEN

What Position Is Best for Patients after Undergoing a Colonoscopy?

Devitt, J., Shellman, L., Gardner, K., & Wernett, L. (2011). Using positioning after a colonoscopy for patient comfort management. *Gastroenterology Nursing, 34*(2), 93-100.

This study compared the effect of patient positioning on comfort and passage of flatus after a colonoscopy. After having a colonoscopy, 512 patients were randomly assigned to one of three body positions: left lateral, right lateral, and supine (168-174 patients per position). The patients' position, pain, bloating, and passage of flatus were assessed and rated every 15 minutes.

The results of the study found significant differences in pain and passage of flatus among the three groups of patients. The researchers concluded that patients who were positioned in the left lateral position

had less discomfort and quicker passage of flatus when compared with the other two groups.

Level of Evidence: 2

This study used a large sample of patients who were randomly assigned to one of three study groups.

Commentary: Implications for Practice and Research

Nurses caring for patients who have a colonoscopy should teach patients about the need to be in a left lateral position after the procedure. Although the study used a convenience sample, patients were randomly assigned to one of three groups to compare the effect of body position on comfort and flatus passage. The study used a large sample size from which a conclusion can be generalized for best practice in nursing and health care.

If a polypectomy or tissue biopsy was performed, there may be a *small* amount of blood in the first stool after the colonoscopy. Complications of colonoscopy are not common. However, splenic injury may occur during the procedure and is difficult to diagnose (Bittler, 2011). *Report excessive bleeding or severe pain to the health care provider immediately* (Chart 52-4).

Chart 52-4 Best Practice for Patient Safety & Quality Care QSEN

Care of the Patient after a Colonoscopy

- Do not allow the patient to take anything by mouth until sedation wears off and he or she is alert and passes flatus.
- Take vital signs every 15 to 30 minutes until the patient is alert.
- Keep patient in left lateral position to promote passing of flatus.
- Keep the top siderails up until the patient is alert.
- Assess for rectal bleeding or severe pain.
- Remind the patient that fullness and mild abdominal cramping are expected for several hours.
- Assess for manifestations of bowel perforation, including *severe* abdominal pain and guarding. Fever may occur later.
- Assess for manifestations of hypovolemic shock, including dizziness, light-headedness, decreased blood pressure, tachycardia, pallor, and altered mental status (may be the first sign in older adults).
- If the procedure is performed in an ambulatory care setting, arrange for another person to drive the patient home.

As with other endoscopic procedures, the patient will need someone to provide transportation home if the procedure was done in an ambulatory care setting. Remind the patient to avoid driving for 12 to 18 hours after the procedure because of the effects of sedation.

Clinical Judgment Challenge

Safety; Evidence-Based Practice QSEN

A 50-year-old man has his first screening colonoscopy today. You are assigned as his preprocedure and postprocedure nurse. When you take the patient's vital signs before the procedure, his blood pressure is 148/86 mm Hg. The patient states that he has a history of hypertension that is being well controlled with medication and diet. He tells you that he took his amlodipine (Norvasc) this morning with a small amount of water.

1. Why do you suspect his blood pressure is increased? What other assessment data will you collect?
2. What actions might you consider to decrease his blood pressure?
3. After the procedure, the patient asks for something to drink. How will you respond to him and why? What evidence supports this decision?
4. What evidence-based position should the patient be in after the procedure and why?
5. The patient tells you that he had a polyp removed. What health teaching about colorectal cancer screening will you provide?

Virtual Colonoscopy.

A noninvasive imaging procedure to obtain multi-dimensional views of the entire colon is the *CT colonography,* most popularly known as the **virtual colonoscopy.** The bowel preparation and dietary restrictions are similar to those for traditional colonoscopy. However, if a polyp is detected during a virtual colonoscopy or bleeding is found, the patient must have a follow-up invasive colonoscopy for treatment. Therefore the advantage of the traditional colonoscopy is that both diagnostic testing and minor surgical procedures can be done at the same time.

Sigmoidoscopy.

Proctosigmoidoscopy, often referred to as a *sigmoidoscopy,* is an endoscopic examination of the rectum and sigmoid colon using a flexible scope. The purpose of this test is to screen for colon cancer, investigate the source of GI bleeding, or diagnose or monitor inflammatory bowel

disease. If sigmoidoscopy is used as an alternative to colonoscopy for colorectal cancer screening, it is recommended that screening begin at 50 years of age and should be done every 5 years thereafter (American Cancer Society, 2014). Patients at high risk for cancer may require more frequent screening.

The patient should have a clear liquid diet for at least 24 hours before the test. A cleansing enema or sodium biphosphate (Fleet's) enema is usually required the morning of the procedure. A laxative may also be prescribed the evening before the test.

The patient is placed on the left side in the knee-chest position. No moderate sedation is required. The endoscope is lubricated and inserted into the anus to the required depth for viewing. Tissue biopsy may be performed during this procedure, but the patient cannot feel it. The examination usually lasts about 30 minutes.

Inform the patient that mild gas pain and flatulence may be experienced from air instilled into the rectum during the examination. If a biopsy was obtained, a small amount of bleeding may be observed. Instruct the patient that excessive bleeding should be reported immediately to the health care provider.

Gastric Analysis.

Although not commonly performed, gastric analysis measures the hydrochloric acid and pepsin content for evaluation of aggressive gastric and duodenal disorders (e.g., Zollinger-Ellison syndrome). There are two tests in gastric analysis: basal gastric secretion and gastric acid stimulation. Basal gastric secretion measures the secretion of hydrochloric acid between meals. If only small amounts of secretion are collected, a follow-up gastric stimulation test is given.

The patient is NPO for at least 12 hours before the test. Teach patients to avoid alcohol, tobacco, and drugs that may affect gastric secretion for 24 hours before the study. A nasogastric (NG) tube is inserted, and gastric residual contents are aspirated and discarded.

The NG tube is attached to suctioning equipment for collecting the contents at 15-minute intervals for 1 hour. Samples are collected and labeled with basal acid output (BAO), time, and volume of each specimen.

For the gastric acid stimulation test, the NG tube is left in place and a drug that stimulates gastric acid secretion (e.g., pentagastrin or betazole dihydrochloride [Histalog]) is given. Fifteen minutes after injection of the drug, specimens are again collected at 15-minute intervals for 1 hour. Samples are collected and labeled with maximal acid output (MAO),

time, and volume of each specimen. Depressed levels of gastric secretion suggest the presence of gastric cancer. Increased levels of gastric secretion may indicate one or more duodenal ulcers (see Chapter 55).

After the test is completed, the NG tube is removed and the patient can resume normal eating patterns. No other follow-up is necessary.

Ultrasonography.

Ultrasonography (US) is a technique in which high-frequency, inaudible vibratory sound waves are passed through the body via a transducer. The echoes created by the sound waves are then recorded and converted into images for analysis. US is commonly used to view soft tissues, such as the liver, the spleen, the pancreas, and the biliary system. The advantages of this test are that it is painless and noninvasive and requires no radiation.

The patient may be fasting, depending on the abdominal organs to be examined. Inform the patient that it will be necessary to lie still during the study.

The patient is usually placed in a supine position. The technician applies insulating gel to the end of the transducer and on the area of the abdomen under study. This gel allows airtight contact of the transducer with the skin. The technician moves the transducer back and forth over the skin until the desired images are obtained. The study takes about 15 to 30 minutes. No follow-up care is necessary.

Endoscopic Ultrasonography.

Endoscopic ultrasonography (EUS) provides images of the GI wall and high-resolution images of the digestive organs. The ultrasonography is performed through the endoscope. This procedure is useful in diagnosing the presence of lymph node tumors, mucosal tumors, and tumors of the pancreas, stomach, and rectum. The patient preparation and follow-up care are similar to the preparation and follow-up care for both endoscopy and ultrasonography.

Liver-Spleen Scan.

A liver-spleen scan uses IV injection of a radioactive material that is taken up primarily by the liver and secondarily by the spleen. The scan evaluates the liver and the spleen for tumors or abscesses, organ size and location, and blood flow.

Teach the patient about the need to lie still during the scanning. Assure the patient that the injection has only small amounts of radioactivity and is not dangerous. Ask female patients of childbearing

age if they may be pregnant or are currently breast-feeding. The radionuclide can be found in breast milk, and radiation from x-rays or scans should be avoided in pregnancy.

The technician or the physician gives the radioactive injection through an IV line, and a wait of about 15 minutes is necessary for uptake. The patient is placed in many different positions while the scanning takes place. Tell the patient that the radionuclide is eliminated from the body through the urine in 24 hours. Careful handwashing after toileting decreases the exposure to any radiation present in the urine.

Nursing Concepts and Clinical Judgment Review

What might you NOTICE in a patient with adequate nutrition and elimination related to the GI system?

Physical assessment:

- No nausea or vomiting
- Sufficient appetite
- No intentional weight loss
- No dyspepsia (indigestion)
- No jaundice
- Abdomen soft and not tender
- Normoactive bowel sounds present is all quadrants
- No change in bowel habits
- No abdominal pain
- Normal brown, formed stool
- No frequent diarrhea or constipation

Diagnostic assessment:

- No occult blood in stool
- Normal liver enzymes, such as ALT
- Normal bilirubin levels
- Serum and urine amylase within normal limits
- Serum ammonia level within normal limit
- Serum albumin within normal limit
- Electrolytes within normal limits

Get Ready for the NCLEX® Examination!

Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Remember that the priority for care is to check for the return of the gag reflex after an upper endoscopic procedure before offering fluids or food; aspiration may occur if the gag reflex is not intact. **Safety** QSEN

Health Promotion and Maintenance

- If an endoscopic procedure on an ambulatory care basis is scheduled, remind the patient to have someone available to drive him or her home because of the effects of moderate sedation. **Safety** QSEN
- Teach patients having invasive colon diagnostic procedures to follow instructions carefully for the bowel preparation before testing; the bowel must be clear to allow visualization of the colon.
- Instruct the patient to drink plenty of fluids and take a laxative as prescribed to eliminate barium if used during diagnostic testing. **Evidence-Based Practice** QSEN

Psychosocial Integrity

- Remember that problems of digestion, nutrition, and elimination can markedly affect lifestyle.
- Recall that patient responses to GI health problems such as cancer or peptic ulcer can include anger, denial, and depression.

Physiological Integrity

- The GI tract is continuous from the mouth to the anus. It is responsible for food digestion and bowel elimination; the secretions of the liver, pancreas, and gallbladder empty into the GI tract to aid in digestion.
- Perform a focused abdominal assessment using inspection, auscultation, and light palpation.
- Do not palpate or auscultate any abdominal pulsating mass because it could be a life-threatening aortic aneurysm. **Safety** QSEN
- Be aware that aging causes changes in the GI system as summarized in Chart 52-1. **Patient-Centered Care** QSEN
- Assess and report any major complications of GI testing to the health care provider.

- Review and interpret laboratory results, and report abnormal findings to the health care provider (see Chart 52-3).
- Monitor vital signs carefully for the patient having any endoscopic procedure and moderate sedation.
- Assess patients who have endoscopies for bleeding, fever, and severe pain. **Safety** QSEN
- For patients who have had a colonoscopy, check for passage of flatus before allowing fluids or food (see Chart 52-4).

CHAPTER 53

Care of Patients with Oral Cavity Problems

Cherie R. Rebar, Nicole Heimgartner and Laura Willis

PRIORITY CONCEPTS

- Infection
- Nutrition
- Gas Exchange
- Pain

Learning Outcomes

Safe and Effective Care Environment

1. Use principles of infection control when caring for a patient with oral cavity problems to promote safety.
2. Collaborate with health care professionals to help patients and families experiencing oral cavity problems achieve their desired health outcomes.
3. Identify appropriate community resources for patients with oral cavity problems.

Health Promotion and Maintenance

4. Teach all people how to prevent oral cancer and maintain good oral health.
5. Develop a teaching plan for patients with stomatitis to promote digestion and nutrition and to minimize pain.
6. Teach patients with oral cancer about community-based resources.

Psychosocial Integrity

7. Reduce the psychological impact for the patient and family regarding changes in the appearance or function of any part of the oral cavity.

8. Refer patients with oral cancer to appropriate support groups.

Physiological Integrity

9. Perform a complete assessment of any oral cavity changes, lesions, and wounds.
10. Prioritize postoperative care for patients undergoing surgery for oral cancer to maintain gas exchange and prevent aspiration.
11. Describe collaborative interventions to promote nutrition for postoperative patients having extensive oral surgery.
12. Identify methods to help patients communicate effectively after oral surgery.
13. Plan care for patients who have disorders of the salivary glands.
14. Identify evidence-based practice for teaching or providing oral care for patients.
15. Coordinate continuity of care between the hospital and community-based agencies for patients having oral surgery.

http://evolve.elsevier.com/Iggy/

Digestion of food begins in the oral cavity. Within the mouth, teeth tear, grind, and crush food into small particles to promote swallowing. The enzymes in saliva begin the breakdown of carbohydrates. If a person cannot take food or fluid into the mouth, cannot chew food, or cannot swallow, the basic human need for nutrition may not be met by use of the GI tract. Adequate intake of fluids and nutrients into the body is vital to promote function of every body organ and system.

The pharynx (throat) is located just behind the mouth and has a role in both digestion and gas exchange (oxygenation). The pharynx is the portal between the mouth and the GI tract, where nutrients are broken down. The pharynx also is a portal for gas exchange, as inhaled air passes through the nose, into the pharynx, and down into the trachea. A blockage of the posterior oral cavity, such as a tumor, can interfere with gas exchange and digestion.

Oral cavity disorders, then, can severely affect nutrition and gas exchange, as well as speech, body image, and self-esteem. These disorders commonly affect people who (World Health Organization, 2014):

- Have developmental delays or mental health disorders
- Are homeless or have less (decreased) access to care

- Reside in institutions
- Use tobacco and/or alcohol
- Consume an unhealthy diet
- Have an oral cancer

This chapter discusses the most common oral health problems. As a nurse, you will play an important role in maintaining and restoring oral health through nursing interventions, including patient and family education. Chart 53-1 lists ways to help maintain a healthy oral cavity.

Chart 53-1 Patient and Family Education: Preparing for Self-Management

Maintaining a Healthy Oral Cavity

- Perform self-examination of your mouth every week; report any unusual finding or any noted change.
- Be sure to eat a well-balanced diet.
- Brush and floss your teeth every day. Set and maintain a consistent routine. Keeping floss where you can see it (e.g., on the countertop by the sink) will encourage you to stick to your routine.
- Manage your stress as much as possible; learn how to maintain your emotional health by using healthy coping mechanisms.
- Avoid contact with agents that may cause inflammation of the mouth, such as mouthwashes that contain alcohol.
- If possible, avoid drugs that may cause inflammation of the mouth or reduce the flow of saliva.
- Be aware of any changes in the occlusion of your teeth, mouth pain, or swelling; seek medical attention promptly if these occur.
- See your dentist regularly; have problems attended to promptly.
- If you wear dentures, make sure they are in good repair and fit properly.

Stomatitis

Pathophysiology

Stomatitis is a broad term that refers to inflammation within the oral cavity and may present in many different ways. Painful single or multiple ulcerations (called *aphthous ulcers* or "canker sores") that appear as inflammation and erosion of the protective lining of the mouth are one of the most common forms of stomatitis. The sores cause pain, and open areas place the person at risk for bleeding and infection. Mild erythema (redness) may respond to topical treatments. Extensive stomatitis may require treatment with opioid analgesics and/or antifungal medications, depending on the source of inflammation. Stomatitis is classified according to the cause of the inflammation. *Primary stomatitis,* the most common type, includes **aphthous** (noninfectious) **stomatitis,** herpes simplex stomatitis, and traumatic ulcers. *Secondary stomatitis* generally results from infection by opportunistic viruses, fungi, or bacteria in patients who are immunocompromised. It can also result from drugs, such as chemotherapy. (See Chapter 22 for discussion of chemotherapy-induced stomatitis.)

A common type of secondary stomatitis is caused by *Candida albicans. Candida* is sometimes present in small amounts in the mouth, especially in older adults. Long-term antibiotic therapy destroys other normal flora and allows the *Candida* to overgrow. The result can be **candidiasis,** also called *moniliasis,* a fungal infection that is very painful. Candidiasis is also common in those undergoing immunosuppressive therapy, such as chemotherapy, radiation, and steroids.

Considerations for Older Adults

Patient-Centered Care QSEN

Older adults are especially at high risk for candidiasis because aging causes a decrease in immune function. The risk increases for patients who are diabetic, malnourished, or under emotional stress. Many older adults take multiple medications that can contribute to oral dryness and decreased salivation, as well. Those who wear dentures may use soft denture liners that provide comfort but can also be colonized by *C. albicans,* contributing to denture stomatitis. In addition, older adults who have poor oral hygiene are at high risk for mouth infections and aspiration pneumonia. All health care professionals in any health care setting should be educated in and aware of best practices for oral care

for older adults. Improved oral care could greatly improve patient outcomes, especially for older intubated adults in critical care settings.

Stomatitis can result from infection, allergy, vitamin deficiency (complex B vitamins, folate, zinc, iron), systemic disease, and irritants such as tobacco and alcohol. Infectious agents, such as bacteria and viruses, may have a role in the development of recurrent stomatitis. Certain foods such as coffee, potatoes, cheese, nuts, citrus fruits, and gluten may trigger allergic responses that cause aphthous ulcers. In some cases, strict diets have resulted in the improvement of ulcers.

Patient-Centered Collaborative Care

Assessment

When performing an oral assessment, ask about a history of recent infections, nutrition changes, oral hygiene habits, oral trauma, and stress. Also collect a drug history, including over-the-counter (OTC) drugs and nutrition and herbal supplements. Document the course of the current outbreak, and determine if stomatitis has occurred frequently. Ask the patient if the lesions interfere with swallowing, eating, or communicating.

The symptoms of stomatitis range in severity from a dry, painful mouth to open ulcerations, placing the patient at risk for infection. These ulcerations can alter nutrition status because of difficulty with eating or swallowing. When they are severe, stomatitis and edema have the potential to obstruct the airway.

In oral candidiasis, white plaque-like lesions appear on the tongue, palate, pharynx (throat), and buccal mucosa (inside the cheeks) (Fig. 53-1). When these patches are wiped away, the underlying surface is red and sore. Patients may report pain, but others describe the lesions as dry or hot.

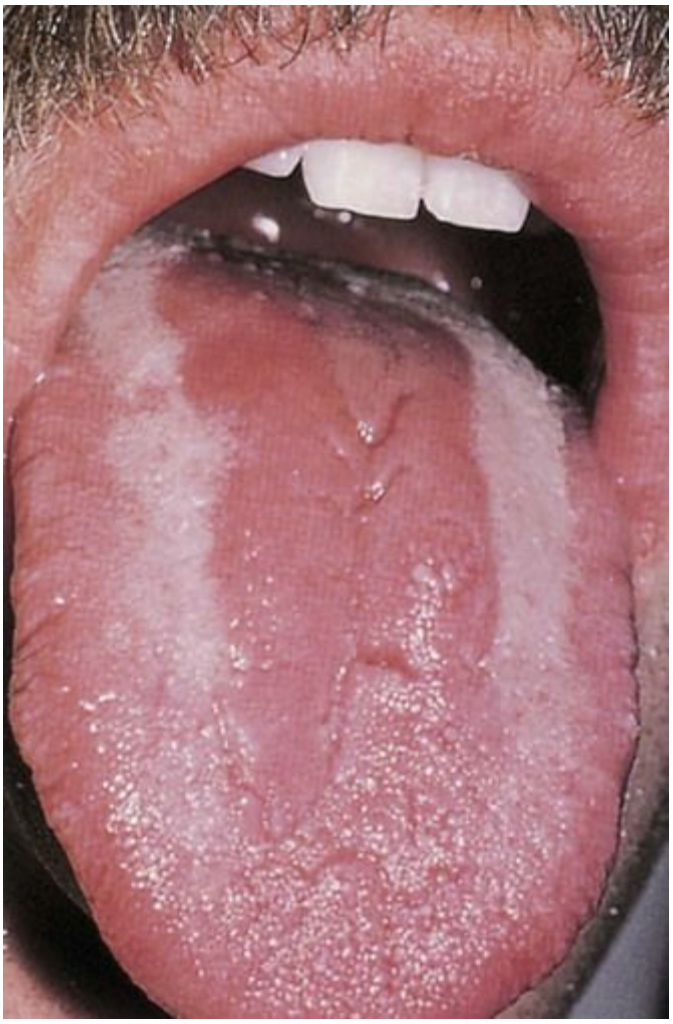

FIG. 53-1 Oral candidiasis.

While examining the mouth, wear gloves, use a penlight to ensure adequate lighting, and use a tongue blade to aid examining the oral cavity. Assess the mouth for lesions, coating, and cracking. Document characteristics of the lesions including their location, size, shape, odor, color, and drainage.

If lesions are seen along the pharynx and the patient reports **dysphagia** (pain on swallowing), the lesions might extend down the esophagus. To establish a definitive diagnosis, the primary care provider may prescribe additional swallowing studies.

The physical assessment also includes palpating the cervical and submandibular lymph nodes for swelling. Advanced practice nurses and other primary care providers usually perform this part of the examination.

Nursing Safety Priority QSEN

Action Alert

When assessing the patient with stomatitis, be alert for signs and symptoms of dysphagia, such as coughing or choking when swallowing, a sensation of food "sticking" in the pharynx, or difficulty initiating the swallowing process. If dysphagia is suspected, document all findings and report these to the health care provider because dysphagia can cause numerous problems, including airway obstruction, aspiration pneumonia, and malnutrition.

Interventions

Interventions for stomatitis are targeted toward health promotion and reduced risk for infection through careful *oral hygiene* (see the Evidence-Based Practice box) and food selection. When providing mouth care for the patient, you may delegate oral care to unlicensed assistive personnel (UAP). Because you are accountable for the delegated task, remind UAP to use a soft-bristled toothbrush or disposable foam swabs to stimulate gums and clean the oral cavity and to use toothpaste that is free of sodium lauryl sulfate (SLS), if possible, because this ingredient has been associated with stomatitis. Teach the patient to rinse the mouth every 2 to 3 hours with a sodium bicarbonate solution or warm saline solution (may be mixed with hydrogen peroxide). He or she should avoid most commercial mouthwashes because they have high alcohol content, causing a burning sensation in irritated or ulcerated areas. Health food stores sell more natural mouthwashes that are not alcohol-based. Teach the patient to check the labels for alcohol content. Frequent, gentle mouth care promotes débridement of ulcerated lesions and can prevent superinfections. Chart 53-2 lists measures for special oral care.

Chart 53-2 Best Practice for Patient Safety & Quality Care QSEN

Care of the Patient with Problems of the Oral Cavity

- Remove dentures if the patient has severe stomatitis or oral pain.
- Encourage the patient to perform oral hygiene or provide it after each meal and as often as needed.
- Increase mouth care to every 2 hours or more frequently if stomatitis is not controlled.
- Use a soft toothbrush or gauze for oral care.
- Encourage frequent rinsing of the mouth with warm saline, sodium bicarbonate (baking soda) solution, or a combination of these solutions.

- Teach the patient to avoid commercial mouthwashes, particularly those with high alcohol content, and lemon-glycerin swabs.
- Assist the patient in selecting soft, bland, and nonacidic foods.
- Apply topical analgesics or anesthetics as prescribed by the health care provider, and monitor their effectiveness.

Evidence-Based Practice QSEN

Does Providing Standard or Comprehensive Oral Care Result in the Best Outcomes for ICU Patients?

Prendergast, V., Jakobsson, U., Renvert, S., & Hallberg, I. (2012). Effects of a standard versus comprehensive oral care protocol among intubated neuroscience ICU patients: Results of a randomized controlled trial. *Journal of Neuroscience Nursing, 44*(3), 134-146.

Evidence shows that proper oral care is essential to prevent infections such as aspiration pneumonia and ventilator-associated pneumonia (VAP). In this study, a 2-year randomized clinical trial (RCT) involving 56 patients was conducted to compare the effect of standard oral care (manual toothbrushing) with that of comprehensive oral care (tongue scraping, electric toothbrushing, and moisturizing) on oral health of intubated neuroscience ICU patients.

Oral health was evaluated based on a standardized tool (Eilers' Oral Assessment Guide) at certain points during patients' hospitalizations. The results of this RCT demonstrated that comprehensive oral care protocols were more effective in maintaining oral health throughout intubation and after extubation when compared with standard oral care protocols.

Level of Evidence: 2

The study was a randomized controlled trial (RCT), which was also part of a larger RCT, comparing the effects of standard versus comprehensive oral care on ventilator-associated pneumonia among patients in a neuroscience ICU.

Commentary: Implications for Practice and Research

The findings of this research clearly indicate that delivery of comprehensive oral care was more effective than delivery of standard oral care in maintaining oral health of neuroscience patients who were intubated in the ICU setting. The review of literature also indicated that existing information about the specific ways in which to deliver oral care to this patient population is lacking. Be aware of best practices to deliver

the most effective, evidence-based care to yield optimal patient outcomes. Further studies using larger and more diverse subjects need to be conducted.

Drug therapy used for stomatitis includes antimicrobials, immune modulators, and symptomatic topical agents. Complementary and alternative therapies may also be tried.

Antimicrobials, including antibiotics, antivirals, and antifungals, may be necessary for control of infection. Tetracycline syrup may initially be prescribed, especially for recurrent aphthous ulcers (RAUs). The patient rinses for 2 minutes and swallows the syrup, thus obtaining both topical and systemic therapy. Minocycline swish/swallow and chlorhexidine mouthwashes may also be used.

A regimen of IV acyclovir (Zovirax) is prescribed for immunocompromised patients who contract herpes simplex stomatitis. Patients with healthy immune systems may be given acyclovir in oral or topical form.

For fungal infections like yeast, nystatin (Mycostatin) oral suspension swish/swallow is most commonly prescribed. Ice pop troches (lozenges) of the antifungal preparation allow the drug to slowly dissolve, and the cold provides an analgesic effect. Topical triamcinolone in benzocaine (Kenalog in Orabase) and oral dexamethasone elixir used as a swish/expectorate preparation are commonly used for stomatitis, especially RAU.

Immune-modulating agents that may be prescribed as second-line therapy include:

- Topical amlexanox (Aphthasol)
- Topical granulocyte-macrophage colony-stimulating factor (GM-CSF)
- Thalidomide

The exact mechanism for how these drugs work is not clear. However, they may inhibit release of mediators that contribute to the inflammation seen in patients with RAU.

Over-the-counter (OTC) benzocaine anesthetics (e.g., Orabase, Anbesol) and camphor phenol (Campho-Phenique) can also control pain. Viscous lidocaine may also be prescribed to use as a gargle or mouthwash. "Magic mouthwash," a mixture of lidocaine, Benadryl, Maalox, Carafate, glucocorticoids, and other ingredients, is also commonly prescribed for those with oral pain due to cancer treatments.

Nursing Safety Priority QSEN

Drug Alert

Teach patients to use viscous lidocaine with extreme caution because its anesthetizing effect may cause burns from hot liquids in the mouth and/or increase the risk for choking.

Dietary changes may also help decrease pain. Cool or cold liquids can be very soothing, whereas hard, spicy, salty, and acidic foods or fluids can further irritate the ulcers. Include foods high in protein and vitamin C to promote healing, including scrambled eggs, bananas, custards, puddings, and ice cream, unless the patient has lactose intolerance.

NCLEX Examination Challenge

Physiological Integrity

Viscous lidocaine is prescribed for a client. What client teaching does the nurse provide?

A "Be certain your food's temperature is not too hot."
B "This medication will kill bacteria found within your mouth."
C "You may use this drug as many times during the day as you wish."
D "Viscous lidocaine is the most effective medication to treat fungal infections."

Oral Tumors

Oral cavity tumors can be benign, precancerous, or cancerous. Whether benign or malignant, tumors of the mouth affect many daily functions, including swallowing, chewing, and speaking. Pain accompanying the tumor can also limit daily activities and self-care. Oral tumors affect body image, especially if treatment involves removal of the tongue or part of the mandible (jaw) or requires a tracheostomy.

Premalignant Lesions

Leukoplakia presents as slowly developing changes in the oral mucous membranes causing thickened, white, firmly attached patches that cannot easily be scraped off. These patches appear slightly raised and sharply rounded. Most of these lesions are benign. However, a small percentage of them become cancerous. Although leukoplakia can be found anywhere on the oral mucosa, lesions on the lips or tongue are more likely to progress to cancer.

Leukoplakia results from mechanical factors that cause long-term oral mucous membrane irritation, such as poorly fitting dentures, chronic cheek nibbling, or broken or poorly repaired teeth. In addition, oral hairy leukoplakia (OHL) can be found in patients with human immune deficiency virus (HIV) infection. The Joint Commission (TJC) Core Measures TOB-1 requires asking about tobacco use, because tobacco products (smoked, dipped, or chewed) have also been implicated in the development of leukoplakia, sometimes referred to as "smoker's patch." Oral leukoplakia can be confused with oral candidal infection. However, unlike candidal infection, leukoplakia cannot be removed by scraping.

Leukoplakia is the most common oral lesion among adults. OHL is associated with Epstein-Barr virus (EBV) and can be an early manifestation of HIV infection. When associated with HIV infection, the appearance of OHL is highly correlated with progression from HIV infection to acquired immune deficiency syndrome (AIDS). Leukoplakia not associated with HIV infection is more often seen in people older than 40 years. The incidence of leukoplakia is two times higher in men than in women; however, this ratio is changing because increasing numbers of women are smoking.

Erythroplakia appear as red, velvety mucosal lesions on the surface of the oral mucosa. There are more malignant changes in erythroplakia than in leukoplakia; therefore erythroplakia is often considered "precancerous" in presentation. As such, these lesions should be regarded with suspicion and analyzed by biopsy. Erythroplakia is most

commonly found on the floor of the mouth, tongue, palate, and mandibular mucosa. It can be difficult to distinguish from inflammatory or immune reactions.

Oral Cancer

Dentists and physicians systematically screen patients for oral cancer. Oral assessment has become a part of the routine dental examination. People should visit a dentist at least twice a year for professional dental hygiene and oral cancer screening, which includes inspecting and palpating the mouth for lesions.

Prevention strategies for oral cancer include minimizing sun and tanning bed exposure, tobacco cessation, and decreasing alcohol intake. Most dentists use digital technology instead of x-rays when performing the annual or biannual dental examination, because excessive, prolonged radiation from x-rays has been associated with head and neck cancer (Oral Cancer Foundation [OCF], 2014). Teach patients to follow the guidelines in Chart 53-1 to maintain oral health.

❖ Pathophysiology

More than 90% of oral cancers are *squamous cell carcinomas* that begin on the surface of the epithelium. Over a period of many years, premalignant (or dysplastic) changes begin. Cells begin to vary in size and shape. Alterations in the thickness of the lining of the epithelium develop, resulting in atrophy. These tumors usually grow slowly, and the lesions may be large before the onset of symptoms unless ulceration is present. *Mucosal erythroplasia is the earliest sign of oral carcinoma. Oral lesions that appear as red, raised, eroded areas are suspicious for cancer. A lesion that does not heal within 2 weeks or a lump or thickening in the cheek is a symptom that warrants further assessment* (OCF, 2013).

Squamous cell cancer can be found on the lips, tongue, buccal mucosa, and oropharynx. The major risk factors in its development are increasing age, tobacco use, and alcohol use. Most oral cancers occur in people older than 40 years. Tobacco use in any form (e.g., smoking or chewing tobacco) can increase the risk for cancer. A person who frequently consumes alcohol and uses tobacco in any form is at the highest risk.

Genetic/Genomic Considerations

Patient-Centered Care QSEN

Genetic changes in patients with oral cancer have been found, especially the mutation of the *TP53* gene (McCance et al., 2014). The *TP53* gene is nicknamed the "guardian of the genome" because tumor protein *p53* is essential for cell division regulation and prevention of tumor formation (National Institutes of Health, 2014). Because mutations in this gene are linked to various cancers, always ask about a personal and family history of ***any*** type of cancer when assessing the patient with oral cavity problems.

An increased rate of squamous cell cancer is found in people with occupations such as textile workers, plumbers, and coal and metal workers, mainly due to prolonged exposure to polycyclic aromatic hydrocarbons (PAHs). People with **periodontal** (gum) **disease** in which mandibular (jaw) bone loss has occurred are especially at risk for cancer of the mouth. Additional factors, such as sun exposure, poor nutrition habits, poor oral hygiene, and infection with the human papilloma virus (HPV16) may also contribute to oral cancer (OCF, 2013).

Research indicates a correlation between specific strains of the human papilloma virus (HPV) and oral cancer. Oral cancer associated with HPV appears in the tonsillar area or along the base of the tongue in younger people. Because HPV-positive oral cancers account for a large number of oral cancer diagnoses, routine oral assessment is essential. Oral cavity inspection combined with neck palpation is recommended yearly to aid in early detection (OCF, 2013).

Basal cell carcinoma of the mouth occurs primarily on the lips. The lesion is asymptomatic and resembles a raised scab. With time, it evolves into a characteristic ulcer with a raised, pearly border. Basal cell carcinomas do not metastasize (spread) but can aggressively involve the skin of the face. The major risk factor for this type of cancer is excessive sunlight exposure.

Basal cell carcinoma occurs as a result of the failure of basal cells to mature into keratinocytes. It is the second most common type of oral cancer, but it is much less common than squamous cell carcinoma.

Kaposi's sarcoma is a malignant lesion in blood vessels, appearing as a raised, purple nodule or plaque, which is usually painless. In the mouth, the hard palate is the most common site of Kaposi's sarcoma, but it can be found also on the gums, tongue, or tonsils. It is most often associated with AIDS. (See Chapter 19 for a complete discussion of Kaposi's sarcoma.)

As a group, oral cancers account for about 3% of all cancers in men and 2% of all cancers in women in the United States. Over 42,000 new cases

are diagnosed each year, with almost 8000 deaths (OCF, 2013). Most cancers occur in middle-aged and older people, although in recent years, younger adults have been affected, probably as a result of sun exposure and HPV.

Patient-Centered Collaborative Care

Assessment

Begin by assessing the patient's routine oral hygiene regimen and use of dentures or oral appliances, which might add to discomfort or mechanically irritate the mucosa. Ask about oral bleeding, which might indicate an ulcerative lesion or periodontal (gum) disease. Determine the patient's past and current appetite and nutrition state, including difficulty with chewing or swallowing. A continuing trend of weight loss may be related to metastasis, heavy alcohol intake, difficulty in eating or chewing, or an underlying health problem (Chart 53-3).

Chart 53-3 Key Features

Oral Cancer

- Bleeding from the mouth
- Poor appetite
- Difficulty chewing
- Difficulty swallowing
- Poor nutrition status and weight loss
- Thick or absent saliva
- Painless oral lesion that is red, raised, or eroded
- Thickening or lump in cheek

An examination of the oral cavity requires adequate lighting. Thoroughly inspect the oral cavity for any lesions, evidence of pain, or restriction of movement. Gently using a tongue blade and penlight, examine all areas of the mouth. Carefully note any change in speech caused by tongue movement. Notice any change in voice or swallowing, and assess for thick or absent saliva. After inspection, the advanced practice nurse, specialty nurse, or other health care provider uses bimanual palpation of any visible nodules to determine size and fixation. The cervical lymph nodes are also palpated (Fig. 53-2).

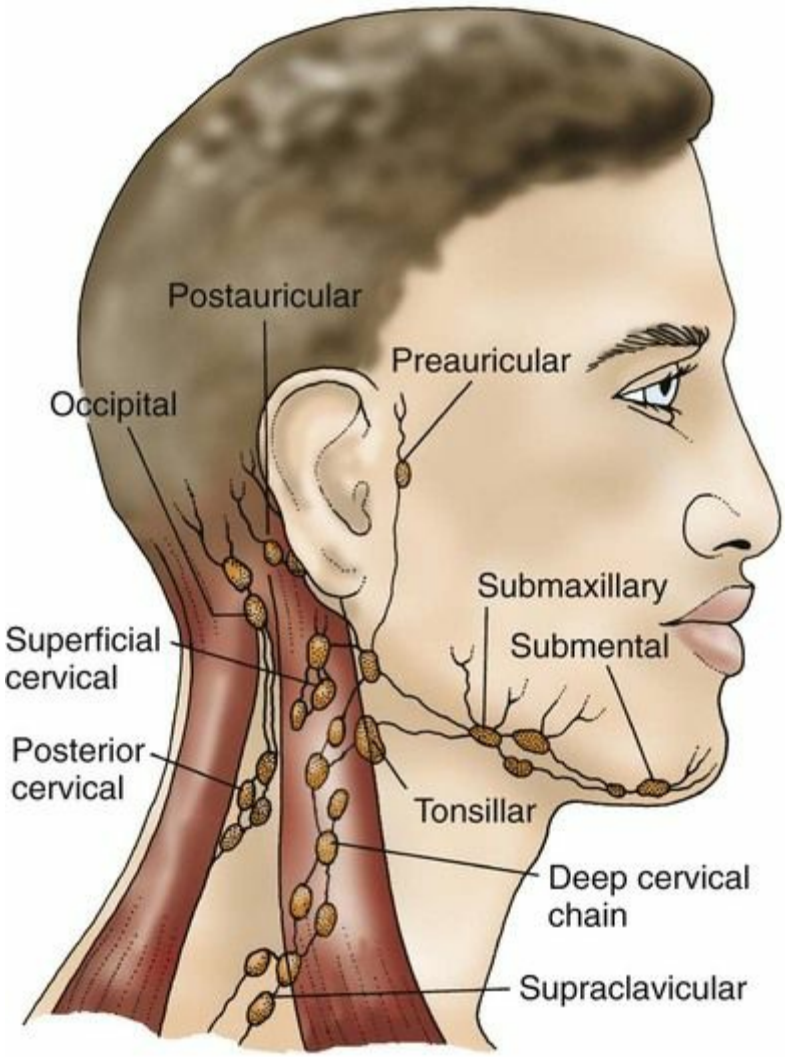

FIG. 53-2 The lymph nodes of the cervical region.

The functioning and appearance of the mouth are strongly linked with body image and quality of life. Therefore it is important to assess the impact of oral lesions on the patient's self-concept. In addition, assess for any educational or cultural needs that might affect health teaching or treatment. Evaluate the patient's support system and past coping mechanisms.

OralCDx is a diagnostic procedure usually performed by a dentist during a routine dental examination. The procedure involves brushing of a lesion and is helpful in determining whether the lesion is precancerous (OralCDx, 2013). However, biopsy is the definitive method for diagnosis of oral cancer. The physician obtains a needle biopsy specimen of the abnormal tissue to assess for malignant or premalignant changes. Incisional biopsies may also be performed. An intraoral biopsy can be done under local anesthesia. In very small lesions, an excisional biopsy can permit complete tumor removal. MRI is useful in detecting perineural involvement and in evaluating thickness in cancers of the tongue. Both CT and MRI can be used to determine spread to the liver or

lungs if further staging of the disease is warranted.

Interventions

Both the presence of tumors of the oral cavity and the effects of their treatment threaten the integrity of the oral mucosa and the patient's airway. Oral cavity lesions can be treated by surgical excision, by nonsurgical treatments such as radiation or chemotherapy, or by a combination of treatments (referred to as *multimodal therapy*). Chemotherapy is currently not used independently in the treatment of oral cancers but is used in addition to other modes of treatment to sensitize malignant cells to radiation, to shrink a malignancy before surgery, or to decrease the potential for malignancy (OCF, 2013). Multimodal therapy is the most costly treatment option yet is more frequently used (OCF, 2013). *If the patient has extensive tumor involvement and copious, tenacious (thick and "stringy") secretions, maintaining an open airway is your priority for care to promote gas exchange.* Other nursing interventions focus on restoring and maintaining oral health.

Nonsurgical Management.

Implement interventions to *manage the patient's airway* by increasing air exchange, removing secretions, and preventing aspiration as needed. Assess for dyspnea resulting from the tumor obstruction or from excessive secretions. Assess the quality, rate, and depth of respirations. Auscultate the lungs for adventitious sounds, such as wheezes caused by aspiration. Listen for stridor caused by partial airway obstruction. Promote deep breathing to help produce an effective cough to mobilize the patient's secretions.

To promote gas exchange, place the patient in a semi-Fowler's or high-Fowler's position. If the patient is able to swallow and gag reflexes are intact, it is beneficial to encourage fluids to liquefy secretions for easier removal. Chest physiotherapy also increases air exchange as well as promotes effective coughing. If available, collaborate with the respiratory therapist about performing this procedure. If needed, use oral suction equipment with a dental tip or a tonsil tip (Yankauer catheter) to remove secretions that obstruct the airway. Teach the patient and family to use the catheters as needed.

If edema occurs with oral cavity lesions, the patient may receive steroids to reduce inflammation. Antibiotics may be prescribed if infection is present because it can increase inflammation and edema. A cool mist supplied by a face tent may assist with oxygen transport and control of edema.

Nursing Safety Priority QSEN

Action Alert

Aspiration Precautions prevent or reduce the risk factors for aspiration. Assess the patient's level of consciousness (LOC), gag reflex, and ability to swallow. To prevent aspiration, place the patient sitting upright at 90 degrees (high-Fowler's position). As a precaution, keep suction equipment nearby. For patients at high risk, assess the gag reflex before giving any fluids. Remind UAP to feed patients at risk for aspiration in small amounts. Teach visitors to speak with you before offering any type of food or drink to the patient. Provide thickened liquids as an aid to prevent aspiration. Referral to the speech/language pathologist can be beneficial for patients who are experiencing aspiration with swallowing. A swallow study may be needed to fully assess the risk for aspiration.

It is important to work with the patient to *establish an oral hygiene routine.* Perform oral hygiene every 2 hours for ulcerated lesions, infection, or in the immediate postoperative period. Modifications might be needed because of oral discomfort, bleeding, or edema. Oral care with a soft-bristled toothbrush is preferred. If the platelet count falls below 40,000/mm^3, switch the patient to an ultrasoft "chemobrush." The use of "Toothettes" or a disposable foam brush is discouraged because these products may not adequately control bacteremia-promoting plaque and may further dry the oral mucosa. Lubricant can be applied to moisten the lips and oral mucosa as needed.

Teach patients and their families that the patient should avoid using commercial mouthwashes and lemon-glycerin swabs. Commercial mouthwashes contain alcohol, and lemon-glycerin swabs are acidic. These substances can cause a burning sensation and contribute to dry oral mucous membranes. Encourage frequent rinsing of the mouth with sodium bicarbonate solution or warm saline (see also Chart 53-2). Follow hospital or health care provider protocol if available.

Radiation therapy for oral cancers can be given by external beam or interstitial implantation to reduce the size of the tumor before surgery. *External-beam* radiation passes through the skin or mucous membrane to the tumor site. Typically, treatments are given as five daily treatments per week, with a 2-day break each week, over a 6- to 9-week period. Each treatment lasts only about 10 to 15 minutes, with more time being dedicated to undertaking special precautions to minimize the dose of

radiation to the brain or spinal cord (OCF, 2013).

Another option is the implantation of radioactive substances (*interstitial radiation therapy* or *brachytherapy*) either to boost the dosage or to deliver a radiation dose close to the tumor bed. This form of implant therapy can be curative in early-stage lesions in the floor of the mouth or anterior tongue. It may also add a boost of radiation to a tumor that received external-beam radiation.

With the exception of radioactive seeds, which have a low level of emission, patients receiving interstitial radiation are usually hospitalized for the duration of treatment. *Place patients on radiation transmission precautions while the materials are active or in place.* Patients need to be placed in a private room with lead-lined walls or moveable panels. When permitted, visitors may stay only 30 minutes or less each day and must sit or stand away from the patient in designated areas. Pregnant women and children younger than 18 years should not be permitted to visit. A tracheostomy may be required with interstitial implants because of edema and increased oral secretions. (See Chapter 22 for general nursing care of patients undergoing radiation therapy.)

Teach the patient undergoing *chemotherapy* and family members about the side effects of these agents, which vary with each drug. Give antiemetics as prescribed, and provide other comfort measures as needed. (See Chapter 22 for general care of patients receiving chemotherapy.)

Nursing Safety Priority QSEN

Drug Alert

Patients who are undergoing radiation and/or chemotherapy treatment may experience a decreased ability to tolerate prescribed and over-the-counter medications due to being immunocompromised. Teach patients about expected side effects, and remind them to not take any medication (including over-the-counter medications, herbs, or vitamin supplements) without first discussing them with their health care provider.

One of the most recent advances in the use of drugs for oral cancer is targeted therapy. Hormone-like substances known as *growth factors (GFs)* occur in the body's cells. Oral tumor cells, along with other types of cancers, grow quickly because they have more GF receptors than does normal healthy tissue. One of these GFs is called *epidermal growth factor*

(EGF), which has been associated with oral cancers. Newer drugs that can target and block EGF receptors (EGF-R) are being tested, and more than a dozen have been approved, including cetuximab (Erbitux), erlotinib (Tarceva), and panitumumab (Vectibix). (Chapter 22 describes targeted molecular therapy.)

NCLEX Examination Challenge

Physiological Integrity

A male client is admitted with a diagnosis of oral cancer. Which statement by the nursing assistant indicates a need for further teaching by the nurse about this client's oral care?
A "I need to do oral care at least every 2 hours."
B "I'll use a soft-bristled toothbrush to prevent bleeding."
C "I'll remind him to use mouthwash after brushing."
D "I'll tell him to rinse his mouth frequently with sodium bicarbonate."

Surgical Management.

The physician can often remove small, noninvasive lesions of the oral cavity in an ambulatory surgical center with local anesthesia. The surgical defect is usually small enough to be closed by sutures. These smaller lesions may also be responsive to carbon dioxide laser therapy or **cryotherapy** (extreme cold application), as well as photodynamic therapy. These procedures can be performed as an ambulatory care procedure in a surgical center but may require general anesthesia.

Small oral cancers are equally responsive to radiation or photodynamic therapy and to surgery. More invasive lesions (stages III and IV) require more extensive surgical excision and result in a greater loss of function and disfigurement. Not all lesions can be excised by the peroral approach (through the mouth). The goal of surgical resection is removal of the tumor with a surgical margin that is free of cancer cells.

Preoperative Care.

Before excision of a lesion in the oral cavity, assess and document the patient's level of understanding of the disease process, the rationale for the surgery, and the planned intervention. Problems associated with cancer therapy can be reduced or optimally managed by collaborating with the patient and family regarding preparation and instruction. Reinforce information as needed. Include family members or other caregivers in the health teaching unless culturally inappropriate.

For small, local excisions, postoperative restrictions include a liquid diet for a day and then advancing as tolerated. There are no activity limitations, and postoperative analgesics are prescribed.

Instructions for the patient undergoing large surgical resections may include but are not limited to these expectations after surgery:

- Placement of a temporary tracheostomy, oxygen therapy, and suctioning
- Temporary loss of speech because of the tracheostomy
- Frequent monitoring of postoperative vital signs
- NPO status until intraoral suture lines are healed
- Need to have IV lines in place for drug delivery and hydration
- Postoperative drug therapy and activity (out of bed on the day or surgery or first postoperative day)
- Possibility of surgical drains

Because communication is interrupted, assess the patient's ability to read, write, and draw pictures to communicate. In coordination with the patient, select the method of communication to use after surgery with staff and family members (e.g., Magic Slate, handheld mobile device, computer, picture board, or pad and pencil). Preprinted flashcards may be used to communicate the patient's needs, such as "I am tired," "I am in pain," or "I am hungry." Urge the patient to practice the chosen method before surgery to reduce frustration after surgery.

Operative Procedures.

Three factors influence the extent of surgery performed for oral cancers: the size and location of the tumor, tumor invasion into the bone, and whether there has been metastasis (cancer spread) to neck lymph nodes. Small, noninvasive tumors can be removed perorally (through the mouth). Otherwise, an external approach may be used. The most extensive oral operations are composite resections, which combine partial or total **glossectomy** (tongue removal) and partial **mandibulectomy** (jaw removal). In the **commando** (co-mandible) **procedure** (**COM**bined neck dissection, **MAND**ibulectomy, and **O**ropharyngeal resection), the surgeon removes a segment of the mandible with the oral lesion and performs a radical neck dissection (see Chapter 29).

Metastasis to cervical lymph nodes usually indicates a poor prognosis for patients with cancer of the oral cavity. In those with cervical node metastasis, a neck dissection may also be performed. A radical neck dissection usually involves the removal of all cervical lymph nodes on the affected side, along with cranial nerve XI (the accessory nerve), the internal jugular vein, and the sternocleidomastoid (front neck) muscle.

Modified and selective neck dissections may be performed in patients with minimal lymph node involvement.

Postoperative Care.

The patient may have a temporary or permanent tracheostomy, requiring intensive nursing care to promote airway clearance. In addition, care must be taken to protect the surgical incision site from mechanical damage and infection (see Chapter 29). Nursing interventions to relieve pain or discomfort and promote nutrition are also important. Older adults are a special risk for surgery and need to be monitored very carefully (Chart 53-4).

Chart 53-4 Focused Assessment

The Postoperative Older Adult with Oral Cancer

- Assess the mouth and surrounding tissues for candidiasis, mucositis, and pain; assess for loss of appetite and taste.
- Monitor the patient's weight.
- Monitor nutrition and fluid intake.
- Assess for difficulty in eating or speech.
- Assess pain status and measures used to control pain.
- Monitor the patient's response to medications.
- Identify psychosocial problems, such as depression, anxiety, and fear.
- Assess the patient's overall physiologic condition and how this may affect pharmacologic therapy.

Nursing Safety Priority QSEN

Action Alert

After extensive excision or resection for oral cancer, the most important nursing intervention is maintaining the patient's airway to promote gas exchange! Upon awakening from anesthesia, the patient may not recall, or realize, that a tracheostomy tube is in place and may initially panic because of the inability to speak. Remind the patient why he or she cannot speak, and provide reassurance that the vocal cords are intact (unless a total laryngectomy has been performed, in which case the loss of voice is permanent).

Ensure that the predetermined method of communication is available for the patient, family members, and staff. When the patient has an

adequate airway and can effectively clear secretions by coughing, the tracheostomy tube may be removed. When the tube is removed, an airtight dressing is placed over the site and the tracheostomy incision heals without the need for sutures.

Patients who have undergone extensive resection may have slurred speech or difficulty in speaking as a result of nerve damage or tongue removal. Collaborate with the speech-language pathologist if speech is altered.

Protect the incision site to avoid infection. Provide gentle mouth care for cleaning away thick secretions and stimulating the flow of saliva. The delivery of oral care depends on the nature and extent of the surgical procedure. Give oral care at least every 4 hours in the early postoperative phase. The presence of unusual odors from the mouth can indicate infection; therefore continual assessment of the oral cavity is very important. In the early postoperative phase, take care to avoid disruption of the suture line during oral hygiene.

Elevate the head of the bed to assist in decreasing edema by gravity. If skin grafting was done, inspect the donor site (generally on the anterior thigh) every 8 hours for bleeding or signs of infection. (See Chapter 29 for specific nursing care of the patient with a radical neck dissection.)

To provide optimal *pain relief* in the postoperative period, rely on subjective and objective data to assess the need for analgesics and their effectiveness. The desired outcome of drug therapy during this period is relief of pain while allowing the patient to function at an optimal level. Those who have undergone surgery for oral cancer describe their pain as throbbing or pounding. IV morphine is usually the initial pain medication given with acetaminophen or ibuprofen to decrease inflammation. Tylox or Percocet (oxycodone plus acetaminophen) may be used for systemic relief of moderate pain after the IV morphine is discontinued.

Patients who have undergone extensive resections of the oral cavity remain on NPO status for several days. This time allows healing in the oral cavity before food comes in contact with the incision. Nasogastric feeding or total parenteral nutrition may be needed until oral nutrition can begin (see Chapter 60).

Nursing Safety Priority QSEN

Action Alert

When oral fluid intake is started, assess for and document signs of difficulty

swallowing, aspiration, or leakage of saliva or fluids from the suture line. Monitor daily weights and hydration. Nutrition supplementation may be used to improve the patient's quality of life. Patients who have weight loss or who are having difficulty maintaining hydration may be candidates for the placement of a gastrostomy tube. Coordinate nutrition care with the dietitian.

Encourage the patient to perform swallowing exercises. Collaborate with the speech-language pathologist to assist with swallowing techniques. Thickened fluids may be needed to prevent aspiration. A swallowing impairment may be temporary or permanent.

Community-Based Care

Continuing care for the patient with an oral tumor depends on the severity of the tumor, its collaborative care, and available support systems. Most patients are maintained at home during follow-up care. Ongoing nutrition management remains a vital part of the treatment plan. In addition, the patient and family may benefit from a community-based support group for cancer patients.

Home Care Management.

If radiation therapy is part of the patient's treatment plan, home care considerations include health teaching and management strategies. Complications due to radiation to the head or neck can be acute or delayed. Acute effects include treatment-related mucositis, stomatitis, and alterations in taste. Long-term effects such as **xerostomia** (excessive mouth dryness) and dental decay require ongoing oral care, the use of saliva substitutes, and follow-up dental visits. Although ongoing dental care is important, the possible adverse effects that radiation has on bone make elective oral surgical procedures, such as tooth extraction, impossible in the area of the radiation. Fatigue is a common side effect of radiation and chemotherapy.

The patient whose tracheostomy tube has been removed is often placed on a soft diet by mouth before discharge. Occasionally, however, patients are discharged from the hospital while still requiring tracheostomy suction, oral suction, and nasogastric feedings. Suction equipment, nutrition supplies, and nursing care can be provided by home care companies. (See Chapter 60 for home care preparation for the patient receiving home parenteral nutrition and Chapter 28 for home care preparation for the patient with a tracheostomy.)

Self-Management Education.

Before hospital discharge, teach the patient and family about drug therapy, nutrition therapies, any treatments (e.g., tracheostomy care, suture line care, dressing changes), and early symptoms of infection (Chart 53-5). Alterations in taste and dysphagia make maintaining adequate nutrition a challenge for the oral cancer patient. Alterations in taste occur when the taste buds are included in the radiation treatment field. Taste sensation may begin to return several weeks after the completion of treatment. Some types of chemotherapy can also affect the patient's taste. Sometimes the loss of taste is permanent.

Chart 53-5 Patient and Family Education: Preparing for Self-Management

Care of the Patient with Oral Cancer at Home

- Follow the treatment plan for cancer therapies.
- Remember that taste sensation may be decreased; add non-spicy seasonings to food to better enjoy it.
- Use a thickening agent for liquids if dysphagia is present.
- Eat soft foods if stomatitis occurs.
- Inspect the mouth every day for changes, such as redness or lesions.
- Continue meticulous oral hygiene at home using a chemobrush and frequent rinsing; clean brush after every use.
- Use saliva substitute as prescribed.
- Avoid sun or tanning bed exposure if radiation is part of therapy.
- Clean with a gentle, nondeodorant soap, such as Ivory.

Changes in taste include dislike of meat, such as beef or pork, and metallic tastes in the mouth. Teach patients to add seasonings to foods, to use gravies or sauces to make foods more palatable, and to use high-protein foods such as cheeses, milk, eggs, puddings, and legumes in place of meat. Instruct patients with dysphagia in swallowing exercises. Recommend thickened liquids because thin liquids, such as water, are difficult to control during swallowing. Collaborate with the dietitian to teach the family how to assess the nutrition intake of the patient who is just beginning to eat. Liquid dietary supplements are usually recommended at this time. If bleeding or stomatitis is present, recommend soft foods to prevent further injury to the mucous membranes.

Teach the patient or family members to inspect the oral cavity daily for areas of redness, which can indicate the onset of stomatitis. Meticulous

oral hygiene should be continued at home, especially with adjuvant chemotherapy or radiation. Reinforce the oral hygiene routine, emphasizing the need for frequent mouth rinsing to reduce the number of microorganisms and to maintain adequate hydration. The patient should use a chemobrush (an extra-soft type of toothbrush), rinse the chemobrush with hydrogen peroxide and water or with a diluted bleach solution after each use, and change chemobrushes weekly. The brush may also be cleaned in a dishwasher.

Saliva production is greatly reduced as a consequence of radiation. The resulting xerostomia (dry mouth) causes the inability to eat dry foods and may be permanent. Teach the patient regarding the use of saliva substitutes.

Skin reactions are also a common side effect of radiation. Instruct the patient to avoid sun exposure, to avoid perfumed lotions and powders, and to cleanse the face and neck area with a gentle nondeodorant soap. Teach male patients to use an electric razor for shaving and to avoid alcohol-based aftershave lotions to prevent further skin irritation.

NCLEX Examination Challenge

Safe and Effective Care Environment

A client has completed chemotherapy and radiation therapy for an oral tumor and is being discharged to home. Which client statements require further teaching by the nurse? **Select all that apply.**

A "Radiation therapy will not affect my sense of taste."
B "I am likely to be fatigued after radiation."
C "It is important for me to keep my oral cavity very clean."
D "I will avoid tanning beds and sun exposure."
E "I am eager to use my perfume soon after radiation therapy."
F "My chemobrush should be replaced monthly."

Health Care Resources.

Patients who have undergone composite resection often require community services because they have both physical and psychosocial needs. Depression related to a change in body image is common. Excision of a portion of the jaw can leave a facial defect that may be difficult to hide. Assess for depression and other behavioral responses. A social worker or other health care professional may be needed for patient and family counseling. Those who have undergone a total glossectomy may be able to speak with special training and the use of an intraoral

prosthesis created by a maxillofacial prosthodontist. The prosthesis is similar to dentures.

Collaborate with the case manager to provide assistance in obtaining special equipment or nutrition resources needed by the patient at home. The case manager assesses the patient's financial needs and makes referrals to government, community, and religious organizations as needed. Refer the patient to the American Cancer Society (ACS) (www.cancer.org), the Oral Cancer Foundation (www.oralcancerfoundation.org), and/or the Canadian Cancer Society (www.cancer.ca/en/region-selector-page/) for local support groups and resources, including additional information. The ACS often provides dressing supplies and transportation to and from follow-up visits or medical treatments.

Clinical Judgment Challenge

Teamwork and Collaboration; Patient-Centered Care QSEN

A 50-year-old businessman has just undergone oral surgery to remove a large oral tumor. Documentation of assessment of the oral cavity shows that the patient has poor oral hygiene. You are preparing to teach the patient methods of self-care management.

1. As the patient's nurse, what is your priority for his care immediately after surgery?
2. As you develop his plan of care, for what complications is this patient most at risk?
3. What would you teach the patient that would be most helpful to improve his oral hygiene?
4. Considering that he is a businessman, what psychosocial or sociocultural concerns would you anticipate he may experience?
5. What follow-up care is most important for this patient?

Disorders of the Salivary Glands

Acute Sialadenitis

Pathophysiology

Acute sialadenitis, the inflammation of a salivary gland, can be caused by infectious agents, irradiation, or immunologic disorders. Salivary gland inflammation can have a bacterial or viral cause, such as infection with cytomegalovirus (CMV). The most common bacterial organisms are *Staphylococcus aureus, Staphylococcus pyogenes, Streptococcus pneumoniae,* and *Escherichia coli.* This disorder most commonly affects the parotid or submandibular gland in adults.

A decrease in the production of saliva (as in dehydrated or debilitated patients or in those who are on NPO status postoperatively for an extended time) can lead to acute sialadenitis. The bacteria or viruses enter the gland through the ductal opening in the mouth. Systemic drugs, such as phenothiazines and the tetracyclines, can also trigger an episode of acute sialadenitis. Untreated infections of the salivary glands can evolve into abscesses, which can rupture and spread infection into the tissues of the neck and the mediastinum.

Patients who receive radiation for the treatment of cancers of the head and neck or thyroid may develop decreased salivary flow, predisposing them to acute or persistent sialadenitis. The effect of radiation on the salivary glands is rapid and dose related. Immunologic disorders such as HIV infection can cause enlargement of the parotid gland that results from secondary infection. Sjögren's syndrome, an autoimmune disorder, is characterized by chronic salivary gland enlargement and inflammation that cause a very dry mouth (see Chapter 20).

Patient-Centered Collaborative Care

During the initial interview, assess for any predisposing factors for sialadenitis, such as ionizing radiation to the head or neck area. Collect a thorough drug history, and ask about systemic illnesses, such as HIV infection.

Dehydration can be assessed by examining the oral membrane for dryness and the skin for turgor. Other assessment findings include pain and swelling of the face over the affected gland. Assess facial function because the branches of cranial nerve VII (the facial nerve) lie close to the salivary glands. Fever and general malaise also occur, and purulent drainage can often be massaged from the affected duct in the oral cavity.

Collaborative care includes the administration of IV fluids and

measures such as these to treat the underlying cause and increase the flow of saliva:

- Hydration
- Application of warm compresses
- Massage of the gland
- Use of a saliva substitute
- Use of **sialagogues** (substances that stimulate the flow of saliva)

Sialagogues include lemon slices and citrus-flavored and other fruit-flavored candy. Massage is accomplished by milking the edematous gland with the fingertips toward the ductal opening. Elevation of the head of the bed promotes gravity drainage of the edematous gland.

Acute sialadenitis is best prevented by adherence to routine oral hygiene. This practice prevents infection from ascending to the salivary glands from the mouth.

Post-Irradiation Sialadenitis

The salivary glands are sensitive to ionizing radiation, such as from radiation therapy or radioactive iodine treatment of thyroid cancers. Exposure of the glands to radiation produces a type of sialadenitis known as **xerostomia** (very dry mouth caused by a severe reduction in the flow of saliva) within 24 hours. Radiation to the salivary glands can also produce pain and edema, which generally abate after several days.

Xerostomia may be temporary or permanent, depending on the dose of radiation and the percentage of total salivary gland tissue irradiated. Little can be done to relieve the patient's dry mouth during the course of radiation therapy. Frequent sips of water and frequent mouth care, especially before meals, are the most effective interventions. After the course of radiation therapy has been completed, saliva substitutes may provide moisture for 2 to 4 hours at a time. Over-the-counter solutions are available, or methylcellulose (Cologel), glycerin, and saline may be mixed to form a solution.

Salivary Gland Tumors

Of all oral tumors, those of the salivary glands are relatively rare. Initially, malignant tumors present as slow-growing, painless masses. Involvement of the facial nerve results in facial weakness or paralysis (partial or total) on the affected side.

Collect information about any prior radiation exposure, because radiation to the head and neck areas is associated with the occurrence of salivary gland tumors. Salivary gland tumors present as localized, firm

masses. Submandibular and minor salivary gland tumors may be tender or painful. Tumor invasion of the hypoglossal nerve causes impaired movement of the tongue, and a loss of sensation can follow. *Pay particular attention to assessment of the facial nerve because of its proximity to the salivary glands.* Assess the patient's ability to:

- Wrinkle the brow
- Raise the eyebrows
- Squeeze and hold the eyes shut while you gently pull upwards on the eyebrows and cheeks beneath the orbit to check for symmetry
- Wrinkle the nose
- Pucker the lips
- Puff out the cheeks
- Grimace or smile

Be aware of any asymmetry when the patient performs these motions. The treatment of choice for both benign and malignant tumors of the salivary glands is surgical excision. However, radiation therapy is often used for salivary gland cancers that are large, have recurred, show evidence of residual disease after excision, or are highly malignant.

Patients who have undergone **parotidectomy** (surgical removal of the parotid glands) or submandibular gland surgery are at risk for weakness or loss of function of the facial nerve because the nerve courses directly through the gland. Facial nerve repair with grafting can be done at the time of surgery. A combination of surgery followed by radiation is common for advanced disease. Care for patients after parotidectomy is similar to that required for those having oral cancer surgery, described on pp. 1105-1106.

Nursing Concepts and Clinical Judgment Review

What might you NOTICE if the patient has inadequate digestion and gas exchange as a result of oral cavity problems?

- Dysphagia (difficulty swallowing)
- Dyspnea
- Stridor or wheezes
- Changes in speech or voice
- Copious, thickened oral secretions
- Excessive coughing during meals

What should you INTERPRET and how should you RESPOND to a patient experiencing inadequate digestion and gas exchange as a result of oral cavity problems?

Perform and interpret focused physical assessment findings, including:

- Breath sounds
- Oxygen saturation by pulse oximetry
- Ability to cough and clear the airway
- Ability to manage excessive oral secretions
- Ability to chew food and swallow

Respond by:

- Placing the patient with the head elevated to at least 30 degrees
- Applying oxygen as needed
- Suctioning the oral cavity as needed
- Encouraging deep breathing and coughing every 2 hours
- Increasing fluids to liquefy secretions, depending on swallowing ability
- Notifying the respiratory therapist or Rapid Response Team if interventions are not successful in restoring gas exchange (oxygenation).

On what should you REFLECT?

- Observe patient for evidence of increased gas exchange (oxygenation), including increased ease of breathing.
- Observe patient for evidence of increased ability to swallow.
- Observe patient for evidence of increased ability to manage oral secretions.
- Consider follow-up interventions to manage patient, including coordinating care with dietitian and speech-language pathologist.
- Think about what else you might do to promote digestion and nutrition.

Get Ready for the NCLEX® Examination!

Key Points

Review these key points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Be aware that airway management is the priority for care for patients having surgery for oral cancer. **Safety** QSEN
- Place patients having oral cancer surgery in a high-Fowler's position to facilitate breathing and prevent aspiration. **Safety** QSEN
- Be sure to assess for swallowing ability to prevent aspiration by checking the gag reflex before offering liquids or food to the patient who has had oral cancer surgery. **Safety** QSEN
- Plan continuity of care to meet patients' needs when they are transferred from the hospital to community-based agencies. **Teamwork and Collaboration** QSEN

Health Promotion and Maintenance

- Teach patients to seek medical or dental attention for oral lesions that do not heal; these lesions could be oral carcinomas.
- Remind patients to visit their dentist regularly for dental hygiene and oral examination.
- Follow the best practice recommendations for maintaining oral health as listed in Chart 53-1.
- Instruct patients to avoid harsh commercial mouthwashes if they have oral lesions.
- In keeping with The Joint Commission (TJC) Core Measures TOB-2, teach patients to avoid tobacco, alcohol, and sun exposure to decrease their chance of having oral cancer.
- Instruct patients with acute sialadenitis to use sialagogues to stimulate saliva, such as citrus foods or candies.

Psychosocial Integrity

- Identify the patient's and family's response to an oral cancer diagnosis.
- Assist the patient and family in identifying and using coping mechanisms to deal with possible changes in body image and altered self-esteem. **Patient-Centered Care** QSEN
- Recognize that patients with stomatitis are often unable to eat or swallow without discomfort.

- Refer patients with oral cancer to support groups, such as those available through the American Cancer Society.

Physiological Integrity

- Remember that stomatitis usually manifests as painful single or multiple ulcerations within the mouth.
- Recognize that stomatitis can be caused by a variety of organisms; *Candida* infections are very common in patients who receive antibiotic therapy and in those who are immunocompromised.
- Provide gentle oral care for patients with oral lesions, including using chemobrushes and warm saline or sodium bicarbonate solution. **Safety** QSEN
- Be aware that patients with stomatitis receive antimicrobials, anti-inflammatory agents, immune modulators, and topical agents for relief of symptoms, including pain. **Evidence-Based Practice** QSEN
- Differentiate leukoplakia and erythroplakia: leukoplakia presents as thin, white patches; and erythroplakia presents as red, velvety lesions.
- Be aware that patients with oral cancer may have chemotherapy, radiation, surgery, or a combination of these treatment methods.
- Be aware that sialadenitis can occur as a result of radiation therapy.
- For patients with salivary gland tumors, assess for facial nerve involvement.
- Remember that a parotidectomy involves the removal of the salivary glands; postoperative care is similar to that for patients who have oral cancer surgery.

CHAPTER 54

Care of Patients with Esophageal Problems

Cherie R. Rebar, Nicole Heimgartner and Laura Willis

PRIORITY CONCEPTS

- Infection
- Nutrition
- Pain

Learning Outcomes

Safe and Effective Care Environment

1. Collaborate with health care team members when providing care to patients with esophageal health problems that impair swallowing or limit nutrition.

Health Promotion and Maintenance

2. Teach patients about lifestyle changes that decrease gastroesophageal reflux disease (GERD) and the pain associated with hiatal hernias.
3. Describe special considerations for the older adult with GERD.
4. Teach patients with esophageal health problems about community-based resources.

Psychosocial Integrity

5. Reduce the psychological impact for the patient and family who have received a diagnosis and treatment of esophageal cancer.

Physiological Integrity

6. Perform focused assessments for patients with esophageal health

problems.

7. Evaluate the impact of esophageal cancer on the patient's nutrition status, including the risk for aspiration.
8. Apply knowledge of pathophysiology to anticipate complications of GERD and esophageal surgical procedures.
9. Teach patients how to reduce the physiological impact of esophageal health problems.
10. Develop an evidence-based teaching plan for the patient and family about postoperative care after esophageal surgery.
11. Plan community-based care for patients diagnosed with esophageal cancer.

 http://evolve.elsevier.com/Iggy/

Partially digested food is moved by the esophagus from the mouth to the stomach. If food cannot reach the stomach, the patient cannot meet the basic human need for nutrition. Nutrients in food are necessary for normal body cell function. Common problems of the esophagus that can interfere with digestion and nutrition are caused by inflammation, structural defects or obstruction, and cancer. Patient-centered collaborative care requires dietary and lifestyle changes, as well as medical and surgical therapies.

Gastroesophageal Reflux Disease

Pathophysiology

Gastroesophageal reflux disease (GERD) is the most common upper GI disorder in the United States. It occurs most often in middle-aged and older adults but can affect people of any age. **Gastroesophageal reflux (GER)** occurs as a result of backward flow of stomach contents into the esophagus. GERD is the chronic and more serious condition that arises from persistent GER.

Reflux produces symptoms by exposing the esophageal mucosa to the irritating effects of gastric or duodenal contents, resulting in inflammation. A person with acute symptoms of inflammation is often described as having mild or severe **reflux esophagitis** (McCance et al., 2014).

The reflux of gastric contents into the esophagus is normally prevented by the presence of two high-pressure areas that remain contracted at rest. A 1.2-inch (3-cm) segment at the proximal end of the esophagus is called the *upper esophageal sphincter (UES),* whereas another small portion at the gastroesophageal junction (near the cardiac sphincter) is called the **lower esophageal sphincter (LES).** The function of the LES is supported by its anatomic placement in the abdomen, where the surrounding pressure is significantly higher than in the low-pressure thorax. Sphincter function is also supported by the acute angle (angle of His) that is formed as the esophagus enters the stomach.

The most common cause of GERD is excessive relaxation of the LES, which allows the reflux of gastric contents into the esophagus and exposure of the esophageal mucosa to acidic gastric contents. Patients who are overweight or obese are at highest risk for development of GERD because increased weight increases intra-abdominal pressure, which contributes to reflux of stomach contents into the esophagus. Nighttime reflux tends to cause prolonged exposure of the esophagus to acid because lying supine decreases peristalsis and the benefit of gravity. **Hiatal hernias** also increase the risk for development of GERD due to the creation of increased intra-abdominal pressure. *Helicobacter pylori* may contribute to reflux (McCance et al., 2014) by causing gastritis and thus poor gastric emptying. This increases frequency of GER events and acid exposure to the esophagus.

A person having reflux may be asymptomatic. However, the esophagus has limited resistance to the damaging effects of the acidic GI contents. The pH of acid secreted by the stomach ranges from 1.5 to 2.0, whereas the pH of the distal esophagus is normally neutral (6.0 to 7.0).

Refluxed material is returned to the stomach by a combination of gravity, saliva, and peristalsis. The inflamed esophagus cannot eliminate the refluxed material as quickly as a healthy one, and therefore the length of exposure increases with each reflux episode. Hyperemia (increased blood flow) and **erosion** (ulceration) occur in the esophagus in response to the chronic inflammation. Gastric acid and pepsin injure tissue. Minor capillary bleeding often occurs with erosion, but hemorrhage is rare.

During the process of healing, the body may substitute **Barrett's epithelium** (columnar epithelium) for the normal squamous cell epithelium of the lower esophagus. Although this new tissue is more resistant to acid and therefore supports esophageal healing, it is considered premalignant and is associated with an increased risk for cancer in patients with prolonged GERD. The fibrosis and scarring that accompany the healing process can produce **esophageal stricture** (narrowing of the esophageal opening). The stricture leads to progressive difficulty swallowing. Uncontrolled esophageal reflux also increases risk for other complications such as asthma, laryngitis, dental decay, cardiac disease, and serious concerns for hemorrhage and aspiration pneumonia.

Gastric distention caused by eating very large meals or delayed gastric emptying predisposes the patient to reflux. Certain foods and drugs, as well as smoking and alcohol, influence the tone function of the LES (Table 54-1).

TABLE 54-1

Factors Contributing to Decreased Lower Esophageal Sphincter Pressure

• Caffeinated beverages, such as coffee, tea, and cola • Chocolate • Citrus fruits • Tomatoes and tomato products • Smoking and use of other tobacco products • Calcium channel blockers
• Nitrates • Peppermint, spearmint • Alcohol • Anticholinergic drugs • High levels of estrogen and progesterone • Nasogastric tube placement

Patients who have a nasogastric tube also have decreased esophageal sphincter function. The tube keeps the cardiac sphincter open and allows acidic contents from the stomach to enter the esophagus. Other factors that increase intra-abdominal and intragastric pressure (e.g., pregnancy, wearing tight belts or girdles, bending over, ascites) overcome the gastroesophageal pressure gradient maintained by the LES and allow reflux to occur. Many patients with obstructive sleep apnea report

frequent episodes of GERD. People with hiatal hernias often have reflux because the upper portion of the stomach protrudes through the diaphragm into the thorax, which allows acid to reach the esophagus (see later discussion of hiatal hernia).

Patient-Centered Collaborative Care

Assessment

Ask the patient about a history of heartburn or atypical chest pain associated with the reflux of GI contents. Ask whether he or she has been newly diagnosed with asthma or has experienced morning hoarseness or pneumonia, because these symptoms may indicate severe reflux reaching the pharynx or mouth or pulmonary aspiration.

Physical Assessment/Clinical Manifestations.

Dyspepsia, also known as "indigestion," and regurgitation are the main symptoms of GERD, although symptoms may vary in severity (Chart 54-1). Symptoms associated with "indigestion" may include abdominal discomfort, feeling uncomfortably full, nausea, and burping. Because indigestion might not be viewed as a serious concern, patients may delay seeking treatment. The symptoms typically worsen when the patient bends over, strains, or lies down. If the indigestion is severe, the pain may radiate to the neck or jaw or may be referred to the back, mimicking cardiac pain. Patients may come to the emergency department (ED) fearing that they are having a myocardial infarction ("heart attack").

Chart 54-1 Key Features

Gastroesophageal Reflux Disease

- Dyspepsia (indigestion)
- Regurgitation (may lead to aspiration or bronchitis)
- Coughing, hoarseness, or wheezing at night
- Water brash (hypersalivation)
- Dysphagia
- Odynophagia (painful swallowing)
- Epigastric pain
- Generalized abdominal pain
- Belching
- Flatulence
- Nausea

- Pyrosis (heartburn)
- Globus (feeling of something in back of throat)
- Pharyngitis
- Dental caries (severe cases)

With severe GERD, pain generally occurs after each meal and lasts for 20 minutes to 2 hours. Discomfort may worsen when the patient lies down. Drinking fluids, taking antacids, or maintaining an upright posture usually provides prompt relief.

Regurgitation (backward flow into the throat) of food particles or fluids is common. Risk for aspiration is increased if regurgitation occurs when the patient is lying down. Even if the patient is in an upright position, he or she may experience warm fluid traveling up the throat without nausea. If the fluid reaches the level of the pharynx, he or she notes a sour or bitter taste in the mouth. A reflex salivary hypersecretion known as **water brash** occurs in response to reflux. Water brash is different from regurgitation. The patient reports a sensation of fluid in the throat, but unlike with regurgitation, there is no bitter or sour taste.

Ask the patient if he or she experiences **eructation** (belching), **flatulence** (gas), and bloating after eating; these are other common manifestations. Nausea and vomiting rarely occur; unplanned weight loss is not common.

Assess for crackles in the lung, which can be an indication of associated aspiration. Patients who have had long-term regurgitation may experience coughing, hoarseness, or wheezing at night, which may be associated with bronchitis.

Chronic GERD can cause **dysphagia** (difficulty swallowing). Dysphagia usually indicates a narrowing of the esophagus because of stricture or inflammation. Assess the patient for degree of dysphagia, whether ingesting solids and/or liquids induces dysphagia, and whether dysphagia occurs intermittently or with each swallowing effort.

Odynophagia (painful swallowing) can also occur with chronic GERD, but it is rare in people with uncomplicated reflux disease. Severe and long-lasting chest pain may be present if esophageal spasms cause the muscle to contract with excess force. The resulting pain can be agonizing and may last for hours.

Other manifestations include atypical chest pain, symptoms of asthma, and chronic cough that occurs mostly at night or when the patient is lying down. Cough and symptoms of asthma occur when refluxed acid is spilled over into the tracheobronchial tree. *Atypical chest pain* is thought to be caused by stimulation of pain receptors in the esophageal wall and

by esophageal spasm. This type of chest pain can mimic angina and needs to be carefully distinguished from cardiac pain.

Considerations for Older Adults

Patient-Centered Care QSEN

Older adults are at risk for developing severe complications associated with GERD due to age-related physiologic changes, medication side effects, and an increased prevalence of hiatal hernias (Solomon & Reynolds, 2012). Instead of heartburn associated with GERD, this population experiences more severe complications of the disease such as atypical chest pain; ear, nose, and throat infections; and pulmonary problems, such as aspiration pneumonia, sleep apnea, and asthma. Barrett's esophagus and esophageal erosions are also more common in older adults (Chait, 2010).

Diagnostic Assessment.

A definitive diagnostic test for GERD does not exist; however, health care providers may use one or more options to attempt to establish a diagnosis when GERD is suspected (The Ohio State University Wexner Medical Center [OSUWMC], 2014).

Patients may drink a solution and then have x-rays performed as part of a *barium swallow,* which shows hiatal hernias, strictures, and other structural or anatomic esophageal problems. Although this test, when conducted by itself, does not confirm GERD, it can be helpful when used in combination with other diagnostic procedures.

Upper endoscopy (also called **esophagogastroduodenoscopy [EGD]**) involves insertion of an endoscope (a flexible plastic tube equipped with a light and lens) down the throat, which allows the health care provider to see the esophagus and look for abnormalities. A biopsy can be taken while the patient undergoes endoscopy (see Chapter 52) (OSUWMC, 2013). This test requires the use of moderate sedation during the procedure, and patients must have someone accompany them home after recovery.

A **pH monitoring examination** is the most accurate method of diagnosing GERD. This involves either (1) placing a small catheter through the nose into the distal esophagus or (2) temporarily attaching a small capsule to the wall of the esophagus during an upper endoscopy (the 48-hour Bravo esophageal ph test). The patient is asked to keep a diary of activities and symptoms over 24 to 48 hours (depending on

diagnostic method), and the pH is continuously monitored and recorded. Ambulatory pH monitoring is especially useful in diagnosing patients with atypical symptoms. A wireless monitoring device may be used to promote patient comfort (OSUWMC, 2014).

Although not as common, *esophageal manometry,* or motility testing, may be performed when the diagnosis is uncertain. Water-filled catheters are inserted in the patient's nose or mouth and slowly withdrawn while measurements of LES pressure and peristalsis are recorded. When used alone, manometry is not sensitive or specific enough to establish a diagnosis of GERD (National Institutes of Health, 2013). A Gastric Emptying Study can also be done while a patient is in the radiology/nuclear medicine department. He or she is given a meal mixed with radiolucent dye, and imaging is performed to determine how well the stomach empties over the next few hours. If food stays too long in the stomach, it can reflux back into the esophagus, causing symptoms (OSUWMC, 2014). Imaging of the lungs can also be conducted 24 hours later to visualize whether the patient has aspirated stomach contents.

Interventions

Nonsurgical Management.

The purpose of treatment for GERD is to relieve symptoms, treat esophagitis, and prevent complications such as strictures or Barrett's esophagus. For most patients, GERD can be controlled by nutrition therapy, lifestyle changes, and drug therapy. *The most important role of the nurse is patient and family education. Teach the patient that GERD is a chronic disorder that requires ongoing management. The disease should be treated more aggressively in older adults (Chait, 2010).*

Nonpharmacologic Interventions.

Nutrition therapy is used to relieve symptoms in patients with relatively mild GERD. Ask about the patient's basic meal patterns and food preferences. Coordinate with the dietitian, patient, and family about how to adapt to changes in eating that may decrease reflux symptoms.

Teach the patient to limit or eliminate foods that decrease LES pressure and that irritate inflamed tissue, causing heartburn, such as peppermint, chocolate, alcohol, fatty foods (especially fried), caffeine, and carbonated beverages. The patient should also restrict spicy and acidic foods (e.g., orange juice, tomatoes) until esophageal healing can occur. Patients who are smartphone users may find different types of applications (“apps”) that can help them follow a healthier diet, such as

MyFitnessPal (www.myfitnesspal.com). In keeping with The Joint Commission Core Measures, teach patients that smoking and alcohol use should also be avoided, because these can also decrease LES pressure. Explore the possibility and methods for smoking cessation, and make appropriate referrals. Ask the patient about his or her use of alcoholic beverages, and if appropriate, assist the patient in finding alcohol-cessation programs.

Large meals increase the volume of and pressure in the stomach and delay gastric emptying. Remind the patient to eat four to six small meals each day rather than three large ones. Encourage patients to avoid eating at least 3 hours before going to bed because reflux episodes are most damaging at night. Advise the patient to eat slowly and chew thoroughly to facilitate digestion and prevent eructation (belching).

The control of GERD involves *lifestyle changes* to promote health and control reflux (Chart 54-2). Teach the patient to elevate the head by 6 to 12 inches for sleep to prevent nighttime reflux. This can be done by placing blocks under the head of the bed or by using a large, wedge-style pillow instead of a standard pillow. Teach the patient to sleep in the right side-lying position to promote oxygenation and frequent swallowing to clear the esophagus. Assist the patient in examining approaches to weight reduction. Decreasing intra-abdominal pressure often reduces reflux symptoms. Teach the patient to avoid wearing constrictive clothing, lifting heavy objects or straining, and working in a bent-over or stooped position. Emphasize that these general adaptations are an essential and effective part of disease management and can produce prompt results in uncomplicated cases.

Chart 54-2 Patient and Family Education: Preparing for Self-Management

Health Promotion and Lifestyle Changes to Control Reflux

- Eat four to six small meals a day.
- Limit or eliminate fatty foods, coffee, tea, cola, and chocolate.
- Reduce or eliminate from your diet any food or spice that increases gastric acid and causes pain.
- Limit or eliminate alcohol and tobacco, and reduce exposure to secondhand smoke.
- Do not snack in the evening, and do not eat for 2 to 3 hours before you go to bed.
- Eat slowly and chew your food thoroughly to reduce belching.

- Remain upright for 1 to 2 hours after meals, if possible.
- Elevate the head of your bed 6 to 12 inches using wooden blocks, or elevate your head using a foam wedge. Never sleep flat in bed.
- If you are overweight, lose weight.
- Do not wear constrictive clothing.
- Avoid heavy lifting, straining, and working in a bent-over position.
- Chew "chewable" antacids thoroughly, and follow with a glass of water.

Obese patients often have obstructive sleep apnea, as well as GERD. Those who receive continuous positive airway pressure (CPAP) treatment report improved sleeping and decreased episodes of reflux at night. See Chapter 29 for a discussion of CPAP.

Some drugs lower LES pressure and *cause* reflux, such as oral contraceptives, anticholinergic agents, sedatives, NSAIDs (e.g., ibuprofen), nitrates, and calcium channel blockers. The possibility of eliminating those drugs causing reflux should be explored with the health care provider.

Drug Therapy.

Drug therapy for GERD management includes three major types—antacids, histamine blockers, and proton pump inhibitors. These drugs, which are also used for peptic ulcer disease, have one or more of these functions (see Chapter 55, Chart 55-3):

- Inhibit gastric acid secretion
- Accelerate gastric emptying
- Protect the gastric mucosa

In uncomplicated cases of GERD, *antacids* may be effective for *occasional* episodes of heartburn. Antacids act by elevating the pH level of the gastric contents, thereby deactivating pepsin. They are not helpful in controlling frequent symptoms because their length of action is too short and their nighttime effectiveness is minimal. These drugs also *increase* LES pressure and therefore are not given for long-term use.

Antacids containing aluminum hydroxide or magnesium hydroxide may be used. Maalox and Mylanta consist of a combination of these two agents. Patients often tolerate them better because they produce fewer side effects, such as constipation and diarrhea. Liquid forms of these medications are preferred, since they coat the esophagus to provide pain relief and to buffer acid. Teach the patient to take the antacid 1 hour before and 2 to 3 hours after each meal.

Gaviscon, a combination of alginic acid and sodium bicarbonate, is often a very effective drug for GERD. It forms thick foam that floats on

top of the gastric contents and theoretically decreases the incidence of reflux. If reflux occurs, the foam enters the esophagus first and buffers the acid in the refluxed material. Remind the patient to take this drug when food is in the stomach.

Histamine receptor antagonists, commonly called *histamine blockers,* such as famotidine (Pepcid) and ranitidine (Zantac), decrease acid, are long acting, have fewer side effects, and allow less-frequent dosing. Although these drugs do not affect the occurrence of reflux directly, they do reduce gastric acid secretion, improve symptoms, and promote healing of inflamed esophageal tissue. With these drugs available over the counter (OTC) and widely advertised for heartburn, many patients self-medicate before seeking professional assistance from their primary care provider. Encourage patients to speak with their primary care provider to determine whether long-term use of these medications is appropriate.

Proton pump inhibitors (PPIs), such as omeprazole (Prilosec), rabeprazole (AcipHex), pantoprazole (Protonix), and esomeprazole (Nexium), are the *main* treatment for more severe GERD. Some PPIs are available as OTC drugs. These agents provide effective, long-acting inhibition of gastric acid secretion by affecting the proton pump of the gastric parietal cells. PPIs reduce gastric acid secretion and can be given in a single daily dose. If once-a-day dosing fails to control symptoms, twice-daily dosing may be used (National Guideline Clearinghouse [NGC], 2013). A newer PPI, omeprazole/sodium bicarbonate (Zegerid), is the first immediate-release PPI and is designed for short-term use. Another newer PPI, dexlansoprazole (Kapidex), is a dual-release (delayed-release) drug that is available in several dosages but tends to be associated with more side and adverse effects than some of the other PPIs.

Some PPIs, such as Nexium and Protonix, may be administered in IV form for short-term use to treat or to prevent stress ulcers that can result from surgery. PPIs promote rapid tissue healing, but recurrence is common when the drug is stopped. Long-term use may mask reflux symptoms, and stopping the drug determines if reflux has been resolved. Long-term use may also cause community-acquired pneumonia and GI infections such as those caused by *Clostridium difficile.*

Considerations for Older Adults

Patient-Centered Care QSEN

Research has also found that long-term use of proton pump inhibitors may increase the risk for hip fracture, especially in older adults. PPIs can

interfere with calcium absorption and protein digestion and therefore reduce available calcium to bone tissue. Decreased calcium makes bones more brittle and likely to fracture, especially as people age (Chait, 2010).

NCLEX Examination Challenge

Physiological Integrity

A client with gastroesophageal reflux disease (GERD) is prescribed to start pantoprazole (Protonix) 40 mg every day. Which statement by the client requires further teaching by the nurse?
A "When I feel better, I can stop taking this drug."
B "I'll take this drug at 8 am every morning."
C "This drug can cause headache and dizziness."
D "I should not crush the drug because it has a delayed release."

Endoscopic Therapies.

The Stretta procedure, a nonsurgical method, can replace surgery for GERD when other measures are not effective. Patients who are very obese or have severe symptoms may not be candidates for this procedure. In the Stretta procedure, the physician applies radiofrequency (RF) energy through the endoscope using needles placed near the gastroesophageal junction. The RG energy decreases vagus nerve activity, thus reducing discomfort for the patient. Postoperative instructions for patients who have undergone the Stretta procedure can be found in Chart 54-3.

Chart 54-3 Patient and Family Education: Preparing for Self-Management

Postoperative Instructions for Patients Having Stretta Procedure

- Remain on clear liquids for 24 hours after the procedure.
- After the first day, consume a soft diet, such as custard, pureed vegetables, mashed potatoes, and applesauce.
- Avoid nonsteroidal anti-inflammatory drugs (NSAIDs) and aspirin for 10 days.
- Continue drug therapy as prescribed, usually proton pump inhibitors.
- Use liquid medications whenever possible.
- Do not allow nasogastric tubes for at least 1 month because the

esophagus could be perforated.

- Contact the health care provider immediately if these problems occur:
  - Chest or abdominal pain
  - Bleeding
  - Dysphagia
  - Shortness of breath
  - Nausea or vomiting

Surgical Management.

A very small percentage of patients with GERD require anti-reflux surgery. It is usually indicated for otherwise healthy patients who have failed to respond to medical treatment or have developed complications related to GERD. Various surgical procedures may be used through conventional open techniques or laparoscope.

Laparoscopic Nissen fundoplication (LNF) is a minimally invasive surgery (MIS) and is the standard surgical approach for treatment of severe GERD (Buckley & Roberts, 2014). Information about this procedure can be found in the next section (Hiatal Hernia) in the Surgical Management discussion. Patients who have surgery are encouraged to continue following the basic anti-reflux regimen of antacids and nutrition therapy because the rate of recurrence is high (University of Michigan Health System, 2012).

Hiatal Hernia

Hiatal hernias, also called *diaphragmatic hernias,* involve the protrusion of the stomach through the esophageal hiatus of the diaphragm into the chest. The esophageal hiatus is the opening in the diaphragm through which the esophagus passes from the thorax to the abdomen. Most patients with hiatal hernias are asymptomatic, but some may have daily symptoms similar to those with GERD (McCance et al., 2014).

Pathophysiology

The two major types of hiatal hernias are sliding hernias (which are most common) and paraesophageal (rolling) hernias. The esophagogastric junction and a portion of the fundus of the stomach slide upward through the esophageal hiatus into the chest, usually as a result of weakening of the diaphragm (Fig. 54-1). The hernia generally moves freely and slides into and out of the chest during changes in position or intra-abdominal pressure. Although **volvulus** (twisting of a GI structure) and obstruction do occur rarely, the major concern for a sliding hernia is the development of esophageal reflux and associated complications (see Gastroesophageal Reflux Disease section earlier in this chapter). The development of reflux is related to chronic exposure of the lower esophageal sphincter (LES) to the low pressure of the thorax, which significantly reduces the effectiveness of the LES. Symptoms associated with decreased LES pressure are worsened by positions that favor reflux, such as bending or lying supine. Coughing, obesity, and ascites also increase reflux symptoms.

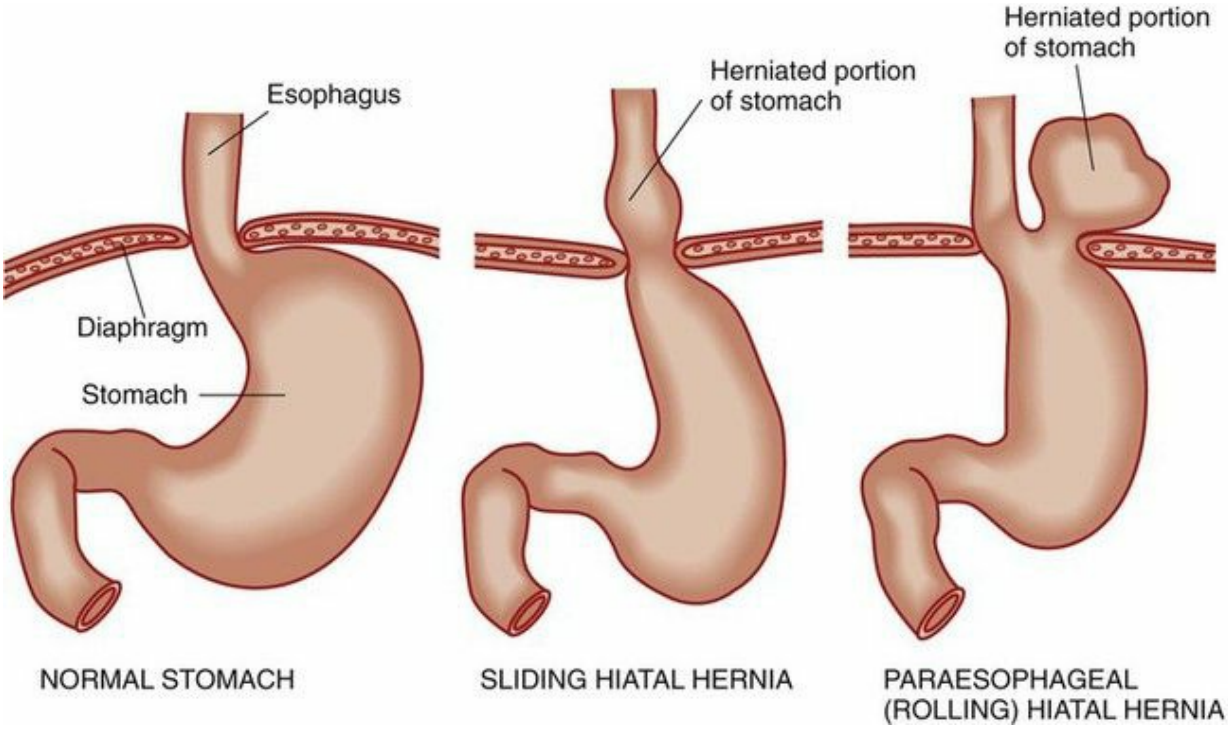

FIG. 54-1 A comparison of the normal stomach and sliding and paraesophageal (rolling) hiatal hernias.

With *rolling hernias,* also known as *paraesophageal hernias,* the gastroesophageal junction remains in its normal intra-abdominal location but the fundus (and possibly portions of the stomach's greater curvature) rolls through the esophageal hiatus and into the chest beside the esophagus (see Fig. 54-1). The herniated portion of the stomach may be small or quite large. In rare cases, the stomach completely inverts into the chest. Reflux is not usually present because the LES remains anchored below the diaphragm. However, the risks for volvulus (twisting of a GI structure), obstruction (blockage), and strangulation (stricture) are high. The development of iron deficiency anemia is common because slow bleeding from venous obstruction causes the gastric mucosa to become engorged and ooze. Significant bleeding or hemorrhage is rare.

Rolling hernias are thought to develop from an anatomic defect occurring when the stomach is not properly anchored below the diaphragm rather than from muscle weakness. They can also be caused by previous esophageal surgeries, including sliding hernia repair.

❖ Patient-Centered Collaborative Care

◆ Assessment

Ask the patient if he or she has heartburn, regurgitation (backward flow of food into the throat), pain, dysphagia (difficulty swallowing), and eructation (belching). Assess general physical appearance and nutrition

status. Note the location, onset, duration, and quality of pain, as well as factors that relieve it or make it worse. The primary symptoms of sliding hiatal hernias are associated with reflux. Auscultate the lungs because pulmonary symptoms similar to asthma may be triggered by episodes of aspiration, particularly at night. A detailed history is crucial in attempting to differentiate angina from noncardiac chest pain caused by reflux. Symptoms resulting from hiatal hernia typically worsen after a meal or when the patient is in a supine position (Chart 54-4).

Chart 54-4 Key Features

Hiatal Hernias

Sliding Hiatal Hernias	Paraesophageal Hernias
• Heartburn • Regurgitation • Chest pain • Dysphagia • Belching	• Feeling of fullness after eating • Breathlessness after eating • Feeling of suffocation • Chest pain that mimics angina • Worsening of manifestations in a recumbent position

In those with rolling hernias, assess for symptoms related to stretching or displacement of thoracic contents by the hernia. Patients may report a feeling of fullness after eating or have breathlessness or a feeling of suffocation if the hernia interferes with breathing. Some may experience chest pain associated with reflux that mimics angina.

The *barium swallow study with fluoroscopy* is the most specific diagnostic test for identifying hiatal hernia. Rolling hernias are usually clearly visible, and sliding hernias can often be observed when the patient moves through a series of positions that increase intra-abdominal pressure. To visualize sliding hernias, an esophagogastroduodenoscopy (EGD) may be performed to view both the esophagus and gastric lining (see Chapter 52).

Interventions

Patients with hiatal hernias may be managed either medically or surgically. Collaborative care is based on the severity of symptoms and the risk for serious complications. Sliding hiatal hernias are most commonly treated medically. Large rolling hernias can become strangulated or obstructed; therefore early surgical repair is preferred.

Nonsurgical Management.

The collaborative interventions for patients with hiatal hernia are similar

to those for GERD and include drug therapy, nutrition therapy, and lifestyle changes. The health care provider typically recommends antacids and a proton-pump inhibitor such as lansoprazole (Prevacid), omeprazole (Prilosec), or esomeprazole (Nexium) in an attempt to control reflux and its symptoms (Harvard Health Publications, 2011). Nutrition therapy is also important and follows the guidelines discussed earlier for GERD.

Nursing Safety Priority QSEN

Action Alert

The most important role of the nurse in caring for a patient with a hiatal hernia is health teaching. Encourage the patient to avoid eating in the late evening and to avoid foods associated with reflux. Teach the patient and family that the patient should follow a restricted diet and should exercise regularly. Reducing body weight is beneficial because obesity increases intra-abdominal pressure and worsens both the hernia and the symptoms of reflux. Teach about positioning, including:

- Sleep at night with the head of the bed elevated 6 inches
- Remain upright for several hours after eating
- Avoid straining or excessive vigorous exercise
- Refrain from wearing clothing that is tight or constrictive around the abdomen

Surgical Management.

Surgery may be required when the risk for complications is high or when damage from chronic reflux becomes severe.

Preoperative Care.

If the surgery is not urgent, the surgeon instructs patients who are overweight to lose weight before surgery. They are also advised to quit or significantly reduce smoking. As part of preoperative teaching, reinforce the surgeon's instructions and prepare the patient for what to expect after surgery.

Operative Procedures.

Several types of hiatal hernia repair procedures are used, each of which involves reinforcement of the lower esophageal sphincter (LES) by fundoplication. The surgeon wraps a portion of the stomach fundus around the distal esophagus to anchor it and reinforce the LES (Fig. 54-2).

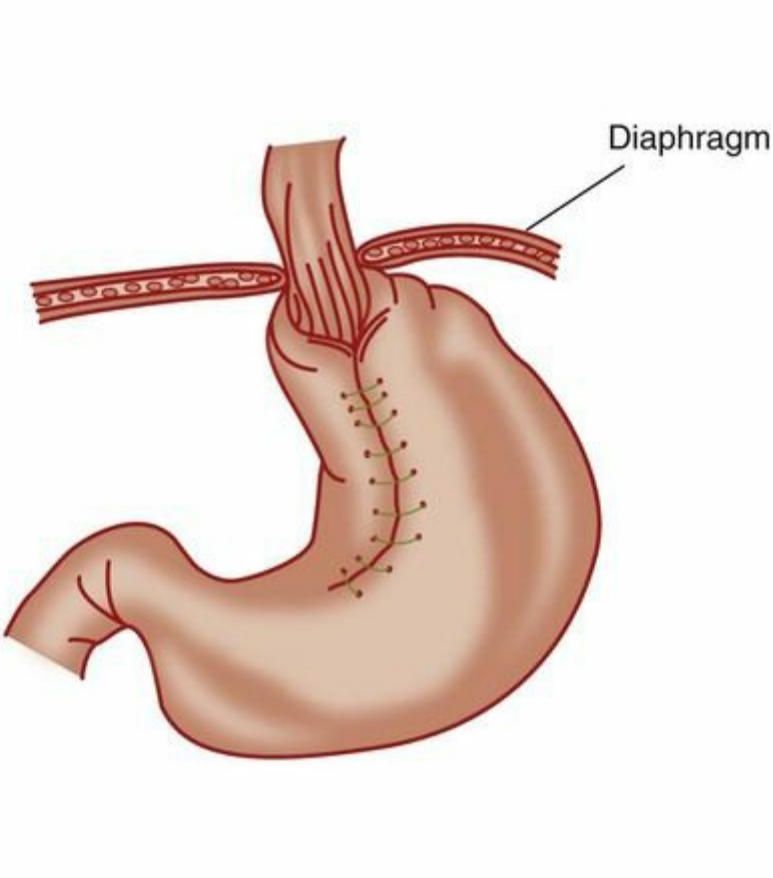

FIG. 54-2 Open surgical approach for Nissen fundoplication for gastroesophageal reflux disease or hiatal hernia repair.

Laparoscopic Nissen fundoplication (LNF) is a minimally invasive surgery commonly used for hiatal hernia repair (Buckley & Roberts, 2014). Complications after LNF occur less frequently compared with those seen in patients having the more traditional open surgical approach. A small percentage of patients are not candidates for LNF and therefore require a conventional open fundoplication.

For the trans-thoracic surgical approach, teach the patient about chest tubes. Inform the patient that a nasogastric tube will be inserted during surgery and will remain in place for several days. Oral intake is started gradually with clear liquids after peristalsis is re-established or to stimulate peristalsis. Instruct the patient how to deep breathe and use the incentive spirometer. These measures are essential to prevent postoperative respiratory complications. The high incision makes deep breathing extremely painful. Teach the patient about postoperative pain, and assure him or her that adequate postoperative analgesic will be given promptly. Pain levels must be continuously monitored.

In paraesophageal repair (a laparoscopic surgery), several ½-inch incisions are made in the abdomen, through which the hernia is closed and is typically reinforced using mesh. Less commonly, a conventional

open procedure is used in which the surgeon uses a high trans-thoracic approach that requires a large chest incision for access to the surgical area.

Postoperative Care.

Patients having the *LNF procedure* or paraesophageal repair via laparoscope are at risk for bleeding and infection, although these problems are not common. *The nursing care priority is to observe for these complications and provide health teaching as described in* Chart 54-5.

Chart 54-5 Patient and Family Education: Preparing for Self-Management

Postoperative Instructions for Patients Having Laparoscopic Nissen Fundoplication (LNF) or Paraesophageal Repair via Laparoscope

- Stay on a soft diet for about a week, including mashed potatoes, puddings, custard, and milkshakes; avoid carbonated beverages, tough foods, and raw vegetables that are difficult to swallow.
- Remain on anti-reflux medications as prescribed for at least a month.
- Do not drive for a week after surgery; do not drive if taking opioid pain medication.
- Walk every day, but do not do any heavy lifting.
- Remove small dressings 2 days after surgery, and shower; do not remove Steri-Strips until 10 days after surgery.
- Wash incisions with soap and water, rinse well, and pat dry; report any redness or drainage from the incisions to your surgeon.
- Report fever above 101° F (38.3° C), nausea, vomiting, or uncontrollable bloating or pain. For patients older than 65 years, report elevations above 100° F (37.8° C).
- Schedule an appointment for follow-up with your surgeon in 3 to 4 weeks.

Postoperative care after *conventional open repair* closely follows that required after any esophageal surgery. Complications after open surgery are more common and potentially serious. Carefully assess for complications of open fundoplication surgery, described next, and report any complications to the health care provider (Chart 54-6).

Chart 54-6 Best Practice for Patient Safety & Quality Care QSEN

Assessment of Postoperative Complications Related to Fundoplication Procedures

COMPLICATION	ASSESSMENT FINDINGS
Temporary dysphagia	The patient has difficulty swallowing when oral feeding begins.
Gas bloat syndrome	The patient has difficulty belching to relieve distention.
Atelectasis, pneumonia	The patient experiences dyspnea, chest pain, or fever.
Obstructed nasogastric tube	The patient experiences nausea, vomiting, or abdominal distention. The nasogastric tube does not drain.

Nursing Safety Priority QSEN

Action Alert

The primary focus of care after conventional surgery for a hiatal hernia repair is the prevention of respiratory complications. Elevate the head of the patient's bed at least 30 degrees to lower the diaphragm and promote lung expansion. Assist the patient out of bed and begin ambulation as soon as possible. Be sure to support the incision during coughing to reduce pain and to prevent excessive strain on the suture line, especially with obese patients.

Incentive spirometry and deep breathing are routinely used after surgery to maintain patency of the airways and lung expansion. Adequate pain control with analgesics is essential for postoperative deep breathing and coughing. Patients with a smoking history or chronic airway limitation (e.g., chronic obstructive pulmonary disease, asthma) require more aggressive management by the respiratory therapist to prevent atelectasis and pneumonia. Patients with large hiatal hernias are at the highest risk for developing respiratory complications.

The patient having the conventional surgery usually has a large-bore (diameter) nasogastric (NG) tube to prevent the fundoplication wrap from becoming too tight around the esophagus. Initially the NG drainage should be dark brown with old blood. The drainage should become normal yellowish green within the first 8 hours after surgery. Check the NG tube every 4 to 8 hours for proper placement in the stomach. The tube should be properly anchored so it is not displaced,

because re-insertion could perforate the fundoplication. Follow the surgeon's directions for care of the patient with an NG tube.

Monitor patency of the NG tube to keep the stomach decompressed. This prevents retching or vomiting, which can strain or rupture the stomach sutures. The NG tube is irritating. Therefore provide frequent oral hygiene to increase comfort. Assess the patient's hydration status regularly, including accurate measures of intake and output. Adequate fluid replacement helps thin respiratory secretions.

After open fundoplication, the patient may begin clear fluids when peristalsis is re-established or in an effort to stimulate peristalsis. Some surgeons create a temporary gastrostomy for feeding to allow for undisturbed healing of the repair. The patient gradually progresses to a near-normal diet during the first 4 to 6 weeks. Some foods, especially caffeinated or carbonated beverages and alcohol, are either restricted or eliminated. The food storage area of the stomach is reduced by the surgery, and meals need to be both smaller and more frequent.

Carefully supervise the first oral feedings because temporary dysphagia is common. Continuous dysphagia usually indicates that the fundoplication is too tight, and dilation may be required.

Another common complication of this surgery is *gas bloat syndrome,* in which patients are unable to voluntarily eructate (belch). The syndrome is usually temporary but may persist, even in those who have the laparoscopic approach. Teach the patient to avoid drinking carbonated beverages and to avoid eating gas-producing foods (especially high-fat foods), chewing gum, and drinking with a straw.

Other patients have *aerophagia* (air swallowing) from attempting to reverse or clear acid reflux. Teach them to relax consciously before and after meals, to eat and drink slowly, and to chew all food thoroughly. Air in the stomach that cannot be removed by belching can be extremely uncomfortable. Frequent position changes and ambulation are often effective interventions for eliminating air from the GI tract. If gas pain is still present, patients are taught to take simethicone, which dissolves in the mouth.

Community-Based Care

Patients undergoing one of the open surgical repairs require activity restrictions during the 3- to 6-week postoperative recovery period. For laparoscopic surgery, activity is typically restricted for a shorter time and the patient can return to his or her usual lifestyle more quickly, usually in a few days to a week.

For long-term management, teach the patient and family about appropriate nutrition modifications. The use of stool softeners or bulk laxatives is recommended for the first postoperative weeks until healing is complete. Instruct the patient to avoid straining and to prevent constipation. Teach him or her to inspect the healing incision daily and to notify the health care provider if swelling, redness, tenderness, discharge, or fever occurs. According to The Joint Commission National Patient Safety Goals for 2014, advise the patient to avoid contact with people with a respiratory infection and to contact the health care provider if symptoms of a cold or influenza develop. Continuous coughing can cause the incision or the fundoplication to dehisce ("break open"). Per The Joint Commission Core Measures to decrease tobacco use, advise the patient to avoid smoking. Provide information about smoking-cessation methods, if appropriate.

If needed, collaborate with the dietitian to educate the patient and family about dietary changes. Encourage the patient to eat smaller and more frequent meals. Few ongoing diet restrictions are needed, but overeating or eating the wrong types of foods can produce discomfort if the patient cannot belch. Instruct the patient to report reflux symptoms to the health care provider.

Although severe surgical complications are rare, conditions such as gas bloat syndrome and dysphagia may continue. Prepare the patient for these problems and for the potential that reflux may not be completely controlled or may occur again. Although surgery controls the condition, a cure is rare and lifestyle modifications need to be ongoing.

Esophageal Tumors

Pathophysiology

Although esophageal tumors can be benign, most are malignant (cancerous) and the majority arise from the epithelium. Squamous cell carcinomas of the esophagus are located in the upper two thirds of the esophagus. Adenocarcinomas are more commonly found in the distal third and at the gastroesophageal junction and are now the most common type of esophageal cancer (McCance et al., 2014). Esophageal tumors grow rapidly because there is no serosal layer to limit their extension. Because the esophageal mucosa is richly supplied with lymph tissue, there is early spread of tumors to lymph nodes. Esophageal tumors can protrude into the esophageal lumen and can cause thickening or invade deeply into surrounding tissue. In rare cases, the lesion may be confined to the epithelial layer (in situ). In most cases, the tumor is large and well established on diagnosis. More than half of esophageal cancers **metastasize** (spread throughout the body).

Primary risk factors associated with the development of esophageal cancer are smoking and obesity. The compounds in tobacco smoke may be responsible for the genetic mutations seen in many squamous cell carcinomas of the esophagus. “Obesity poses a sixteen-fold increased risk of esophageal adenocarcinoma” (American Cancer Society [ACS], 2012, p. 29). Increased abdominal pressure associated with obesity is linked to reflux as well as Barrett's esophagus (a pre-malignant condition). Both conditions can contribute to changes in cellular structure in the esophagus increasing the potential for adenocarcinoma of the esophagus (ACS, 2012). In addition to these primary risk factors, malnutrition, untreated gastroesophageal reflux disease (GERD), and excessive alcohol intake are also associated with esophageal cancer. **Barrett's esophagus** results from exposure to acid and pepsin, which leads to the replacement of normal distal squamous mucosa with columnar epithelium as a response to tissue injury. This tissue undergoes dysplasia (cell appearance changes) and, ultimately, becomes cancerous. In parts of the world where esophageal cancer is more common, the incidence of squamous cell carcinoma appears to be linked to high levels of nitrosamines (which are found in pickled and fermented foods) and foods high in nitrate. Diets that are chronically deficient in fresh fruits and vegetables have also been implicated in the development of squamous cell carcinoma.

Genetic/Genomic Considerations

Patient-Centered Care QSEN

Certain genetic factors may have a role in the development of esophageal cancers. It is thought that these cancers result from mutations in tumor suppressor genes. Tumor suppressor genes are normal genes that control cell growth and division. When this type of gene is mutated and does not work properly, cells are unable to stop growing and dividing and tumors can result. (See Chapter 21 for a more complete discussion.)

Overexpression and mutations of the *Tp53, Tp16,* and *Tp17* tumor suppressor genes have been found in people with esophageal cancer (Nussbaum et al., 2007). In addition, the presence of the mutated *Tp53* gene may be an indication of advanced disease, especially in patients with adenocarcinomas.

Overexpression of *cyclin D1,* a protein that promotes cell growth and division, has also been found in patients with esophageal squamous cell cancers. Cyclins are products of oncogenes, which are normal genes involved in cell division and are controlled by suppressor genes. Prolonged exposure to carcinogens, such as tobacco, can cause oncogenes to escape the control of suppressor genes, leading to overexpression of cyclins and uncontrolled cell growth (cancer).

NCLEX Examination Challenge

Health Promotion and Maintenance

Over the past 3 months, a client with a history of gastroesophageal reflux disease and obesity has implemented lifestyle changes. What lifestyle changes does the nurse recognize as important for the client to decrease chances of development of cancer of the esophagus? **Select all that apply.**

A Lost 10 pounds
B Sleeps with two pillows
C Has quit eating processed foods
D Drinks a glass of wine every night
E Uses a nicotine patch instead of smoking

Patient-Centered Collaborative Care

Assessment

History.

Assess for risk factors related to the development or symptoms of esophageal cancer, such as gender, history of alcohol consumption, tobacco use, dietary habits, and other esophageal problems (e.g., dysphagia, reflux). In the United States, adenocarcinoma of the esophagus is more common than squamous cell carcinoma (National Cancer Institute at the National Institutes of Health, 2013). Men, regardless of race or ethnicity, have higher incidence and mortality rates associated with esophageal cancer (National Cancer Institute, 2013). Ask the patient about consumption of smoked and/or pickled foods, changes in appetite, changes in taste, or weight loss.

Physical Assessment/Clinical Manifestations.

Cancer of the esophagus is a silent tumor in its early stages, with few observable signs. By the time the tumor causes symptoms, it usually has spread extensively.

Dysphagia *(difficulty swallowing) is the most common symptom of esophageal cancer, but it may not be present until the esophageal opening has gotten much smaller.* Dysphagia is persistent and progressive when **stricture** (narrowing) occurs. It is initially associated with swallowing solids, particularly meat, and then progresses rapidly over a period of weeks or months to difficulty in swallowing soft foods and liquids. Late in the disease, even saliva can cause choking. Patients usually report a sensation of food sticking in the throat or in the substernal area. Careful assessment of dysphagia is important because dysphagia associated with other esophageal disorders is not usually continuous. Weight loss often accompanies dysphagia and can exceed 20 pounds over several months.

Odynophagia (painful swallowing) is reported by many patients as a steady, dull, substernal pain that may radiate. It occurs most often when the patient drinks cold liquids. The presence of severe or persistent pain often indicates tumor invasion of the mediastinal structures. Assess for regurgitation, vomiting, **halitosis** (foul breath), and chronic hiccups, which often accompany advanced disease. In most patients, pulmonary problems develop. Assess for chronic cough, increased secretions, and a history of recent infections. Tumors in the upper esophagus may involve the larynx and thus cause hoarseness. Chart 54-7 summarizes the common clinical manifestations of esophageal tumors.

Chart 54-7 Key Features

Esophageal Tumors

- Persistent and progressive dysphagia (most common feature)
- Feeling of food sticking in the throat
- Odynophagia (painful swallowing)
- Severe, persistent chest or abdominal pain or discomfort
- Regurgitation
- Chronic cough with increasing secretions
- Hoarseness
- Anorexia
- Nausea and vomiting
- Weight loss (often more than 20 pounds)
- Changes in bowel habits (diarrhea, constipation, bleeding)

Psychosocial Assessment.

The diagnosis of esophageal cancer causes high patient anxiety. The disease is accompanied by distressing symptoms and is often terminal. The fear of choking can place unusual stress, especially at mealtimes. The loss of pleasure and social aspects of eating may affect relationships with family and friends. Assess the patient's response to the diagnosis and prognosis. Ask about his or her usual coping strengths and resources. Assess the impact of the disease on the patient's usual daily activity routine. Determine the availability of support systems and the potential financial impact of the disease and its treatment. Refer the patient and family members to psychological counseling, pastoral care, and/or the social worker or case manager as needed. Chapter 7 describes end-of-life care for patients in the terminal stage of the disease.

Diagnostic Assessment.

A *barium swallow* study with fluoroscopy may be the first diagnostic test requested to evaluate dysphagia. In a barium swallow, the margins of a tumor may be seen. The definitive diagnosis of esophageal cancer is made by *esophageal ultrasound (EUS)* with fine needle aspiration to examine the tumor tissue. An *esophagogastroduodenoscopy (EGD)* may also be performed to inspect the esophagus and obtain tissue specimens for cell studies and disease staging. A complete cancer staging workup is performed to determine the extent of the disease and plan appropriate therapy.

Positron emission tomography (PET) may identify metastatic disease with more accuracy than a CT scan. PET can also help evaluate response to chemotherapy to treat the cancer.

Analysis

The most specific common problem for patients with esophageal cancer is *decreased nutrition intake related to impaired swallowing and possible metastasis*. Many patients with cancer also have pain and are fearful because of the diagnosis of cancer. Chapter 22 describes problems that are typically seen with any patient with cancer.

Planning and Implementation

Promoting Nutrition

Planning: Expected Outcomes.

The major concern for a patient with esophageal cancer is weight loss secondary to dysphagia. Therefore he or she is expected to maintain adequate nutrient intake and weight either orally or via an alternative method.

Interventions.

Interventions to maintain or improve nutrition status focus on treatments that remove or shrink the obstructive tumor. Methods to reduce the effects of treatment that can impact nutrition are also a priority. Surgery is the most definitive intervention for esophageal cancer.

Nonsurgical treatment options for cancer of the esophagus that can assist in both disease and nutrition management include:

- Nutrition therapy
- Swallowing therapy
- Chemotherapy
- Radiation therapy
- Chemoradiation
- Targeted therapies
- Photodynamic therapy
- Esophageal dilation
- Endoscopic therapies

Nonsurgical Management.

The treatment of esophageal cancer often involves a combination of therapies. Patients with cancer of the esophagus experience many physical problems, and symptom management becomes essential.

Nutrition and Swallowing Therapy.

The purpose of nutrition therapy is to administer food and fluids to support the patient who is malnourished or at high risk for becoming malnourished. Conduct a screening assessment to provide information about the patient's nutrition status. The dietitian determines the caloric needs of the patient to meet daily requirements. Be sure the patient is weighed daily before breakfast on the same scale each day. To keep the esophagus patent, careful positioning is essential for a patient who is experiencing frequent reflux or who has tubes. Teach the patient to remain upright for several hours after meals and to avoid lying completely flat. Remind unlicensed assistive personnel (UAP) and other health care team members to keep the head of the bed elevated to a 30-degree angle or more to prevent reflux.

Semisoft foods and thickened liquids are preferred because they are easier to swallow. Record the amount of food and fluid intake every day to monitor progress in meeting desired nutrition outcomes. Liquid nutrition supplements (e.g., Boost, Ensure) are used between feedings to increase caloric intake. Ongoing efforts are made to preserve the ability to swallow, but enteral feedings (tube feedings) may be needed temporarily when dysphagia is severe. In patients with complete esophageal obstruction or life-threatening fistulas, the surgeon may create a gastrostomy or jejunostomy for feeding. Encourage the patient and family to meet with the dietitian for diet teaching and planning. Chapter 60 describes care for patients receiving enteral feeding.

Collaborate with the speech-language pathologist (SLP) to assist the patient with oral exercises to improve swallowing *(swallowing therapy)* and with the occupational therapist (OT) for feeding therapy. Ask the patient to suck on a lollipop to enhance tongue strength. Teach the patient to reach for food particles on the lips or chin using the tongue. In preparation for swallowing, remind the patient to position the head in forward flexion (chin tuck). Then tell him or her to place food at the back of the mouth. Monitor him or her for sealing of the lips and for tongue movements while eating. Check for pocketing of food in the cheeks after swallowing.

Nursing Safety Priority QSEN

Critical Rescue

When the patient with an esophageal tumor is eating or drinking, monitor for signs and symptoms of aspiration, such as choking or coughing. Food aspiration can cause airway obstruction, pneumonia, or

both, especially in older adults. In coordination with the SLP, teach family members and caregivers how to feed the patient, if needed. Teach them how to monitor for aspiration and implement appropriate measures if choking occurs.

Chemotherapy and Radiation.

The use of *chemotherapy* in the treatment of esophageal cancer has been only moderately effective. It can be given as a primary treatment if the patient is not a candidate for surgery or given for palliation (control of symptoms). In most cases, however, chemotherapy is given in combination with radiation therapy to provide the patient the best chance of cure. The rationale for this approach is to shrink the primary tumor and eliminate any other tumor that may be in the local lymph nodes, improving the odds for a complete surgical resection. The most commonly used paired chemotherapeutic agents for esophageal cancer are carboplatin and paclitaxel (Taxol) or cisplatin and 5-fluorouracil (5-FU). These drugs are often combined with radiation because they make the tumor cells more sensitive to radiation effects (American Cancer Society [ACS], 2014a). Because chemotherapeutic drugs affect healthy cells as well as cancer cells, they have many side effects that cause discomfort to the patient. Chapter 22 describes chemotherapy in detail and discusses the role of the nurse in caring for patients receiving these drugs.

Radiation therapy to manage esophageal cancer is only moderately effective and can be used alone or in combination with other treatments. Radiation alone can provide palliation of symptoms by shrinking the tumor. It is contraindicated for patients with tracheoesophageal fistula, mediastinitis, mediastinal hemorrhage, or infiltration of the cancer to the trachea or bronchus. Normal esophageal tissue is very sensitive to the effects of radiation. Although high doses of radiation demonstrate the best results for tumor shrinkage, esophageal stricture or stenosis can result in many patients, which then requires esophageal dilation. Chapter 22 describes radiation methods and the general nursing care for the patient having radiation therapy.

Chemoradiation is a treatment for esophageal cancer that involves the use of chemotherapy at the same time as radiation therapy. One cycle of chemotherapy is given during the first week of radiation and another is delivered during the fifth week of radiation. Additional drug cycles are given after radiation therapy is complete.

Other Therapies.

Targeted therapies may be used in combination with radiation and chemotherapy. Unlike chemotherapy, these therapies interfere with cancer cell growth in a variety of ways with less impact on healthy cells. Many of these drugs focus on proteins that are involved in signaling cells when to grow and divide. A key to success with targeted therapy is that the cancer cells must overexpress the targeted protein. Thus each patient's cancer cells are first examined for the overexpression to determine if targeted therapy is appropriate and which drug to use. Trastuzumab (Herceptin) is a commonly used drug that is used for patients whose esophageal cancer tests positive for an excess of the *HER2* protein on the cell surface. It is given by IV injection once every 3 weeks, in addition to chemotherapy (ACS, 2014b). Chapter 22 describes targeted therapies in detail, including nursing implications for patient safety and quality care.

Photodynamic therapy (PDT) is used as a palliative treatment for patients with advanced esophageal cancer who are not candidates for surgery. It may be used also as a cure for patients who have very small, localized tumors. The patient is injected with porfimer sodium (Photofrin), a light-sensitive drug that collects in cancer cells. Two days after the injection, a fiberoptic probe with a light at the tip is threaded into the esophagus through an endoscope. The light activates the Photofrin, destroying only cancer cells. PDT is far less invasive than surgery and is performed on an ambulatory care basis under moderate sedation. Endoscopy nurses observe the patient's rate and depth of respirations and monitor the patient's oxygen saturation and end-tidal (exhaled) carbon dioxide to ensure adequate oxygenation.

The side effects of Photofrin are rare but include nausea, fever, and constipation. Before the procedure, the patient is given written guidelines concerning photosensitivity measures. Remind the patient to avoid exposure to sunlight for 1 to 3 months. Sunglasses and protective clothing that covers all exposed body areas are essential. The patient may experience chest pain secondary to tissue damage and will require pain relief with opioid analgesics for a short time. Teach the patient to follow a clear liquid diet for 3 to 5 days after the procedure and advance to full liquids as tolerated. Warn the patient that tissue particles may release from the tumor site and be present in the sputum. Chapter 22 describes in detail the health teaching needed to promote patient safety associated with PDT.

Esophageal dilation may be performed as necessary throughout the course of the disease to achieve temporary but immediate relief of dysphagia. It is usually performed on an ambulatory care basis. Dilators

are used to tear soft tissue, thereby widening the esophageal lumen (opening). In most cases, malignant tumors can be dilated safely, but perforation remains a significant risk. Large metal stents may be used to keep the esophagus open for longer periods. A stent covered with graft material can be used to seal a perforation. Bacteremia can also occur. To reduce the risk for endocarditis, antibiotics are given. The treatment is repeated as often as needed to preserve the patient's ability to swallow. Prolonged stent embedment into benign esophageal tissue can cause ulceration, bleeding, fistula, dysphagia, and formation of new stricture if the stent is not removed (Patel & Siddiqui, 2013).

When patients are not candidates for surgery or the tumor is too large to remove surgically, laser therapy or electrocoagulation using endoscopy may be performed as a palliative measure. Both of these methods destroy some cancer cells and reduce tumor size to improve swallowing. The procedures are done in ambulatory care settings or same-day surgery centers using moderate sedation.

Surgical Management.

The purposes of surgical resection vary from palliation to cure. **Esophagectomy** is the removal of all or part of the esophagus. An **esophagogastrostomy** involves the removal of part of the esophagus and proximal stomach. The remaining stomach may be "pulled up" to take the place of the esophagus, or a section of the jejunum or colon may be placed as a conduit. Conventional open surgical techniques are lengthy and are associated with many complications or death. Fistula formation between the trachea and esophagus, abscess, and respiratory complications are common.

For patients with early-stage cancer, a laparoscopic-assisted **minimally invasive esophagectomy (MIE)** may be performed. However, most patients require the conventional open surgery because of tumor size and metastasis by the time they are diagnosed with the disease.

Preoperative Care.

Preoperative preparation for patients undergoing esophagectomy or esophagogastrostomy can be quite extensive, especially before conventional techniques. Advise the patient to stop smoking 2 to 4 weeks before surgery to enhance pulmonary function. Patient preparation may include 5 days to 2 to 3 weeks of nutrition support to decrease the risk for postoperative complications. Ideally this supplementation is given orally, but many patients require tube feeding or parenteral nutrition. Teach the patient and family to monitor the patient's weight and intake and output.

A preoperative evaluation may be required to treat dental disease. Teach the patient to use meticulous oral care 4 times daily to decrease the risk for postoperative infection.

Preoperative nursing care focuses on teaching and on psychological support regarding the surgical procedure and preoperative and postoperative instructions. Teach the patient about:

- The number and sites of all incisions and drains
- The placement of a jejunostomy tube for initial enteral feedings
- The need for chest tubes if the pleural space is entered
- The purpose of the nasogastric tube
- The need for IV infusion

Teach the patient about routines for turning, coughing, deep breathing, and chest physiotherapy. Emphasize the crucial nature of postoperative respiratory care. If colon interposition (resecting a piece of colon and creating an esophagus) is planned, the patient also has a complete bowel preparation before surgery.

The patient facing a serious illness and extensive surgery can be expected to have feelings of grief and anxiety. Encourage the patient to talk about personal feelings and fears, and involve the family or significant others in all preoperative teaching and discussions. A social worker, certified hospital chaplain, or case manager can be extremely helpful in providing continuity of care and support to the entire family.

Operative Procedures.

In the MIE procedure, the surgeon makes four or five small incisions in the chest and abdomen using a video-assisted thoracoscope and laparoscope. The lower esophagus and gastric fundus are removed. The remaining portion of the esophagus is then anastomosed (reconnected) to the stomach.

For most patients, the surgeon performs an open subtotal or total esophagectomy because tumors are often large and involve distant lymph nodes. For a subtotal (partial) removal, the diseased portion of the esophagus is removed and the cervical portion is anastomosed (connected) to the stomach (Fig. 54-3). A **pyloromyotomy** is done by cutting and suturing the pylorus. Finally, a jejunostomy tube may be placed for postoperative enteral feeding.

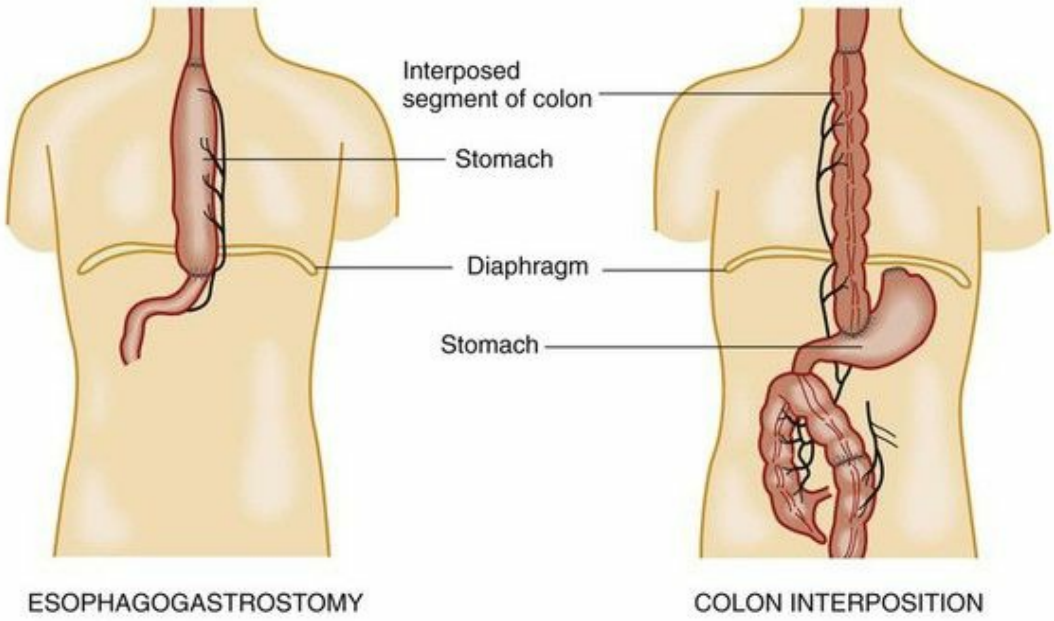

FIG. 54-3 Open surgical approaches to the treatment of esophageal cancer.

For patients with early-stage tumors of the lower third of the esophagus, a transhiatal esophagectomy is the preferred surgical approach. The surgery is performed through an upper midline cervical incision. With this approach, the pleural space is not entered, reducing respiratory complications. For patients with tumors in the upper esophagus, a radical neck dissection and laryngectomy may also be needed if the disease has spread to the larynx. Chapter 29 discusses the care of patients having these procedures.

The surgeon may perform a **colon interposition** when the tumor involves the stomach or the stomach is otherwise unsuitable for anastomosis. A section of right or left colon is removed and brought up into the thorax to substitute for the esophagus (see Fig. 54-3).

Postoperative Care.

The patient requires intensive postoperative care and is at risk for multiple serious complications. The patient having an MIE has the same risk for postoperative complications as one having the open procedure. The advantages of MIE, though, include:

- Less blood loss during surgery; fewer blood transfusions
- Decreased healing and recovery time
- Decreased trauma to the body
- No large incisions
- Less postoperative pain
